Quick Table of Contents

Introduction to Pathophysiology xviii

UNIT 1 • Cell and Tissue Function 1
CHAPTER 1 Cell Structure and Function 1
CHAPTER 2 Cellular Responses to Stress, Injury, and Aging 31
CHAPTER 3 Inflammation, the Inflammatory Response, and Fever 49
CHAPTER 4 Cell Proliferation and Tissue Regeneration and Repair 71
CHAPTER 5 Genetic Control of Cell Function and Inheritance 87
CHAPTER 6 Genetic and Congenital Disorders 106
CHAPTER 7 Neoplasia 129

UNIT 2 • Integrative Body Functions 159
CHAPTER 8 Disorders of Fluid, Electrolyte, and Acid–Base Balance 159
CHAPTER 9 Stress and Adaptation 206
CHAPTER 10 Disorders of Nutritional Status 223

UNIT 3 • Hematopoietic Function 241
CHAPTER 11 Disorders of White Blood Cells and Lymphoid Tissues 241
CHAPTER 12 Disorders of Hemostasis 261
CHAPTER 13 Disorders of Red Blood Cells 277

UNIT 4 • Infection and Immunity 297
CHAPTER 14 Mechanisms of Infectious Disease 297
CHAPTER 15 Innate and Adaptive Immunity 318
CHAPTER 16 Disorders of the Immune Response 344

UNIT 5 • Circulatory Function 375
CHAPTER 17 Control of Cardiovascular Function 375
CHAPTER 18 Disorders of Blood Flow and Blood Pressure 402
CHAPTER 19 Disorders of Cardiac Function 444
CHAPTER 20 Heart Failure and Circulatory Shock 486

UNIT 6 • Respiratory Function 513
CHAPTER 21 Control of Respiratory Function 513
CHAPTER 22 Respiratory Tract Infections, Neoplasms, and Childhood Disorders 539
CHAPTER 23 Disorders of Ventilation and Gas Exchange 565

UNIT 7 • Kidney and Urinary Tract Function 599
CHAPTER 24 Structure and Function of the Kidney 599
CHAPTER 25 Disorders of Renal Function 617
CHAPTER 26 Acute Kidney Injury and Chronic Kidney Disease 639

CHAPTER 27 Disorders of the Bladder and Lower Urinary Tract 656

UNIT 8 • Gastrointestinal and Hepatobiliary Function 675
CHAPTER 28 Structure and Function of the Gastrointestinal System 675
CHAPTER 29 Disorders of Gastrointestinal Function 696
CHAPTER 30 Disorders of Hepatobiliary and Exocrine Pancreas Function 724

UNIT 9 • Endocrine System 753
CHAPTER 31 Mechanisms of Endocrine Control 753
CHAPTER 32 Disorders of Endocrine Control of Growth and Metabolism 767
CHAPTER 33 Diabetes Mellitus and the Metabolic Syndrome 793

UNIT 10 • Nervous System 821
CHAPTER 34 Organization and Control of Neural Function 821
CHAPTER 35 Somatosensory Function, Pain, and Headache 854
CHAPTER 36 Disorders of Neuromuscular Function 880
CHAPTER 37 Disorders of Brain Function 916
CHAPTER 38 Disorders of Special Sensory Function: Vision, Hearing, and Vestibular Function 955

UNIT 11 • Genitourinary and Reproductive Function 993
CHAPTER 39 Disorders of the Male Genitourinary System 993
CHAPTER 40 Disorders of the Female Genitourinary System 1017
CHAPTER 41 Sexually Transmitted Infections 1049

UNIT 12 • Musculoskeletal Function 1063
CHAPTER 42 Structure and Function of the Skeletal System 1063
CHAPTER 43 Disorders of the Skeletal System: Trauma, Infections, Neoplasms, and Childhood Disorders 1078
CHAPTER 44 Disorders of the Skeletal System: Metabolic and Rheumatic Disorders 1111

UNIT 13 • Integumentary Function 1141
CHAPTER 45 Structure and Function of the Integumentum 1141

CHAPTER 46 Disorders of Skin Integrity and Function 1153

Glossary 1185
Appendix A: Lab Values 1197
Index 1199
This book is dedicated to
All the Students who use the book, for it is for them that the book was written.

CAROL MATTSON PORTH
Jacqueline M. Akert, RNC, MSN, WHNP-BC
Nurse Practitioner, Women’s Health
Aurora Health Care
Waukesha, Wisconsin
(Chapters 40, 41 with Patricia McCowen Mehring)

Aoy Tomita-Mitchell, PhD
Associate Professor
Department of Surgery
Medical College of Wisconsin
Children’s Research Institute
Milwaukee, Wisconsin
(Chapters 5, 6)

Diane Book, MD
Associate Professor, Neurology
Co-Director Stroke & Neurovascular Program
Froedtert Hospital & Medical College of Wisconsin
Milwaukee, Wisconsin
(Chapter 37)

Freddy W. Cao, MD, PhD
Clinical Associate Professor
College of Nursing
University of Wisconsin–Milwaukee
Milwaukee, Wisconsin
(Chapters 18, 34)

Paula Cox-North, PhD, ARNP
Hepatitis & Liver Clinic
Harborview Medical Center
Clinical Assistant Professor
University of Washington School of Nursing
Seattle, Washington
(Chapters 29, 30)

Herodotos Ellinas, MD, FAAP, FACP
Assistant Professor, Department of Anesthesiology
Med–Anesthesia and PGY-1 Program Director
Medical College of Wisconsin
Milwaukee, Wisconsin
(Chapters 11, 12, 13)

Jason R. Faulhaber, MD
Division of Infectious Diseases, Carilion Clinic
Assistant Program Director, Fellowship in Infectious Diseases, Carilion Clinic
Assistant Professor, Virginia Tech, Carilion School of Medicine
Adjunct Professor, Department of Biomedical Sciences, Jefferson College of Health Sciences
Roanoke, Virginia
(Chapters 15, 16)

Anne M. Fink, RN, PhD
Postdoctoral Research Associate
University of Illinois–Chicago College of Nursing
Chicago, Illinois
(Chapters 19, 20 with Karen M. Vuckovic)

Susan A. Fontana, PhD, APRN-BC
Associate Professor and Family Nurse Practitioner
University of Wisconsin–Milwaukee College of Nursing
Milwaukee, Wisconsin
(Chapter 36)

Kathleen E. Gunta, MSN, RN, OCNS-C
Clinical Nurse Specialist
Aurora St. Luke's Medical Center
Milwaukee, Wisconsin
(Chapter 43)

Nathan A. Ledeboer, PhD, D(ABMM)
Associate Professor of Pathology
Medical College of Wisconsin
Milwaukee, Wisconsin
(Chapter 14)

Kim Litwack, PhD, RN, FAAN, APNP
Associate Dean for Academic Affairs
Family Nurse Practitioner
Advanced Pain Management
University of Wisconsin–Milwaukee
Milwaukee, Wisconsin
(Chapter 35)

Glenn Matfin, MSc (Oxon), MB, ChB, FACE, FACP, FRCP
Medical Director
International Diabetes Center
Clinical Professor of Medicine
University of Minnesota
Minneapolis, Minnesota
(Chapters 10, 31, 32, 33, 39)

Patricia McCowen Mehring, RNC, MSN, WHNP
Nurse Practitioner
Women’s Health
Milwaukee, Wisconsin
(Chapter 40, 41 with Jacqueline M. Akert)

Carrie J. Merkle, PhD, RN, FAAN
Associate Professor
College of Nursing
The University of Arizona
Tucson, Arizona
(Chapters 1, 2, 3, 4, 7)

Kathleen Mussatto, PhD, RN
Nurse Scientist, Herma Heart Center
Children’s Hospital of Wisconsin
Assistant Clinical Professor of Surgery
Medical College of Wisconsin
Milwaukee, Wisconsin
(Chapter 19, Heart Disease in Infants and Children)

Debra Bancroft Rizzo, RN, MSN, FNP-BC
Nurse Practitioner
Division of Rheumatology
University of Michigan
Ann Arbor, Michigan
(Chapter 44)

Jonathan Shoopman, MD
Assistant Professor of Anesthesiology and Critical Care
Medical College of Wisconsin
Milwaukee, Wisconsin
(Chapters 22, 23)

Gladys Simandl, RN, PhD
Nurse Scientist, Herma Heart Center
Children’s Hospital of Wisconsin
Assistant Clinical Professor of Surgery
Medical College of Wisconsin
Milwaukee, Wisconsin
(Chapter 19, Heart Disease in Infants and Children)

Karen M. Vuckovic, RN, PhD, ACNS-BC
Assistant Clinical Professor
University of Illinois–Chicago College of Nursing
Chicago, Illinois
(Chapters 19, 20 with Anne M. Fink)

Jill M. Winters, RN, PhD, FAHA
President and Dean
Columbia College of Nursing
Milwaukee, Wisconsin
(Chapter 9)

Assistant Professor of Nursing  
Arkansas State University  
Jonesboro, Arkansas
Preface

As the 21st century unfolds, more information is available to more people at a faster pace than ever before. This ever-evolving ability to communicate has produced phenomenal advances in the ability to understand and treat disease. Yet despite these advances, we are also reminded that illness and disease continue to occur and impact the physiologic, social, psychological, and economic well-being of individuals, their families, the community, and the world.

As a nurse–physiologist, my major emphasis with this edition, as in previous editions, is to relate normal body functioning to the physiologic changes that participate in disease production and occur as a result of disease, as well as the body’s remarkable ability to compensate for these changes. The beauty of physiology is that it integrates all of the aspects of human genetics, molecular and cellular biology, and organ anatomy and physiology into a functional whole that can be used to explain both the physical and psychological aspects of altered health. Indeed, it has been my philosophy to share the beauty of the human body and to emphasize that in disease, as in health, there is more “going right” in the body than is “going wrong.”

With the creation of this text, I focused on presenting information that is fundamental to understanding the physiologic processes of altered health states; information that necessary to support an understanding pathophysiology. One of the strengths of Essentials of Pathophysiology is that it is a book to grow with. Although intended as a course textbook for students, it is also designed to serve as a reference book that students can take with them and use in their practice once the course is finished.

Updated to reflect state-of-the-art science, content remains organized in a manner that is logical, understandable, and draws readers into the wonders of the human body. Concepts build on one another, with concepts from physiology, biochemistry, physics, and other sciences reviewed as deemed appropriate. A conceptual model that integrates the developmental and preventative aspects of health has been used. Selection of content was based on common health problems, including the special needs of children, pregnant women, and elderly persons. The fourth edition expands the art program, increasing the number of photographs depicting clinical manifestations of selected disorders while also providing more than 500 full-color illustrations, many created specifically to supplement and expand the concepts presented.

Newly created Summary Concepts follow each section and provide a review of material that focuses on integrating and linking concepts rather than fostering rote memorization. Once again, the “Understanding” feature depicts physiologic processes and phenomena, breaking them down into an easy-to-follow sequence for easier learning. “Clinical Features” are illustrations that depict the clinical features of persons with selected diseases. As with other types of illustrations in this edition, they are designed to help the reader develop a visual memory—in this case, the memory of the entire spectrum of clinical manifestations that are associated with a disease state.

Review exercises appear at the end of each chapter and assist the reader in using the conceptual approach to solving problems related to chapter content. The glossary defines the specialized terms of pathophysiology. Tables of normal laboratory values provide a handy reference of conventional and SI units, as well as conversion units.

As with previous editions, every effort has been taken to make the text as accurate and up to date as possible. This was accomplished through an extensive review of the literature and through the use of critiques provided by students, faculty, and content specialists. This book is an extension of my career and, as such, of my philosophy. It is my hope that readers will learn to appreciate the marvelous potential of the body, incorporating it into their own philosophy and ultimately sharing it with their clients.

Carol Mattson Porth

A Comprehensive Package for Teaching and Learning

To further facilitate teaching and learning, a carefully designed ancillary package has been developed to assist faculty and students.

Instructor Resources

Tools to assist you with teaching your course are available upon adoption of this text at http://thePoint.lww.com/PorthEssentials4e.

- A thoroughly revised and augmented Test Generator contains more than 1,100 NCLEX-style questions mapped to chapter learning objectives.
- An extensive collection of materials is provided for each book chapter:
  - Pre-Lecture Quizzes (and answers) allow you to check students’ reading.
  - PowerPoint Presentations provide an easy way to integrate the textbook with your students’ classroom experience; multiple-choice questions are included to promote class participation.
  - Guided Lecture Notes offer corresponding PowerPoint slide numbers to simplify preparation for lecture.
  - Discussion Topics (and suggested answers) can be used in the classroom or in online discussion boards to facilitate interaction with your students.
Preface

Student Resources

An exciting set of free learning resources is available to help students review and apply vital concepts of pathophysiology. For the fourth edition, multimedia engines have been optimized so that students can access many of these resources on mobile devices. Students can activate the codes printed in the front of their textbooks at http://thePoint.lww.com/activate to access these resources:

- **Student Review Questions** for each chapter, totaling more than 900 questions, help students review important concepts and practice for certification examinations.
- Interactive learning resources appeal to a variety of learning styles. Icons in the text direct readers to relevant resources:
  - **Concepts in Action Animations** bring physiologic and pathophysiologic concepts to life.
  - **Interactive Clinical Simulation Case Studies** present case scenarios and offer interactive exercises and questions to help students apply what they have learned.
- A **Spanish–English Audio Glossary** provides helpful terms and phrases for communicating with patients who speak Spanish.
- **Journal articles** offer access to current articles relevant to each chapter and available in Lippincott Williams & Wilkins journals to familiarize students with health care literature.

Study Guide

A comprehensive study aid for reviewing key concepts, Study Guide for Porth’s Essentials of Pathophysiology, 4th edition, has been thoroughly revised and presents a variety of exercises, including case studies and practice NCLEX-style questions, to reinforce textbook content and enhance learning.

Adaptive Learning | Powered by PrepU

Updated to accompany the 4th edition, Lippincott Adaptive Learning | Powered by PrepU helps every student learn more, while giving instructors the data they need to monitor each student’s progress, strengths, and weaknesses. The adaptive learning system allows instructors to assign quizzes or students to take quizzes on their own—quizzes that adapt to each student’s individual mastery level. Visit at http://thePoint.lww.com/PrepU to learn more.

A Comprehensive, Digital, Integrated Course Solution

Lippincott CoursePoint is the only integrated digital course solution for health care education, combining the power of digital course content, interactive resources, and Adaptive Learning | Powered by PrepU. Pulling these resources together into one solution, the integrated product offers a seamless experience for learning, studying, applying, and remediating.

Lippincott CoursePoint provides a personalized learning experience that is structured in the way students study. It drives students to immediate remedia- tion in their text; digital course content and interactive course resources like case studies, videos, and journal articles are also immediately available in the same digitally integrated course solution to help expand on concepts and bring them to life. After students complete an adaptive, formative assessment on the reading, the results identify students’ specific weaknesses and, at the moment it’s identified they don’t understand the material, they can immediately remediate to that content. Instructors also have a powerful and measurable way to assess their students’ understanding and to help engage them in the course content. Knowing where students are struggling allows instructors to adapt class time as appropriate.

Lippincott CoursePoint can bring Adaptive Learning | Powered by PrepU and digital resources together on the same platform to provide all of the aids that students need to study more effectively, score higher on exams, and prepare for clinical practice. The SmartSense links feature included throughout CoursePoint integrates all of the content, offering immediate remediation and additional learning resources at the click of a mouse. With Lippincott CoursePoint, instructors can collaborate with students at any time, identify common misunderstandings, evaluate student comprehension, and differentiate instruction as needed. This unique offering creates an unparalleled learning experience for students because they can learn and retain course material in an adaptive, personalized way.

Contact your Wolters Kluwer Health sales representative or visit http://thePoint.lww.com/coursepoint-porthessentials4e for more information about Lippincott CoursePoint solution.

It is with pleasure that we introduce these resources—the textbook, ancillary resources, and additional
supplements and learning tools—to you. One of our primary goals in creating these resources has been to help students learn how to provide quality care to patients and families across health care settings. We hope that we have succeeded in that goal, and we welcome feedback from our readers.

To the Reader

This book was written with the intent of making the subject of pathophysiology an exciting exploration that relates normal body functioning to the physiologic changes that occur as a result of disease, as well as the body’s remarkable ability to compensate for these changes. Indeed, it is these changes that represent many of the signs and symptoms of disease.

Using a book such as this can be simplified by taking time out to find what is in the book and how to locate information when it is needed. The Table of Contents provides an overall view of the organization and content of the book. The Index can be viewed as a roadmap for locating content. Using the Index, readers can quickly locate related content in different chapters of the book or answer questions that come up in other courses.

Organization

The book is organized into units and chapters. The units identify broad areas of content, such as alterations in the circulatory system. Many of the units have introductory chapters that contain information about the normal structure and function of the body systems discussed in the unit. These chapters, which are intended as a review of content from previous courses as well as an update on recent scientific advances in genetic and molecular biology, provide the foundation for understanding the pathophysiology content presented in the subsequent chapters. The disorder chapters focus on specific areas of pathophysiology content, such as heart failure and circulatory shock. The chapter outline that appears at the beginning of each chapter provides an overall view of the chapter content and organization. Icons identify specific content related to infants and children, pregnant women, and older adults.

Reading and Learning Aids

In an ever-expanding world of information, you will not be able to read, let alone remember, everything that is in this (or any other) book. With this in mind, we have developed a number of special features that will help you focus on and master the essential content for your current as well as future needs.

It is essential for any professional to use and understand the vocabulary of his or her profession. Throughout the text, you will encounter terms in italics. This is a signal that a word and the ideas associated with it are important to learn. To help, the Glossary contains concise definitions of frequently encountered terms. If you are unsure of the meaning of a term you encounter in your reading, check the Glossary in the back of the book before proceeding.

Summary Concepts

Summary concepts at the end of each section provide a review and a reinforcement of the main content that has been covered. One of the ways to approach learning is to focus on the major ideas or concepts rather than trying to memorize significant amounts of information. As you have probably already discovered, it is impossible to memorize everything that is in a particular section or chapter of the book. Not only does your brain have a difficult time trying to figure out where to store all the different bits of information, your brain doesn’t know how to retrieve the information when you need it. Most important of all, memorized lists of content can seldom, if ever, be applied directly to an actual clinical situation. Summary concepts guide you in identifying the major ideas or concepts that form the foundation for truly understanding the major areas of content. When you understand the concepts in these sections, you will have a framework for remembering and using the facts given in the text.

Tables, Charts, and Boxes

Tables, charts, and boxes are designed to present complex information in a format that makes it more meaningful and easier to remember. Tables have two or more
columns, and are often used for the purpose of comparing or contrasting information. Charts have one column and are used to summarize information. Boxes highlight key information.

### Illustrations and Photographs

The full-color illustrations will help you to build your own mental image of the content that is being presented. Each drawing has been developed to fully support and build upon the ideas in the text. Some illustrations are used to help you picture the complex interactions of the multiple phenomena that are involved in the development of a particular disease; others can help you visualize normal function or understand the mechanisms whereby the disease processes exert their effects. In addition, photographs depicting clinical manifestations and detailing pathologic processes provide a realistic view of selected disorders and pathologic processes.

### Clinical Features

This edition retains the illustrations that depict the clinical features of persons with selected diseases. This feature is designed to help you visualize the entire spectrum of clinical manifestations that are associated with these disease states.
Understanding Physiologic Processes

Included in a number of chapters is an Understanding feature that focuses on the physiologic processes and phenomena that form the basis for understanding disorders presented in the text. This feature breaks a process or phenomenon down to its component parts and presents them in a sequential manner, providing an insight into the many opportunities for disease processes to disrupt the sequence.

Material for Review

An important feature has been built into the text to help you verify your understanding of the material presented. After you have finished reading and studying the chapter, work on answering the Review Exercises at the end of the chapter. They are designed to help you integrate, conceptualize, and apply material from the text. If you are unable to answer a question, reread the relevant section in the chapter.

Appendix

The Lab Values tables in the appendix provide rapid access to normal values for many laboratory tests in conventional and SI units, as well as a description of the prefixes, symbols, and factors (e.g., micro, µ, 10^{-6}) used for describing these values. Knowledge of normal values can help you put abnormal values in context.

We hope that this guide has given you a clear picture of how to use this book. Good luck and enjoy the journey!
Acknowledgments

As in past editions, many persons participated in the creation of this work. The contributing authors deserve a special mention. Dr. Gaspard, in particular, deserves thanks. Her wide breadth of knowledge and skillful assistance were invaluable in preparing the text and developing the illustrations for the book. Another person who deserves recognition is Georgianne Heymann, who assisted in editing the manuscript. As with previous editions, she provided not only excellent editorial assistance but also encouragement and support when the tasks associated with manuscript preparation became most frustrating. I would also like to acknowledge Jody Erickson, RN, BSN, DNP, FNP, BC for her assistance with selected work in the text.

Special thanks also to those at Wolters Kluwer Health who participated in the development of this edition: Sherry Dickinson, executive editor; Dawn Lagrosa, associate product development editor; Joan Wendt, design coordinator; and Marian Bellus, production project manager. Thanks also to Wendy Beth Jackelow, MFA, CMI, for her talent and expertise in creating and modifying the illustrations.

The students in the classes I have taught over the years also deserve a special salute, for they are the inspiration upon which this book was founded. They provided the questions, suggestions, and contact with the “real world” of patient care that directed the organization and selection of content for the book.

Last, but certainly not least, I would like to acknowledge my family and friends for their unlimited patience, understanding, and encouragement throughout the entire process.
Introduction to Pathophysiology  xviii

UNIT 1 • Cell and Tissue Function  1

CHAPTER 1  Cell Structure and Function  1
Functional Components of the Cell  1
Cell Metabolism and Energy Storage  8
Integration of Cell Function  12
Tissues  17

CHAPTER 2  Cellular Responses to Stress, Injury, and Aging  31
Cellular Responses to Persistent Stress  31
Cell Injury, Death, and Senescence  36

CHAPTER 3  Inflammation, the Inflammatory Response, and Fever  49
General Features of Inflammation  49
Acute Inflammation  53
Chronic Inflammation  61
Systemic Manifestations of Inflammation  62

CHAPTER 4  Cell Proliferation and Tissue Regeneration and Repair  71
Cell Proliferation and Tissue Regeneration  71
Healing by Connective Tissue Repair  78

CHAPTER 5  Genetic Control of Cell Function and Inheritance  87
Genetic Control of Cell Function  87
Chromosomes  95
Patterns of Inheritance  98
Gene Technology  99

CHAPTER 6  Genetic and Congenital Disorders  106
Disorders Involving Single or Multiple Genes  106
Chromosomal Disorders  115
Disorders Due to Environmental Influences  120
Prenatal Screening and Diagnosis  124

CHAPTER 7  Neoplasia  129
Characteristics of Benign and Malignant Neoplasms  129
Etiology of Cancer  137
Clinical Manifestations  144
Screening, Diagnosis, and Treatment  147
Childhood Cancers and Late Effects on Cancer Survivors  153

UNIT 2 • Integrative Body Functions  159

CHAPTER 8  Disorders of Fluid, Electrolyte, and Acid–Base Balance  159
Composition and Compartmental Distribution of Body Fluids  159
Water and Sodium Balance  167
Potassium Balance  177
Calcium, Phosphorus, and Magnesium Balance  181
Acid–Base Balance  191

CHAPTER 9  Stress and Adaptation  206
Stress and Adaptation  206
Disorders of the Stress Response  215

CHAPTER 10  Disorders of Nutritional Status  223
Energetics and Nutritional Status  223
Overweight and Obesity  230
Undernutrition and Eating Disorders  234

UNIT 3 • Hematopoietic Function  241

CHAPTER 11  Disorders of White Blood Cells and Lymphoid Tissues  241
Hematopoietic and Lymphoid Tissues  241
Nonneoplastic Disorders of White Blood Cells  246
Neoplastic Disorders of Hematopoietic and Lymphoid Origin  249

CHAPTER 12  Disorders of Hemostasis  261
Hemostasis and Blood Coagulation  261
Hypercoagulability States  267
Bleeding Disorders  269

CHAPTER 13  Disorders of Red Blood Cells  277
The Red Blood Cell  277
Anemia  282
Polycythemia  291
Age-Related Changes in Red Blood Cells  291

UNIT 4 • Infection and Immunity  297

CHAPTER 14  Mechanisms of Infectious Disease  297
General Concepts of Infectious Diseases  297
Epidemiology of Infectious Diseases  306
Diagnosis of Infectious Diseases  311
Treatment of Infectious Diseases  314
New and Emerging Infectious Diseases  316

CHAPTER 15  Innate and Adaptive Immunity  318
Introduction to the Immune System  318
Innate Immunity  325
Adaptive Immunity  331
Developmental Aspects of the Immune System  341

CHAPTER 16  Disorders of the Immune Response  344
Hypersensitivity Disorders  344
Transplantation Immunopathology  352
Autoimmune Disease  354
Immunodeficiency Disorders  358

UNIT 5 • Circulatory Function  375

CHAPTER 17  Control of Cardiovascular Function  375
Organization of the Circulatory System  375
Principles of Blood Flow  378
The Heart as a Pump  382
The Systemic Circulation and Control of Blood Flow 394

CHAPTER 18 Disorders of Blood Flow and Blood Pressure 402
Blood Vessel Structure and Function 402
Disorders of the Arterial Circulation 404
Disorders of Arterial Blood Pressure 420
Disorders of the Venous Circulation 436

CHAPTER 19 Disorders of Cardiac Function 444
Coronary Artery Disease 444
Endocardial and Valvular Disorders 457
Disorders of the Pericardium 465
Cardiomyopathies 468
Heart Disease in Infants and Children 472

CHAPTER 20 Heart Failure and Circulatory Shock 486
Heart Failure 486
Circulatory Failure (Shock) 500

UNIT 6 • Respiratory Function 513

CHAPTER 21 Control of Respiratory Function 513
Structural Organization of the Respiratory System 513
Exchange of Gases Between the Atmosphere and the Lungs 520
Oxygen and Carbon Dioxide Transport 530
Control of Breathing 535

CHAPTER 22 Respiratory Tract Infections, Neoplasms, and Childhood Disorders 539
Respiratory Tract Infections 539
Cancer of the Lung 552
Respiratory Disorders in Children 555

CHAPTER 23 Disorders of Ventilation and Gas Exchange 565
Physiologic Effects of Ventilation and Diffusion Disorders 565
Disorders of Lung Inflation 568
Obstructive Airway Disorders 572
Interstitial Lung Diseases 586
Disorders of the Pulmonary Circulation 588
Acute Respiratory Disorders 592

UNIT 7 • Kidney and Urinary Tract Function 599

CHAPTER 24 Structure and Function of the Kidney 599
Functional Anatomy of the Kidney 599
Elimination and Endocrine Functions of the Kidney 611
Tests of Renal Function 614

CHAPTER 25 Disorders of Renal Function 617
Congenital and Hereditary Disorders of the Kidney 617
Disorders of Glomerular Function 621
Tubular and Interstitial Disorders 628
Obstructive Disorders 631
Malignant Tumors of the Kidney 636

CHAPTER 26 Acute Kidney Injury and Chronic Kidney Disease 639
Acute Kidney Injury 639
Chronic Kidney Disease 643
Chronic Kidney Disease in Children and Elderly Persons 652

CHAPTER 27 Disorders of the Bladder and Lower Urinary Tract 656
Control of Urinary Elimination 656
Disorders of the Lower Urinary Tract Structures and Function 661
Urinary Tract Infections 667
Cancer of the Bladder 671

UNIT 8 • Gastrointestinal and Hepatobiliary Function 675

CHAPTER 28 Structure and Function of the Gastrointestinal System 675
Organization and Function of the Gastrointestinal Tract 675
Gastrointestinal Innervation and Motility 680
Secretory Functions of the Gastrointestinal Tract 686
Digestion and Absorption in the Gastrointestinal Tract 689
Anorexia, Nausea, and Vomiting 693

CHAPTER 29 Disorders of Gastrointestinal Function 696
Disorders of the Esophagus 696
Disorders of the Stomach 701
Disorders of the Small and Large Intestines 705

CHAPTER 30 Disorders of Hepatobiliary and Exocrine Pancreas Function 724
The Liver and Hepatobiliary System 724
Disorders of Hepatic and Biliary Function 731
Disorders of the Hepatobiliary System and Exocrine Pancreas 745

UNIT 9 • Endocrine System 753

CHAPTER 31 Mechanisms of Endocrine Control 753
The Endocrine System 753

CHAPTER 32 Disorders of Endocrine Control of Growth and Metabolism 767
General Aspects of Altered Endocrine Function 767
Anterior Pituitary and Growth Hormone Disorders 768
Thyroid Hormone Disorders 775
Adrenal Cortical Hormone Disorders 783

CHAPTER 33 Diabetes Mellitus and the Metabolic Syndrome 793
Hormonal Control of Nutrient Metabolism and Storage 793
Diabetes Mellitus 799
UNIT 10 • Nervous System 821

CHAPTER 34 Organization and Control of Neural Function 821
Nervous Tissue Cells 821
Nerve Cell Communication 825
Developmental Organization of the Nervous System 830
Spinal Cord and Brain 837
The Autonomic Nervous System 847

CHAPTER 35 Somatosensory Function, Pain, and Headache 854
Organization and Control of Somatosensory Function 854
Pain Sensation 860
Alterations in Pain Sensitivity and Special Types of Pain 869
Headache and Associated Pain 872
Pain in Children and Older Adults 875

CHAPTER 36 Disorders of Neuromuscular Function 880
Organization and Control of Motor Function 880
Disorders of the Motor Unit 888
Disorders of the Cerebellum and Basal Ganglia 897

Pathophysiology, which is the focus of this book, may be defined as the physiology of altered health. The term combines the words pathology and physiology. Pathology (from the Greek pathos, meaning “disease”) deals with the study of the structural and functional changes in cells, tissues, and organs of the body that cause or are caused by disease. Physiology deals with the functions of the human body. Thus, pathophysiology deals not only with the cellular and organ changes that occur with disease, but also with the effects that these changes have on total body function. In addition, pathophysiology focuses on the mechanisms of the underlying disease process and provides the background for preventive as well as therapeutic health care measures and practices.

Disease

Disease may be defined as an interruption, cessation, or disorder of a body system or organ structure that is characterized usually by a recognized etiologic agent or agents, an identifiable group of signs and symptoms, or consistent anatomic alterations. The aspects of the disease process include etiology, pathogenesis, morphologic changes, and clinical manifestations.

Etiology

The causes of disease are known as etiologic factors. Among the recognized etiologic agents are biologic agents (e.g., bacteria, viruses), physical forces (e.g., trauma, burns, radiation), chemical agents (e.g., poisons, alcohol), and nutritional excesses or deficits. At the molecular level, it is important to distinguish between abnormal molecules and molecules that cause disease. This is true of diseases such as cystic fibrosis, sickle cell anemia, and familial hypercholesterolemia, in which the genetic abnormality of a single amino acid, transporter molecule, or receptor protein produces widespread effects on health.

Most disease-causing agents are nonspecific, and many different agents can cause disease of a single organ. A single agent or traumatic event can, however, lead to disease of a number of organs or systems. Although a disease-causing agent can affect more than a single organ and a number of disease-causing agents can affect the same organ, most disease states do not have a single cause. Instead, the majority of diseases are multifactorial in origin. This is particularly true of diseases such as cancer, heart disease, and diabetes. The multiple factors that predispose to a particular disease often are referred to as risk factors.

One way to view the factors that cause disease is to group them into categories according to whether they were present at birth or acquired later in life. Congenital conditions are defects that are present at birth, although they may not be evident until later in life. Congenital conditions may be caused by genetic influences, environmental factors (e.g., viral infections in the mother, maternal drug use, irradiation, or intrauterine crowding), or a combination of genetic and environmental factors. Acquired defects are those that are caused by events that occur after birth. These include injury, exposure to infectious agents, inadequate nutrition, lack of oxygen, inappropriate immune responses, and neoplasia. Many diseases are thought to be the result of a genetic predisposition and an environmental event or events that serve as a trigger to initiate disease development.

Pathogenesis

Pathogenesis is the sequence of cellular and tissue events that take place from the time of initial contact with an etiologic agent until the ultimate expression of a disease. Etiology describes what sets the disease process in motion, while pathogenesis describes how the disease process evolves. Although the two terms often are used interchangeably, their meanings are quite different. For example, atherosclerosis often is cited as the cause or etiology of coronary heart disease. In reality, the progression from fatty streak to the occlusive vessel lesion seen in persons with coronary heart disease represents the pathogenesis of the disorder. The true etiology of atherosclerosis remains largely uncertain.

Morphology

Morphology refers to the fundamental structure or form of cells or tissues. Morphologic changes are concerned with both the gross anatomic and microscopic changes that are characteristic of a disease. Histology deals with the study of the cells and extracellular matrix of body tissues. The most common method used in the study of tissues is the preparation of histologic sections—thin, translucent sections of human tissues and organs—that can be examined with the aid of a microscope. Histologic sections play an important role in the diagnosis of many types of cancer. A lesion represents a pathologic or traumatic discontinuity of a body organ or tissue. Descriptions of lesion size and characteristics often can be obtained through the use of radiographs, ultrasonography, and other imaging methods. Lesions also may be sampled by biopsy and the tissue samples subjected to histologic study.

Clinical Manifestations

Diseases can manifest in a number of ways. Sometimes the condition produces manifestations, such as fever, that make it evident that the person is sick. In other cases, the condition is silent at the onset and is detected during examination for other purposes or after the disease is far advanced.

Signs and symptoms are terms used to describe the structural and functional changes that accompany a disease. A symptom is a subjective complaint that is noted
by the person with a disorder, whereas a sign is a manifestation that is noted by an observer. Pain, difficulty in breathing, and dizziness are symptoms of a disease. An elevated temperature, a swollen extremity, and changes in pupil size are objective signs that can be observed by someone other than the person with the disease. Signs and symptoms may be related to the primary disorder or they may represent the body’s attempt to compensate for the altered function caused by the pathologic condition. Many pathologic states are not observed directly—one cannot see a sick heart or a failing kidney. Instead, what can be observed is the body’s attempt to compensate for changes in function brought about by the disease, such as the tachycardia that accompanies blood loss or the increased respiratory rate that occurs with pneumonia.

A syndrome is a compilation of signs and symptoms (e.g., chronic fatigue syndrome) that are characteristic of a specific disease state. Complications are possible adverse extensions of a disease or outcomes from treatment. Sequelae are lesions or impairments that follow or are caused by a disease.

**Diagnosis**

A diagnosis is the designation as to the nature or cause of a health problem (e.g., bacterial pneumonia or hemorrhagic stroke). The diagnostic process usually requires a careful history and physical examination. The history is used to obtain a person’s account of his or her symptoms and their progression, and the factors that contribute to a diagnosis. The physical examination is done to observe for signs of altered body structure or function.

The development of a diagnosis involves weighing competing possibilities and selecting the most likely one from among the conditions that might be responsible for the person’s clinical presentation. The clinical probability of a given disease in a person of a given age, gender, race, lifestyle, and locality often is influential in arriving at a presumptive diagnosis. Laboratory tests, radiologic studies, computed tomography (CT) scans, and other tests often are used to confirm a diagnosis.

An important factor when interpreting diagnostic test results is the determination of whether they are normal or abnormal. Is a blood count above normal, within the normal range, or below normal? What is termed a normal value for a laboratory test is established statistically from test results obtained from a selected sample of people. The normal values refer to the 95% distribution (mean plus or minus two standard deviations [mean ± 2 SD]) of test results for the reference population. Thus, the normal levels for serum sodium (136 to 145 mEq/L) represent the mean serum level for the reference population ± 2 SD. The normal values for some laboratory tests are adjusted for sex or age. For example, the normal hemoglobin range for women is 12.0 to 16.0 g/dL, and for men, 14.0 to 17.4 g/dL. Serum creatinine levels often are adjusted for age in the elderly, and normal values for serum phosphate differ between adults and children.

The quality of data on which a diagnosis is based may be judged for their validity, reliability, sensitivity, specificity, and predictive value. Validity refers to the extent to which a measurement tool measures what it is intended to measure. This often is assessed by comparing a measurement method with the best possible method of measure that is available. For example, the validity of blood pressure measurements obtained by a sphygmomanometer might be compared with those obtained by intra-arterial measurements. Reliability refers to the extent to which an observation, if repeated, gives the same result. A poorly calibrated blood pressure machine may give inconsistent measurements of blood pressure, particularly of pressures in either the high or low range. Reliability also depends on the persons making the measurements. For example, blood pressure measurements may vary from one observer to another because of the technique used (e.g., different observers may deflate the cuff at a different rate, thus obtaining different values), the way the numbers on the manometer are read, or differences in hearing acuity.

In the field of clinical laboratory measurements, standardization is aimed at increasing the trueness and reliability of measured values. Standardization relies on the use of written standards, reference measurement procedures, and reference materials. In the United States, the Food and Drug Administration (FDA) regulates in vitro diagnostic devices, including clinical laboratory instruments, test kits, and reagents. Manufacturers who propose to market new diagnostic devices must submit information on their instrument, test kit, or reagent to the FDA, as required by existing statutes and regulations. The FDA reviews this information to decide whether the product may be marketed in the United States.

Measures of sensitivity and specificity are concerned with determining how likely or how well the test or observation will identify people with or without the disease. Sensitivity refers to the proportion of people with a disease who are positive for that disease on a given test or observation (called a true-positive result). If the result of a very sensitive test is negative, it tells us the person does not have the disease and the disease has been excluded or “ruled out.” Specificity refers to the proportion of people without the disease who are negative on a given test or observation (called a true-negative result). Specificity can be calculated only from among people who do not have the disease. A test that is 95% specific correctly identifies 95 of 100 normal people. The other 5% are false-positive results. A false-positive test result can be unduly stressful for the person being tested, whereas a false-negative test result can delay diagnosis and jeopardize the outcome of treatment.

Predictive value is the extent to which an observation or test result is able to predict the presence of a given disease or condition. A positive predictive value refers to the proportion of true-positive results that occurs in a given population. In a group of women found to have “suspect breast nodules” in a cancer screening program, the proportion later determined to have breast cancer would constitute the positive predictive value. A negative predictive value refers to the true-negative observations in a population. In a screening test for breast cancer, the negative predictive value represents the proportion of women without suspect nodules who do not
have breast cancer. Although predictive values rely in part on sensitivity and specificity, they depend more heavily on the prevalence of the condition in the population. Despite unchanged sensitivity and specificity, the positive predictive value of an observation rises with prevalence, whereas the negative predictive value falls.

**Clinical Course**

The clinical course describes the evolution of a disease. A disease can have an acute, subacute, or chronic course. An acute disorder is one that is relatively severe, but self-limiting. Chronic disease implies a continuous, long-term process. A chronic disease can run a continuous course or can present with exacerbations (aggravation of symptoms and severity of the disease) and remissions (a period during which there is a decrease in severity and symptoms). Subacute disease is intermediate or between acute and chronic: it is not as severe as an acute disease and not as prolonged as a chronic disease.

The spectrum of disease severity for infectious diseases, such as hepatitis B, can range from preclinical to persistent chronic infection. During the preclinical stage, the disease is not clinically evident but is destined to progress to clinical disease. As with hepatitis B, it is possible to transmit a virus during the preclinical stage. Subclinical disease is not clinically apparent and is not destined to become clinically apparent. It is diagnosed with antibody or culture tests. Most cases of tuberculosis are not clinically apparent, and evidence of their presence is established by skin tests. Clinical disease is manifested by signs and symptoms. A persistent chronic infectious disease persists for years—sometimes for life. Carrier status refers to an individual who harbors an organism but is not infected, as evidenced by antibody response or clinical manifestations. This person still can infect others. Carrier status may be of limited duration or it may be chronic, lasting for months or years.

**Perspectives and Patterns of Disease**

The health of individuals is closely linked to the health of the community and to the population it encompasses. The ability to traverse continents in a matter of hours has opened the world to issues of populations at a global level. Diseases that once were confined to limited areas of the world now pose a threat to populations throughout the world.

As we move through the 21st century, we are continually reminded that the health care system and the services it delivers are targeted to particular populations. Managed care systems are focused on a population-based approach to planning, delivering, providing, and evaluating health care. The focus of health care also has begun to emerge as a partnership in which individuals are asked to assume greater responsibility for their own health.

**Epidemiology and Patterns of Disease**

Epidemiology is the study of disease occurrence in human populations. It was initially developed to explain the spread of infectious diseases during epidemics and has emerged as a science to study risk factors for multifactorial diseases, such as heart disease and cancer. Epidemiology looks for patterns, such as age, race, dietary habits, lifestyle, or geographic location, of persons affected with a particular disorder. In contrast to biomedical researchers, who seek to elucidate the mechanisms of disease production, epidemiologists are more concerned with whether something happens than how it happens. For example, the epidemiologist is more concerned with whether smoking itself is related to cardiovascular disease and whether the risk of heart disease decreases when smoking ceases. The biomedical researcher, however, is more concerned about the causative agent in cigarette smoke and the pathway by which it contributes to heart disease.

Much of our knowledge about disease comes from epidemiologic studies. Epidemiologic methods are used to determine how a disease is spread, how to control it, how to prevent it, and how to eliminate it. Epidemiologic methods also are used to study the natural history of disease, to evaluate new preventative and treatment strategies, to explore the impact of different patterns of health care delivery, and to predict future health care needs. As such, epidemiologic studies serve as a basis for clinical decision making, allocation of health care dollars, and development of policies related to public health issues.

Measures of disease frequency are an important aspect of epidemiology. They establish a means for predicting what diseases are present in a population and provide an indication of the rate at which they are increasing or decreasing. A disease case can be either an existing case or the number of new episodes of a particular illness that are diagnosed within a given period. Incidence reflects the number of new cases arising in a population at risk during a specified time. The population at risk is considered to be persons who are without the disease but are at risk for developing it. It is determined by dividing the number of new cases of a disease by the population at risk for development of the disease during the same period (e.g., new cases per 1000 or 100,000 persons in the population who are at risk). The cumulative incidence estimates the risk of developing the disease during that period of time. Prevalence is a measure of existing disease in a population at a given point in time (e.g., number of existing cases divided by the current population). The prevalence is not an estimate of risk of developing a disease because it is a function of both new cases and how long the cases remain in the population. Incidence and prevalence are always reported as rates (e.g., cases per 100 or cases per 100,000).

Morbidity and mortality statistics provide information about the functional effects (morbidity) and death-producing (mortality) characteristics of a disease. These statistics are useful in terms of anticipating health care needs, planning of public education programs, directing health research efforts, and allocating health care dollars.

Mortality statistics provide information about the causes of death in a given population. In most countries, people are legally required to record certain facts such as age, sex, and cause of death on a death certificate.
Internationally agreed-upon classification procedures (the International Classification of Diseases [ICD] by the World Health Organization) are used for coding the cause of death, and these data are expressed as death rates. \(^4\) Crude mortality rates (i.e., number of deaths in a given period) do not account for age, sex, race, socioeconomic status, and other factors. For this reason, mortality often is expressed as death rates for a specific population, such as the infant mortality rate. Mortality also can be described in terms of the leading causes of death according to age, sex, race, and ethnicity.

**Morbidity** describes the effects an illness has on a person’s life. Many diseases, such as arthritis, have low death rates but a significant impact on quality of life. Morbidity is concerned not only with the occurrence or incidence of a disease but also the persistence and long-term consequences of the disease.

**Determination of Risk Factors**

Conditions suspected of contributing to the development of a disease are called *risk factors*. They may be inherent to the person (high blood pressure or overweight) or external (smoking or drinking alcohol). There are different types of studies used to determine risk factors, including cross-sectional studies, case-control studies, and cohort studies. **Cross-sectional studies** use the simultaneous collection of information necessary for classification of exposure and outcome status. They can be used to compare the prevalence of a disease in those with the factor (or exposure) with the prevalence of a disease in those who are unexposed to the factor, such as the prevalence of coronary heart disease in smokers and nonsmokers. **Case-control studies** are designed to compare persons known to have the outcome of interest (cases) with those known not to have the outcome of interest (controls).\(^4\) Information on exposures or characteristics of interest is then collected from persons in both groups. For example, the characteristics of maternal alcohol consumption in infants born with a fetal alcohol spectrum disorder (cases) can be compared with those in infants born without one of these disorders (controls).

A **cohort** is a group of persons who were born at approximately the same time or share some characteristics of interest.\(^4\) Persons enrolled in a cohort study (also called a **longitudinal study**) are followed over a period of time to observe a specific health outcome. A cohort may consist of a single group of persons chosen because they have or have not been exposed to suspected risk factors; two groups specifically selected because one has been exposed and the other has not; or a single exposed group in which the results are compared with the general population.

One of the best-known examples of a cohort study is the Framingham Study, which was carried out in Framingham, Massachusetts.\(^12\) Framingham was selected because of the size of its population, the relative ease with which the people could be contacted, and the stability of the population in terms of moving into and out of the area. This longitudinal study, which began in 1950, was set up by the U.S. Public Health Service to study the characteristics of people who would later develop coronary heart disease. The study consisted of 5000 persons, aged 30 to 59 years, selected at random and followed for an initial period of 20 years, during which time it was predicted that 1500 of them would develop coronary heart disease. The advantage of such a study is that it can explore a number of risk factors at the same time and determine the relative importance of each. Another advantage is that the risk factors can later be related to other diseases, such as stroke.

A second well-known cohort study is the Nurses’ Health Study, which was developed by Harvard University and Brigham and Women’s Hospital. The study began in 1976 with a cohort of 121,700 female nurses, 30 to 55 years of age, living in the United States.\(^13\) Initially designed to explore the relationship between oral contraceptives and breast cancer, nurses in the study have provided answers to detailed questions about their menstrual cycle, smoking habits, diet, weight and waist measurements, activity patterns, health problems, and medication use. They have given urine and blood samples, and even provided researchers with their toenail clippings. In selecting the cohort, it was reasoned that nurses would be well-organized, accurate, and observant in their responses, and that physiologically they would be no different from other groups of women. It also was anticipated that their childbearing, eating, and smoking patterns would be similar to those of other working women.

**Natural History**

The **natural history** of a disease refers to the progression and projected outcome of the disease without medical intervention.\(^4\) By studying the patterns of a disease over time in populations, epidemiologists can better understand its natural history. Knowledge of the natural history can be used to determine disease outcome, establish priorities for health care services, determine the effects of screening and early detection programs on disease outcome, and compare the results of new treatments with the expected outcome without treatment.

There are some diseases for which there are no effective treatment methods available, or for which the current treatment measures are only effective in certain people. In this case, the natural history of the disease can be used as a predictor of outcome. For example, the natural history of hepatitis C indicates that 80% of people who become infected with the virus fail to clear the virus and progress to chronic infection.\(^14\) Information about the natural history of a disease and the availability of effective treatment methods provides directions for preventive measures. In the case of hepatitis C, careful screening of blood donations and education of intravenous drug abusers can be used to prevent transfer of the virus. At the same time, scientists are striving to develop a vaccine that will prevent infection in persons exposed to the virus. The development of vaccines to prevent the spread of infectious diseases such as polio and hepatitis B undoubtedly has been motivated by knowledge about
the natural history of these diseases and the lack of effective intervention measures. With other diseases, such as breast cancer, early detection through use of clinical breast examination and mammography increases the chances for a cure.

**Prognosis** refers to the probable outcome and prospect of recovery from a disease. It can be designated as chances for full recovery, possibility of complications, or anticipated survival time. Prognosis often is presented in relation to treatment options—that is, the expected outcomes or chances for survival with or without a certain type of treatment. The prognosis associated with a given type of treatment usually is presented along with the risk associated with the treatment.

**Levels of Prevention**

Leading a healthy life contributes to the prevention of disease. There are three fundamental types of prevention: primary prevention, secondary prevention, and tertiary prevention. It is important to note that all three levels are aimed at prevention. **Primary prevention** is directed at keeping disease from occurring by removing all risk factors. Examples of primary prevention include the administration of folic acid to pregnant women and women who may become pregnant to prevent fetal neural tube defects, giving immunizations to children to prevent communicable disease, and counseling people to adopt healthy lifestyles as a means of preventing heart disease. Primary prevention is often accomplished outside the health care system at the community level. Some primary prevention measures are mandated by law (e.g., wearing seat belts in automobiles and helmet use on motorcycles). Other primary prevention activities (e.g., use of earplugs or dust masks) occur in specific occupations. **Secondary prevention** detects disease early when it is still asymptomatic and treatment measures can affect a cure or stop the disease from progressing. The use of a Papanicolaou (Pap) smear for early detection of cervical cancer is an example of secondary prevention. Screening also includes history taking (asking if a person smokes), physical examination (blood pressure measurement), laboratory tests (cholesterol level determination), and other procedures (colonoscopy) that can be applied to asymptomatic people. Most secondary prevention is done in clinical settings. All types of health care professionals (e.g., physicians, nurses, dentists, audiologists, optometrists) participate in secondary prevention. **Tertiary prevention** is directed at clinical interventions that prevent further deterioration or reduce the complications of a disease once it has been diagnosed.

Cell Structure and Function

The cell is the smallest functional unit of life. Cells are the smallest unit capable of self-reproduction and are vehicles for transmitting genetic information that defines the organism. Cells with similar specialized functions are often organized into larger functional aggregates called tissues. These tissues in turn combine to form the various body structures and organs. Although the cells of different tissues and organs vary in structure and function, they are remarkably similar in their ability to exchange materials with their immediate environment, obtain energy from organic nutrients, synthesize complex molecules, and replicate themselves. Because most diseases begin at the cellular level, an understanding of cell function is crucial to understanding the disease process. Some diseases affect the cells of a single organ, others affect the cells of a particular tissue type, and still others affect the cells of the entire organism.

This chapter discusses the structural and functional components of the cell, basic cellular mechanisms, and tissue types.

Although diverse in their organization, all eukaryotic cells (cells with a true nucleus) have in common structures that perform unique functions. Under a light microscope, three primary components of the eukaryotic cell become evident: the plasma membrane, the nucleus, and the cytoplasm, while numerous structures are visible by higher magnification electron microscopy (Fig. 1-1).
Two distinct regions exist in the cell: the cytoplasm, which lies outside the nucleus, and the nucleoplasm, which lies inside the nucleus. The cytoplasm contains membrane-enclosed organelles (“little organs”) and inclusions in an aqueous gel called the cytoplasmic matrix. The matrix consists of a variety of solutes including inorganic ions (Na\(^+\), K\(^+\), Ca\(^+\)) and organic molecules such as intermediate metabolites, carbohydrates, lipids, proteins, and RNA. The nucleus is the largest organelle within the cell and its nucleoplasm contains the genome along with the enzymes necessary for deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) transcription.

**The Cell Membrane**

In many respects, the cell membrane (also called the plasma membrane) is one of the most important parts of the cell. It acts as a semipermeable structure that separates the intracellular and extracellular environments. It controls the transport of materials from the extracellular fluids to the interior of the cell, holds and binds receptors for hormones and other biologically active substances, participates in the generation and conduction of electrical currents in nerve and muscle cells, and aids in the regulation of cell growth and proliferation.

The cell membrane is a dynamic and fluid structure consisting of an organized arrangement of lipids, carbohydrates, and proteins (Fig. 1-2). A main structural component of the membrane is its lipid bilayer that consists primarily of phospholipids, cholesterol, and glycoproteins. This lipid bilayer provides the basic fluid structure of the membrane and serves as a relatively impermeable barrier to all but lipid-soluble substances. The most abundant lipids are phospholipids, each with a hydrophilic (water-soluble) head and a hydrophobic (water-insoluble) tail. Phospholipid molecules along with the glycolipids are aligned such that their hydrophilic heads face outward on each side of the membrane and their hydrophobic tails project toward the middle of the membrane. The presence of cholesterol makes the membrane regionally less deformable and less permeable to small water soluble molecules.

Although the lipid bilayer provides the basic structure of the cell membrane, proteins carry out most of the specific functions. The integral proteins span the entire lipid bilayer and are part of the membrane. Because most of the integral proteins pass directly through the membrane, they are also referred to as transmembrane proteins. Other proteins, called the peripheral proteins, are bound to one or the other side of the membrane and do not pass into the lipid bilayer.

The manner in which proteins are associated with the cell membrane often determines their function. Thus, peripheral proteins are associated with functions involving the inner or outer side of the membrane where they
are found. Several peripheral proteins serve as receptors or are involved in intracellular signaling systems. By contrast, only the transmembrane proteins can function on both sides of the membrane or transport molecules across it. Many integral transmembrane proteins form the ion channels found on the cell surface. These channel proteins have a complex morphology and are selective with respect to the substances they transmit.

A fuzzy-looking layer, called the cell coat or glycocalyx, surrounds the cell surface. It consists of long, complex carbohydrate chains attached to protein molecules that penetrate the outside portion of the membrane (i.e., glycoproteins); outward-facing membrane lipids (i.e., glycolipids); and carbohydrate-binding proteins called lectins. The cell coat participates in cell-to-cell recognition due to antigens that label cells as self or nonself and are important in tissue transplantation. The cell coat of a red blood cell contains the ABO blood group antigens.

### The Nucleus

The nucleus of a nondividing cell appears as a rounded or elongated structure situated near the center of the cell (see Fig. 1-1). It is enclosed in a nuclear envelope and contains chromatin, the genetic material of the nucleus, and a distinct region called the nucleolus. All eukaryotic cells have at least one nucleus (prokaryotic cells, such as bacteria, lack a nucleus and nuclear membrane).

The nucleus is regarded as the control center for the cell. It contains the DNA that is essential to the cell because its genes encode the information necessary for the synthesis of proteins that the cell must produce to stay alive. The genes also represent the individual units of inheritance that transmit information from one generation to another. The nucleus also is the site for the synthesis of the three types of RNA that move to the cytoplasm and carry out the actual synthesis of proteins. Messenger RNA (mRNA) copies and carries the DNA instructions for protein synthesis to the cytoplasm; ribosomal RNA (rRNA) is the site of protein synthesis; and transfer RNA (tRNA) transports amino acids to the site of protein synthesis for incorporation into the protein being synthesized (see Chapter 5).

The complex structure of DNA and DNA-associated proteins dispersed in the nuclear matrix is called chromatin. Depending on its transcriptional activity, chromatin may be condensed as an inactive form of chromatin called heterochromatin or extended as a more active form called euchromatin. Because heterochromatic regions of the nucleus stain more intensely than regions consisting of euchromatin, nuclear staining can be a guide to cell activity. The nucleus also contains the darkly stained round body called the nucleolus that is the site of rRNA synthesis and initial ribosomal assembly. Cells that are actively synthesizing proteins can be recognized because their nucleoli are large and prominent and the nucleus as a whole is euchromatic or slightly stained.

Surrounding the nucleus is the nuclear envelope formed by an inner and outer nuclear membrane containing a perinuclear space between them (Fig. 1-3). The inner nuclear membrane is supported by a rigid network of protein filaments called nuclear lamina that bind to chromosomes and secure their position in the nucleus. The outer nuclear membrane resembles and is continuous with the membrane of the endoplasmic reticulum.
At the site where the inner and outer membranes fuse, the nuclear envelope is penetrated by pores containing nuclear pore complexes. Structures of the nuclear pore complexes act as barriers and enable selective transport of RNA, ribosomes, and lipids and proteins with signaling functions between the nucleus and cytoplasm to coordinate events such as gene transcription and metabolic activities.

The Cytoplasm and Its Membrane-Bound Organelles

The cytoplasm surrounds the nucleus, and it is in the cytoplasm that the work of the cell takes place. Embedded in the cytoplasm are various membrane-enclosed organelles (e.g., endoplasmic reticulum [ER], Golgi apparatus, mitochondria, and lysosomes) and complexes without membranes (e.g., ribosomes and proteasomes) that have important functions in cells.

Ribosomes, Endoplasmic Reticulum, and Golgi Apparatus

The endoplasmic reticulum (with its associated ribosomes) and Golgi apparatus represent the primary sites of protein synthesis in the cell (Fig. 1-4). Following protein synthesis in the ribosomes, the endoplasmic reticulum and Golgi apparatus use transport vesicles to move newly synthesized proteins, membrane components, and soluble molecules from one organelle to another.

Ribosomes. The ribosomes are small particles of nucleoproteins (rRNA and proteins) that are held together by a strand of mRNA. Polyribosomes exist as clusters of free ribosomes within the cytoplasm or attached to the membrane of the ER (see Fig. 1-4). Free ribosomes are involved in the synthesis of proteins that remain in the cell as cytoplasmic structural or functional elements, whereas those attached to the ER translate mRNAs that code for proteins to be bound in membranes or destined for secretion.

Endoplasmic Reticulum. The endoplasmic reticulum is an extensive dynamic system of interconnected membranous tubes and sac-like cisternae (see Figs. 1-3 and 1-4). Within the lumen of the ER is a matrix that connects the space between the two membranes of the nuclear envelope to the cell periphery. The ER functions as a tubular communication system for transporting various substances from one part of the cell to another. A large surface area and multiple enzyme systems attached to the ER membranes also provide the machinery for many cellular metabolic functions.

Two forms of ER exist in cells: rough and smooth. Rough ER is studded with ribosomes attached to specific binding sites on the membrane. These ribosomes, with their accompanying strand of mRNA, synthesize proteins destined to be incorporated into cell membranes, used in the generation of lysosomal enzymes, or exported...
from the cell. The smooth ER is free of ribosomes and is continuous with the rough ER. It does not participate in protein synthesis; instead, its enzymes are involved in the synthesis of lipid and steroid hormone molecules, regulation of intracellular calcium, and metabolism and detoxification of certain hormones and drugs. The sarcoplasmic reticulum of skeletal and cardiac muscle cells is a form of smooth ER. Calcium ions needed for muscle contraction are stored and released from cisternae of the sarcoplasmic reticulum. The smooth ER of the liver is involved in glycogen storage and metabolism of lipid-soluble drugs.

**Golgi Apparatus.** The Golgi apparatus, sometimes called the Golgi complex, consists of stacks of thin, flattened vesicles or sacs (see Fig. 1-4). These Golgi bodies are found near the nucleus and function in association with the ER. Substances produced in the ER are transported to the Golgi complex in small, membrane-bound transport vesicles. Many cells synthesize proteins that are larger than the active product. The Golgi complex modifies these substances and packages them into secretory granules or vesicles. Insulin, for example, is synthesized as a large, inactive proinsulin molecule that is cleaved to produce a smaller, active insulin molecule within the Golgi complex of the beta cells of the pancreas. In addition to producing secretory granules, the Golgi complex is thought to produce large carbohydrate molecules that are added to proteins produced by the rough ER to form glycoproteins.

**Lysosomes**

The lysosomes, which can be viewed as digestive organelles in the cell, are small, membrane-bound sacs filled with hydrolytic enzymes. These enzymes can break down excess and worn-out cell parts as well as foreign substances that are taken into the cell. All of the lysosomal enzymes are acid hydrolases, which means that they require an acid environment. The lysosomes provide this environment by maintaining a pH of approximately 5.0 in their interior. The pH of the cytosol and other cellular components is approximately 7.2. Like all other cellular organelles, lysosomes not only contain a unique collection of enzymes, but also have a unique surrounding membrane that prevents the release of its digestive enzymes into the cytosol.

Lysosomes are formed from digestive vesicles called endosomes. These vesicles fuse to form multivesicular bodies called early endosomes (Fig. 1-5). The early endosomes mature into late endosomes as they recycle lipids, proteins, and other membrane components back to the plasma membrane in vesicles called recycling vesicles. Lysosomal enzymes are synthesized in the rough ER and then transported to the Golgi apparatus, where they are biochemically modified and packaged for transport to the endosomes. The late endosomes mature into lysosomes as they progressively accumulate newly synthesized acid hydrolases from the Golgi apparatus and attain digestive abilities.

Depending on the nature of the substance, different pathways are used for lysosomal degradation of unwanted materials (see Fig. 1-5). Small extracellular particles such as extracellular proteins and plasma membrane proteins form endocytotic vesicles after being internalized by pinocytosis or receptor-mediated endocytosis. These vesicles are converted into early and late endosomes, after which they mature into lysosomes. Large extracellular particles such as bacteria, cell debris, and other foreign particles are engulfed in a process called phagocytosis. A phagosome, formed as the material is internalized within the cell, fuses with a lysosome to form a phagolysosome. Intracellular particles, such as entire organelles, cytoplasmic proteins, and other
cellular components, are engulfed in a process called autophagy. These particles are isolated from the cytoplasmic matrix by ER membranes to form an autophagosome, which then fuses with a lysosome to form an autophagolysosome.

Although the lysosomal enzymes can break down most proteins, carbohydrates, and lipids to their basic constituents, some materials remain undigested. These undigested materials may remain in the cytoplasm as residual bodies or be extruded from the cell. In some long-lived cells, such as neurons and heart muscle cells, large quantities of residual bodies accumulate as lipofuscin granules or age pigments. Other indigestible pigments, such as inhaled carbon particles and tattoo pigments, also accumulate and may persist in residual bodies for decades.

Lysosomes are also repositories where cells accumulate abnormal substances that cannot be completely digested or broken down. In some genetic diseases known as lysosomal storage diseases, a specific lysosomal enzyme is absent or inactive, in which case the digestion of certain cellular substances (e.g., glucocerebrosides, gangliosides, sphingomyelin) does not occur. As a result, these substances accumulate in the cell. In Tay-Sachs disease (see Chapter 6), an autosomal recessive disorder, hexosaminidase A, which is the lysosomal enzyme needed for degrading the GM₂ ganglioside found in nerve cell membranes, is absent. Although the GM₂ ganglioside accumulates in many tissues, such as the heart, liver, and spleen, its accumulation in the nervous system and retina of the eye causes the most damage.

**Peroxisomes**

Spherical membrane-bound organelles called peroxisomes contain enzymes that are used in oxidative reactions. Reactions occurring in peroxisomes use oxygen to produce peroxides and convert hydrogen peroxide to water. Unless degraded, these highly unstable reactive oxygen species and free radicals (see Chapter 2) would damage other cellular molecules and structures. Peroxisomes also contain the enzymes needed for breaking down very-long-chain fatty acids, which are ineffectively degraded by mitochondrial enzymes. In liver cells, peroxisomal enzymes are involved in the formation of the bile acids.

**Proteasomes**

Proteasomes are cytoplasmic protein complexes that are not bound by membranes. Proteasomes are responsible for proteolysis of malformed and misfolded proteins and have roles in many cellular responses and events. The process of cytosolic proteolysis is carefully controlled by the cell and requires that the protein be targeted for degradation. This process involves ubiquitination, a process whereby several small ubiquitin molecules (a small 76-amino-acid polypeptide chain) are attached to an amino acid residue of the targeted protein. Once a protein is so tagged, it is degraded by proteasomes. After the targeted protein has been degraded, the resultant amino acids join the intracellular pool of free amino acids and the ubiquitin molecules are released and recycled.

**Mitochondria**

The mitochondria are literally the “power plants” of the cell because they contain the enzymes needed for capturing most of the energy in foodstuffs and converting it into cellular energy. This multistep process requires oxygen and is often referred to as aerobic metabolism. Much of this energy is stored in the high-energy phosphate bonds of adenosine triphosphate (ATP) that serves to power various cell activities. Mitochondria are found close to the site of energy consumption in the cell (e.g., near the myofibrils in muscle cells). The number of mitochondria in a given cell type is largely determined by the type of activity the cell performs and how much energy is needed to undertake the activity. For example, a dramatic increase in mitochondria occurs in skeletal muscle repeatedly stimulated to contract.

The mitochondria are composed of two membranes: an outer membrane that encloses the periphery of the mitochondrion and an inner membrane that forms shelflike projections, called cristae (Fig. 1-6). The narrow space between the outer and inner membranes is called the intermembrane space, whereas the large space enclosed by the inner membrane is termed the matrix space. The outer mitochondrial membrane contains a large number of transmembrane porins, through which inorganic ions and metabolites may pass. The inner membrane contains the respiratory chain enzymes and transport proteins needed for the synthesis of ATP.

Mitochondria contain their own DNA and ribosomes and are self-replicating. The DNA is found in the mitochondrial matrix and is distinct from the chromosomal DNA found in the nucleus. Mitochondrial DNA, known as the “other human genome,” is a double-stranded, circular molecule that encodes the rRNA and tRNA required for intramitochondrial synthesis of the proteins needed for the energy-generating function of the mitochondria. Although mitochondrial DNA directs the synthesis of 13 of the proteins required for mitochondrial function, the DNA of the nucleus encodes the structural
proteins of the mitochondria and other proteins needed to carry out cellular respiration. Mitochondrial DNA is inherited matrilineally (i.e., from the mother) and provides a basis for familial lineage studies. Mutations have been found in each of the mitochondrial genes, and an understanding of the role of mitochondrial DNA in certain diseases and of mechanisms to maintain the integrity of the mitochondrial genome is beginning to emerge. Most tissues in the body depend to some extent on oxidative metabolism and can therefore be affected by mitochondrial DNA mutations.

Mitochondria also function as key regulators of apoptosis or programmed cell death (discussed in Chapter 2). The initiation of the mitochondrial pathway for apoptosis results from an increase in mitochondrial membrane permeability and the subsequent release of proapoptotic molecules into the cytoplasm. One of these proapoptotic molecules, cytochrome c, is well known for its role in cellular respiration. In the cytosol, cytochrome c binds to a protein called the apoptosis protease activating factor-1 protein, initiating the molecular events involved in the apoptosis cascade. Other apoptotic proteins also enter the cytoplasm, where they bind to and neutralize the various apoptotic inhibitors, whose normal function consists of blocking the apoptotic cascade. Both the formation of reactive oxygen species (e.g., peroxide) and the activation of the p53 tumor-suppressor gene by DNA damage or other means initiate apoptotic signaling through the mitochondria. Dysregulated apoptosis (too little or too much) has been implicated in a wide range of diseases, including cancer, in which there is an inappropriately low rate of apoptosis, and neurodegenerative diseases, in which there is an increased or excessive rate of apoptosis.

The Cytoskeleton

In addition to its organelles, the cytoplasm contains a network of microtubules, microfilaments, and intermediate filaments (Fig. 1-7). Because they control cell shape and movement, these structures are a major component of the structural elements called the cytoskeleton.

Microtubules

Microtubules are slender and rigid tubular structures composed of globular proteins called tubulin. Each microtubule consists of parallel protofilaments, each composed of α- and β-tubulin dimers. Microtubules function in many ways, including the development and maintenance of cell form; participation in intracellular transport mechanisms, including axoplasmic transport in neurons; and formation of the basic structure for several complex cytoplasmic organelles, including the cilia, flagella, and centrioles. Cilia and flagella are microtubule-filled cellular extensions extending from the cell membrane that are capable of sweeping movements. Cilia are found on the apical (luminal) surfaces of many epithelial linings, including the nasal sinuses and passages of the upper respiratory system.

Removal of mucus from the respiratory passages is highly dependent on the proper functioning of the cilia. Flagella form the tail-like structures that provide motility for sperm. Centrioles are small, barrel-shaped bodies oriented at right angles to each other. In dividing cells, the two cylindrical centrioles form the mitotic spindle that aids in the separation and movement of the chromosomes during cell division.

Abnormalities of the microtubules occur in a number of pathologic states. These abnormalities may be manifested by an abnormal appearance and function, aberrant movements of intracellular organelles, and defective cell locomotion. Defective organization of the microtubules can cause sterility by inhibiting sperm motility, as well as defective motility of cilia in the epithelial lining of the respiratory tract, resulting in chronic respiratory tract infections. Proper functioning of the microtubules is also essential for various stages of leukocyte migration. Drugs that bind to tubulin molecules and prevent their assembly of microtubules (colchicine) are useful in the treatment of gout, in which symptoms are due to movement of leukocytes toward urate crystals in the tissues. Since microtubules form the mitotic spindle, which is essential for cell proliferation, drugs that bind microtubules (e.g., vinca alkaloids) are useful in the treatment of cancer.
Actin Microfilaments and Intermediate Filaments

In addition to microtubules, two other cytoskeletal structures exist: microfilaments and intermediate filaments. Microfilaments are composed of actin, whereas intermediate filaments are a heterogeneous group of filaments with diameter sizes between those of microtubules and actin filaments.

Actin, which can exist in globular and filamentous forms, is of central importance to cellular biology. It contributes to cell motility, positioning of organelles in the cell, and cell shape and polarity. Many functions of actin filaments are performed in association with myosin motor proteins. Contractile activities involving actin microfilaments and associated thick myosin filaments contribute to muscle contraction.

The intermediate filaments include the cytokeratins, vimentin, and neurofilaments. They have structural and maintenance functions that are important in tissue, cellular, developmental, and differentiation processes. They are also very responsive to cellular stresses, such as heat, radiation, toxins, pathogens and oxidation. Neurofibrillary tangles found in the brain in Alzheimer disease contain microtubule-associated proteins and neurofilaments, evidence of a disrupted neuronal cytoskeleton.

SUMMARY CONCEPTS

- Cells are the smallest functional unit of the body. They are autonomous units that contain structures that are strikingly similar to those needed to maintain total body function.

- The cell membrane is a protein-studded lipid bilayer that surrounds the cell and separates it from its surrounding external environment. It contains receptors for hormones and other biologically active substances, participates in the electrical events that occur in nerve and muscle cells, and aids in the regulation of cell growth and proliferation. The cell surface is surrounded by a fuzzy-looking layer called the cell coat or glycocalyx. The cell coat participates in cell-to-cell recognition and adhesion, and it contains tissue transplant antigens.

- The nucleus is the control center for the cell. It contains deoxyribonucleic acid (DNA), which provides the information necessary for the synthesis of the various proteins that the cell must produce to stay alive and to transmit information from one generation to another.

- The cytoplasm contains the cell's organelles. Ribosomes serve as sites for protein synthesis in the cell. The endoplasmic reticulum (ER) functions as a tubular communication system through which substances can be transported from one part of the cell to another and as the site of protein (rough ER), carbohydrate, and lipid (smooth ER) synthesis. The Golgi apparatus modifies materials synthesized in the ER and packages them into secretory granules for transport within the cell or export from the cell. Lysosomes, which can be viewed as the digestive system of the cell, contain hydrolytic enzymes that digest worn-out cell parts and foreign materials. The mitochondria serve as power plants for the cell because they transform food energy into ATP, which is used to power cell activities. They contain their own extrachromosomal DNA, which is used in the synthesis of certain proteins required for mitochondrial function.

- In addition to its organelles, the cytoplasm also contains a network of microtubules, actin microfilaments, and intermediate filaments called the cytoskeleton. Microtubules are slender, stiff tubular structures that influence cell shape, provide a means of moving organelles through the cytoplasm, and form cilia, flagella, and centrioles. Actin microfilaments are dynamic, thin, threadlike cytoplasmic structures that are important in cell movement and organelle positioning. Many types of intermediate filaments function in supporting and maintaining the shape of cells and participate in numerous cellular processes.

Cell Metabolism and Energy Storage

Energy metabolism refers to the chemical processes involved in converting carbohydrates, fats, and proteins from the foods we eat into the energy needed for cell functions. Cells use oxygen to transform the breakdown products of the foods we eat into the energy needed for muscle contraction; the transport of ions and other molecules across cell membranes; and the synthesis of enzymes, hormones, and other macromolecules.

The special “unit of currency” for transferring energy in living cells is ATP. Adenosine triphosphate molecules consist of adenosine, a nitrogenous base; ribose, a five-carbon sugar; and three phosphate groups (Fig. 1-8). The last two phosphate groups are attached to the remainder of the molecule by two high-energy bonds. Each bond releases a large amount of energy when hydrolyzed. Adenosine triphosphate is hydrolyzed to form adenosine...
diphosphat (ADP) with the loss of one high-energy bond and to adenosine monophosphate (AMP) with the loss of two such bonds. The energy liberated from the hydrolysis of ATP is used to drive reactions that require free energy, such as muscle contraction and active transport mechanisms. Energy from foodstuffs is used to convert ADP back to ATP. Hence ATP is often called the energy currency of the cell; energy can be “saved” or “spent” using ATP as an exchange currency.

Two types of energy production are present in the cell: the anaerobic (i.e., without oxygen) glycolytic pathway, occurring in the cytoplasm, and the aerobic (i.e., with oxygen) pathway, occurring in the mitochondria. The glycolytic pathway serves as the prelude to the aerobic pathway.

**Anaerobic Metabolism**

Glycolysis is the anaerobic process by which energy is liberated from glucose. It is an important source of energy for cells that lack mitochondria. The process also provides a temporary source of energy for cells that are deprived of an adequate supply of oxygen. Glycolysis involves a sequence of reactions that convert glucose to pyruvic acid, with the concomitant production of ATP from ADP. The net gain of energy from the glycolytic metabolism of one molecule of glucose is two ATP molecules. Although relatively inefficient as to energy yield, the glycolytic pathway is important during periods of decreased oxygen delivery, such as occurs in skeletal muscle during the first few minutes of exercise.

Glycolysis requires the presence of nicotinamide adenine dinucleotide (NAD\(^+\)), a hydrogen carrier. The end products of glycolysis are pyruvate and NADH (the reduced form of NAD\(^+\)) plus \(\text{H}^+\). When oxygen is present, pyruvate moves into the aerobic mitochondrial pathway, and NAD\(^+\) is regenerated as NADH delivers its electron and proton (\(\text{H}^+\)) to the oxidative electron transport system. Under anaerobic conditions, such as cardiac arrest or circulatory shock, pyruvic acid is converted to lactic acid, which diffuses out of the cells into the extracellular fluid. Conversion of pyruvate to lactic acid is reversible, and once the oxygen supply has been restored, lactic acid is converted back to pyruvic acid and used directly for energy or to synthesize glucose.

**Aerobic Metabolism**

Aerobic metabolism, which supplies 90% of the body’s energy needs, occurs in the cell’s mitochondria and requires oxygen. It is here that the hydrogen and carbon molecules from dietary fats, proteins, and carbohydrates are broken down and combined with molecular oxygen to form carbon dioxide and water as energy is released. Unlike lactic acid, which is an end product of anaerobic metabolism, carbon dioxide and water are relatively harmless and easily eliminated from the body. In a 24-hour period, oxidative metabolism produces 150 to 300 mL of water.

The citric acid cycle, sometimes called the tricarboxylic acid (TCA) or Krebs cycle, provides the final common pathway for the metabolism of nutrients. In the citric acid cycle, which takes place in the matrix of the mitochondria, an activated two-carbon molecule of acetyl-coenzyme A (acetyl-CoA) condenses with a four-carbon molecule of oxaloacetic acid and moves through a series of enzyme-mediated steps. This process produces hydrogen atoms and carbon dioxide. As hydrogen is generated, it combines with NAD\(^+\) or flavin adenine dinucleotide (FAD) for transfer to the electron transport system. Besides pyruvate from the glycolysis of glucose, products of amino acid and fatty acid degradation enter the citric acid cycle and contribute to the generation of ATP.

Oxidation of electrons from the hydrogen atoms generated during glycolysis and the citric acid cycle takes place in the electron transport system located on the inner mitochondrial membrane. The electrons are used to reduce elemental oxygen, which combines with hydrogen to form water. During this sequence of oxidative reactions, large amounts of energy are released and used to convert ADP to ATP. Because the formation of ATP involves the addition of a high-energy phosphate bond to ADP, the process is called oxidative phosphorylation.
Cell metabolism is the process that converts dietary fuels from carbohydrates, proteins, and fats into adenosine triphosphate (ATP), which provides energy for the cell. Adenosine triphosphate is formed through three major pathways: (1) the glycolytic pathway, (2) the citric acid cycle, and (3) the electron transport chain. In fuel metabolism, which is an oxidation–reduction reaction, the fuel donates electrons and is oxidized, and the coenzymes nicotinamide adenine dinucleotide (NAD) and flavin adenine dinucleotide (FAD) accept electrons and are reduced.

**Understanding Cell Metabolism**

**Glycolytic Pathway.** Glycolysis, which occurs in the cytoplasm of the cell, involves the splitting of the six-carbon glucose molecule into two three-carbon molecules of pyruvic acid. Because the reaction that splits glucose requires two molecules of ATP, there is a net gain of only two molecules of ATP from each molecule of glucose that is metabolized. The process is anaerobic and does not require oxygen ($O_2$) or produce carbon dioxide ($CO_2$). When $O_2$ is present, pyruvic acid moves into the mitochondria, where it enters the aerobic citric acid cycle. Under anaerobic conditions, pyruvate is converted to lactic acid, allowing glycolysis to continue as a means of supplying cells with ATP when $O_2$ is lacking.

**Citric Acid Cycle.** Under aerobic conditions, both of the pyruvic acid molecules formed by the glycolytic pathway enter the mitochondria, where each combines with acetyl-coenzyme to form acetyl-coenzyme A (acetyl-CoA). The formation of acetyl-CoA begins the reactions that occur in the citric acid cycle. Some reactions release $CO_2$ and some transfer electrons from the hydrogen atom to NADH or FADH. In addition to pyruvic acid from the glycolysis of glucose, fatty acid and amino acid breakdown products can also enter the citric acid cycle. Fatty acids, which are the major source of fuel in the body, are oxidized by a process called β-oxidation to acetyl-CoA for entry into the citric acid cycle.
Electron Transport Chain. At the completion of the citric acid cycle, each glucose molecule has yielded only four new molecules of ATP (two from glycolysis and two from the citric acid cycle). In fact, the principal function of these earlier stages is to make the electrons (e-) from glucose and other food substrates available for oxidation. Oxidation of the electrons carried by NADH and FADH$_2$ is accomplished through a series of enzymatically catalyzed reactions in the mitochondrial electron transport chain. During these reactions, protons (H$^+$) combine with O$_2$ to form water (H$_2$O), and large amounts of energy are released and used to add a high-energy phosphate bond to adenosine diphosphate (ADP), converting it to ATP. There is a net yield of 36 molecules of ATP from 1 molecule of glucose (2 from glycolysis, 2 from the citric acid cycle, and 32 from the electron transport chain). In general, the net amount of ATP formed from each gram of protein that is metabolized is less than for glucose, whereas that obtained from fat is greater (e.g., each 16-carbon fatty acid molecule yields about 129 molecules of ATP).

SUMMARY CONCEPTS

- Metabolism is the process whereby the carbohydrates, fats, and proteins from the foods we eat are broken down and subsequently converted into the energy needed for cell function. Energy is stored in the high-energy phosphate bonds of adenosine triphosphate (ATP), which serves as the energy currency for the cell.

- Two sites of energy conversion are present in cells: the anaerobic glycolytic pathway in the cytoplasm and the aerobic pathways in the mitochondria. The most efficient of these pathways is the aerobic citric acid cycle and electron transport chain in the mitochondria. This pathway, which requires oxygen, produces carbon dioxide and water as end products and results in the release of large amounts of energy that is used to convert adenosine diphosphate (ADP) to ATP. The glycolytic pathway in the cytoplasm involves the breakdown of glucose to form ATP. This pathway can function without oxygen by producing lactic acid.
Cell Signaling and Communication

Mechanisms

Signaling systems consist of receptors that reside either on the cell membrane (surface receptors) or within the cells (intracellular receptors). Receptors are activated by a variety of chemical messengers including neurotransmitters, hormones, growth factors, and other chemical messengers, as well as signaling proteins called cytokines and lipids. Some lipid-soluble chemical messengers move through the membrane and bind to cytoplasmic or nuclear receptors to exert their physiologic effects. Signaling systems often rely on the intermediary activity of a separate class of membrane-bound regulatory proteins to convert extracellular signals, or first messengers, into intracellular signals, or second messengers, such as a unique form of adenosine monophosphate called cyclic adenosine monophosphate (cAMP). Many molecules involved in signal transduction within cells are enzymes and other proteins. Some of the enzymes are protein kinases that catalyze the phosphorylation of proteins, thereby changing their activity and function.

Cell Surface Receptors

Each cell type in the body contains numerous receptor proteins, which as a set may characterize the cell type, that enable it to respond to a complementary set of ligands (i.e., molecules with a high affinity for a receptor) or signaling molecules in a specific, preprogrammed way. These receptors, which span the cell membrane, relay information to a series of intracellular intermediates that eventually pass the signal to its final destination. There are three major classes of cell surface receptor proteins: G protein–linked receptors, enzyme-linked receptors, and ion channel–linked receptors.

G Protein–Linked Receptors. G protein–linked receptors mediate cellular responses for numerous types of first messengers through regulatory proteins called G proteins that bind to guanine nucleotides such as guanine diphosphate (GDP) and guanine triphosphate (GTP). With more than 1000 members, G protein–linked receptors are the largest family of cell surface receptors. Although there are differences among the G protein–linked receptors, all share a number of features. They all have a ligand-binding extracellular receptor component, which recognizes a specific ligand or first messenger. Upon ligand-binding, they all undergo conformational changes that activate the G protein found on the cytoplasmic side of the cell membrane (Fig. 1-9). All G proteins incorporate the guanosine triphosphatase (GTPase) cycle, which functions as a molecular switch that exists in two states: an activated (on) state and an inactivated (off) state. Receptor activation causes the α subunit to dissociate from the receptor and the β and γ subunits and transmit the signal from the first messenger to a membrane-bound intermediate called an effector. Often, the effector is an enzyme that converts an inactive precursor molecule into a second messenger, which diffuses into the cytoplasm and carries the signal beyond the cell membrane. One common effector is the enzyme adenyl cyclase, which converts the precursor ATP to the second messenger cAMP, transferring the two phosphate groups to other proteins. This transfer changes the conformation and function of these proteins. Such changes eventually produce the cell response initiated by the first messenger, whether it is a secretion, muscle contraction or relaxation, or change in metabolism. Sometimes it is the opening of membrane channels involved in calcium or potassium influx.

Enzyme-Linked Receptors. Like G protein–linked receptors, enzyme-linked receptors are transmembrane...
proteins with their ligand–binding site on the outer surface of the cell membrane. Instead of having a cytosolic domain that associates with a G protein, their cytosolic domain either has intrinsic enzyme activity or associates directly with an enzyme. There are several classes of enzyme-linked receptors, including one widely used in hormonal control of cell function. The binding of the hormone to a special transmembrane receptor results in activation of the enzyme adenyl cyclase at the intracellular portion of the receptor. This enzyme then catalyzes the formation of the second messenger cAMP, which has multiple effects on cell function. Insulin, for example, acts by binding to an enzyme-linked receptor (see Chapter 33).

**Ion Channel–Linked Receptors.** Ion channel–linked receptors are involved in the rapid synaptic signaling between electrically excitable cells. Many neurotransmitters mediate this type of signaling by transiently opening or closing ion channels formed by integral proteins in the cell membrane (to be discussed). This type of signaling is involved in the transmission of impulses in nerve and muscle cells.

**Intracellular Receptors**

Some messengers, such as thyroid hormone and steroid hormones, do not bind to membrane receptors but move directly across the lipid bilayer of the cell membrane and are transported to the cell nucleus, where they influence DNA activity (see Chapter 31). Many of these hormones bind to a receptor within the cytoplasm, and the receptor–hormone complex enters the nucleus. There it binds to DNA, initiating processes that increase the production of proteins that alter cell function.

**Membrane Transport Mechanisms**

The lipid layer of the cell membrane serves as a barrier against the movement of water and water-soluble substances between the intracellular and extracellular fluids, while allowing a few lipid-soluble (e.g., alcohols with lower numbers of hydrocarbons, oxygen, nitrogen) and uncharged molecules (glycerol, water) to cross the cell membrane by simple diffusion. The cell membrane also contains large numbers of protein molecules, many of which insert completely through the membrane (Fig. 1-10). Most ions and small molecules rely on these proteins for transport.

Different membrane proteins function in different ways. For example, channel proteins form water-lined passageways through the membrane and allow free movement of water as well as selected ions or molecules. Membrane transport proteins bind molecules or ions and undergo a series of conformational changes to transfer the bound solute across the membrane. Some transport proteins, called uniporters, simply mediate the movement of a single solute from one side of the membrane to the other, whereas others function as coupled transporters in which the transfer of one solute depends on the transfer of a second solute (Fig. 1-11). This coupled transport involves either the simultaneous transport in the same direction, performed by transporters called symporters, or the transport of a second solute in the opposite direction, by transporters called antiporters.

All channels and many transporters allow solutes to cross the membrane only passively by passive transport or facilitated diffusion. Cells also require transport proteins that actively pump certain solutes across the membrane against an electrochemical gradient, in a process called active transport. Active transport is directional and requires an energy source such as ATP. The cell membrane can also engulf substances, forming a membrane-bound vesicle; this vesicle is brought into the cell by endocytosis. The process by which cellular vesicles fuse to the cell membrane releasing contents outside of the cell is called exocytosis.

Many integral transmembrane proteins form the ion channels found on the cell surface. These channel proteins have a complex morphology and are selective with respect to the substances that can transverse the channel.
A host of genetic disorders known as channelopathies involve mutations in channel proteins. For example, in cystic fibrosis (see Chapter 23), the primary defect resides in an abnormal chloride channel, which results in increased sodium and water reabsorption that causes respiratory tract secretions to thicken and occlude the airways.

**Diffusion**

Diffusion refers to the passive process by which molecules and other particles in a solution become widely dispersed and reach a uniform concentration because of energy created by their spontaneous kinetic movements. In the process of reaching a uniform concentration, these molecules and particles move “downhill” from an area of higher to an area of lower concentration. If the molecules or particles carry a net charge, both the concentration gradient and the electrical potential difference across the membrane influence transport.

Lipid-soluble molecules, such as oxygen, carbon dioxide, alcohol, and fatty acids, become dissolved in the lipid matrix of the cell membrane and diffuse through the membrane in the same manner that diffusion occurs in water. Other substances diffuse through minute pores of the cell membrane.

**Simple Diffusion.** Simple diffusion means that the kinetic movement of molecules or ions occurs through a membrane opening or through intermolecular spaces without any interaction with a carrier protein. The rate of diffusion depends on how many particles are available for diffusion, the kinetic movement of the particles, and the number and size of the openings in the membrane through which the molecules or ions can move.

**Facilitated Diffusion.** Like simple diffusion, facilitated diffusion occurs down a concentration gradient; thus, it does not require input of metabolic energy. Unlike simple diffusion, however, facilitated diffusion requires a transport protein. Some substances, such as glucose, cannot pass unassisted through the cell membrane because they are not lipid soluble or they are too large to pass through the membrane’s pores. These substances combine with special transport proteins at the membrane’s outer surface, are carried across the membrane attached to the transporter, and then are released. In facilitated diffusion, a substance can move only from an area of higher concentration to one of lower concentration. The rate at which a substance moves across the membrane by facilitated diffusion depends on the difference in concentration between the two sides of the membrane. Also important are the availability of transport proteins and the rapidity with which they can bind and release the substance being transported. It is thought that insulin, which facilitates the movement of glucose into cells, acts by increasing the availability of glucose transporters in the cell membrane.

**Ion Channels and Gates.** Ion channels (leak channels) are integral proteins that span the width of the membrane and are normally composed of several polypeptides or protein subunits that form a gating system (Fig. 1-12). Specific stimuli cause the protein subunits to undergo conformational changes to form an open channel or gate through which the ions can move. In this way, ions do not need to cross the lipid-soluble portion of the membrane but can remain in the aqueous solution that fills the ion channel. Many of the ion channels are highly selective for transport of one or more specific ions or molecules. This selectivity results from the characteristics of the channel itself, such as its diameter, its shape, and the nature of electrical charges and chemical bonds along its inside surface.

The cell membrane contains two basic groups of ion channels: leakage channels and gated channels. Leakage channels are open even in the unstimulated state, whereas gated channels open and close in response to specific stimuli. Three main types of gated channels are present in the cell membrane: voltage-gated channels, which have electrically operated channels that open when the membrane potential changes beyond a certain point; ligand-gated channels, which are chemically operated and respond to specific receptor-bound ligands, such as the neurotransmitter acetylcholine; and mechanically gated channels, which open or close in response to such mechanical stimulations as vibrations, tissue stretching, or pressure.

**Movement of Water Across the Cell Membrane.** Water molecules move through adjacent phospholipid...
molecules in the cell membrane by osmosis without actually dissolving in the region occupied by the fatty acid side of the chains. Osmosis is regulated by the concentration of nondiffusible particles on either side of the membrane, with water moving from the side with the lower concentration of particles to the side with the higher concentration. The cell membranes of most cells also contain transmembrane proteins, called aquaporins, that function as water channels. Aquaporins are especially abundant in cells that must transport water at particularly high rates, such as certain cells of the kidney.

**Active Transport**

The process of diffusion describes particle movement from an area of higher concentration to one of lower concentration, resulting in an equal distribution of permeable substances across the cell membrane. Sometimes, however, different concentrations of a substance are needed in the intracellular and extracellular fluids. For example, to function, a cell requires a higher intracellular concentration of potassium ions than is present in the extracellular fluid, while maintaining a much lower concentration of sodium ions than the extracellular fluid. In these situations, energy is required to pump the ions “uphill” or against their concentration gradient. When cells use energy to move ions against an electrical or chemical gradient, the process is called *active transport*. Two types of active transport systems exist: primary active transport and secondary active transport.

**Primary Active Transport.** Among the substances that are transported by primary active transport are sodium, potassium, calcium, and hydrogen ions. The active transport system studied in the greatest detail is the sodium/potassium (Na+/K+) pump, or Na+/K+-ATPase membrane pump. The Na+/K+-ATPase membrane pump moves sodium from inside the cell to the extracellular region, where its concentration is approximately 14 times greater than inside; the pump also returns potassium to the inside, where its concentration is approximately 35 times greater than it is outside the cell. If it were not for the activity of the Na+/K+-ATPase membrane pump, the osmotically active sodium particles would accumulate in the cell, causing cellular swelling because of an accompanying influx of water.

**Secondary Active Transport.** Secondary active transport mechanisms harness the energy derived from the primary active transport of one substance, usually sodium, for the cotransport of a second substance. For example, when sodium ions are actively transported out of a cell by primary active transport, a large concentration gradient develops (i.e., high concentration on the outside and low on the inside). This concentration gradient represents a large storehouse of energy because sodium ions are always attempting to diffuse into the cell. Similar to facilitated diffusion, secondary transport uses membrane transport proteins. These proteins have two binding sites: one for sodium and the other for the substance undergoing secondary transport. Secondary active transport systems are classified into two groups: cotransport, or symport systems, in which sodium and the solute are transported in the same direction, and countertransport, or antiport systems, in which sodium and the solute are transported in the opposite directions. An example of cotransport occurs in the intestine, where the absorption of glucose and amino acids is coupled with sodium transport.

**Vesicular Transport**

Vesicular transport is a mechanism in which materials are transported in membrane-bound vesicles. There are two types of vesicular transport: endocytosis, in which materials are moved into a cell in a vesicle formed from the cell membrane, and exocytosis, in which materials are moved out of a cell by fusion of a vesicle with the cell membrane.

Endocytosis is the process by which cells engulf materials from their surroundings. In the process, the material is progressively enclosed in small portions of the cell membrane, which invaginates (folds inward) and then pinches off to become an endocytotic vesicle. If the vesicle is small (>150 nm in diameter), the process is called pinocytosis, and the vesicle is called a pinocytotic vesicle; if the vesicle is large (>250 nm in diameter), the process is called phagocytosis, and the vesicle is called

---

**FIGURE 1-12.** Gated ion channels that open in response to specific stimuli. (A) Voltage-gated channels are controlled by a change in the membrane potential. (B) Ligand-gated channels are controlled by binding of a ligand to a receptor.
a phagosome. The process of pinocytosis, which means “cell drinking,” is important in the transport of proteins and strong solutions of electrolytes. Phagocytosis, which means “cell eating,” involves the engulfment and subsequent killing or degradation of microorganisms and other particulate matter. Certain cells, such as macrophages and neutrophils, are adept at engulfing and disposing of invading organisms, damaged cells, and unneeded extracellular constituents.

Exocytosis is the mechanism for the secretion of intracellular substances into the extracellular spaces. It may be considered a reverse of endocytosis in that the membrane of the secretory granule fuses with the cell membrane and allows the contents of the granule to be released into the extracellular fluid. Exocytosis is important in removing cellular debris and releasing substances, such as hormones and cytokines, synthesized in the cell.

Receptor-mediated endocytosis involves the binding of substances to a receptor on the cell surface. Many of these receptor proteins are concentrated in clathrin-coated pits, which are specific areas of the cell where the membrane is lined on its cytoplasmic side by a peripheral protein called clathrin. The interaction between the proteins in the receptor–ligand complex causes the membrane to invaginate. The edges of the membrane around the clathrin-coated pit then fuse, and a portion of the membrane pinches off as an endocytic vesicle. Almost immediately after it is formed, the vesicle loses its clathrin coat and becomes fused with an early endosome in a manner similar to that involved in non–receptor-mediated endocytosis. The uptake of cholesterol transported in the blood as low-density lipoprotein (LDL) relies on receptor-mediated removal associated with clathrin-coated pits. This pathway for cholesterol removal is disrupted in persons who inherit defective genes for encoding LDL receptors (see Chapter 18).

In addition to clathrin-coated pits and vesicles, there are a number of other mechanisms by which cells can form endocytic vesicles. One of these pathways involves the formation of small invaginations or “little cavities” in the cell membrane, called caveolae, that extend inward, indenting the cell membrane and the cytoplasm. These cavities may pinch off and form free vesicles within the cytoplasm. Caveolae are considered to be sites for uptake of material into the cell, for expulsion of material from the cell, and for addition or removal of cell membrane components. In smooth muscle, caveolae project into the cytoplasm and, analogous to the T tubules in striated muscle, play an important role in regulating intracellular calcium concentration and smooth muscle tone. In addition to transport, caveolae are involved in a number of other functions such as signal transduction and may be involved in the pathogenesis of a number of diseases, including muscular dystrophy.

Generation of Membrane Potentials
Living organisms have electrical properties in which current flow involves the movement of ions in water. Electrical potentials exist across the membranes of most cells in the body. Because these potentials occur at the level of the cell membrane, they are called membrane potentials. In excitable tissues, such as nerve or muscle cells, changes in the membrane potential are necessary for generation and conduction of nerve impulses and muscle contraction. In other types of cells, such as glandular cells, changes in the membrane potential contribute to hormone secretion and other functions.

Electrical potentials describe the ability of separated electrical charges of opposite polarity (+ and −) to do work. In regard to cells, the oppositely charged particles are ions, and the barrier that separates them is the cell membrane. Electrical potentials are measured in volts (V) or units of electromotive force (EMF). Voltage is always measured with respect to two points in a system. For example, the voltage in a car battery (6 or 12 V) is the potential difference between the two battery terminals. In a cell it is the potential difference between the inside and outside of the cell membrane. Because the total amount of charge that can be separated by a biologic membrane is small, the potential differences are small and are therefore measured in millivolts (mV), or 1/1000 of a volt.

There are two main factors that alter membrane potentials: the difference in the concentration of ions on the inside and outside of the membrane and the permeability of the membrane to these ions. Extracellular and intracellular fluids are electrolyte solutions containing approximately 150 to 160 mmol/L of positively charged ions and an equal concentration of negatively charged ions. The diffusion of these current-carrying ions is responsible for generating and conducting membrane potentials. A diffusion potential describes the voltage generated by ions that diffuse across the cell membrane.

An equilibrium potential is one in which there is no net movement of a particular ion across a membrane because the diffusion potential and electrical forces generated by the movement of the ion are exactly balanced. The magnitude of the equilibrium potential, also known as the Nernst potential, is determined by the ratio of the concentration of a specific ion on the two sides of the membrane. The greater the ratio, the greater the tendency for the ion to diffuse in one direction, and therefore the greater the electrical forces required to prevent further diffusion. The Nernst equation (described in the figure on Understanding Membrane Potentials) can be used to calculate the equilibrium potential for any univalent ion at a given concentration difference, assuming that membrane is permeable to the ion. When using the equation, it is generally assumed that the electrical potential of the extracellular fluid outside the membrane remains at zero and the potential being calculated is the electrical potential inside the membrane. It is also assumed that the sign of the potential is negative (−) if a positively charged ion diffuses from the inside to the outside of the membrane and positive (+) if a positively charged ion diffuses from the outside to the inside of the membrane.

The resting membrane potential represents the period of time when excitable cells, such as nerve fibers, are not transmitting signals. Because resting cell membranes are
membrane reflects the diffusion of potassium ions. The Na+/K+ATPase membrane pump, which removes three Na+ from inside the cell while returning two K+ to the inside, assists in maintaining the resting membrane potential. During an action potential, the cell membrane becomes more permeable to sodium, causing its polarity to change so that it is positive on the inside and negative on the outside (discussed in Chapter 34).

SUMMARY CONCEPTS

- Cells communicate with each other by chemical messenger systems. Chemical messengers bind to receptors on or near the cell surface. There are three classes of cell surface receptor proteins: G protein-linked, enzyme-linked, and channel-linked. G protein-linked receptors rely on a class of molecules called G proteins that function as an on-off switch to convert external signals into internal signals (second messengers). Enzyme-linked receptors have intrinsic enzyme activity or rely on enzymes that are closely associated with the receptor they activate. One type of enzyme-linked receptor is widely used in hormonal control of cell function and involves the activation of the enzyme adenyl cyclase, which catalyzes the formation of cAMP, a second messenger that has multiple effects inside the cell. Activation of ion channel-linked receptors (e.g., by neurotransmitters) may trigger signaling to transiently open or close ion channels formed by integral proteins in the cell.

- Substances that enter or leave the cell must cross the cell membrane. Diffusion is a process by which substances such as ions move from areas of greater concentration to areas of lesser concentration until reaching a uniform distribution. Facilitated diffusion is a passive process, in which molecules that cannot normally pass through the cell's membranes do so with the assistance of a carrier molecule. Active transport requires the cell to expend energy in moving ions against a concentration gradient. The Na+/K+ATPase membrane pump is the best-known type of active transport. Vesicular transport is a mechanism in which a cell encloses extracellular material in a membrane-bound vesicle. There are two types of vesicular transport: endocytosis, in which materials are brought into the cell by invagination of the cell membrane to form a vesicle, and exocytosis, in which materials are exported from the cell by fusion of a vesicle with the cell membrane.

- Electrical potentials, which are measured in volts, describe the ability of separated electrical charges of opposite polarity (+ and −) to do work. In regard to cells, the oppositely charged particles are ions, and the barrier that separates them is the cell membrane. There are two main factors that alter membrane potentials and excitability: the difference in concentration of ions on the inside and outside of the membrane and the permeability of the membrane to these ions. An equilibrium potential is one in which there is no net movement of a particular ion across a membrane because the diffusion and electrical forces generated by the movement of the ions are exactly balanced. The resting membrane potential (− outside and + inside) is essentially a potassium equilibrium potential that results from the selective permeability of the membrane to potassium ions and the large difference in potassium concentration that exists between the inside and the outside of the membrane. During an action potential, the cell membrane becomes highly permeable to sodium, causing it to depolarize and reverse its polarity (− inside and + outside).

Tissues

In the preceding sections, we discussed the individual cell, its metabolic processes, and mechanisms of signaling and communication. Although cells have similarities, their structures and functions vary according to the specific needs of the body. For example, muscle cells are specialized to perform different functions from skin cells or nerve cells. Groups of cells that are closely associated in structure and have common or similar functions are called tissues. Four categories of tissue exist: (1) epithelial, (2) connective, (3) muscle, and (4) nervous. These tissues do not exist in isolated units but in association with each other and in variable proportions, forming different structures and organs of the body. This section of the chapter provides a brief overview of the cells in each of the four tissue types, the structures that hold these cells together, and the extracellular matrix in which they live.

Embryonic Origin of Tissue Types

After conception, the fertilized ovum undergoes a series of divisions, ultimately forming different cell types that comprise the various tissues of the body. The formation of different, more specialized types of cells and (text continues on page 20)
Electrochemical potentials are present across the membranes of virtually all cells in the body. Some cells, such as nerve and muscle cells, are capable of generating rapidly changing electrical impulses and transmitting these impulses along their membranes. Generation of membrane potentials relies on (1) diffusion of current-carrying ions, (2) development of an electrochemical equilibrium, and (3) establishment of a resting membrane potential and triggering an action potential.

**1 Diffusion potentials.** A diffusion potential is a potential difference generated across a membrane when a current-carrying ion, such as the potassium (K⁺) ion, diffuses down its concentration gradient. Two conditions are necessary for this to occur: (1) the membrane must be selectively permeable to a particular ion, and (2) the concentration of the diffusible ion must be greater on one side of the membrane than the other.

The magnitude of the diffusion potential, measured in millivolts (mV), depends on the size of the concentration gradient. The sign (+ or −) or polarity of the potential depends on the diffusing ion. It is negative on the inside when a positively charged ion such as K⁺ diffuses from the inside to the outside of the membrane, carrying its charge with it.

**2 Equilibrium potentials.** An equilibrium potential is the membrane potential that exactly balances and opposes the net diffusion of an ion down its concentration gradient. As a cation diffuses down its concentration gradient, it carries its positive charge across the membrane, thereby generating an electrical force that will eventually retard and stop its diffusion. An electrochemical equilibrium is one in which the chemical forces driving diffusion and the repelling electrical forces are exactly balanced so that no further diffusion occurs. The equilibrium potential (EMF, electromotive force) can be calculated by inserting the inside and outside ion concentrations into the Nernst Equation.
**Resting membrane potential (RMP).** The RMP, which is necessary for electrical excitability, is present when the cell is not transmitting impulses. Because the resting membrane is permeable to K⁺, it is essentially an K⁺ equilibrium potential. This can be explained in terms of the large K⁺ concentration gradient (e.g., 140 mEq/L inside and 4 mEq/L outside), which causes the positively charged K⁺ to diffuse outward, leaving the nondiffusible, negatively charged intracellular anions (A⁻) behind. This causes the membrane to become polarized, with negative charges aligned along the inside and positive charges along the outside. The Na⁺/K⁺ membrane pump, which removes three Na⁺ from inside while returning only two K⁺ to the inside, contributes to the maintenance of the RMP.

**Action potentials.** Action potentials involve rapid changes in the membrane potential. Each action potential begins with a sudden change from the negative RMP to a positive threshold potential, causing an opening of the membrane channels for Na⁺ (or other ions of the action potential). Opening of the Na⁺ channels allows large amounts of the positively charged Na⁺ ions to diffuse to the interior of the cell, causing the membrane potential to undergo depolarization or a rapid change to positive on the inside and negative on the outside. This is rapidly followed by closing of Na⁺ channels and opening of the K⁺ channels, which leads to a rapid efflux of K⁺ from the cell and reestablishment of the RMP.
tissues is called **cell differentiation**, a process that is controlled by mechanisms that switch genes on and off (see Chapter 4).

All of the approximately 200 different cells of the body can be classified into the four basic or primary tissue types: epithelial, connective, muscle, and nervous (Table 1-1). These basic tissue types are often described by their embryonic origin. The embryo is essentially a three-layered tubular structure (Fig. 1-13). The outer layer of the tube is called the **ectoderm**; the middle layer, the **mesoderm**; and the inner layer, the **endoderm**. All of the mature tissue types originate from these three cellular layers. Epithelium has its origin in all three embryonic layers, connective tissue and muscle develop mainly from the mesoderm, and nervous tissue develops from the ectoderm.

Epithelial Tissue

Epithelial tissue forms sheets that cover the body’s outer surface, line the internal surfaces, and form glandular tissue. Underneath all types of epithelial tissue is a fibrous extracellular layer, called the **basement membrane**, which serves to attach the epithelial cells to adjacent connective tissue and may serve other functions, such as providing a barrier against cancer cell invasion and contributing to the filtration function of the glomerulus.

The cells that make up epithelium have three general characteristics: (1) they have three distinct surfaces: a free surface or apical surface, a lateral surface, and a basal surface; (2) they are closely apposed and joined by cell-to-cell adhesion molecules, which form specialized cell junctions; and (3) their basal surface is attached
to the underlying basement membrane (Fig. 1-14). The characteristics and geometric arrangement of the cells in the epithelium contribute to their function. In an epithelium formed from a single layer of epithelial cells, the free or apical surface is directed toward the exterior surface or lumen of an enclosed cavity or tube, the lateral surface communicates with adjacent cells and is characterized by specialized attachment areas, and the basal surface rests on the basement membrane anchoring the cell to the surrounding connective tissue.

Epithelial tissues are classified according to the shape of the cells and the number of layers that are present: simple, stratified, and pseudostratified. Glandular epithelial tissue is formed by cells specialized to produce a fluid secretion. The terms squamous (thin and flat), cuboidal (cube shaped), and columnar (resembling a column) refer to the cells’ shape (Fig. 1-15).

**Simple Epithelium**

Simple epithelium contains a single layer of cells, all of which rest on the basement membrane. Simple squamous epithelium is adapted for filtration; it is found lining the blood vessels, lymph nodes, and alveoli of the lungs. The single layer of squamous epithelium lining the heart and blood vessels is known as the endothelium. A similar type of layer, called the mesothelium, forms the serous membranes that line the pleural, pericardial, and peritoneal cavities and covers the organs of these cavities. A simple cuboidal epithelium is found on the surface of the ovary and in the thyroid. Simple columnar epithelium lines the intestine. One form of a simple columnar epithelium has hair-like projections called cilia, often with specialized mucus-secreting cells called goblet cells. This form of simple columnar epithelium lines the airways of the respiratory tract.

**Stratified and Pseudostratified Epithelium**

Stratified epithelium contains more than one layer of cells, with only the deepest layer resting on the basement membrane. It is designed to protect the body surface. Stratified squamous keratinized epithelium makes up the epidermis of the skin. Keratin is a tough, fibrous protein that polymerizes to form intermediate filaments that are abundant in the outer cells of skin. A stratified squamous keratinized epithelium is made up of many layers. The layers closest to the underlying tissues are cuboidal or columnar. The cells become more irregular and thinner as they move closer to the surface. Surface cells become totally filled with keratin and die, are sloughed off, and then replaced by the deeper cells. A stratified squamous nonkeratinized epithelium is found on moist surfaces such as the mouth and tongue. Stratified cuboidal and

**FIGURE 1-13. Cross-section of human embryo illustrating the development of the somatic and visceral structures.**
columnar epithelia are found in the ducts of salivary glands and the larger ducts of the mammary glands. In smokers, the normal columnar ciliated epithelial cells of the trachea and bronchi are often replaced with stratified squamous epithelial cells that are better able to withstand the irritating effects of cigarette smoke.

**Pseudostratified epithelium** is a type of epithelium in which all of the cells are in contact with the underlying intercellular matrix, but some do not extend to the surface. A pseudostratified ciliated columnar epithelium with goblet cells forms the lining of most of the upper respiratory tract. All of the tall cells reaching the surface of this type of epithelium are either ciliated cells or mucus-producing goblet cells. The basal cells that do not reach the surface serve as stem cells for ciliated and goblet cells.

**Transitional epithelium** is a stratified epithelium characterized by cells that can change shape and become thinner when the tissue is stretched. Such tissue can be stretched without pulling the superficial cells apart. Transitional epithelium is well adapted for the lining of organs that are constantly changing their volume, such as the urinary bladder.

**Glandular Epithelium**

Glandular epithelial tissue is formed by cells specialized to produce a fluid secretion. This process is usually accompanied by the intracellular synthesis of macromolecules. The chemical nature of these macromolecules is variable. The macromolecules typically are stored in the cells in small membrane-bound vesicles called secretory granules. For example, glandular epithelia can synthesize, store, and secrete proteins (e.g., insulin), lipids (e.g., adrenocortical hormones), secretions of the sebaceous glands), and complexes of carbohydrates and proteins (e.g., saliva). Less common are secretions that require minimal synthetic activity, such as those produced by the sweat glands.

**FIGURE 1-14.** Typical arrangement of epithelial cells in relation to underlying tissues and blood supply. Epithelial tissue has no blood supply of its own but relies on the blood vessels in the underlying connective tissue for nutrition (N) and elimination of wastes (W).

**FIGURE 1-15.** Representation of the various epithelial tissue types.
All glandular cells arise from surface epithelia by means of cell proliferation and invasion of the underlying connective tissue. Epithelial glands can be divided into two groups: exocrine and endocrine glands. Exocrine glands, such as the sweat glands and lactating mammary glands, retain their connection with the surface epithelium from which they originated. This connection takes the form of epithelium-lined tubular ducts through which the secretions pass to reach the surface. Endocrine glands are epithelial structures that have had their connection with the surface obliterated during development. These glands are ductless and produce secretions (i.e., hormones) that move directly into the bloodstream.

**Epithelial Cell Renewal**

Cells making up the epithelial tissues generally exhibit a high rate of turnover, which is related to their location and function. The rate of cell turnover is characteristic of specific epithelium. For example, the epithelial cells of the small intestine are renewed every 4 to 6 days by regenerative cells in the lower portion of the intestinal glands (crypts). Similarly, the cells of the stratified squamous epithelium of the skin are constantly being renewed at the basal layer by cell division.

**Connective Tissue**

Connective or supportive tissue is the most abundant tissue in the body. As its name suggests, it connects and binds or supports the various tissues. Connective tissue is unique in that its cells produce the extracellular matrix that supports and holds tissues together. The proximity of the extracellular matrix to blood vessels allows it to function as an exchange medium through which nutrients and metabolic wastes pass.

The functions of the various connective tissues are reflected by the types of cells and fibers present in the tissue and the characteristics of the extracellular matrix (Fig. 1-16). The capsules that surround organs of the body are composed of connective tissue. Bone, adipose tissue, and cartilage are specialized types of connective tissue that function to support the soft tissues of the body and store fat. One type of cell, the fibroblast, is responsible for synthesis of collagen, elastic, reticular fibers, and ground substance of the extracellular matrix. Other cells, such as lymphocytes, plasma cells, macrophages, and eosinophils, are associated with body defense systems.

Adult connective tissue can be divided into two types: connective tissue proper, which is the focus of the discussion in this chapter, and specialized connective tissue (cartilage, bone, and blood cells), which is discussed in other chapters. There are four recognized types of connective tissue proper: loose (areolar), adipose, reticular, and dense connective tissue.

**Loose Connective Tissue**

Loose connective tissue, also known as areolar tissue, is soft and pliable. It fills spaces between muscle sheaths, forms a layer that encases blood and lymphatic vessels, and provides support for epithelial tissues and the means by which these tissues are nourished. Loose connective tissue is characterized by an abundance of ground substance and tissue fluid housing the fixed connective tissue cells: fibroblasts, mast cells, adipose or fat cells, macrophages, and leukocytes. Fibroblasts are the most abundant of these cells. They produce all three fiber types—collagen, elastic, and reticular fibers—found in loose connective tissue, and synthesize the ground substance that fills the intercellular tissue spaces.

**Adipose Tissue**

Adipose tissue is a special form of connective tissue in which adipocytes predominate. Adipocytes do not generate an extracellular matrix but maintain a large intracellular space. These cells store large quantities of triglycerides and are the largest repository of energy in the body. Adipose tissue helps fill spaces between tissues and to keep organs in place. The subcutaneous fat helps to shape the body. Because fat is a poor conductor of heat, adipose tissue serves as thermal insulation for the body. Adipose tissue exists in two forms: unilocular and multilocular. Unilocular (white) adipose tissue is composed of cells in which the fat is contained in a single, large droplet in the cytoplasm. Multilocular (brown) adipose tissue is composed of cells that contain multiple droplets of fat and numerous mitochondria.

**Reticular and Dense Connective Tissue**

Reticular and dense connective tissue is characterized by a network of fibers interspersed with macrophages and fibroblasts that synthesize collagen fibers. Reticular fibers provide the framework for capillaries, nerves, and muscle.
cells. They also constitute the main supporting elements for the blood-forming tissues and the liver.

Dense connective tissue exists in two forms: dense irregular and dense regular. Dense irregular connective tissue consists of the same components found in loose connective tissue but exhibits a predominance of collagen fibers and fewer cells. This type of tissue can be found in the dermis of the skin (i.e., reticular layer), the fibrous capsules of many organs, and the fibrous sheaths of cartilage (i.e., perichondrium) and bone (i.e., periosteum). It also forms the fascia that invests muscles and organs. Dense regular connective tissues are rich in collagen fibers and form the tendons and aponeuroses that join muscles to bone or other muscles and the ligaments that join bone to bone.

Muscle Tissue

Muscle tissue, whose primary function is contraction, is responsible for movement of the body and its parts and for changes in the size and shape of internal organs. Muscle tissue contains two types of fibers that are responsible for contraction: thin actin and thick myosin filaments.

There are three types of muscle tissues: skeletal, cardiac, and smooth. Skeletal and cardiac muscles are striated muscles, in which the actin and myosin filaments are arranged in large parallel arrays in bundles, giving the muscle fibers a striped or striated appearance when observed with a microscope. Smooth muscle lacks striations and is found in the iris of the eye; the walls of blood vessels; hollow organs, such as the stomach and urinary bladder; and hollow tubes, such as the ureters and common bile duct that connect internal organs.

Although the three types of muscle tissues differ significantly in structure, contractile properties, and control mechanisms, they have many similarities. In the following section, the structural properties of skeletal muscle are presented as the prototype of striated muscle tissue. Smooth muscle and the ways in which it differs from skeletal muscle are also discussed. Cardiac muscle is described in Chapter 17.

Skeletal Muscle

Skeletal muscle is the most abundant tissue in the body, accounting for 40% to 45% of the total body weight. Most skeletal muscles are attached to bones, and their contractions are responsible for movements of the skeleton.

Skeletal Muscle Structure. Skeletal muscle fibers are packaged into skeletal muscles that attach to and cover the body skeleton. Each skeletal muscle is a discrete organ made up of hundreds or thousands of muscle fibers. Although muscle fibers predominate, substantial amounts of connective tissue, blood vessels, and nerve fibers are present. In an intact muscle, several different layers of connective tissue hold the individual muscle fibers together. Skeletal muscles such as the biceps brachii are surrounded by a dense irregular connective tissue covering called the epimysium (Fig. 1-17A). Each muscle is subdivided into smaller bundles called fascicles, which are surrounded by a connective tissue covering called the perimysium. The number of fascicles and their size vary among muscles. Fascicles consist of many elongated structures called muscle fibers, each of which is surrounded by connective tissue called the endomysium.

Skeletal muscles are syncytial or multinucleated structures, meaning there are no true cell boundaries within a skeletal muscle fiber. The cytoplasm or sarcoplasm of the muscle fiber is contained within the sarcolemma, which

![Diagram of skeletal muscle components](image-url)
represents the cell membrane. Embedded throughout the sarcoplasm are the contractile elements actin and myosin, which are arranged in parallel bundles (i.e., myofibrils). Each myofibril consists of regularly repeating units called sarcomeres along its length.

Sarcomeres, which are the structural and functional units of striated muscle, extend from one Z line to another Z line (Fig. 1-17B). The central portion of the sarcomere contains the dark band (A band) consisting mainly of myosin filaments, with some overlap with actin filaments. Straddling the Z line, the lighter I band contains only actin filaments; therefore, it takes two sarcomeres to complete an I band. An H zone is found in the middle of the A band and represents the region where only myosin filaments are found. In the center of the H zone is a thin, dark band, the M band or M line, produced by linkages between the myosin filaments. Z lines consist of short elements that interconnect and provide the thin actin filaments from two adjoining sarcomeres with an anchoring point. Muscle contraction involves the actin filaments sliding inward among the myosin filaments (Fig. 1-17C). In the relaxed state, the ends of the actin filaments extend from two successive Z lines, barely overlapping one another. In the contracted state, these actin filaments have been pulled inward among the myosin filaments so their ends overlap one another.

The sarcoplasmic reticulum, which is comparable to the smooth ER, is composed of longitudinal tubules that run parallel to the muscle fiber and surround each myofibril (Fig. 1-17D). This network ends in enlarged, saclike regions called the lateral sacs or terminal cisternae. These sacs store calcium that is released during muscle contraction. A second system of tubules consists of the transverse or T tubules, which are extensions of the cell membrane and run perpendicular to the muscle fiber. The hollow portion or lumen of the T tubule is continuous with the extracellular fluid compartment. Action potentials, which are rapidly conducted over the surface of the muscle fiber, are in turn propagated by the T tubules into the sarcoplasmic reticulum. As the action potential moves through the lateral sacs, the sacs release calcium, initiating muscle contraction. The membrane of the sarcoplasmic reticulum also has an active transport mechanism for pumping calcium ions back into the reticulum. This prevents interactions between calcium ions and the actin and myosin myofilaments after cessation of a muscle contraction.

**Skeletal Muscle Contraction.** Muscle contraction involves the sliding of the thick myosin and thin actin filaments over each other to produce shortening of the muscle fiber, while the actual length of the individual thick and thin filaments remains unchanged. The thick myosin filaments consist of a thin tail, which provides the structural backbone for the filament, and a globular head that forms cross-bridges with the thin actin filaments (Fig. 1-18A). Myosin molecules are bundled together side by side in the thick filaments such that one half have their heads toward one end of the filament and their tails toward the other end, and the other half are arranged in the opposite manner. Each globular myosin head contains a site able to bind to a complementary site on the actin molecule. Besides the binding site for actin, each myosin head has a separate active site that catalyzes the breakdown of ATP to provide the energy needed to activate the myosin head so it can form a cross-bridge with actin. After contraction, myosin also

---

**FIGURE 1-18.** Molecular structure of the thicker myosin filament (A) and the thinner actin filament (B) of striated muscle. The thin filament is a double-stranded helix of actin molecules with tropomyosin and troponin molecules lying along the grooves of the actin strands. (C) Sequence of events involved in sliding of adjacent actin and myosin filaments: (1) cocking of the myosin head, which occurs as adenosine triphosphate (ATP) is split to adenosine diphosphate (ADP); (2) cross-bridge attachment; (3) power stroke during which the myosin head bends as it moves the actin forward; and (4) cross-bridge detachment, which occurs as a new ATP attaches to the myosin head.
binds ATP, thus breaking the linkage between actin and myosin.

The thin filaments are composed mainly of actin, a globular protein lined up in two rows that coil around each other to form a long helical strand (Fig. 1-18B). Associated with each actin filament are two regulatory proteins, tropomyosin and troponin. *Tropomyosin*, which lies in grooves of the actin strand, provides the site for attachment of the globular heads of the myosin filament. In the noncontracted state, *troponin* covers the tropomyosin-binding sites and prevents formation of cross-bridges between the actin and myosin. During an action potential, calcium ions released from the sarcoplasmic reticulum diffuse to the adjacent myofibrils, where they bind to troponin. The binding of calcium to troponin uncovers the tropomyosin-binding sites such that the myosin heads can attach and form cross-bridges.

Muscle contraction begins with activation of the cross-bridges from the myosin filaments and uncovering of the tropomyosin-binding sites on the actin filament (Fig. 1-18C). When activated by ATP, the heads of the myosin filaments swivel in a fixed arc, much like the oars of a boat, as they become attached to the actin filament. During contraction, each myosin head undergoes its own cycle of movement, forming a bridge attachment and releasing it, then moving to another site where the same sequence of movement occurs. This pulls the thin and thick filaments past each other. Energy from ATP is used to break the actin and myosin cross-bridges, stopping the muscle contraction. After the linkage between actin and myosin, the concentration of calcium around the myofibrils decreases as calcium is actively transported into the sarcoplasmic reticulum by a membrane pump that uses energy derived from ATP.

**Smooth Muscle**

Smooth muscle is often called *involuntary muscle* because its activity arises spontaneously or through the activity of the autonomic nervous system. Smooth muscle is usually arranged in sheets or bundles and its contractions are slower and more sustained than skeletal or cardiac muscle contractions.

Smooth muscle cells are spindle shaped and smaller than skeletal muscle fibers. Each smooth muscle cell has one centrally positioned nucleus. Z bands and M lines are not present in smooth muscle fibers, and the cross-striations are absent because the bundles of filaments are not parallel but criss-cross obliquely through the cell. Instead, the actin filaments are attached to structures called *dense bodies*. Some dense bodies are attached to the cell membrane, and others are dispersed in the cell and linked together by structural proteins (Fig. 1-19).

The lack of Z lines and regular overlapping of contractile elements provide a greater range of tension development. This is important in hollow organs that undergo changes in volume, with consequent changes in the length of the smooth muscle fibers in their walls. Even with the distention of a hollow organ, the smooth muscle fiber retains some ability to develop tension, whereas such distention would stretch skeletal muscle beyond the area where the thick and thin filaments overlap.

As with cardiac and skeletal muscle, smooth muscle contraction is initiated by an increase in intracellular calcium. However, smooth muscle differs from skeletal muscle in the way its cross-bridges are formed. The sarcoplasmic reticulum of smooth muscle is less developed than in skeletal muscle, and no transverse tubules are present. Smooth muscle relies on the entrance of extracellular calcium for muscle contraction. This dependence on movement of extracellular calcium across the cell membrane during muscle contraction is the basis for the action of calcium-blocking drugs used in the treatment of cardiovascular disease.

Smooth muscle also lacks the calcium-binding regulatory protein troponin, which is found in skeletal and cardiac muscle. Instead, it relies on another calcium-regulated mechanism involving the cytoplasmic protein calmodulin and an enzyme called myosin light chain kinase. Increased calcium ions form a calcium–calmodulin complex that binds to and activates myosin light chain kinase, which in turn phosphorylates myosin to initiate contraction.

**Nervous Tissue**

Nervous tissue is distributed throughout the body as an integrated communication system. Nerve cells, which develop from the embryonic ectoderm, are highly differentiated and have long been considered incapable of regeneration in postnatal life. However, it is now known that parts of the brain, such as the hippocampus, contain...
areas where neurogenesis occurs from neural stem cells/progenitor cells throughout life. Embryonic development of the nervous system and the structure and functions of the nervous system are discussed more fully in Chapter 34.

Structurally, nervous tissue consists of two cell types: nerve cells or neurons and supporting cells or neuroglia. Most nerve cells consist of three parts: the soma or cell body, dendrites, and the axon. The cytoplasm-filled dendrites, which are multiple elongated processes, receive and carry stimuli from the environment, sensory epithelial cells, and other neurons to the cell. The axon, which is a single cytoplasm-filled process, is specialized for generating and conducting nerve impulses away from the cell body to other nerve cells, muscle cells, and glandular cells.

Neurons can be classified as afferent and efferent neurons according to their function. Afferent or sensory neurons carry information toward the central nervous system; they are involved in the reception of sensory information from the external environment and from within the body. Efferent or motor neurons carry information away from the central nervous system (CNS); they are needed for control of muscle fibers and endocrine and exocrine glands.

Communication between neurons and effector organs, such as muscle cells, occurs at specialized structures called synapses. At the synapse, chemical messengers (i.e., neurotransmitters) alter the membrane potential to conduct impulses from one nerve to another or from a neuron to an effector cell. In addition, electrical synapses exist in which nerve cells are linked through gap junctions that permit the passage of ions from one cell to another.

Neuroglia (glia means “glue”) are the cells that support neurons, form myelin, and have trophic and phagocytic functions. Four types of neuroglia are found in the CNS: astrocytes, oligodendrocytes, microglia, and ependymal cells. Astrocytes are the most abundant of the neuroglia. They have many long processes that surround blood vessels in the CNS. They provide structural support for the neurons, and their extensions form a sealed barrier that protects the CNS. In last decade, investigations have established important roles for astrocytes in the response of the brain to injury, calcium ion-based excitation, CNS metabolism, neural stem cell source, blood–brain barrier maintenance, and numerous diseases and pathological conditions. The oligodendrocytes provide myelination of neuronal processes in the CNS. The microglia are phagocytic cells that represent the mononuclear phagocytic system in the nervous system. Ependymal cells line the cavities of the brain and spinal cord and are in contact with the cerebrospinal fluid. In the peripheral nervous system, supporting cells consist of the Schwann and satellite cells. The Schwann cells provide myelination of the axons and dendrites, and the satellite cells enclose and protect the dorsal root ganglia and autonomic ganglion cells.

**Extracellular Tissue Components**

The discussion thus far has focused on the cellular components of the different tissue types. Within tissues, cells are held together by cell junctions, and adhesion molecules form intercellular contacts.

**Cell Junctions**

The junctions between tissue cells are important in governing the shape of the body, transmitting mechanical stresses from one cell to another, and creating pathways for communication. Cell junctions occur at many points in cell-to-cell contact, but they are particularly plentiful and important in epithelial tissue. These specialized junctions enable cells to form barriers to the movement of water, solutes, and cells from one body compartment to the next. Three basic types of intercellular junctions are observed: tight junctions, adhering junctions, and gap junctions (Fig. 1.20).

*Tight or occluding junctions* (i.e., zonula occludens), which are found in epithelial tissue, seal the surface membranes of adjacent cells together. This type of intercellular junction prevents fluids and materials such as macromolecules present in the intestinal contents from entering the intercellular space.

*Adhering junctions* represent sites of strong adhesion between cells. The primary role of adhering junctions may be that of preventing cell separation. Adhering junctions are not restricted to epithelial tissue; they provide adhesion between adjacent cardiac muscle cells as well. Adhering junctions are found as continuous, beltlike adhesive junctions (i.e., zonula adherens) or scattered, spotlike adhesive junctions, called desmosomes (i.e., macula adherens). A special feature of the adhesion belt junction is that it provides an anchoring site to the cell membrane for actin filaments. In epithelial desmosomes, bundles of keratin intermediate filaments (i.e., tonofilaments) are anchored to the junction on the cytoplasmic area of the cell membrane. A primary disease of desmosomes is pemphigus, which is caused by antibody binding to the desmosome proteins and the resulting separation of neighboring cells. Affected persons have skin and mucous membrane blistering. *Hemidesmosomes*, which resemble a half desmosome, are another type of junction. They are found at the base of epithelial cells and help attach the epithelial cell to the underlying connective tissue.

*Gap or nexus junctions* involve the close adherence of adjoining cell membranes with the formation of channels that connect the cytoplasm of the two cells. Because they are low-resistance channels, gap junctions are important in cell-to-cell conduction of electrical signals (e.g., between cells in sheets of smooth muscle or between adjacent cardiac muscle cells, where they function as electrical synapses). Gap junctions also enable ions and small molecules to pass directly from one cell to another.

**Extracellular Matrix**

Tissues are not made up solely of cells. A large part of their volume is made up of an extracellular matrix. This matrix is composed of a variety of proteins and polysaccharides (i.e., polymers made up of many sugar monomers). These proteins and polysaccharides are secreted locally and are organized into a supporting meshwork in close association with the cells that produced them. The amount and composition of the matrix vary with the different tissues and their function. In bone, for example, the matrix is more plentiful than the cells that surround it; in the brain, the cells are much more abundant and the matrix is only a minor constituent.
Two main classes of extracellular macromolecules make up the extracellular matrix. The first is an amorphous gel-like material called ground substance. Ground substance is composed of polysaccharide chains of proteins called glycosaminoglycans (GAGs), which are usually found linked to protein as proteoglycans. The second type consists of the fibrous proteins (i.e., collagen and elastin) and the fibrous adhesive proteins (i.e., fibronectin and laminin) that are found in the basement membrane. Members of each of these two classes of extracellular macromolecules come in a variety of shapes and sizes.

**Ground Substance.** The proteoglycan and GAG molecules form a highly hydrated, gel-like substance, or tissue gel, in which the fibrous proteins are embedded. The polysaccharide gel resists compressive forces; the collagen fibers strengthen and help organize the matrix; the rubberlike elastin adds resilience; and the adhesive proteins help cells attach to the appropriate part of the matrix. Polysaccharides in the tissue gel are highly hydrophilic, and they form gels even at low concentrations. They also produce a negative charge that attracts cations such as sodium, which are osmotically active, causing large amounts of water to be sucked into the matrix. This creates a swelling pressure, or turgor, that enables the matrix to withstand extensive compressive forces. For example, the cartilage matrix that lines the knee joint can support pressures of hundreds of atmospheres by this mechanism.

**Fibrous Proteins.** Three types of fibers are found in the extracellular space: collagen, elastin, and reticular fibers. Collagen is the most common protein in the body. It is a tough, nonliving, white fiber that serves as the structural framework for skin, ligaments, tendons, and many other structures. Elastin acts like a rubber band; it can be stretched and then returns to its original form. Elastin fibers are abundant in structures subjected to frequent stretching, such as the aorta and some ligaments. Reticular fibers are extremely thin fibers that create a flexible network in organs subjected to changes in form or volume, such as the spleen, liver, uterus, or intestinal muscle layer.

**Cell Adhesion Molecules**

Important classes of extracellular macromolecules are the cell adhesion molecules (CAMs). Cell adhesion molecules can be cell-to-cell or cell-to-matrix adhesion molecules. There are four major classes of CAMs: cadherins, selectins, integrins, and the immunoglobulin (Ig) superfamily of proteins. These proteins are located on the cell surface where they function as receptors, or they can be stored in the cytoplasm. As receptors, CAMs can bind to similar or
different molecules in other cells, providing for interaction between the same cell types or different cell types.

**Cadherins.** Cadherins are the major CAMs responsible for calcium-dependent cell-to-cell adhesion junctions. The word cadherin is derived from the term “calcium-dependent adhesion protein.” There are over 90 members of the cadherin superfamily. The first three cadherins that were discovered were named according to the main tissues in which they were found: the E-cadherins, which are present in many types of epithelial cells; the N-cadherins, which are present in nerve and muscle cells; and the P-cadherins, which are found on cells in the placenta and epidermis. All are found in various other tissues; N-cadherin, for example, is expressed in fibroblasts, and E-cadherin is expressed in parts of the brain.

Most cadherins function as transmembrane adhesive proteins that indirectly link the actin cytoskeletons of cells they join together, an arrangement that occurs in adhering junctions. Cadherins also form desmosomes that interact with intermediate filaments of the cytoskeleton, rather than the actin filaments. Cell-to-cell interactions mediated by cadherins play a major role in regulating cell motility, proliferation, and differentiation.

**Selectins.** Selectins are cell surface carbohydrate-binding proteins (lectins) that mediate a variety of transient, cell-to-cell adhesion interactions in the bloodstream. They are found on activated endothelial cells of blood vessels, on leukocytes, and on platelets. Selectins, together with integrins and immunoglobulins, participate in leukocyte movement through the endothelial lining of blood vessels during inflammation.

**Integrins.** Integrins usually assist in attaching epithelial cells to the underlying basement membrane. Extracellularly, they are attached to fibronectin and laminin, the two major components of the basement membrane. Like the cadherins, their intracellular portion is linked to actin. One group of integrins is associated with hemidesmosomes, whereas others are associated with the surface of white blood cells, macrophages, and platelets. Integrins usually have a weak affinity for their ligands unless they are associated with cellular focal contacts and hemidesmosomes. This allows some movement between cells except where a firm attachment is required to attach epithelial cells to the underlying connective tissue.

Certain integrins play an important role in allowing white blood cells to pass through the vessel wall, a process called transmigration. Persons affected with leukocyte adhesion deficiency are unable to synthesize appropriate integrin molecules. As a result, they experience repeated bacterial infections because their white blood cells are not able to transmigrate through vessel walls.

**Immunoglobulin Superfamily.** The Ig superfamily consists of a group of one or more immunoglobulin-like adhesion proteins that are similar structurally to those of antibody molecules. They have many functions outside the immune system that are unrelated to immune defenses. The best-studied example of Ig superfamily proteins are the neural cell adhesion molecules (N-CAMs), which are expressed in a variety of cells, including most nerve cells. During early development, N-CAMs play an important role in connecting the neurons of the developing nervous system.
### REVIEW EXERCISES

1. Persons who drink sufficient amounts of alcohol display rapid changes in central nervous system function, including both motor and behavioral changes, and the odor of alcohol can be detected on their breath.

   **A.** Use the concepts related to the lipid bilayer structure of the cell membrane to explain these observations.

2. Tattoos consist of pigments that have been injected into the skin.

   **A.** Explain what happens to the dye once it has been injected and why it does not eventually wash away.

3. Insulin is synthesized in the beta cells of the pancreas as a prohormone and then secreted as an active hormone.

   **A.** Using your knowledge of the function of DNA, the RNAs, the endoplasmic reticulum, and the Golgi complex, propose a pathway for the synthesis of insulin.

4. Mitochondrial disorders, whether due to mutations in mitochondrial or nuclear genes, often produce muscle weakness, sometimes with severe involvement of the muscles that move the eyes, other neurologic symptoms, lactacidosis, and cardiomyopathy.

   **A.** Mitochondrial disorders that are responsible for these manifestations are often classified as mitochondrial encephalomyopathies. Propose an explanation for the propensity to develop encephalopathies and myopathies with mitochondrial disorders rather than disorders of other body systems such as the kidney or digestive tract.

   **B.** Relate the function of the mitochondria in terms of oxidative metabolism to the development of lactacidosis.

5. The absorption of glucose from the intestine involves a cotransport mechanism in which the active primary transport of sodium is used to provide for the secondary transport of glucose.

   **A.** Hypothesize how this information might be used to design an oral rehydration solution for someone who is suffering from diarrhea.

In their simplest form, all diseases exert their effects on the smallest living unit of the body—the cell. When confronted with stresses that endanger its normal structure and function, the cell undergoes adaptive changes that permit survival and maintenance of function. It is only when the stress is overwhelming or adaptation is ineffective that injury, maladaptive changes, and cell death occur. Biologic aging produces its own changes in cell structure and function.

**Chapter 2**

**Cellular Responses to Stress, Injury, and Aging**

Cells adapt to changes in the internal environment just as the total organism adapts to changes in the external environment. Cells may adapt by undergoing changes in size, number, and type. These changes, occurring singly or in combination, may lead to atrophy, hypertrophy, hyperplasia, metaplasia, and dysplasia (Fig. 2-1). Cellular stresses also include intracellular accumulations and storage of products in abnormal amounts.¹ ²

**Adaptations of Growth and Differentiation**

Numerous molecular mechanisms mediate cellular adaptation, including factors in the cellular microenvironment and the cells themselves. These mechanisms largely depend on extracellular signals and cues, which in turn activate intracellular signaling mechanisms transmitted by chemical messengers that alter gene expression. Once the primary stimulus for adaptation is removed, the cause of changing gene expression patterns is removed and the cell may revert back to its previous state. Whether adaptive cellular changes are normal or abnormal depends in part on whether the response was mediated by an appropriate stimulus. Normal adaptive responses occur in response to need and an appropriate
stimulus. After the need has been removed, the adaptive response ceases.

**Atrophy**

When confronted with a decrease in work demands or adverse environmental conditions, most cells are able to revert to a smaller size and a lower and more efficient level of functioning that is compatible with survival. This decrease in cell size is called *atrophy*. Cells that are atrophied reduce oxygen consumption and other cellular functions by decreasing the number and size of their organelles and other structures. There are fewer mitochondria, myofilaments, and endoplasmic reticulum structures. When a sufficient number of cells are involved, the entire tissue atrophies.

Cell size, particularly in muscle tissue, is related to workload. As the workload of a cell declines, oxygen consumption and protein synthesis decrease. Furthermore, proper muscle mass is maintained by sufficient levels of insulin/insulin-like growth factor-1 (IGF-1). When insulin/IGF-1 levels are low or catabolic signals are present, muscle atrophy occurs by a variety of mechanisms. One such mechanism is increased proteolysis by the ubiquitin-proteasome system, in which intracellular proteins destined for destruction are covalently bonded to a small protein called *ubiquitin* and then degraded by small cytoplasmic organelles called *proteasomes* (see Chapter 1). Other mechanisms, such as reduced synthetic (anabolic) processes and apoptosis (programmed cell death), are also involved (to be discussed).

The general causes of atrophy can be grouped into five categories: (1) disuse, (2) denervation, (3) loss of endocrine stimulation, (4) inadequate nutrition, and (5) ischemia or decreased blood flow. Disuse atrophy occurs when there is a reduction in skeletal muscle use. An extreme example of disuse atrophy is seen in the muscles of extremities that have been encased in casts. Because atrophy is adaptive and reversible, muscle size is restored after the cast is removed and muscle use is resumed. Denervation atrophy is a form of disuse atrophy that occurs in the muscles of paralyzed limbs. Lack of endocrine stimulation produces a form of disuse atrophy when there is a reduction in skeletal muscle use. An extreme example of disuse atrophy is seen in the muscles of extremities that have been encased in casts. Because atrophy is adaptive and reversible, muscle size is restored after the cast is removed and muscle use is resumed. Denervation atrophy is a form of disuse atrophy that occurs in the muscles of paralyzed limbs. Lack of endocrine stimulation produces a form of disuse atrophy that occurs in the muscles of paralyzed limbs. Because atrophy is adaptive and reversible, muscle size is restored after the cast is removed and muscle use is resumed. Denervation atrophy is a form of disuse atrophy that occurs in the muscles of paralyzed limbs. Lack of endocrine stimulation produces a form of disuse atrophy that occurs in the muscles of paralyzed limbs. Because atrophy is adaptive and reversible, muscle size is restored after the cast is removed and muscle use is resumed. Denervation atrophy is a form of disuse atrophy that occurs in the muscles of paralyzed limbs. Lack of endocrine stimulation produces a form of disuse atrophy that occurs in the muscles of paralyzed limbs. Because atrophy is adaptive and reversible, muscle size is restored after the cast is removed and muscle use is resumed. Denervation atrophy is a form of disuse atrophy that occurs in the muscles of paralyzed limbs. Lack of endocrine stimulation produces a form of disuse atrophy that occurs in the muscles of paralyzed limbs. Because atrophy is adaptive and reversible, muscle size is restored after the cast is removed and muscle use is resumed. Denervation atrophy is a form of disuse atrophy that occurs in the muscles of paralyzed limbs. Lack of endocrine stimulation produces a form of disuse atrophy that occurs in the muscles of paralyzed limbs. Because atrophy is adaptive and reversible, muscle size is restored after the cast is removed and muscle use is resumed.

**Hypertrophy**

*Hypertrophy* represents an increase in cell size, and with it an increase in the amount of functioning tissue mass. It results from an increased workload imposed on an organ or body part and is commonly seen in cardiac and skeletal muscle tissue, which cannot adapt to an increase in workload through mitotic division and formation of more cells. Hypertrophy involves an increase in the functional components of the cell that allows it to achieve equilibrium between demand and functional capacity. For example, as muscle cells hypertrophy, additional actin and myosin filaments, cell enzymes, and adenosine triphosphate (ATP) are synthesized.

Hypertrophy may occur as the result of normal physiologic or abnormal pathologic conditions. The increase in muscle mass associated with exercise is an example of physiologic hypertrophy. Pathologic hypertrophy occurs as the result of disease conditions and may be adaptive or compensatory. Examples of adaptive hypertrophy are...
the thickening of the urinary bladder from long-continued obstruction of urinary outflow and myocardial hypertrophy from valvular heart disease or hypertension. Compensatory hypertrophy is the enlargement of a remaining organ or tissue after a portion has been surgically removed or rendered inactive. For instance, if one kidney is removed, the remaining kidney enlarges to compensate for the loss.

The initiating signals for hypertrophy appear to be complex and related to ATP depletion, mechanical forces such as stretching of the muscle fibers, activation of cell degradation products, and hormonal factors. In the case of the heart, initiating signals can be divided into two broad categories: (1) biomechanical and stretch-sensitive mechanisms and (2) neurohumoral mechanisms associated with the release of hormones, growth factors, cytokines, and chemokines. Internal stretch-sensitive receptors for the biochemical signals and an array of membrane-bound receptors for the specific neurohumoral ligands, such as IGF-1 and epidermal growth factor (EGF), activate specific signal transduction pathways. These pathways control myocardial growth by altering gene expression to increase protein synthesis and reduce protein degradation, thereby causing hypertrophic enlargement of the heart. A limit is eventually reached beyond which further enlargement of the tissue mass is no longer able to compensate for the increased work demands. The limiting factors for continued hypertrophy might be related to limitations in blood flow. In hypertension, for example, the increased workload required to pump blood against an elevated arterial pressure results in a progressive increase in left ventricular muscle mass and need for coronary blood flow (Fig. 2-2).

There continues to be interest in the signaling pathways that control the arrangement of contractile elements in myocardial hypertrophy. Research suggests that certain signal molecules can alter gene expression controlling the size and assembly of the contractile proteins in hypertrophied myocardial cells. For example, the hypertrophied myocardial cells of well-trained athletes have proportional increases in width and length. This is in contrast to the hypertrophy that develops in dilated cardiomyopathy, in which the hypertrophied cells have a relatively greater increase in length than width. In pressure overload, as occurs with hypertension, the hypertrophied cells have greater width than length. It is anticipated that further elucidation of the signal pathways that determine the adaptive and nonadaptive features of cardiac hypertrophy will lead to new targets for treatment.

**Hyperplasia**

*Hyperplasia* refers to an increase in the number of cells in an organ or tissue. It occurs in tissues with cells that are capable of mitotic division, such as the epidermis, intestinal epithelium, and glandular tissue. Certain cells, such as neurons, rarely divide and therefore have little (if any) capacity for hyperplastic growth. There is evidence that hyperplasia involves activation of genes controlling cell proliferation and the presence of intracellular messengers that control cell replication and growth. As with other normal adaptive cellular responses, hyperplasia is a controlled process that occurs in response to an appropriate stimulus and ceases after the stimulus has been removed.

The stimuli that induce hyperplasia may be physiologic or nonphysiologic. There are two common types of physiologic hyperplasia: hormonal and compensatory. Breast and uterine enlargement during pregnancy are examples of a physiologic hyperplasia that results from estrogen stimulation. The regeneration of the liver that occurs after partial heptectomy (i.e., partial removal of the liver) is an example of compensatory hyperplasia. Hyperplasia is also an important response of connective tissue in wound healing, during which proliferating fibroblasts and blood vessels contribute to wound repair. Although hypertrophy and hyperplasia are two distinct processes, they may occur together and are often triggered by the same mechanism. For example, the pregnant uterus undergoes both hypertrophy and hyperplasia as a result of estrogen stimulation.

Most forms of nonphysiologic hyperplasia are due to excessive hormonal stimulation or the effects of growth factors on target tissues. Excessive estrogen production can cause endometrial hyperplasia and abnormal menstrual bleeding (see Chapter 40). Benign prostatic hyperplasia, which is a common disorder of men older than 50 years of age, is thought to be related to the action of androgens (see Chapter 39). Skin warts are an example of hyperplasia caused by growth factors produced by certain viruses, such as the papillomaviruses.

**Metaplasia**

*Metaplasia* represents a reversible change in which one adult cell type (epithelial or mesenchymal) is replaced by another adult cell type. These changes are thought...
to involve the reprogramming of undifferentiated stem cells that are present in the tissue undergoing the metaplastic changes.

Metaplasia usually occurs in response to chronic irritation and inflammation and allows for substitution of cells that are better able to survive under circumstances in which a more fragile cell type might succumb. However, the conversion of cell type never oversteps the boundaries of the primary tissue type (e.g., one type of epithelial cell may be converted to another type of epithelial cell, but not to a connective tissue cell). An example of metaplasia is the adaptive substitution of stratified squamous epithelial cells for the ciliated columnar epithelial cells in the trachea and large airways of a habitual cigarette smoker. Although the squamous epithelium is better able to survive in these situations, the protective function that the ciliated epithelium provides for the respiratory tract is lost. Also, continued exposure to the influences that cause metaplasia may predispose to cancerous transformation of the metaplastic epithelium.

**Dysplasia**

Dysplasia is characterized by deranged cell growth of a specific tissue that results in cells that vary in size, shape, and organization. Minor degrees of dysplasia are associated with chronic irritation or inflammation. The pattern is most frequently encountered in areas of metaplastic squamous epithelium of the respiratory tract and uterine cervix. Although dysplasia is abnormal, it is adaptive in that it is potentially reversible after the irritating cause has been removed. Dysplasia is strongly implicated as a precursor of cancer. In cancers of the respiratory tract and the uterine cervix, dysplastic changes have been found adjacent to the foci of cancerous transformation. Through the use of the Papanicolaou (Pap) test, it has been documented that cancer of the uterine cervix develops in a series of incremental epithelial changes ranging from severe dysplasia to invasive cancer (discussed in Chapter 40). However, dysplasia is an adaptive process and as such does not necessarily lead to cancer. In many cases, the dysplastic cells revert to their former structure and function.

**Intracellular Accumulations**

Intracellular accumulations represent the buildup of substances that cells cannot immediately use or eliminate. The substances may accumulate in the cytoplasm (frequently in the lysosomes) or in the nucleus. In some cases the accumulation may be an abnormal substance that the cell has produced, and in other cases the cell may be storing exogenous materials or products of pathologic processes occurring elsewhere in the body. These substances can be grouped into three categories: (1) normal body substances, such as lipids, proteins, carbohydrates, melanin, and bilirubin, that are present in abnormally large amounts; (2) abnormal endogenous products, such as those resulting from inborn errors of metabolism; and (3) exogenous products, such as environmental agents and pigments that cannot be broken down by the cell. These substances may accumulate transiently or permanently, and they may be harmless or, in some cases, toxic.

Under some conditions cells may accumulate abnormal amounts of various substances, some of which may be harmless while others may be associated with varying degrees of injury. Frequently, normal substances accumulate because they are synthesized at a rate that exceeds their metabolism or removal. An example of this type of process is a condition called fatty liver, which is due to intracellular accumulation of triglycerides. Liver cells normally contain some fat, which is either oxidized and used for energy or converted to triglycerides. This fat is derived from free fatty acids released from adipose tissue. Abnormal accumulation occurs when the delivery of free fatty acids to the liver is increased, as in starvation and diabetes mellitus, or when the intrahepatic metabolism of lipids is disturbed, as in alcoholism.

Intracellular accumulation can result from genetic disorders that disrupt the enzymatic degradation of selected substances or their transport to other sites. A normal enzyme may be replaced with an abnormal one, resulting in the formation of a substance that cannot be used or eliminated from the cell, or an enzyme may be missing, so that an intermediate product accumulates in the cell. For example, there are at least 10 genetic disorders that affect glycogen metabolism, most of which lead to the accumulation of intracellular glycogen stores. In the most common form of this disorder, von Gierke disease, large amounts of glycogen accumulate in the liver and kidneys because of a deficiency of the enzyme glucose-6-phosphatase. Without this enzyme, glycogen cannot be broken down to form glucose. The disorder leads not only to an accumulation of glycogen but also to a reduction in blood glucose levels. In Tay-Sachs disease, another genetic disorder, abnormal lipids accumulate in the brain and other tissues, causing motor and mental deterioration beginning at approximately 6 months of age, followed by death at 2 to 3 years of age (see Chapter 6).

Pigments are colored substances that may accumulate in cells. They can be endogenous (i.e., arising from within the body) or exogenous (i.e., arising from outside the body). Icterus, also called jaundice, is characterized by a yellow discoloration of tissue due to the retention of bilirubin, an endogenous bile pigment. This condition may occur because of increased bilirubin production from red blood cell destruction, obstruction of bile passage into the intestine, or diseases that affect the liver’s ability to remove bilirubin from the blood. Lipofuscin is a yellow-brown pigment that results from the accumulation of the indigestible residues produced during normal turnover of cell structures (Fig. 2-3). The accumulation of lipofuscin increases with age and is sometimes referred to as the wear-and-tear pigment. It is more common in heart, nerve, and liver cells than other
tissues and is seen more often in conditions associated with atrophy of an organ.

One of the most common exogenous pigments is carbon in the form of coal dust. In coal miners or persons exposed to heavily polluted environments, the accumulation of carbon dust blackens the lung tissue and may cause serious lung disease. The formation of a blue lead line along the margins of the gum is one of the diagnostic features of lead poisoning. Tattoos are the result of insoluble pigments introduced into the skin, where they are engulfed by macrophages and persist for a lifetime.

The significance of intracellular accumulations depends on the cause and severity of the condition. Many accumulations, such as lipofuscin and mild fatty changes, have no effect on cell function. Some conditions, such as the hyperbilirubinemia that causes jaundice, are reversible. Other disorders, such as glycogen storage diseases, produce accumulations that result in organ dysfunction and other alterations in physiologic function.

**Pathologic Calcifications**

Pathologic calcification involves the abnormal tissue deposition of calcium salts, together with smaller amounts of iron, magnesium, and other minerals. It is known as **dystrophic calcification** when it occurs in dead or dying tissue and as **metastatic calcification** when it occurs in normal tissue.\(^1,2\)

**Dystrophic Calcification**

Dystrophic calcification represents the macroscopic deposition of calcium salts in injured tissue. It is often visible to the naked eye as deposits that range from gritty sand-like grains to firm, hard, rock-like material. The pathogenesis of dystrophic calcification involves the intracellular or extracellular formation of crystalline calcium phosphate. The components of the calcium deposits are derived from the bodies of dead or dying cells as well as from the circulation and interstitial fluid.

Dystrophic calcification is commonly seen in atherosclerotic lesions of advanced atherosclerosis, areas of injury in the aorta and large blood vessels, and damaged heart valves. While the presence of calcification may only indicate the presence of previous cell injury, as in healed tuberculosis lesions, it is also a frequent cause of organ dysfunction. For example, calcification of the aortic valve is a frequent cause of aortic stenosis in the elderly (Fig. 2-4).

**Metastatic Calcification**

In contrast to dystrophic calcification, which occurs in injured tissues, metastatic calcification occurs in normal tissues as the result of increased serum calcium levels (hypercalcemia). Almost any condition that increases the serum calcium level can lead to calcification in inappropriate sites such as the lung, renal tubules, and blood vessels. The major causes of hypercalcemia are hyperparathyroidism, either primary or secondary to phosphate retention in renal failure; increased release of calcium from bone as in immobilization, Paget disease, or cancer with metastatic bone lesions; and vitamin D intoxication.
SUMMARY CONCEPTS

- Cells adapt to changes in their environment and in their work demands by changing their size, number, and characteristics. These adaptive changes are consistent with the needs of the cell and occur in response to an appropriate stimulus. The changes are usually reversed after the stimulus has been withdrawn.
- When confronted with a decrease in work demands or adverse environmental conditions, cells atrophy, or reduce in size. When confronted with an increase in work demands they undergo hypertrophy, an increase in size. An increase in the number of cells in an organ or tissue is called hyperplasia.
- Metaplasia occurs in response to chronic irritation and represents the substitution of cells of a type that are better able to survive under circumstances in which a more fragile cell type might succumb. Dysplasia is characterized by deranged cell growth of a specific tissue that results in cells that vary in size, shape, and appearance. It is often a precursor of cancer.
- Under some circumstances, cells may accumulate abnormal amounts of various substances. If the accumulation reflects a correctable systemic disorder, such as the hyperbilirubinemia that causes jaundice, the accumulation is reversible. If the disorder cannot be corrected, as often occurs in many inborn errors of metabolism, the cells become overloaded, causing cell injury and death.
- Pathologic calcification involves the abnormal tissue deposition of calcium salts. Dystrophic calcification occurs in dead or dying tissue, whereas metastatic calcification occurs in normal tissues as the result of elevated serum calcium levels.

Cell Injury, Death, and Senescence

Cells can be injured in many ways. The extent to which any injurious agent can cause reversible or irreversible cell injury and death depends in large measure on the intensity and duration of the injury and the type of cell that is involved, as well as variables such as blood supply, nutritional status, and regenerative capacity. Cell injury and death are ongoing processes, and in the healthy state, they are balanced by cell renewal.

Causes of Cell Injury

Cell damage can occur in many ways. For purposes of discussion, the ways by which cells are injured have been grouped into five categories: (1) injury from physical agents, (2) radiation injury, (3) chemical injury, (4) injury from biologic agents, and (5) injury from nutritional imbalances.

Injury from Physical Agents

Physical agents responsible for cell and tissue injury include mechanical forces, extremes of temperature, and electrical forces. They are common causes of injuries due to environmental exposure, occupational and transportation accidents, and physical violence and assault.

Mechanical Forces. Injury or trauma due to mechanical forces occurs as the result of body impact with another object. The body or the mass can be in motion or, as sometimes happens, both can be in motion at the time of impact. These types of injuries split and tear tissue, fracture bones, injure blood vessels, and disrupt blood flow.

Extremes of Temperature. Extremes of heat and cold cause damage to the cell, its organelles, and its enzyme systems. Exposure to low-intensity heat (43°C to 46°C), such as occurs with partial-thickness burns and severe heat stroke, causes cell injury by inducing vascular injury, accelerating cell metabolism, inactivating temperature-sensitive enzymes, and disrupting the cell membrane. With more intense heat, coagulation of blood and tissue proteins occurs. Exposure to cold increases blood viscosity and induces vasoconstriction by direct action on blood vessels and through reflex activity of the sympathetic nervous system. The resultant decrease in blood flow may lead to hypoxic tissue injury, depending on the degree and duration of cold exposure. Injury from freezing probably results from a combination of ice crystal formation and vasoconstriction. The decreased blood flow leads to capillary stasis and arteriolar and capillary thrombosis. Edema results from increased capillary permeability.

Electrical Forces. Injuries due to electrical forces can affect the body through extensive tissue injury and disruption of neural and cardiac impulses. The effect of electricity on the body is mainly determined by its voltage, the type of current (i.e., direct or alternating), its amperage, the resistance of the intervening tissue, the pathway of the current, and the duration of exposure.

Lightning and high-voltage wires that carry several thousand volts produce the most severe damage. Alternating current (AC) is usually more dangerous than direct current (DC) because it causes violent muscle contractions, preventing the person from releasing the electrical source and sometimes resulting in fractures and dislocations. In electrical injuries, the body acts as
a conductor of the electrical current. The current enters the body from an electrical source, such as an exposed wire, and passes through the body and exits to another conductor, such as the moisture on the ground or a piece of metal the person is holding. The pathway that a current takes is critical because the electrical energy disrupts impulses in excitable tissues. Current flow through the brain may interrupt impulses from respiratory centers in the brain stem, and current flow through the chest may cause fatal cardiac arrhythmias.

The resistance to the flow of current in electrical circuits transforms electrical energy into heat. This is why the elements in electrical heating devices are made of highly resistive metals. Much of the tissue damage produced by electrical injuries is caused by heat production in tissues that have the highest electrical resistance. Resistance to electrical current varies from the greatest to the least in bone, fat, tendons, skin, muscles, blood, and nerves. The most severe tissue injury usually occurs at the skin sites where the current enters and leaves the body (Fig. 2-5). After electricity has penetrated the skin, it rapidly passes through the body along the lines of least resistance—through body fluids and nerves. Degeneration of vessel walls may occur, and thrombi may form as current flows along the blood vessels. This can cause extensive muscle and deep tissue injury. Thick, dry skin is more resistant to the flow of electricity than thin, wet skin. It is generally believed that the greater the skin resistance, the greater is the amount of local skin burn; and the less the resistance, the greater are the deep and systemic effects.

**Radiation Injury**

Electromagnetic radiation comprises a wide spectrum of wave-propagated energy, ranging from ionizing gamma rays to radiofrequency waves. A photon is a particle of radiation energy. Radiation energy with frequencies above the ultraviolet (UV) range is called ionizing radiation because the photons have enough energy to knock electrons off atoms and molecules. Nonionizing radiation refers to radiation energy at frequencies below those of visible light. Ultraviolet radiation represents the portion of the spectrum of electromagnetic radiation just above the visible range.

**Ionizing Radiation.** Ionizing radiation affects cells by causing ionization of molecules and atoms in the cell, by directly hitting the target molecules in the cell, or by producing free radicals (highly reactive chemical species) that destabilize molecules in critical cell components. It can immediately kill cells, interrupt cell replication, or cause a variety of genetic mutations, which may or may not be lethal. Most radiation injury is caused by localized irradiation that is used in the treatment of cancer (see Chapter 7). Except for unusual circumstances such as the use of high-dose irradiation that precedes bone marrow transplantation, exposure to whole-body irradiation is rare.

The injurious effects of ionizing radiation vary with the dose, dose rate (a single large dose can cause greater injury than divided or fractionated doses), and the differential sensitivity of the exposed tissue to radiation injury. Because of the effect on deoxyribonucleic acid (DNA) synthesis and interference with mitosis, rapidly dividing cells of the bone marrow and intestine are much more vulnerable to radiation injury than tissues such as bone and skeletal muscle. Over time, occupational and accidental exposure to ionizing radiation can result in increased risk for the development of various types of cancers, including skin cancers, leukemia, osteogenic sarcomas, and lung cancer.

Many of the clinical manifestations of radiation injury result from acute cell injury, dose-dependent changes in the blood vessels that supply the irradiated tissues, and fibrotic tissue replacement. The cell’s initial response to radiation injury involves swelling, disruption of the mitochondria and other organelles, alterations in the cell membrane, and marked changes in the nucleus. The endothelial cells in blood vessels are particularly sensitive to irradiation. During the immediate post-irradiation period, only vessel dilatation is apparent (e.g., the initial erythema of the skin after radiation therapy). Later or with higher levels of radiation, destructive changes occur in small blood vessels such as the capillaries and venules. Acute reversible necrosis is represented by such disorders as radiation cystitis, dermatitis, and diarrhea from enteritis. More persistent damage can be attributed to acute necrosis of tissue cells that are not capable of regeneration, or because of chronic ischemia. Chronic effects of radiation damage are characterized by fibrosis and scarring of tissues and organs in the irradiated area (e.g., interstitial fibrosis of the heart and lungs after irradiation of the chest). Because the radiation delivered in radiation therapy inevitably travels through the skin, radiation dermatitis is common. There may be necrosis of the skin, impaired wound healing, and chronic radiation dermatitis.
**Ultraviolet Radiation.** Ultraviolet radiation contains increasingly energetic rays that are powerful enough to disrupt intracellular bonds, cause sunburn, and increase the risk of skin cancers (see Chapter 46). The degree of risk depends on the type of UV rays, the intensity of exposure, and the amount of protective melanin pigment in the skin. Skin damage induced by UV radiation is thought to be caused by reactive oxygen species and by damage to melanin-producing processes in the skin. Ultraviolet radiation also damages DNA, resulting in the formation of pyrimidine dimers (i.e., the insertion of two identical pyrimidine bases into replicating DNA instead of one). Other forms of DNA damage include the production of single-stranded breaks and formation of DNA–protein cross-links. Normally, errors that occur during DNA replication are repaired by enzymes that remove the faulty section of DNA and repair the damage. The importance of DNA repair in protecting against UV radiation injury is evidenced by the vulnerability of persons who lack the enzymes needed to repair UV-induced DNA damage. In a genetic disorder called *xeroderma pigmentosum*, an enzyme needed to repair sunlight-induced DNA damage is lacking. This autosomal recessive disorder is characterized by extreme photosensitivity and a 2000-fold increased risk of skin cancer in sun-exposed skin.  

**Nonionizing Radiation.** Nonionizing radiation includes infrared light, ultrasound, microwaves, and laser energy. Unlike ionizing radiation, which can directly break chemical bonds, nonionizing radiation exerts its effects by causing vibration and rotation of atoms and molecules. All of this vibrational and rotational energy is eventually converted to thermal energy. Low-frequency nonionizing radiation is used widely in radar, television, industrial operations (e.g., heating, welding, melting of metals, processing of wood and plastic), household appliances (e.g., microwave ovens), and medical applications (e.g., diathermy). Isolated cases of skin burns and thermal injury to deeper tissues have occurred in industrial settings and from improperly used household microwave ovens. Injury from these sources is mainly thermal and, because of the deep penetration of infrared or microwave rays, tends to involve dermal and subcutaneous tissue injury.

**Chemical Injury**

Chemicals capable of damaging cells are everywhere around us. Pollutants in the air, water, and soil, such as carbon monoxide, pesticides, and trace metals including lead, are capable of tissue injury, as are certain chemicals in foods. Chemical agents can injure the cell membrane and other cell structures, block enzymatic pathways, coagulate cell proteins, and disrupt the osmotic and ionic balance of the cell. Corrosive substances such as strong acids and bases destroy cells as the substances come into contact with the body. Other chemicals may injure cells in the process of metabolism or elimination. For example, carbon tetrachloride (CCl₄), a chemical used in manufacturing, causes little damage until it is metabolized by liver enzymes to a highly reactive free radical that is extremely toxic to liver cells.

**Drugs.** Many drugs—alcohol, prescription drugs, over-the-counter drugs, and street drugs—are capable of directly or indirectly damaging tissues. Ethyl alcohol can harm the gastric mucosa, liver (see Chapter 30), developing fetus (see Chapter 6), and other organs. Antineoplastic (anticancer) and immunosuppressant drugs can directly injure cells. Other drugs produce metabolic end products that are toxic to cells. Acetaminophen, a commonly used over-the-counter analgesic drug, is detoxified in the liver, where small amounts of the drug are converted to a highly toxic metabolite. This metabolite is detoxified by a metabolic pathway that uses a substance (i.e., glutathione) normally present in the liver. When large amounts of the drug are ingested, this pathway becomes overwhelmed and toxic metabolites accumulate, causing massive liver necrosis.

**Lead Toxicity.** Lead is a particularly toxic metal. Small amounts accumulate to reach toxic levels. There are innumerable sources of lead in the environment, including flaking paint, lead-contaminated dust and soil, pottery glazes, traditional remedies, cosmetics, and wild game contaminated by lead shot. Adults often encounter lead through occupational exposure. Lead and other metal smelters, miners, welders, storage battery workers, and pottery makers are particularly at risk. Children are exposed to lead through ingestion of peeling lead paint, by breathing dust from lead paint (e.g., during remodeling), playing in contaminated soil, or playing with toys or items made or decorated with lead. Factors that increase the risk of lead toxicity include preschool age, low socioeconomic status, and living in housing built before 1960. Lead is absorbed through the gastrointestinal tract or the lungs into the blood. A deficiency in calcium, iron, or zinc increases lead absorption. In children, most lead is absorbed through the lungs. Although infants and children may have the same or a lower intake of lead as compared to adults, their absorption is greater. Also, the more permeable blood–brain barrier of infants and children makes them highly susceptible to brain damage. Lead crosses the placenta, exposing the fetus to levels of lead that are comparable with those of the mother. Most of the absorbed lead (80% to 85%) is stored in bone (and teeth of young children), 5% to 10% remains in the blood, and the remainder accumulates in soft tissues. Although the half-life of lead is hours to days, bone serves as a repository from which blood levels are maintained. In a sense, bone protects other tissues, but the slow turnover maintains blood levels for months to years. The toxicity of lead is related to its multiple biochemical effects. It has the ability to inactivate enzymes, compete with calcium for incorporation into bone, and interfere with nerve transmission and brain development. The major targets of lead toxicity are the red blood cells, the gastrointestinal tract, the kidneys, and the nervous system. Anemia is a cardinal sign of lead toxicity.
Lead competes with the enzymes required for hemo-
globin synthesis and with the membrane-associated
enzymes that prevent hemolysis of red blood cells. The
life span of the red cell is decreased. The gastrointestinal
tract is the main source of symptoms in the adult. This
is characterized by “lead colic,” a severe and poorly local-
ized form of acute abdominal pain. A lead line formed
by precipitated lead sulphate may appear along the gin-
gival margins. The lead line is seldom seen in children.
The kidneys are the major route for excretion of lead.
Lead can cause diffuse kidney damage, eventually lead-
ing to renal failure. Even without overt signs of kidney
damage, lead toxicity leads to hypertension.

In the nervous system, lead toxicity is characterized by
demyelination of cerebral and cerebellar white matter and
death of brain cells. When this occurs in early childhood,
it can affect neurobehavioral development and result in
lower IQ levels and poorer classroom performance.9
Demyelination of peripheral nerves may occur in adults.
The most serious manifestation of lead poisoning is acute
encephalopathy. It is manifested by persistent vomiting,
ataxia, seizures, papilledema, impaired consciousness,
and coma. Acute encephalopathy may manifest suddenly,
or it may be preceded by other signs of lead toxicity such
as behavioral changes or abdominal complaints.

The threshold level at which lead causes subclinical and
clinical disturbances has been redefined a number of
times over the past 50 years. At one time, a blood
level of 25 µg/dL was considered safe. Recent research
suggests that even levels below 10 µg/dL are associated
with declines in children’s IQ at 3 to 5 years of age.10,11
Approximately 99% of children are identified by
screening procedures, which are recommended for high-
risk populations based on the likelihood of lead expo-
sure. A screening value greater than 10 µg/dL requires
repeat testing for a diagnosis and to determine the need
for treatment. Treatment involves removal of the lead
source and, in cases of severe toxicity, administration of
a chelating agent. A public health team should evaluate
the source of lead because meticulous removal is needed.

Mercury Toxicity. Mercury has been used for industrial
and medical purposes for hundreds of years. Mercury
is toxic, and the hazards of mercury-associated occupu-
opational and accidental exposures are well known. In
recent times, the primary concern of the general pub-
c about the potential hazards of mercury has focused
on exposure from eating certain fish, amalgams used in
dentistry, and vaccines.12 Mercury is present in four pri-
mary forms: mercury vapor, inorganic divalent mercury,
methyl mercury, and ethyl mercury.12 Depending on the
form of mercury exposure, toxicity involving the central
nervous system and kidney can occur.

In the case of dental fillings, the concern involves
mercury vapor being released into the mouth. However,
the amount of mercury vapor released from fillings is
very small. There is no clear evidence supporting health
risk from this type of exposure, and removal of amalgams
can temporarily increase blood levels of mercury.12 The main source of methyl mercury exposure
is from consumption of long-lived fish, such as tuna and
swordfish. Fish concentrate mercury from sediment in
the water. Because the developing brain is more suscepti-
table to mercury-induced damage, it is recommended
that young children and pregnant and nursing women
avoid consumption of fish known to contain high mer-
cury content. Thimerosal is an ethyl mercury-containing
preservative that helps prevent microbial growth in
vaccines. Concern about potential adverse effects have
led to the creation of single-dose vials that eliminate the
need for thimerosal.12 In the United States and Canada,
most vaccines are either free of thimerosal or contain
only trace amounts.

Injury from Biologic Agents

Biologic agents differ from other injurious agents in that
they are able to replicate and can continue to produce
their injurious effects (see Chapter 14). These agents
range from submicroscopic viruses to the larger para-
sites. Biologic agents injure cells by diverse mechanisms.
Viruses enter the cell and incorporate its genetic mate-
rial into their cellular DNA, which then enables synthe-
sis of new viruses. Certain bacteria produce exotoxins
that may interfere with cellular protein synthesis. Other
bacteria, such as the gram-negative bacilli, release endo-
toxins that cause cell injury and increased capillary
permeability.

Injury from Nutritional Imbalances

Nutritional excesses and nutritional deficiencies predis-
pose cells to injury. Obesity and diets high in saturated
fats are thought to predispose persons to atherosclerosis.
The body requires more than 60 organic and inorganic
substances in amounts ranging from micrograms to
grams. These nutrients include minerals, vitamins, cer-
tain fatty acids, and specific amino acids. Dietary defi-
ciciencies can occur because of a selective deficiency of
a single nutrient. Iron-deficiency anemia, scurvy, beriberi,
and pellagra are examples of injury caused by a lack of
specific vitamins or minerals. The protein and calorie
deficiencies that occur with starvation cause widespread
tissue damage.

Mechanisms of Cell Injury

The mechanisms by which injurious agents cause cell
injury and death are complex. Some agents, such as heat,
produce direct cell injury; other factors, such as genetic
derangements, produce their effects indirectly through
metabolic disturbances and altered immune responses.
There seem to be at least three major mechanisms
whereby most injurious agents exert their effects: free
radical formation, hypoxia and ATP depletion, and dis-
ruption of intracellular calcium homeostasis (Fig. 2-6).

Free Radical Injury

Cell injury in many circumstances involves the production
of reactive chemical species known as free radicals.1,2,13–15
These circumstances include ischemia-reperfusion injury,
chemical and radiation injury, toxicity from oxygen and other gases, cellular aging, responses to microbial infections, and tissue injury caused by inflammation.

Free radicals are highly reactive chemical species with an unpaired electron in the outer orbit (valence shell) of the molecule. In the literature, the unpaired electron is denoted by a dot, for example, NO\textsuperscript{·}. The unpaired electron causes free radicals to be unstable and highly reactive, so that they react nonspecifically with molecules in the vicinity. Moreover, free radicals can establish chain reactions consisting of many events that generate new free radicals. In cells and tissues, free radicals react with proteins, lipids, and carbohydrates, thereby damaging cell membranes, inactivating enzymes, and damaging nucleic acids that make up DNA.

Many free radicals that are harmful in human physiology are derived from oxygen. These reactive oxygen species (ROS) include free radicals, such as superoxide anion (O\textsubscript{2}·\superscript{-}) and hydroxyl radical (OH\textsuperscript{·}), as well as reactive oxygen-containing species that are not free radicals, such as hydrogen peroxide (H\textsubscript{2}O\textsubscript{2}). Reactive oxygen species are normal products of mitochondrial respiration and energy metabolism, and are typically removed by cellular antioxidative systems. Exogenous causes, including ionizing and UV radiation, can also cause ROS production in the body. Oxidative stress is a condition that occurs when the generation of ROS exceeds the ability of the body to neutralize and eliminate ROS. Oxidative stress can lead to oxidation of cell components, activation of signal transduction pathways, DNA damage, and changes in gene expression. In addition to focusing on nuclear DNA as a target of oxidative injury, current studies are focusing on mitochondrial DNA as a target of oxidation and subsequent cause of mitochondrial dysfunction.\textsuperscript{16}

Although ROS and oxidative stress are clearly associated with cell and tissue damage, recent evidence suggests that ROS are not always acting in a random and damaging manner. Current studies find that ROS are also important signaling molecules that are used in healthy cells to regulate normal functions such as vascular smooth muscle tone and vascular endothelial growth factor (VEGF) signaling, and even function as a preconditioning factor to protect cells from injury.\textsuperscript{17}

Antioxidants are natural and synthetic molecules that inhibit the reactions of ROS with biologic structures or that prevent the uncontrolled formation of ROS. Antioxidants include enzymatic and nonenzymatic compounds. Enzymes known to function as antioxidants include superoxide dismutase (SOD), catalase, glutathione peroxidase, and thioreductase. Superoxide dismutase forms hydrogen peroxide from superoxide. Catalase,
present in peroxisomes, catalyzes the reaction that forms water from hydrogen peroxide. Nonenzymatic antioxidants include carotenoids (e.g., vitamin A), tocopherols (e.g., vitamin E), ascorbate (vitamin C), glutathione, and flavonoids, as well as micronutrients such as selenium and zinc. Nonenzymatic antioxidants often directly react with oxidants to “disarm” them. For example, vitamin C directly scavenges superoxide and hydroxyl radicals.

Oxidative damage has been implicated in many diseases. Mutations in the gene for SOD are associated with amyotrophic lateral sclerosis (ALS; so-called Lou Gehrig disease). Oxidative stress is thought to have an important role in the development of cancer. Reestablishment of blood flow following loss of perfusion, as occurs during heart attack and stroke, is associated with oxidative injury to vital organs. The endothelial dysfunction that contributes to the development, progression, and prognosis of cardiovascular diseases is thought to be caused in part by oxidative stress. In addition, oxidative stress has been associated with age-related functional declines.

**Hypoxic Cell Injury**

Hypoxia deprives the cell of oxygen and interrupts oxidative metabolism and the generation of ATP. The actual time necessary to produce irreversible cell damage depends on the degree of oxygen deprivation and the metabolic needs of the cell. Some cells, such as those in the heart, brain, and kidney, require large amounts of oxygen to provide the energy to perform their functions. Brain cells, for example, begin to undergo permanent damage after 4 to 6 minutes of oxygen deprivation. A thin margin of time exists between reversible and irreversible cell damage. A classic study found that the epithelial cells of the proximal tubule of the kidney in the rat could survive 20 but not 30 minutes of ischemia.

Recent work has identified a group of proteins called hypoxia-inducible factors (HIFs). During hypoxic conditions, HIFs cause the expression of genes that stimulate red blood cell formation, manufacture glycolytic enzymes that produce ATP in the absence of oxygen, and increase angiogenesis (i.e., the formation of new blood vessels).

Hypoxia can result from an inadequate amount of oxygen in the air, respiratory disease, ischemia (i.e., decreased blood flow due to vasoconstriction or vascular obstruction), anemia, edema, or inability of the cells to use oxygen. Ischemia is characterized by impaired oxygen delivery and impaired removal of metabolic end products such as lactic acid. In contrast to pure hypoxia, which depends on the oxygen content of the blood and affects all cells in the body, ischemia commonly depends on blood flow through limited numbers of blood vessels and produces local tissue injury. In some cases of edema, the distance for diffusion of oxygen may become a limiting factor in the delivery of oxygen. In hypermetabolic states, the cells may require more oxygen than can be supplied by normal respiratory function and oxygen transport. Hypoxia also serves as the ultimate cause of cell death in other injuries. For example, physical factors such as a cold temperature can cause severe constriction and impair blood flow.

Hypoxia causes a power failure in the cell, with widespread effects on the cell’s structural and functional components. As oxygen tension in the cell falls, oxidative metabolism ceases, and the cell reverts to anaerobic metabolism, using its limited glycogen stores in an attempt to maintain vital cell functions. Cellular pH falls as lactic acid accumulates in the cell. This reduction in pH can have adverse effects on intracellular structures and biochemical reactions. Low pH can alter cell membranes and cause chromatin clumping and cell volume changes.

An important effect of reduced ATP is acute cell swelling caused by failure of the energy-dependent sodium/potassium (Na+/K+)–adenosine triphosphatase (ATPase) membrane pump, which extrudes sodium from and returns potassium to the cell. With impaired function of this pump, intracellular potassium levels decrease, and sodium and water accumulate in the cell. The movement of water and ions into the cell is associated with dilation of the endoplasmic reticulum, increased membrane permeability, and decreased mitochondrial function. To a point, the cellular changes due to hypoxia are reversible if oxygenation is restored. However, if the oxygen supply is not restored there is continued loss of enzymes, proteins, and ribonucleic acid through the hyperpermeable cell membrane. Injury to the lysosomal membranes results in the leakage of destructive lysosomal enzymes into the cytoplasm and enzymatic digestion of cell components. Leakage of intracellular enzymes through the permeable cell membrane into the extracellular fluid provides an important clinical indicator of cell injury and death. These enzymes enter the blood and can be measured by laboratory tests.

**Impaired Calcium Homeostasis**

Calcium functions as an important second messenger and cytosolic signal for many cell responses. Various calcium-binding proteins, such as troponin and calmodulin, act as transducers for cytosolic calcium signaling. Calcium/calmodulin–dependent kinases indirectly mediate the effects of calcium on responses such as smooth muscle contraction and glycogen breakdown. Normally, intracellular calcium ion levels are kept extremely low compared with extracellular levels. These low intracellular levels are maintained by energy-dependent membrane-associated calcium/magnesium (Ca2+/Mg2+)–ATPase exchange systems and sequestration of calcium ions within organelles such as the mitochondria and smooth endoplasmic reticulum. Ischemia and certain toxins lead to an increase in cytosolic calcium because of the increased influx across the cell membrane and the release of calcium from intracellular stores. The increased calcium level may inappropriately activate a number of enzymes with potentially damaging effects. These enzymes include phospholipases that can damage the cell membrane, proteases that damage the cytoskeleton and membrane proteins, ATPases that break down ATP and hasten its depletion, and endonucleases that fragment chromatin. Although it is known that injured cells accumulate calcium, it is unknown whether this is the ultimate cause of irreversible cell injury.
Reversible Cell Injury and Cell Death

The mechanisms of cell injury can produce sublethal and reversible cellular damage or lead to irreversible injury with cell destruction or death (Fig. 2-7). Cell destruction and removal usually involve one of two mechanisms: apoptosis, which is designed to remove injured or worn-out cells, or cell death or necrosis, which occurs in irreversibly damaged cells.

Reversible Cell Injury

Reversible cell injury, although impairing cell function, does not result in cell death. Two patterns of reversible cell injury can be observed under the microscope: cellular swelling and fatty change. Cellular swelling occurs with impairment of the energy-dependent Na⁺/K⁺-ATPase membrane pump, usually as the result of hypoxic cell injury.

Fatty changes are linked to intracellular accumulation of fat. When fatty changes occur, small vacuoles of fat disperse throughout the cytoplasm. The process is usually more ominous than cellular swelling, and although it is reversible, it usually indicates severe injury. These fatty changes may occur because normal cells are presented with an increased fat load or because injured cells are unable to metabolize the fat properly. In obese persons, fatty infiltrates often occur within and between the cells of the liver and heart because of an increased fat load. Pathways for fat metabolism may be impaired during cell injury, and fat may accumulate in the cell as production exceeds use and export. The liver, where most fats are synthesized and metabolized, is particularly susceptible to fatty change, but fatty changes may also occur in the kidney, the heart, and other organs.

Programmed Cell Death

In most normal nontumor cells, the number of cells in tissues is regulated by balancing cell proliferation and cell death. Cell death occurs by necrosis or a form of programmed cell death called apoptosis.

Apoptosis, from the Greek apo for “apart” and ptosis for “fallen,” means “fallen apart.” Apoptosis is a highly selective process that eliminates injured and aged cells, thereby controlling tissue regeneration. Cells undergoing apoptosis have characteristic morphologic features, as well as biochemical changes. As shown in Figure 2-8, shrinking and condensation of the nucleus and cytoplasm occur. The chromatin aggregates at the nuclear envelope, and DNA fragmentation occurs. Then, the cell becomes fragmented into multiple apoptotic bodies in a manner that maintains the integrity of the plasma membrane and does not initiate inflammation. Changes in the plasma membrane induce phagocytosis of the apoptotic bodies by macrophages and other cells, thereby completing the degradation process.

Apoptosis is thought to be responsible for several normal physiologic processes, including the programmed destruction of cells during embryonic development, hormone-dependent involution of tissues, death of immune cells, cell death by cytotoxic T cells, and cell death in proliferating cell populations. During embryogenesis, in the development of a number of organs such as the heart, which begins as a pulsating tube and is gradually modified to become a four-chambered pump, apoptotic cell death allows for the next stage of organ development.
It also separates the webbed fingers and toes of the developing embryo. Apoptotic cell death occurs in the hormone-dependent involution of endometrial cells during the menstrual cycle and in the regression of breast tissue after weaning from breast-feeding. The control of immune cell numbers and destruction of autoreactive T cells in the thymus have been credited to apoptosis. Cytotoxic T cells and natural killer cells are thought to destroy target cells by inducing apoptotic cell death.

Apoptosis is linked to many pathologic processes and diseases. For example, interference with apoptosis is known to be a mechanism that contributes to carcinogenesis. Apoptosis is also known to be involved in the cell death associated with viral infections, such as hepatitis B and C. Apoptosis may also be implicated in neurodegenerative disorders such as ALS, Alzheimer disease, and Parkinson disease. However, the exact mechanisms involved in these diseases remains under investigation.

Two basic pathways for apoptosis have been described (Fig. 2-9). These are the extrinsic pathway, which is death receptor dependent, and the intrinsic pathway, which is death receptor independent. The execution phase of both pathways is carried out by proteolytic enzymes called caspases (cysteine proteases that cleave aspartate residues), which are present in the cell as procaspases and are activated by cleavage of an inhibitory portion of their polypeptide chain.

The extrinsic pathway involves extracellular signaling proteins that bind to cell surface molecules called death receptors and trigger apoptosis. The prototype death receptors are tumor necrosis factor (TNF) receptor and the Fas ligand receptor. Fas ligand may be expressed on the surface of certain cells, such as cytotoxic T cells, or appear in a soluble form. When Fas ligand binds to its receptor, proteins congregate at the cytoplasmic end of the Fas receptor to form a death-initiating complex. The complex then converts procaspase-8 to caspase-8. Caspase-8, in turn, activates a cascade of caspases that execute the process of apoptosis. The end result includes activation of endonucleases that cause fragmentation of DNA and cell death. In addition to TNF and Fas ligand, primary signaling molecules known to activate the extrinsic pathway include TNF-related apoptosis-inducing ligand (TRAIL), the cytokine interleukin-1 (IL-1); and lipopolysaccharide (LPS), the endotoxin found in the outer cell membrane of gram-negative bacteria.

The intrinsic pathway, or mitochondrion-induced pathway, of apoptosis is activated by conditions such as DNA damage, ROS, hypoxia, decreased ATP levels, cellular senescence, and activation of the p53 protein by DNA damage. The intrinsic pathway is tightly regulated to ensure that cells kill themselves only when appropriate. A major class of intracellular regulators of apoptosis is the Bcl-2 family of proteins. Some of these proteins insert into the mitochondrial membrane opening channels through which proteins escape into the cytoplasm. A crucial protein released from the mitochondria is cytochrome c, a component of the mitochondrial electron transport chain (see Chapter 1). When released into the cytoplasm, cytochrome c binds to a proapoptosis-activating protein that activates caspases, including caspase-3. Caspase-3 activation is a common step to both the extrinsic and intrinsic pathways. Activation of caspase-8 in the extrinsic pathway can also lead to activation of pro-apoptotic proteins, such as Bid and Bax, thereby bridging the two pathways for apoptosis. While some members of the Bcl-2 family are pro-apoptotic, others are anti-apoptotic and inhibit apoptosis by binding to pro-apoptotic proteins, either on the mitochondrial membranes or in the cytoplasm.

Inhibitors of apoptosis are thought to contribute to cancer and autoimmune diseases. The Bcl-2 gene
was first identified in B-cell lymphoma, in which a chromosomal translocation causes excessive production of Bcl-2, giving the gene its name. Excessive levels of Bcl2 in the lymphocytes that carry the translocation promote the development of cancer by inhibiting apoptosis. Similarly, mutation of the genes encoding the tumor-suppressor protein p53 so that it no longer suppresses apoptosis or cell cycle arrest in response to DNA damage is implicated in a number of other cancers (see Chapter 7). The therapeutic actions of certain drugs may induce or facilitate apoptosis. Apoptosis continues to be an active area of investigation to better understand and treat a variety of diseases.

Necrosis

Necrosis refers to cell death in an organ or tissue that is still part of a living person. Necrosis differs from apoptosis in that it involves unregulated enzymatic digestion of cell components, loss of cell membrane integrity with uncontrolled release of the products of cell death into the extracellular space, and initiation of the inflammatory response. In contrast to apoptosis, which functions in removing cells so new cells can replace them, necrosis often interferes with cell replacement and tissue regeneration.

With necrosis, there are marked changes in the appearance of the cytoplasmic contents and the nucleus. These changes often are not visible, even under a microscope, for hours after cell death. The dissolution of the necrotic cell or tissue can follow several paths. Liquefaction necrosis occurs when some of the cells die but their catalytic enzymes are not destroyed. An example of liquefaction necrosis is the softening of the center of an abscess with discharge of its contents. During coagulation necrosis, acidosis develops and denatures the enzymatic and structural proteins of the cell. This type of necrosis is characteristic of hypoxic injury and is seen in infarcted areas. Infarction (i.e., tissue death) occurs when an artery supplying an organ or part of the body becomes occluded and no other source of blood supply exists. As a rule, the shape of the infarction is conical and corresponds to the distribution of the artery and its branches. An artery may be occluded by an embolus, a thrombus, disease of the arterial wall, or pressure from outside the vessel.

Caseous necrosis is a distinctive form of coagulation necrosis in which the dead cells persist indefinitely as soft, cheese-like debris. It is most commonly found in the center of tuberculosis granulomas, or tubercles, and is thought to result from immune mechanisms (see Chapter 22).

The term gangrene is applied when a considerable mass of tissue undergoes necrosis. Gangrene may be classified as dry or moist. In dry gangrene, the part becomes dry and shrinks, the skin wrinkles, and its color changes to dark brown or black. The spread of dry gangrene is slow, and its symptoms are not as marked as those of wet gangrene. The irritation caused by the dead tissue produces a line of inflammatory reaction (i.e., line of demarcation) between the dead tissue of the gangrenous area and the healthy tissue (Fig. 2-10). Dry gangrene usually results from interference with arterial blood supply to a part without interference with venous return and is a form of coagulation necrosis.

In moist or wet gangrene, the area is cold, swollen, and pulseless. The skin is moist, black, and under tension. Blebs form on the surface, liquefaction occurs, and a foul odor is caused by bacterial action. There is no line of demarcation between the normal and diseased tissues, and the spread of tissue damage is rapid. Systemic symptoms are usually severe, and death may occur unless the condition can be arrested. Moist or wet gangrene primarily results from interference with venous return from the part. Bacterial invasion plays an important role in the development of wet gangrene and is responsible for many of its prominent symptoms. Dry gangrene is confined almost exclusively to the extremities, but moist gangrene may affect the internal organs or the extremities. If bacteria invade the necrotic tissue, dry gangrene may be converted to wet gangrene.

Gas gangrene is a special type of gangrene that results from infection of devitalized tissues by one of several Clostridium bacteria, most commonly Clostridium perfringens. These anaerobic and spore-forming organisms are widespread in nature, particularly in soil; gas gangrene is prone to occur in trauma and compound fractures in which dirt and debris are embedded. Some species have been isolated in the stomach, gallbladder, intestine, vagina, and skin of healthy persons. The bacteria produce toxins that dissolve cell membranes, causing death of muscle cells, massive spreading edema, hemolysis of red blood cells, hemolytic anemia, hemoglobinuria, and renal failure. Characteristic of this disorder are the bubbles of hydrogen sulfide gas that form in the muscle. Gas gangrene is a serious and potentially fatal disease. Antibiotics are used to treat the infection and surgical methods are used to remove the infected tissue. Amputation may be required to prevent spreading...
infection involving a limb. Hyperbaric oxygen therapy has been used, but clinical data supporting its efficacy has not been rigorously assessed.

**Cellular Aging**

Aging is a complex natural process in which there are physiologic and structural alterations in almost all organ systems. Even in the absence of disease, beginning in the fourth decade of life, there is a progressive decline in muscle strength, cardiac reserve, vital capacity, nerve conduction time, and glomerular filtration rate. Although the biologic basis of aging is poorly understood, there is general consensus that its elucidation should be sought at the cellular level. Many cell functions decline with age. Oxidative phosphorylation by the mitochondria is reduced, as is synthesis of nucleic acids and transcription factors, cell receptors, and cell proteins.

A number of theories have been proposed to explain the cause of aging. The main theories are based on scientific observations at the molecular, cellular, organ, and system levels. In general, these theories can be divided into either programmed or error theories. The programmed theories propose that the changes that occur with aging are genetically programmed, whereas the damage or error theories maintain that the changes result from an accumulation of random events or environmental agents or influences that are associated with DNA damage. Evidence suggests that the process of aging and longevity is multifaceted, with both genetic and environmental factors playing a role. In animal studies, genetics accounted for less than 35% of the effects of aging, whereas environmental influences accounted for over 65%. In humans, long life appears to have a stronger genetic basis, which explains why centenarians and near centenarians tend to cluster in families.

**Replicative Senescence**

Replicative senescence implies that cells have a limited capacity for replication. At the cellular level, Hayflick and Moorhead observed more than 40 years ago that cultured human fibroblasts have a limited ability to replicate and then die. Before achieving this maximum, they slow their rate of division and manifest identifiable and predictable morphologic changes characteristic of senescent cells.

One explanation of replicative senescence is related to the length of the outermost regions of each chromosome, called telomeres, that contain short repeat sequences of DNA bases. During mitosis, the molecular machinery that replicates DNA cannot copy the extreme ends of the chromosome. Thus, with each cell division, a small segment of telomeric DNA is lost. Over time, it is theorized that as the telomeres become progressively shorter, the DNA at the ends of the chromosomes cannot be protected, resulting in inhibition of cell replication. The lengths of the telomeres are normally maintained by an enzyme called telomerase, which is present in low levels in stem cells, but is usually absent in most adult cells. Therefore, as cells age, their telomeres become shorter and they lose their ability to replicate and replace damaged or senescent cells. Moreover, oxidative stress induces single-stranded damage to telomeric DNA, and this defect cannot be repaired in telomeres. In theory, such mechanisms could also provide a safeguard against uncontrolled cell proliferation of abnormal cells. It has been shown that telomerase is reactivated and telomeres are not shortened in immortal cancer cells, suggesting that telomere elongation may be important in tumor formation.

**Genetic Influences**

There is ongoing interest in genes that determine longevity. Longevity genes have been found in fruit flies and roundworms, organisms that have attracted considerable attention from scientists because of their short life span and their well-characterized genomes. One example is the mutation of the Indy (I’m Not Dead Yet) gene in the fruit fly, which can double the length of its life. Scientists have also found genetic clues to the aging process in the tiny roundworm, Caenorhabditis elegans. By altering one of its daf-2 genes, which codes for a protein that is similar to insulin and insulin growth factor (IGF)-1 receptors found in humans, researchers can substantially extend the longevity of these worms. Pathways related to the daf-2 gene, for example, may be responsible for relationships between caloric restriction and prolonged life span in rodents and other animals. Whether human counterparts of genes found in these laboratory organisms exist and whether they have similar effects remain an ongoing area of inquiry.

However, many genes that are associated with human life span are not intrinsically “longevity genes,” per se. For example, because mutations in the tumor-suppressor genes BRAC1 and BRAC2 increase mortality associated with breast and ovarian cancer, they are rare among long-lived women. Conversely, genes that reduce the risk of atherosclerosis may be more common in long-lived individuals. Genetic studies of biologic aging have also explored the involvement of variants of genes encoding apolipoproteins (proteins that bind lipids for transport in the circulatory system), in particular, the APOE gene encoding the synthesis of apolipoprotein E. The presence of the variant apoE4 is associated with breast and ovarian cancer, they are rare among long-lived women. Conversely, genes that reduce the risk of atherosclerosis may be more common in long-lived individuals. Genetic studies of biologic aging have also explored the involvement of variants of genes encoding apolipoproteins (proteins that bind lipids for transport in the circulatory system), in particular, the APOE gene encoding the synthesis of apolipoprotein E. The presence of the variant apoE4 is associated with breast and ovarian cancer, they are rare among long-lived women. Conversely, genes that reduce the risk of atherosclerosis may be more common in long-lived individuals.

**Accumulation of Environmental and Genetic Damage**

In addition to the importance of timing and a genetic clock, cellular life span may be determined by a balance between cellular damage resulting from metabolic events occurring within the cell and molecular responses that repair the damage. The damage eventually accumulates to a level sufficient to result in the physiologic decline
associated with aging. The most prominent example of the damage theory is the somatic mutation theory of aging, which states that the longevity and function of cells in various tissues of the body are determined by the double-stranded DNA molecule and its specific repair enzymes. Deoxyribonucleic acid undergoes continuous change in response to both exogenous agents and intrinsic processes. It has been suggested that aging results from conditions that produce mutations in DNA or deficits in DNA repair mechanisms.

The oxidative free radical explanation of aging is an error theory in which aging is thought to result partially from oxidative stress and the effects of free radical damage. The major by-products of oxidative metabolism include superoxides that react with DNA, ribonucleic acid, proteins, and lipids, leading to cellular damage and aging. Blood glucose is another suspect in cellular deterioration. In a process called nonenzymatic glycation, glucose molecules attach to proteins, setting in motion a chain of chemical reactions that ends with proteins binding together or cross-linking, thus altering their structure and function. Investigators hypothesize that glycation and oxidation are interdependent, since free radicals and cross-links seem to accelerate the formation of one another. Cross-links, also known as advanced glycation end products (AGES), tend to stiffen tissues and cause some of the deterioration associated with aging. For example, AGES may help trap low-density cholesterol in arterial walls and thus contribute to atherosclerosis. They also have been linked to cataract formation, reduced kidney function, and neurologic disorders such as Alzheimer disease.

** Syndromes of Premature Aging **

The syndromes of premature aging, or progeria, represent a range of phenotypes seen in usual aging, but with much earlier ages of onset and more rapid rates of progression. Hutchinson-Gilford progeria syndrome is a rare fatal genetic disorder characterized by accelerated aging in children. The disorder is caused by a mutation in the LMNA gene, which codes for a precursor of lamin A—a scaffolding protein that lines the nucleus. The mutant gene leads to abnormal nuclear structure and altered gene regulation and DNA replication. Although they are born looking healthy, children with the disorder begin to display many characteristics of accelerated aging at around 18 to 24 months of age. Progeria signs include growth failure, loss of body fat and hair, aged-looking skin, cataracts, and coronary artery disease and stroke (Fig. 2-11). Death occurs at an early age of atherosclerotic heart disease (average age 13 years).

Other progeroid syndromes include Werner syndrome, also known as adult progeria, which does not have an onset until the late teens, with a life span into the 40s and 50s. The gene responsible for the disorder has been localized to chromosome 8 and appears to code for an enzyme involved in unwinding DNA, a process that is necessary for DNA repair and replication.
and free radicals, promotion of cell hypoxia, or impaired regulation of intracellular calcium levels. Free radicals are an important cause of cell injury in hypoxia and after exposure to radiation and certain chemical agents. Lack of oxygen, which underlies the pathogenesis of cell injury in hypoxia and ischemic, can result from inadequate oxygen in the air, cardiopulmonary disease, cardiorespiratory disease, anemia, or the inability of the cells to use oxygen. Increased intracellular calcium activates a number of enzymes with potentially damaging effects.

- Injurious agents may produce sublethal and reversible cellular damage or may lead to irreversible cell injury and death. Cell death can involve two mechanisms: apoptosis or necrosis. Apoptosis involves controlled cell destruction and is the means by which the body removes and replaces cells that have been produced in excess, developed improperly, have genetic damage, or are worn out. Necrosis refers to cell death that is characterized by cell swelling, rupture of the cell membrane, and inflammation.

- A number of body functions decline with age, including muscle strength, cardiac reserve, vital capacity, nerve conduction time, and glomerular filtration rate. At the cellular level, oxidative phosphorylation by the mitochondria is reduced, as is the synthesis of nucleic acids and transcription factors, cell receptors, and structural and enzymatic proteins.

### REVIEW EXERCISES

1. A 30-year-old man sustained a fracture of his leg 2 months ago. The leg has been encased in a cast and he has just had the cast removed. He is amazed at the degree to which the muscles in his leg have shrunk.

   A. Explain.

2. A 45-year-old woman has been receiving radiation therapy for breast cancer.

   A. Explain the effects of ionizing radiation in eradicating the tumor cells.

   B. Why is the radiation treatment given in small divided, or fractionated, doses rather than as a single large dose?

   C. Partway through the treatment schedule, the woman notices that her skin over the irradiated area has become reddened and irritated. What is the reason for this?

3. People who have had a heart attack may experience additional damage once blood flow has been restored, a phenomenon referred to as reperfusion injury.

   A. What is the proposed mechanism underlying reperfusion injury?

   B. What factors might influence this mechanism?

4. Every day blood cells in our body become senescent and die without producing signs of inflammation, yet massive injury or destruction of tissue, such as occurs with a heart attack, produces significant signs of inflammation.

   A. Explain.

### REFERENCES

Inflammation is a complex nonspecific response to tissue injury intended to minimize the effects of injury or infection, remove the damaged tissue, generate new tissue, and facilitate healing. As part of the innate immune system, inflammation dilutes, destroys, and gets rid of damaged or necrotic tissues and foreign agents, such as microbes. Although first described over 2000 years ago, the inflammatory response has been the subject of intense research during the past several decades. As a result, it is now recognized as playing a key role in both the contributing factors and consequences of numerous diseases and altered health states including, but not limited to, atherosclerosis, obesity and diabetes, many types of cancers, stroke, bronchial asthma, rheumatoid arthritis, and certain dementias, including Alzheimer disease.

The discussion in this chapter is divided into four sections: (1) the general features of inflammation, (2) acute inflammation, (3) chronic inflammation, and (4) systemic manifestations of inflammation, including fever. The innate and adaptive immune responses that are closely intertwined with the inflammatory response are discussed in Chapter 15.

**General Features of Inflammation**

Inflammation is the reaction of vascularized tissues to cell injury or death. It is characterized by the production and release of inflammatory mediators and the movement of fluid and leukocytes from the vasculature into the extravascular tissues. Inflammatory conditions are commonly named by adding the suffix -itis to the affected organ or system. For example, *appendicitis* refers to inflammation of the appendix, *pericarditis* to inflammation of the pericardium, and *neuritis* to inflammation of the nerve.
Inflammation can be acute or chronic.\(^1,2\) Acute inflammation is triggered by noxious stimuli, such as infection or tissue injury, is rapid in onset (typically minutes), and is of relatively short duration, lasting from a few minutes to several days. It is characterized by the exudation of fluid and plasma proteins and emigration of leukocytes. Chronic inflammation is of a longer duration, lasting for days to years, and is often associated with the proliferation of blood vessels (angiogenesis), tissue necrosis, and fibrosis (scarring). Acute and chronic inflammation may coexist, with episodes of acute inflammation being superimposed on chronic inflammation.

**Cells of Inflammation**

Many cells and tissue components are involved in the inflammatory process, including the endothelial cells that line blood vessels and form capillaries, circulating platelets and leukocytes, cells in the connective tissue (mast cells, fibroblasts, tissue macrophages), and components of the extracellular matrix (Fig. 3-1).\(^1,3\) The principal leukocytes in acute inflammation are neutrophils, whereas macrophages, lymphocytes, eosinophils, and mast cells predominate in chronic infection.

**Endothelial Cells**

Endothelial cells, which make up the single-cell-thick linings of blood vessels, help to separate the intravascular and extravascular spaces.\(^1,2,5\) They normally have a nonthrombogenic surface and produce agents that maintain vessel patency, as well as vasodilators and vasoconstrictors that regulate blood flow. Endothelial cells are also key players in the inflammatory response. As such, they provide a selective permeability barrier to exogenous (microbial) and endogenous inflammatory stimuli; regulate leukocyte extravasation by expression of adhesion molecules and receptor activation; contribute to the regulation and modulation of immune responses through synthesis and release of inflammatory mediators; and regulate immune cell proliferation through secretion of hematopoietic colony-stimulating factors (CSFs). Endothelial cells also participate in the repair process that accompanies inflammation through the production of growth factors that stimulate angiogenesis and extracellular matrix synthesis.

**Platelets**

Platelets or thrombocytes are small, membrane-bound disks circulating in the blood that play an active role in normal hemostasis (see Chapter 12). Activated platelets also release a number of potent inflammatory mediators, thereby increasing vascular permeability and altering the chemotactic, adhesive, and proteolytic properties of the endothelial cells.\(^6,7\) When a platelet undergoes activation, over 300 proteins are released. While the functions of only a relatively small proportion of these proteins have been fully elucidated, it appears that many help mediate inflammation.\(^6\) The association between the platelet and inflammatory diseases is highlighted by the number of inflammatory disease processes (e.g., atherosclerosis, migraine headaches, systemic lupus erythematosus) shown to be associated with platelet activation.\(^6\)

Leukocytes

Leukocytes or white blood cells are the major cellular components of the inflammatory response. They include the granulocytes (neutrophils, eosinophils, and basophils), which contain specific cytoplasmic granules and a multilobed nucleus, and the agranulocytes (monocytes/macrophages and lymphocytes), which lack cytoplasmic granules and have a single nucleus.

Neutrophils. Neutrophils are the most numerous leukocytes in the circulating blood, accounting for 60% to 70% of all white blood cells. These leukocytes have nuclei that are divided into three to five lobes; therefore, they often are referred to as polymorphonuclear neutrophils (PMNs). Because of their ability to form pseudopods used in ameboid movement, neutrophils are highly mobile, and are the first cells to appear at the site of acute inflammation, usually arriving within 90 minutes of injury (Fig. 3-2A). Neutrophils are scavenger cells capable of engulfing bacteria and other cellular debris through phagocytosis. Their cytoplasmic granules, which resist staining and remain a neutral color, contain enzymes and other antibacterial substances that are used in destroying and degrading engulfed microbes and dead tissue. Neutrophils also have oxygen-dependent metabolic pathways that generate toxic reactive oxygen (e.g., hydrogen peroxide) and nitrogen (e.g., nitric oxide) species that aid in the destruction of engulfed pathogens. Neutrophils have a short life span. They die by apoptosis and disappear within 24 to 48 hours after entering the site of inflammation.

Eosinophils. Eosinophils account for 2% to 3% of circulating leukocytes and are recruited to tissues in a similar way as the neutrophils. Their appearance at the site of inflammation occurs 2 to 3 hours after the neutrophils. This is, in part, because of their slower mobility and comparatively slower reaction to chemotactic stimuli. The granules of eosinophils, which stain pink with the acid dye eosin, contain a protein that is highly toxic to large parasitic worms that cannot be phagocytized. Eosinophils also play an important role in allergic reactions by controlling the release of specific chemical mediators. They interact with basophils and are prominent in allergic reactions such as hay fever and bronchial asthma. Eosinophils have a longer life span than neutrophils and therefore are present in chronic inflammation.

Basophils and Mast Cells. Basophils are granulocytes with granules that stain blue with a basic dye. Although they account for less than 1% of the circulating leukocytes, they are important participants in inflammatory reactions and are most prominent in allergic reactions mediated by immunoglobulin E (IgE). Binding of IgE triggers release of histamine and vasoactive agents from the basophil granules. Mast cells derive from the same hematopoietic stem cells as basophils but do not develop until they leave the circulation and lodge in tissue sites. They are particularly prevalent along mucosal surfaces of the lung, gastrointestinal tract, and dermis of the skin. This distribution places them in a sentinel position between environmental antigens and the host for a variety of acute and chronic inflammatory conditions. Activation of mast cells

**FIGURE 3-2.** Inflammatory cells of acute and chronic inflammation. (A) Acute inflammation with densely packed polymorphonuclear neutrophils with multilobed nucleus (arrows). (B) Chronic inflammation with lymphocytes, plasma cells (arrows), and a few macrophages. (From Murphy HS. Inflammation. In: Rubin R, Strayer DS, eds. Rubin’s Pathology: Clinicopathologic Foundations of Medicine. 5th ed. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins; 2008:39.)
results in release of the preformed contents of their granules (e.g., histamine, proteases, cytokines such as tumor necrosis factor-α [TNF-α] and interleukin-16 [IL-16], growth factors such as vascular endothelial growth factor [VEGF]) and synthesis of lipid mediators derived from cell membrane precursors (arachidonic acid metabolites, such as prostaglandins, and platelet-activating factor). Finally, the release of mast cell contents stimulates cytokine and chemokine synthesis by other inflammatory cells such as monocytes and macrophages.

**Monocyte/Macrophages.** Monocytes constitute 3% to 8% of the white blood cell count. They have a single kidney-shaped nucleus and are the largest of the circulating leukocytes. The half-life of circulating monocytes is about a day, after which they begin to migrate to the site of injury and mature into larger macrophages, which have a longer half-life and greater phagocytic ability than do blood monocytes. Circulating monocytes have been linked to a number of inflammatory disorders, particularly atherosclerosis, in which they are transformed into macrophages that accumulate in atherosclerotic plaques and turn into lipid-laden foam cells (see Chapter 18).

Monocyte/macrophages produce potent vasoactive mediators including prostaglandins and leukotrienes, platelet-activating factor (PAF), inflammatory cytokines, and growth factors that promote regeneration of tissues. As their name implies, macrophages are capable of phagocytosis and are active in bacterial killing. They engulf larger and greater quantities of foreign material than the neutrophils, and their circulating life span is three to four times longer than that of any granulocyte. These longer-lived phagocytes help to destroy the causative agent, aid in the signaling processes of immunity, serve to resolve the inflammatory process, and contribute to initiation of the healing processes. Macrophages are especially important in maintaining chronic inflammation.

**Lymphocytes and Plasma Cells.** Lymphocytes are the smallest of the leukocytes and have a thin rim of cytoplasm surrounded by a deeply staining nucleus (Fig. 3-2B). They participate in immune-mediated inflammation caused by infectious agents as well as non–immune-mediated inflammation associated with cell injury and death. Both T and B lymphocytes (T and B cells) migrate into inflammatory sites using some of the same adhesion molecules and chemokines that recruit neutrophils and other leukocytes (discussed in Chapter 15). Lymphocytes and macrophages communicate in a bidirectional way, and these interactions play an important role in chronic inflammation. Macrophages display antigen to T cells, express membrane molecules called costimulators (meaning that their response requires the action of two signaling molecules), and produce cytokines that stimulate T-cell responses. Activated T cells, in turn, produce cytokines that activate macrophages, increasing antigen presentation and further cytokine production. (Cytokines and other inflammatory mediators are discussed later in this chapter.) The result is a perpetuating cycle of cellular responses that fuel and sustain chronic inflammation.

Plasma cells develop from B lymphocytes that have become activated after encountering an antigen and receiving T cell help. In the inflammatory site, they produce antibodies directed against persistent antigens and altered tissue components. In some intense, chronic inflammatory reactions, plasma cells and other lymphocytes may accumulate to form germinal centers that resemble lymph nodes. This pattern of lymphocyte accumulation, with formation of germinal centers, is often seen in the inflamed synovium of persons with long-standing rheumatoid arthritis.

### Cell Adhesion Molecules

Several families of cell adhesion molecules, including selectins, integrins, and the immunoglobulin superfamily, are involved in leukocyte recruitment and trafficking (see Chapter 1). The selectins are a family of three closely related proteins (E-selectin, L-selectin, P-selectin) that differ in their cellular distribution but all function in adhesion of leukocytes or platelets to endothelial cells. The integrins consist of different types of structurally similar transmembrane receptor proteins that function as heterodimers to promote cell-to-cell and cell–to–extracellular matrix interactions. The name integrin derives from the hypothesis that they integrate the signals of extracellular ligands with cytoskeleton-dependent motility, shape change, and phagocytic responses of immune cells. Cell adhesion molecules of the immunoglobulin superfamily include intercellular adhesion and vascular adhesion molecules, which interact with integrins on leukocytes to mediate their recruitment.

The importance of the leukocyte adhesion molecules is demonstrated in persons with an inherited disorder called leukocyte adhesion deficiency (LAD) type I, in which deficiency of a member of the integrin superfamily leads to severe leukocytosis and recurrent infections. A similar deficiency is seen in individuals with impaired expression of a member of the selectin superfamily and has been labeled LAD type 2. There is also evidence that excessive expression of cell adhesion molecules or their receptors contributes to the pathogenesis of some chronic inflammatory diseases such as rheumatoid arthritis.

**SUMMARY CONCEPTS**

- **Inflammation** is the body’s response to injury and is characterized by the elaboration of chemical mediators and movement of fluid and leukocytes from the vascular compartment into the extravascular tissue space.

- There are two types of inflammation: acute inflammation, which is of short duration and characterized by the exudation of fluid and
plasma proteins, and chronic inflammation, which is associated with angiogenesis, tissue necrosis, and fibrosis (scarring).

Many cells and tissue components contribute to the inflammatory response, including the endothelial cells that form capillaries and line blood vessels, circulating platelets and white blood cells, cells in connective tissue, and components of the extracellular matrix.

**Acute Inflammation**

Acute inflammation is the early or almost immediate reaction of local tissues and their blood vessels to injury. It typically occurs before the adaptive immune response becomes established (see Chapter 15) and is aimed primarily at removing the injurious agent and limiting the extent of tissue damage. Acute inflammation can be triggered by a variety of stimuli, including infections, immune reactions, blunt and penetrating trauma, physical or chemical agents (e.g., burns, frostbite, irradiation, caustic chemicals), and tissue necrosis from any cause.

The classic description of inflammation has been handed down through the ages. In the first century AD, the Roman physician Aulus Celsus described the local reaction of injury in terms that are now known as the cardinal signs of inflammation.¹ These signs are rubor (redness), tumor (swelling), calor (heat), and dolor (pain). In the second century AD, the Greek physician Galen added a fifth cardinal sign, functio laesa (loss of function). In addition to the cardinal signs that appear at the site of injury, systemic manifestations (e.g., fever) may occur as chemical mediators (e.g., cytokines) produced at the site of inflammation lead to increased levels in the plasma. The constellation of systemic manifestations and increases in serum proteins that may occur during acute inflammation is known as the acute-phase response.

**Stages of Acute Inflammation**

Acute inflammation has two stages: vascular and cellular. The vascular stage is characterized by increased blood flow (vasodilation) and structural changes (increased vascular permeability) that allow plasma proteins to leave the circulation. The cellular stage involves the emigration of leukocytes (mainly neutrophils) from the microcirculation and their accumulation at the site of injury or infection.

**Vascular Stage**

The vascular changes that occur with inflammation involve the arterioles, capillaries, and venules of the microcirculation. These changes begin almost immediately after injury and are characterized by vasodilation and changes in blood flow followed by increased vascular permeability and leakage of protein-rich fluid into the extravascular tissue space.²,³

Vasodilation, which is one of the earliest manifestations of inflammation, follows a transient constriction of the arterioles, lasting a few seconds. Dilation begins in the arterioles and opens capillary beds in the area. As a result, the area becomes congested, causing the redness (erythema) and warmth associated with acute inflammation. Vasodilation is induced by the action of several mediators, most notably histamine and nitric oxide.

Vasodilation is quickly followed by increased permeability of the microvasculature, with the outpouring of a protein-rich fluid (exudate) into the extravascular spaces. The loss of fluid results in an increased concentration of blood constituents (red blood cells, leukocytes, platelets, and clotting factors), stagnation of flow, and clotting of blood at the site of injury. This aids in limiting the spread of infectious microorganisms. The loss of plasma proteins reduces the intracapillary osmotic pressure and increases the osmotic pressure of the interstitial fluid, increasing fluid movement from the vascular compartment into the tissue space and producing the swelling, pain, and impaired function that are the cardinal signs of acute inflammation. The exudation of fluid into the tissue spaces also serves to dilute the offending agent.

The increased permeability characteristic of acute inflammation results from formation of endothelial gaps in the venules of the microcirculation. Binding of the chemical mediators to endothelial receptors causes contraction of endothelial cells and separation of intercellular junctions. This is the most common mechanism of vascular leakage and is elicited by histamine, bradykinin, leukotrienes, and many other classes of chemical mediators.

Depending on the severity of injury, the vascular changes that occur with inflammation follow one of three patterns of responses.² The first pattern is an immediate transient response, which occurs with minor injury. It develops rapidly after injury and is usually reversible and of short duration (15 to 30 minutes). The second pattern is an immediate sustained response, which occurs with more serious types of injury and continues for several days. It affects all levels of the microcirculation (arterioles, capillaries, and venules) and is usually due to direct damage of the endothelium by injurious stimuli, such as burns or the products of bacterial infections.² Neutrophils that adhere to the endothelium may also injure endothelial cells. The third pattern is a delayed response, in which the increased permeability begins after a delay of 2 to 12 hours, lasts for several hours or even days, and involves venules as well as capillaries.² A delayed response often accompanies injuries due to radiation, such as sunburn.

**Cellular Stage**

The cellular stage of acute inflammation is marked by changes in the endothelial cells lining the vasculature and movement of phagocytic leukocytes into the area of (text continues on page 56)
Acute inflammation is the immediate and early response to an injurious agent. The response, which serves to control and eliminate altered cells, microorganisms, and antigens, occurs in two phases: (1) the vascular phase, which leads to an increase in blood flow and changes in the small blood vessels of the microcirculation; and (2) the cellular phase, which leads to the migration of leukocytes from the circulation and their activation to eliminate the injurious agent. The primary function of the inflammatory response is to limit the injurious effect of the pathologic agent and remove the injured tissue components, thereby allowing tissue repair to take place.

**Vascular Phase.** The vascular phase of acute inflammation is characterized by changes in the small blood vessels at the site of injury. It begins with momentary vasoconstriction followed rapidly by vasodilation. Vasodilation involves the arterioles and venules with a resultant increase in capillary blood flow causing heat and redness, which are two of the cardinal signs of inflammation. This is accompanied by an increase in vascular permeability with outpouring of protein-rich fluid (exudate) into the extravascular spaces. The loss of proteins reduces the capillary osmotic pressure and increases the interstitial osmotic pressure. This, coupled with an increase in capillary pressure, causes a marked outflow of fluid and its accumulation in the tissue spaces, producing the swelling, pain, and impaired function that represent the other cardinal signs of acute inflammation. As fluid moves out of the vessels, stagnation of flow and clotting of blood occur. This aids in localizing the spread of infectious microorganisms.
Cellular Phase: Leukocyte Margination, Adhesion, and Transmigration. The cellular phase of acute inflammation involves the delivery of leukocytes, mainly neutrophils, to the site of injury so they can perform their normal functions of host defense. The delivery and activation of leukocytes can be divided into the following steps: adhesion and margination, transmigration, and chemotaxis.

The recruitment of leukocytes to the precapillary venules, where they exit the circulation, is facilitated by the slowing of blood flow and margination along the vessel surface. Leukocyte adhesion and transmigration from the vascular space into the extravascular tissue is facilitated by complementary adhesion molecules (e.g., selectins, integrins) on the leukocyte and endothelial surfaces. After extravasation, leukocytes migrate in the tissues toward the site of injury by chemotaxis, or locomotion oriented along a chemical gradient.

Leukocyte Activation and Phagocytosis. Once at the sight of injury, the products generated by tissue injury trigger a number of leukocyte responses, including phagocytosis and cell killing. Opsonization of microbes (1) by complement factor C3b and antibody facilitates recognition by neutrophil C3b and the antibody Fc receptor. Receptor activation (2) triggers intracellular signaling and actin assembly in the neutrophil, leading to formation of pseudopods that enclose the microbe within a phagosome. The phagosome (3) then fuses with an intracellular lysosome to form a phagolysosome into which lysozomal enzymes and oxygen radicals (4) are released to kill and degrade the microbe.
injury or infection. Although attention has been focused on the recruitment of leukocytes from the blood, a rapid response also requires the release of chemical mediators from certain resident cells in the tissues (mast cells and macrophages). The sequence of events in the cellular response to inflammation includes leukocyte (1) margination and adhesion, (2) transmigration, (3) chemotaxis, and (4) activation and phagocytosis.1

During the early stages of the inflammatory response, signaling between blood leukocytes and the endothelial cells defines the inflammatory event and ensures arrest of the leukocytes along the endothelium.2 As a consequence, blood flow—and leukocyte circulation—slows. This process of leukocyte accumulation is called margination. The subsequent release of cell communication molecules called cytokines causes the endothelial cells lining the vessels to express cell adhesion molecules that bind to carbohydrates on the leukocytes. This interaction, which is called tethering, slows their flow and causes the leukocytes to roll along the endothelial cell surface, finally coming to rest and adhering strongly to intercellular adhesion molecules on the endothelium.2 The adhesion is followed by endothelial cell separation, allowing the leukocytes to extend pseudopodia and transmigrate through the vessel wall and then, under the influence of chemotactic factors, migrate into the tissue spaces.

Chemotaxis is a dynamic and energy-directed process of cell migration.1 Once leukocytes exit the capillary, they move through the tissue guided by a gradient of secreted chemooattractants, such as chemokines, bacterial and cellular debris, and fragments generated from activation of the complement system (see Chapter 15). Chemokines, an important subgroup of chemotactic cytokines, are small proteins that direct the trafficking of leukocytes during the early stages of inflammation or injury.13 Several immune (e.g., macrophages) and nonimmune cells secrete these chemooattractants to ensure the directed movement of leukocytes to the site of infection.

During the next and final stage of the cellular response, neutrophils, monocytes, and tissue macrophages are activated to engulf and degrade the bacteria and cellular debris in a process called phagocytosis.1,2,14 Phagocytosis involves three distinct steps: recognition and adherence, engulfment, and intracellular killing. It is initiated by recognition and binding of particles by specific receptors on the surface of phagocytic cells. This binding is essential for trapping the agent, triggering engulfment, and intracellular killing of microbes. Microbes can be bound directly to the membrane of phagocytic cells by several types of pattern recognition receptors (e.g., toll-like and mannose receptors) or indirectly by receptors that recognize microbes coated with carbohydrate-binding lectins, antibody, and/or complement (see innate immunity, Chapter 15). The enhanced binding of an antigen to a coated microbe or particle is called opsonization. Engulfment follows the recognition of an agent as foreign. During the process of engulfment, extensions of cytoplasm move around and eventually enclose the particle in a membrane-surrounded phagocytic vesicle or phagosome. Once in the cell cytoplasm, the phagosome fuses with a cytoplasmic lysosome containing antibacterial molecules and enzymes that can kill and digest the microbe (see Chapter 1).

Intracellular killing of pathogens is accomplished through several mechanisms, including toxic reactive oxygen- and nitrogen-containing species, lysozymes, proteases, and defensins. The metabolic burst pathways that generate toxic reactive oxygen- and nitrogen-containing species (e.g., hydrogen peroxide, nitric oxide) require oxygen and metabolic enzymes such as nicotinamide adenine dinucleotide phosphate (NADPH) oxidase and nitric oxide synthetase. Individuals who are born with genetic defects in some of these enzymes have immunodeficiency conditions that make them susceptible to repeated bacterial infection.

### Inflammatory Mediators

Having described the events of acute inflammation, we can now turn to a discussion of the chemical mediators responsible for the events. Inflammatory mediators may be derived from the plasma or produced locally by cells at the site of inflammation (Fig. 3-3). The plasma-derived mediators, which are synthesized in the liver, include the acute-phase proteins, coagulation (clotting) factors (discussed in Chapter 12), and complement proteins (discussed in Chapter 15). These mediators are present in the plasma in a precursor form that must be activated by a series of proteolytic processes to acquire their biologic properties. Cell-derived mediators are normally sequestered in intracellular granules that need to be secreted (e.g., histamine from mast cells) or newly synthesized (e.g., cytokines) in response to a stimulus. The major sources of these mediators are platelets, neutrophils, monocyte/macrophages, and mast cells, but most endothelial cells, smooth muscle cells, and fibroblasts can be induced to produce some of the mediators.

Mediators can act on one or a few target cells, have diverse targets, or have differing effects on different types of cells. Once activated and released from the cell, most mediators are short-lived. They may be transformed into inactive metabolites, inactivated by enzymes, or otherwise scavenged or degraded.

### Plasma-Derived Mediators

The plasma is the source of inflammatory mediators that are products of three major protein cascades or systems: the kallikrein–kininogen system, which generates kinins; the coagulation system, which includes the important fibrin end product; and the complement system that includes the various complement proteins. Kinins are products of the liver and factors in the coagulation system (see Chapter 12). One kinin, bradykinin, causes increased capillary permeability and pain. The coagulation system also contributes to the vascular phase of inflammation mainly through formation of the fibrin mesh formed during the final steps of the clotting process. The complement system consists of a cascade of plasma proteins that play important roles in both immunity and inflammation. These proteins contribute to the inflammatory response by (1) causing vasodilation and
increasing vascular permeability; (2) promoting leukocyte activation, adhesion, and chemotaxis; and (3) augmenting phagocytosis (see Chapter 15).

**Cell-Derived Mediators**

The cell-derived mediators are released from cells that are present at sites of inflammation. Tissue macrophages, mast cells, endothelial cells, as well as leukocytes that are recruited to the site from the blood are all capable of releasing the different mediators of inflammation, as are platelets, which are cellular fragments (see Fig. 3-3).

**Histamine and Serotonin.** Histamine and serotonin are classified as vasoactive amines, meaning they are derived from amino acids (histamine from histidine and serotonin from tryptamine) and act by producing changes in blood vessel tone. Both histamine and serotonin are stored as preformed molecules in mast cells and other cells and are among the first mediators to be released in acute inflammatory reactions.

Preformed histamine is widely distributed in tissues, the highest concentrations being found in mast cells adjacent to blood vessels. It is also found in circulating platelets and basophils and is released in response to a variety of stimuli, including trauma and immune reactions involving binding of IgE to basophils and mast cells. Histamine produces dilation of arterioles and increases the permeability of venules. It acts at the level of the microcirculation by binding to histamine, (H₁) receptors on endothelial cells and is considered the principal mediator of the immediate transient phase of increased vascular permeability in the acute inflammatory response. Antihistamine drugs (H₁ receptor antagonists), which bind to the H₁ receptors, act to competitively antagonize many of the effects of the immediate inflammatory response. Serotonin (5-hydroxytryptamine) is also a preformed vasoactive mediator, with effects similar to histamine. It is found primarily within platelet granules and is released during platelet aggregation.

**Arachidonic Acid Metabolites.** Arachidonic acid is a 20-carbon unsaturated fatty acid found in the phospholipids of cell membranes. Release of arachidonic acid by phospholipases initiates a series of complex reactions that lead to the production of the eicosanoid family of inflammatory mediators (prostaglandins, leukotrienes, and related metabolites). Eicosanoid synthesis follows one of two pathways: the cyclooxygenase pathway, which culminates in the synthesis of prostaglandins; and the lipoxygenase pathway, which culminates in the synthesis of the leukotrienes (Fig. 3-4). The corticosteroid drugs block the inflammatory effects of both pathways by inhibiting phosphodiesterase activity and thus preventing the release of arachidonic acid.
Several prostaglandins are synthesized from arachidonic acid through the cyclooxygenase metabolic pathway. The prostaglandins (e.g., PGD$_2$, PGE$_2$, PGF$_{2\alpha}$, and PGI$_2$) induce inflammation and potentiate the effects of histamine and other inflammatory mediators. The prostaglandin thromboxane A$_2$ promotes platelet aggregation and vasoconstriction. Aspirin and the nonsteroidal anti-inflammatory drugs (NSAIDs) reduce inflammation by inactivating the first enzyme in the cyclooxygenase pathway for prostaglandin synthesis.

Like the prostaglandins, the leukotrienes are formed from arachidonic acid, but through the lipoxygenase pathway. Histamine and leukotrienes have similar functions; however, histamine is produced rapidly and transiently while the more potent leukotrienes are being synthesized. The leukotrienes also have been reported to affect the permeability of the postcapillary venules, the adhesion properties of endothelial cells, and the extravasation and chemotaxis of neutrophils, eosinophils, and monocytes. Leukotriene (LT) C$_4$, LTD$_4$, and LTE$_4$ are collectively known as the slow-reacting substance of anaphylaxis (SRS-A), cause slow and sustained constriction of the bronchioles and are important inflammatory mediators in bronchial asthma and anaphylaxis.

**Omega-3 Polyunsaturated Fatty Acids.** There has been recent interest in dietary modification of the inflammatory response through the use of omega-3 polyunsaturated fatty acids. These include eicosapentaenoic acid and docosahexaenoic acid, which are present in oily fish and fish oil, but can be derived in limited quantities from $\alpha$-linolenic acid. The $\alpha$-linolenic acid, which is present in flax seed, canola oil, green leafy vegetables, walnuts, and soybeans, is an essential omega-3 fatty acid that cannot be produced in the body and must be obtained through the diet. The omega-3 polyunsaturated fatty acids, which are considered antithrombotic and anti-inflammatory, are structurally different from the prothrombotic and proinflammatory omega-6 polyunsaturated fatty acids, which are present in most seeds, vegetable oils, and meats. Typically, the cell membranes of inflammatory cells contain high proportions of omega-6 arachidonic acid, which is the source of prostaglandin and leukotriene inflammatory mediators. Eating oily fish and other foods that are high in omega-3 fatty acids results in partial replacement of omega-6 arachidonic acid in inflammatory cell membranes by eicosapentaenoic acid, a change that leads to decreased production of arachidonic acid–derived inflammatory mediators. This response alone is a potentially beneficial effect of omega-3 fatty acids. However, omega-3 fatty acids may have a number of other anti-inflammatory effects that occur downstream of altered eicosanoid production or might be independent of this function.

**Platelet-Activating Factor.** Originally named for its ability to cause platelet aggregation and granulation, PAF is another phospholipid-derived mediator with a broad spectrum of inflammatory effects. Platelet-activating factor is generated from the membrane phospholipids of virtually all activated inflammatory cells and affects a variety of cell types. In addition to activating platelets, PAF stimulates neutrophils, monocytes/macrophages, endothelial cells, and vascular smooth muscle. Platelet activating...
factor-induced platelet aggregation and degranulation at the site of injury enhances serotonin release, thereby causing changes in vascular permeability. It also enhances leukocyte adhesion, chemotaxis, and leukocyte degranulation and stimulates the synthesis of other inflammatory mediators, especially the prostaglandins.

**Cytokines and Chemokines.** Cytokines are low-molecular-weight proteins that are important cellular messengers. They modulate the function of cells by paracrine and autocrine mechanisms to cause responses in neighboring cells and the cells that produced the cytokine, respectively. They are produced by many cell types, including activated macrophages and lymphocytes, endothelial cells, epithelial cells, and fibroblasts. Although well known for their role in adaptive immune responses, these proteins also play important roles in both acute and chronic inflammation.

Tumor necrosis factor-α (TNF-α) and interleukin-1 (IL-1) are two of the major cytokines that mediate inflammation. The major cellular source of TNF-α and IL-1 is activated macrophages (Fig. 3-5). Interleukin-1 is also produced by many other cell types, including neutrophils, endothelial cells, and epithelial cells (e.g., keratinocytes). The secretion of TNF-α and IL-1 can be stimulated by bacterial toxins, immune cells, injury, and a variety of inflammatory stimuli. TNF-α and IL-1 induce endothelial cells to express adhesion molecules and release other cytokines, chemokines, and reactive oxygen species. Tumor necrosis factor-α induces priming and aggregation of neutrophils, leading to augmented responses of these cells to other mediators. Interleukin-1 and TNF-α are also mediators of the acute-phase responses associated with infection or injury. Features of these systemic responses include fever, hypotension, and increased heart rate, anorexia, release of neutrophils into the circulation, and increased levels of corticosteroid hormones.

Chemotactic cytokines, or chemokines, are a family of small proteins that act primarily as chemoattractants that both recruit and direct the migration of inflammatory and immune cells (see Chapter 15). Chemokines generate a chemotactic gradient by binding to proteoglycans on the surface of endothelial cells or in the extracellular matrix. As a result, high concentrations of chemokines persist at sites of tissue injury or infection. Two classes of chemokines have been identified: inflammatory chemokines and homing chemokines. Inflammatory chemokines are produced in response to bacterial toxins and inflammatory cytokines (i.e., IL-1, TNF-α). These chemokines recruit leukocytes during an inflammatory response. Homing chemokines are constantly produced, with the genes that control their production being up-regulated during inflammatory reactions.

**Nitric Oxide.** Nitric oxide (NO), which is produced by a variety of cells, plays multiple roles in inflammation, including relaxation of vascular smooth muscle; antagonism of platelet adhesion, aggregation, and degranulation; and as regulator of leukocyte recruitment. Blocking of NO production under normal conditions promotes leukocyte rolling and adhesion to postcapillary venules and delivery of exogenous NO reduces leukocyte recruitment. Thus, production of NO appears to be an endogenous compensatory mechanism that reduces the cellular phase of inflammation. Impaired production of NO by vascular endothelial cells is implicated in the inflammatory changes that occur with atherosclerosis (see Chapter 18). Nitric oxide and its derivatives also have antimicrobial actions, and thus NO is also a host mediator against infection.

**Reactive Oxygen Species.** Reactive oxygen species may be released extracellularly from leukocytes after exposure to microbes, cytokines, and immune complexes, or in the phagocytic process that occurs during the cellular phase of the inflammatory process. The superoxide radical, hydrogen peroxide, and hydroxyl radical (discussed in Chapter 2) are the major species produced within the cell. These species can combine with NO to form other reactive nitrogen intermediates. Extracellular release of low levels of these potent mediators can increase the expression of cytokines and endothelial adhesion molecules, amplifying the cascade that elicits the inflammatory process, and increase cell...
As part of the normal defense reaction, inflammation swells and redness to abscess formation or ulceration. The local manifestations of acute inflammation, which include increased vascular permeability; inactivation of antiproteases, such as α1-antitrypsin, which protect against lung damage in smokers; and produce injury to other cell types, including red blood cells. Thus, the influence of ROS in any inflammatory process depends on a balance between the generation and inactivation of these metabolites.

**Local Manifestations**

The local manifestations of acute inflammation, which are determined by severity of the reaction, its specific cause, and the site of involvement, can range from mild swelling and redness to abscess formation or ulceration. As part of the normal defense reaction, inflammation can also injure adjacent tissues. In some infections, such as tuberculosis and certain viral infections, the host response can cause more damage than the microbe itself. As a normal attempt to clear damaged and dead tissues (e.g., after a myocardial infarction), the inflammatory response may prolong and exacerbate the injurious consequences of the infarction.

Characteristically, the acute inflammatory response involves the production of exudates. These exudates vary in terms of fluid type, plasma protein content, and presence or absence of cells. They can be serous, hemorrhagic, fibrinous, membranous, or purulent. Often the exudate is composed of a combination of these types. Serous exudates are watery fluids low in protein content that result from plasma entering the inflammatory site. Hemorrhagic exudates occur when there is severe tissue injury that causes damage to blood vessels or when there is significant leakage of red cells from the capillaries. Fibrinous exudates contain large amounts of fibrinogen and form a thick and sticky meshwork, much like the fibers of a blood clot. Membranous or pseudo-membranous exudates develop on mucous membrane surfaces and are composed of necrotic cells enmeshed in a fibrinopurulent exudate. A purulent or suppurative exude contains pus, which is composed of degraded white blood cells, proteins, and tissue debris. The term pyogenic refers to “pus forming.” Certain pyogenic microorganisms, such as *Staphylococcus*, are more likely to induce localized suppurative inflammation than others. An abscess is a localized area of inflammation containing a purulent exudate. Abscesses typically have a central necrotic core containing purulent exudates surrounded by a layer of neutrophils. Fibroblasts may eventually enter the area and wall off the abscess. Because antimicrobial agents cannot penetrate the abscess wall, surgical incision and drainage may be required as a cure. An ulceration refers to a site of inflammation where an epithelial surface (e.g., skin or gastrointestinal epithelium) has become necrotic and eroded, often with associated subepithelial inflammation. Ulceration may occur as the result of traumatic injury to the epithelial surface (e.g., peptic ulcer) or because of vascular compromise (e.g., foot ulcers associated with diabetes). In chronic lesions where there is repeated insult, the area surrounding the ulcer develops fibroblastic proliferation, scarring, and accumulation of chronic inflammatory cells.

**Resolution**

Although the manifestations of acute inflammation are largely determined by the nature and intensity of injury, the tissue affected, and the person’s ability to mount a response, the outcome generally results in one of three processes: resolution, progression to chronic inflammation, or substantial scarring and fibrosis. Resolution involves the replacement of any irreversibly injured cells and return of tissues to their normal structure and function. It is seen with short-lived and minimal injuries and involves neutralization or degradation of inflammatory mediators, normalization of vascular permeability, and cessation of leukocyte infiltration. Progression to chronic inflammation may follow acute inflammation if the offending agent is not removed. Depending on the extent of injury, as well as the ability of the affected tissues to regenerate, chronic inflammation may be followed by restoration of normal structure and function. Scarring and fibrosis occurs when there is substantial tissue injury or when inflammation occurs in tissues that do not regenerate.

Although the mechanisms involved in the resolution of acute inflammation have remained somewhat elusive, emerging evidence suggests that an active, coordinated program of resolution begins in the first hours after an inflammatory response begins. Studies suggest that after entering the site of acute inflammation, neutrophils trigger a switch from the previously described proinflammatory eicosanoids (e.g., prostaglandins and leukotrienes) to other anti-inflammatory classes of eicosanoids, also generated from arachidonic acid. These eicosanoids initiate the termination sequence during which neutrophil recruitment ceases and programmed cell death by apoptosis commences. The apoptotic neutrophils then undergo phagocytosis by macrophages, leading to their clearance and release of anti-inflammatory and reparative cytokines. Although much new information regarding the resolution of inflammation has been obtained over the past few years, many issues require further clarification. New therapeutic targets are currently being investigated and potential proresolution properties of existing drugs studied. These discoveries may bring profound advances in therapies aimed at reducing the adverse effects of persistent inflammation.

**SUMMARY CONCEPTS**

- The classic signs of an acute inflammatory response are redness, swelling, local heat, pain, and loss of function. These manifestations can be attributed to the immediate vascular changes that occur (vasodilation and increased capillary...
Chronic Inflammation

In contrast to acute inflammation, which is usually self-limited and of short duration, chronic inflammation is self-perpetuating and may last for weeks, months, or even years. It may develop as a result of a recurrent or progressive acute inflammatory process or from low-grade, smoldering responses that fail to evoke an acute response. Instead of the vascular permeability changes, edema, and predominantly neutrophilic infiltration seen in acute inflammation, chronic inflammation is characterized by infiltration with mononuclear cells (macrophages, lymphocytes, and plasma cells) and attempted connective tissue repair involving angiogenesis and fibrosis. Although it may follow acute inflammation, chronic inflammation often begins insidiously as a low-grade, smoldering, and asymptomatic process. This type of process is the cause of tissue damage in some of the most common disabling diseases such as atherosclerosis, chronic lung disease, rheumatoid arthritis, and inflammatory bowel disease.

There is also evidence that recurrent and persistent inflammation induces, promotes, and/or influences susceptibility to cancer by causing deoxyribonucleic acid (DNA) damage, inciting tissue reparative proliferation, and/or creating an environment that is enriched with cytokines and growth factors that favor tumor development and growth (see Chapter 7). Among the cancers associated with chronic infection and inflammation are cervical cancer (human papillomavirus [HPV]), cancer of the liver (hepatitis B and C), cancer of the stomach (Helicobacter pylori), and cancer of the gallbladder (chronic cholecystitis and cholelithiasis).

Causes of Chronic Inflammation

Agents that evoke chronic inflammation typically are low-grade, persistent infections or irritants that are unable to penetrate deeply or spread rapidly. Among the causes of chronic inflammation are foreign agents such as talc, silica, asbestos, and surgical suture materials. Many viruses provoke chronic inflammatory responses, as do certain bacteria, such as the tubercle bacillus and the actinomycoses, as well as fungi, and larger parasites of moderate to low virulence. The presence of injured tissue such as that surrounding a healing fracture also may incite chronic inflammation. Diseases that cause excessive and inappropriate activation of the immune system are increasingly being recognized as causes of chronic inflammation. Under certain conditions, immune reactions may develop against the person's own tissues, leading to autoimmune disease.

Obesity is a newly suspected cause of chronic inflammation. During the last decade, white adipose tissue was recognized to be an active endocrine organ and a source of a number of proinflammatory mediators. Many of the mediators appear to play an important role in the pathogenesis of obesity-related diseases including accelerated atherosclerosis and diabetes mellitus. The link between obesity and inflammation dates back to the discovery that adipose tissue was a source of the proinflammatory cytokine TNF-α, and that adipose tissue TNF-α concentrations are correlated with insulin resistance both in persons with and without type 2 diabetes mellitus. It was later found that obesity is related not only to increased number and size of adipocytes, but also to infiltration of adipose tissue by macrophages that possess the ability to produce TNF-α, nitric oxide, and other inflammatory mediators. The mechanisms mediating the proinflammatory state associated with obesity are still unclear, but recent studies suggest that circulating free fatty acids may play a role.

Granulomatous Inflammation

A granulomatous lesion is a distinctive form of chronic inflammation. A granuloma typically is a small, 1- to 2-mm lesion in which there is a massing of macrophages surrounded by lymphocytes. The macrophages are modified and, because they resemble epithelial cells, sometimes are called epithelioid cells. Like other macrophages, these epithelioid cells are derived originally from blood monocytes. Granulomatous inflammation is associated with foreign bodies such as splinters, sutures, silica, and asbestos and with microorganisms that cause tuberculosis, syphilis, sarcoidosis, deep fungal
infections, and brucellosis. These types of agents have one thing in common: they are poorly degraded and usually are not easily controlled by other inflammatory mechanisms. The epithelioid cells in granulomatous inflammation may clump in a mass or coalesce, forming a multinucleated giant cell (often referred to as a foreign body giant cell) that attempts to surround the foreign agent (Fig. 3-6). A dense membrane of connective tissue eventually encapsulates the lesion and isolates it.

**SUMMARY CONCEPTS**

- Chronic inflammation involves infiltration with macrophages, lymphocytes, and fibroblasts, leading to persistent inflammation, fibroblast proliferation, and scar formation.
- Among the conditions associated with chronic inflammation and inappropriate activation of the immune system are low-grade inflammation associated with atherosclerosis and type 2 diabetes mellitus; autoimmune disorders; and susceptibility to cancer due to deoxyribonucleic acid damage, increased tissue proliferation, and creation of an environment rich in cytokines and growth factors that favor tumor cell development and growth.
- A granulomatous lesion is a distinctive form of chronic inflammation characterized by aggregates of epithelioid macrophages that “wall off” the causal agent. Granulomatous inflammation is associated with foreign bodies such as splinters, sutures, silica, and asbestos and with microorganisms that cause tuberculosis, syphilis, sarcoidosis, deep fungal infections, and brucellosis.

**Systemic Manifestations of Inflammation**

Under optimal conditions, the inflammatory response remains confined to a localized area. In some cases, however, local injury can result in prominent systemic manifestations as inflammatory mediators are released into the circulation. The most prominent systemic manifestations of inflammation include the acute-phase response, alterations in white blood cell count (leukocytosis or leukopenia), and fever. Localized acute and chronic inflammation may extend to the lymphatic system and lead to a reaction in the lymph nodes that drain the affected area. Painful palpable lymph nodes are more commonly associated with inflammatory processes, whereas nonpainful nodes are more characteristic of neoplasms.

**Acute-Phase Response**

Along with the cellular responses that occur during the inflammatory response, a constellation of systemic effects called the *acute-phase response* occurs. The acute-phase response, which usually begins within hours or days of the onset of inflammation or infection, includes changes in the concentrations of plasma proteins, skeletal muscle catabolism, negative nitrogen balance, elevated erythrocyte sedimentation rate, and increased numbers of leukocytes. Other manifestations of the acute-phase response include fever, increased heart rate, anorexia, somnolence, and malaise.

**Acute-Phase Proteins**

During the acute-phase response, the liver dramatically increases the synthesis of acute-phase proteins such as fibrinogen, C-reactive protein (CRP), and serum amyloid A protein (SAA) that serve several different defense functions. The synthesis of these proteins is stimulated by cytokines, especially TNF-α, IL-1 (for SAA), and IL-6 (for fibrinogen and CRP).

*C-reactive protein* was named because it precipitated with the C fraction (C polypeptide) of pneumococci. The function of CRP is thought to be protective, in that it binds to the surface of invading microorganisms and targets them for destruction by complement and phagocytosis. Although everyone maintains a low level of CRP, this level rises when there is an acute inflammatory response. Recent interest has focused on the use of high-sensitivity CRP (hsCRP) serum measurements as a marker for increased risk of myocardial infarction in persons with coronary heart disease. It is believed that inflammation involving atherosclerotic plaques in coronary arteries may predispose to thrombosis and myocardial infarction (see Chapter 18). During the acute-phase response, SAA protein replaces apolipoprotein A, a component of high-density lipoprotein (HDL) particles (see Chapter 18). This presumably increases the transfer of HDLs from liver cells to macrophages, which can then utilize these particles...
for energy. The rise in fibrinogen causes red blood cells to form stacks (rouleaux) that settle or sediment more rapidly than individual erythrocytes. This is the basis for the accelerated erythrocyte sedimentation rate (ESR) that occurs in disease conditions characterized by the systemic inflammatory response.

**White Blood Cell Response**

Leukocytosis, or the increase in white blood cells, is a frequent sign of an inflammatory response, especially those caused by bacterial infection. In acute inflammatory conditions, the white blood cell count commonly increases from a normal value of 4000 to 10,000 cells/µL to 15,000 to 20,000 cells/µL. After being released from the bone marrow, circulating neutrophils have a life span of only about 10 hours and therefore must be constantly replaced if their numbers are to be adequate. With excessive demand for phagocytes, immature forms of neutrophils (bands) are released from the bone marrow. The phrase “a shift to the left” in a white blood cell differential count refers to the increase in immature neutrophils seen in severe infections.

Bacterial infections produce a relatively selective increase in neutrophils (neutrophilia), while parasitic and allergic responses induce eosinophilia. Viral infections tend to produce a decrease in neutrophils (neutropenia) and an increase in lymphocytes (lymphocytosis). A decrease in white blood cells (leukopenia) may also occur in persons with overwhelming infections or impaired ability to produce white blood cells.

**Systemic Inflammatory Response**

In severe bacterial infections (sepsis), the large quantities of microorganisms in the blood result in an uncontrolled inflammatory response with the production and release of enormous quantities of inflammatory cytokines (most notably IL-1 and TNF-α) and development of what is referred to as the systemic inflammatory response syndrome (see Chapter 20). A decrease in total white blood cells (leukopenia) may occur in persons with overwhelming infections or impaired ability to produce white blood cells.

**Fever**

Fever (pyrexia) is an elevation in body temperature caused by an upward displacement of the set point of the thermoregulatory center in the hypothalamus. It is one of the most prominent manifestations of the acute-phase response.

**Body Temperature Regulation**

The temperature in the deep tissues of the body (core temperature) is normally maintained within a range of 36.0°C to 37.5°C (97.0°F to 99.5°F). Within this range, there are individual differences and diurnal variations; internal core temperatures reach their highest point in late afternoon and evening and their lowest point in the early morning hours (Fig. 3-7). Virtually all biochemical processes in the body are affected by changes in temperature. Metabolic processes speed up or slow down depending on whether body temperature is rising or falling.

Body temperature, which reflects the difference between heat production and heat loss, is regulated by the thermoregulatory center in the hypothalamus. Body heat is generated in the tissues of the body, transferred to the skin surface by the blood, and then released into the environment surrounding the body. The thermoregulatory center regulates the temperature of the deep body tissues, or “core” of the body, rather than the surface temperature. It does so by integrating input from cold and warmth receptors located throughout the body and participating in negative feedback mechanisms.

The *thermostat set point* of the thermoregulatory center is the level at which body temperature is regulated so that core temperature is maintained within the normal range. When body temperature begins to rise above this set point, heat-dissipating behaviors are initiated, and when the temperature falls below the set point, heat production is increased. A core temperature greater than 41°C (105.8°F) or less than 34°C (93.2°F) usually indicates that the body’s thermoregulatory ability is impaired (Fig. 3-8). Body responses that produce, conserve, and dissipate heat are described in Table 3-1. Spinal cord injuries that transect the cord at T6 or above can seriously impair temperature regulation because the hypothalamus no longer can control skin blood flow or sweating.

In addition to physiologic thermoregulatory mechanisms, humans engage in voluntary behaviors to help regulate body temperature. These behaviors include the selection of proper clothing and regulation of environmental temperature through heating systems and air conditioning. Body positions that hold the extremities close to the body (e.g., huddling) prevent heat loss and are commonly assumed in cold weather.

**Mechanisms of Heat Production.** Metabolism is the body’s main source of heat production. The sympathetic neurotransmitters epinephrine and norepinephrine, which are released when an increase in body temperature is needed, act at the cellular level to shift body metabolism to heat production rather than energy generation. This may be one of the reasons fever tends to produce feelings of weakness and fatigue. Thyroid hormone
increases cellular metabolism, but this response usually requires several weeks to reach maximal effectiveness.

Fine involuntary actions such as shivering and chattering of the teeth can produce a threefold to fivefold increase in body temperature. Shivering is initiated by impulses from the hypothalamus. The first muscle change that occurs with shivering is a general increase in muscle tone, followed by an oscillating rhythmic tremor involving the spinal-level reflex that controls muscle tone. Because no external work is performed, all of the energy liberated by the metabolic processes from shivering is in the form of heat. Contraction of the pilomotor muscles of the skin, which raises the skin hair and produces goose bumps, reduces the surface area available for heat loss.

Physical exertion also increases body temperature. With strenuous exercise, more than three fourths of the increased metabolism resulting from muscle activity appears as heat within the body, and the remainder appears as external work.

**Mechanisms of Heat Loss.** Most of the body’s heat is produced by the deeper core tissues (i.e., muscles and viscera) and then transferred in the blood to the body surface, where it is released into the environment.

There are numerous arteriovenous (AV) shunts under the skin surface that allow blood to move directly from the arterial to the venous system. These AV shunts are much like the radiators in a heating system. When the shunts are open, body heat is freely dissipated to the skin and surrounding environment; when the shunts are closed, heat is retained in the body. The blood flow in the AV shunts is controlled almost exclusively by the sympathetic nervous system in response to changes in core temperature and environmental temperature. The transfer of heat to the body’s surface is influenced by blood volume. In hot weather, the body compensates by increasing blood volume as a means of dissipating heat. Exposure to cold produces a cold diuresis and a reduction in blood volume as a means of controlling the transfer of heat to the body’s surface.

Heat is lost from the body through radiation and conduction from the skin surface; through evaporation

**FIGURE 3-8.** Body temperatures under different conditions. (From Dubois EF. Fever and the Regulation of Body Temperature. Springfield, IL: Charles C. Thomas; 1948.)
Chapter 3: Inflammation, the Inflammatory Response, and Fever

Fevers, or pyrexias, can be described as an elevation in body temperature that is caused by cytokine-induced upward displacement of the set point of the hypothalamic thermoregulatory center. It is resolved when the factor that caused the increase in the set point is removed. Fevers that are regulated by the hypothalamus usually do not rise above 41°C (105°F), suggesting a built-in thermostatic regulatory mechanism. Temperatures above that level are usually the result of superimposed activity, such as convulsions, hypermetabolic states, or direct impairment of the temperature control center.

**Causes of Fever.** Fever can be caused by a number of microorganisms and substances that are collectively called pyrogens.33–35 Many proteins, including lipopolysaccharide toxins released from bacterial cell membranes, can raise the set point of the hypothalamic thermostat. Noninfectious disorders, such as myocardial infarction and pulmonary emboli, also produce fever. In these conditions, the injured or abnormal cells incite the production of fever-producing pyrogens. Some malignant cells, such as those of leukemia and Hodgkin disease, also secrete pyrogens.

Some pyrogens act directly and immediately on the hypothalamic thermoregulatory center to increase its set point. Other pyrogens, often referred to as exogenous pyrogens, act indirectly and may require several hours to produce their effect.31 Exogenous pyrogens induce host cells, such as blood leukocytes and tissue macrophages, to produce fever-producing mediators called endogenous pyrogens (e.g., IL-1). For example, the breakdown products of phagocytosed bacteria that are present in the blood lead to the release of endogenous pyrogens. The endogenous pyrogens are thought to increase the set point of the hypothalamic thermoregulatory center through the action of prostaglandin E2 (PGE2) (Fig. 3-9).31 In response to the sudden increase in set point, the hypothalamus initiates heat production behaviors (shivering and vasoconstriction) that increase the core body temperature to the new set point, and fever is established.

A fever that has its origin in the central nervous system is sometimes referred to as a neurogenic fever.36 It usually is the result of damage to the hypothalamus caused by central nervous system trauma, intracerebral bleeding, or an increase in intracranial pressure. Neurogenic fevers are characterized by a high temperature that is resistant to antipyretic therapy and is not associated with sweating.

**Purpose of Fever.** The purpose of fever is not completely understood. However, from a purely practical standpoint, fever signals the presence of an infection and may legitimize the need for medical treatment. In ancient times, fever was thought to “cook” the poisons that caused the illness. With the availability of antipyretic drugs in the late 19th century, the belief that fever was useful began to wane, probably because most antipyretic drugs also had analgesic effects.

**Fever Patterns.** The patterns of temperature change in persons with fever vary and may provide information about the nature of the causative agent.37 These patterns can be described as intermittent, remittent, sustained, or relapsing (Fig. 3-10). An intermittent fever is one in which temperature returns to normal at least once every 24 hours. Intermittent fevers are commonly associated with conditions such as gram-negative/positive sepsis, abscesses, and acute bacterial endocarditis. In a remittent fever, the temperature does not return to normal and varies a few degrees in either direction.
In a sustained or continuous fever, the temperature remains above normal with minimal variations (usually less than 0.55°C or 1°F). Sustained fevers are seen in persons with drug-induced fever in which a drug inadvertently leads to a hypermetabolic fever-inducing state.

A recurrent or relapsing fever is one in which there is one or more episodes of fever, each as long as several days, with one or more days of normal temperature between episodes. Relapsing fevers may be caused by a variety of infectious diseases, including tuberculosis, fungal infections, Lyme disease, and malaria.

Critical to the analysis of a fever pattern is the relation of heart rate to the level of temperature elevation. Most persons respond to an increase in temperature with an appropriate increase in heart rate. The observation that a rise in temperature is not accompanied by the anticipated change in heart rate can provide useful information about the cause of the fever. For example, a heart rate that is slower than would be anticipated can occur with Legionnaires’ disease and drug fever, and a heart rate that is more rapid than anticipated can be symptomatic of hyperthyroidism.
Manifestations of Fever

The physiologic behaviors that occur during the development of fever can be divided into four successive stages: a prodrome; a chill, during which the temperature rises; a flush; and defervescence (see Fig. 3-9). During the first or prodromal period, there are nonspecific complaints, such as mild headache and fatigue, general malaise, and fleeting aches and pains. During the second stage or chill, there is the uncomfortable sensation of being cold and the onset of generalized shaking, although the temperature is rising. Vasodistraction and piloerection usually precede the onset of shivering. At this point the skin is pale and covered with goose flesh. There is an urge to put on more clothing or covering and to curl up in a position that conserves body heat. When the shivering has caused the body temperature to reach the new set point of the temperature control center, the shivering ceases, and a sensation of warmth develops. At this point, the third stage or flush begins, during which cutaneous vasodilatation occurs and the skin becomes warm and reddened. The fourth, or defervescence, stage of the febrile response is marked by the initiation of sweating. Not all persons proceed through all four stages of fever development. Sweating may be absent, and fever may develop gradually, with no indication of a chill or shivering.

Common manifestations of fever are anorexia, myalgia, arthralgia, and fatigue. These discomforts are worse when the temperature rises rapidly or exceeds 39.5°C (103.1°F). Respiration is increased, and the heart rate usually is elevated. Dehydration occurs because of sweating and the increased vapor losses caused by the rapid respiratory rate. The occurrence of chills commonly coincides with the introduction of pyrogen into the circulation. This is one of the reasons that blood cultures to identify the organism causing the fever are usually drawn during the first signs of a chill.

Many of the manifestations of fever are related to the increases in the metabolic rate, increased need for oxygen, and use of body proteins as an energy source. During fever, the body switches from using glucose (an excellent medium for bacterial growth) to metabolism based on protein and fat breakdown. With prolonged fever, there is increased breakdown of endogenous fat stores. If fat breakdown is rapid, metabolic acidosis may result (see Chapter 8).

Headache is a common accompaniment of fever and is thought to result from the vasodilatation of cerebral vessels occurring with fever. Delirium is possible when the temperature exceeds 40°C (104°F). In the elderly, confusion and delirium may follow moderate elevations in temperature. Because of the increasingly poor oxygen uptake by the aging lung, pulmonary function may prove to be a limiting factor in the hypermetabolism that accompanies fever in older persons. Confusion, incoordination, and agitation commonly reflect cerebral hypoxemia. Febrile seizures can occur in some children. They usually occur with rapidly rising temperatures and/or at a threshold temperature that differs with each child.

Herpetic lesions, or fever blisters, develop in some persons during fever. They are caused by a separate infection by the type 1 herpes simplex virus that established latency in the regional ganglia and is reactivated by a rise in body temperature.

Management of Fever

Fever usually is a manifestation of a disease state, and as such, determining the cause of a fever is an important aspect of its treatment. Sometimes it is difficult to establish the cause. A prolonged fever for which the cause is difficult to ascertain is often referred to as fever of unknown origin (FUO). Fever of unknown origin is defined as a temperature of 38.3°C (101°F) or higher that is present for 3 weeks or longer.40,41 Among the causes of FUO are malignancies (i.e., lymphomas, metastases to the liver or central nervous system); infections such as human immunodeficiency virus or tuberculosis, or abscessed infections; and drug fever. Malignancies, particularly non-Hodgkin lymphoma, are important causes of FUO in the elderly. Cirrhosis of the liver is another cause of FUO.

The methods of fever treatment focus on modifications of the external environment intended to increase heat transfer from the internal to the external environment, support of the hypermetabolic state that accompanies fever, protection of vulnerable body organs and systems, and treatment of the infection or condition causing the fever. Because fever is a disease symptom, its manifestation suggests the need for treatment of the primary cause.

Modification of the environment ensures that the environmental temperature facilitates heat transfer away from the body. Sponge baths with cool water or an alcohol solution can be used to increase evaporative heat losses. More profound cooling can be accomplished through the use of a cooling blanket or mattress, which facilitates the conduction of heat from the body into the coolant solution that circulates through the mattress. Care must be taken so that cooling methods do not produce vasoconstriction and shivering that decrease heat loss and increase heat production.

Adequate fluids and sufficient amounts of simple carbohydrates are needed to support the hypermetabolic state and prevent the tissue breakdown that is characteristic of fever. Additional fluids are needed for sweating and to balance the insensible water losses from the lungs that accompany an increase in respiratory rate. Fluids also are needed to maintain an adequate vascular volume for heat transport to the skin surface.

Antipyretic drugs, such as aspirin, ibuprofen, and acetaminophen, often are used to alleviate the discomforts of fever and protect vulnerable organs, such as the brain, from extreme elevations in body temperature. These drugs act by resetting the hypothalamic temperature control center to a lower level, presumably by blocking the activity of cyclooxygenase, an enzyme that is required for the conversion of arachidonic acid to prostaglandin E2.
**Fever in Children**

Fever occurs frequently in infants and young children (i.e., ages 1 day to 3 years) and is a common reason for visits to the clinic or emergency department. The differential diagnosis of fever is broad and includes both infectious and noninfectious causes, with the majority of febrile children having an underlying infection. The most common causes are minor or more serious infections of the respiratory system, gastrointestinal tract, urinary tract, or central nervous system. The epidemiology of serious bacterial disease has changed dramatically with the introduction of the Haemophilus influenzae and Streptococcus pneumoniae vaccines in developed countries. H. influenzae type b has been nearly eliminated and the incidence of pneumococcal disease has declined substantially. Febrile children who are younger than 1 year of age and females between 1 and 2 years of age should be considered at risk for a urinary tract infection (see Chapter 24).

While most children have identifiable causes for their fevers, many have fevers without localizing signs or symptoms. These fevers, which are usually of rapid onset and present for less than a week, are commonly referred to as fever without source. The American College of Emergency Physicians has developed clinical guidelines for use in the treatment of previously healthy infants and children ages 1 day to 3 years with fever without a source. The guidelines define fever in this age group as a rectal temperature of at least 38°C (100.4°F). The reliability of other methods of temperature measurements (e.g., axillary, ear) is lower and must be considered when making decisions about the seriousness of the fever.

The approach to the young child who has fever without a source varies depending on the age of the child (neonate [0 to 28 days], young infant [1 to 3 months], and older infants and toddlers [3 to 36 months]). All have decreased immunologic function and are more commonly infected with virulent organisms. Neonates are at particularly high risk for serious bacterial infections that can cause bacteremia or meningoitis. Also, neonates and young infants demonstrate limited signs of infection, often making it difficult to distinguish between serious bacterial infections that require immediate medical attention and other causes of an elevated temperature.

Fever without source in children younger than age 3 months requires careful history and physical examination. The temperature-lowering response to antipyretic medications does not change the likelihood of a child having a serious bacterial infection and should not be used as an indicator of infection severity. Neonates with signs of toxicity (and high risk) including lethargy, poor feeding, hypoventilation, poor tissue oxygenation, and cyanosis usually require hospitalization and treatment with antibiotics. Diagnostic tests such as white blood cell count, blood and urine cultures, chest radiographs, and lumbar puncture usually are done to determine the cause of fever. Infants with fever who are considered to be at low risk for bacterial infections often are managed on an outpatient basis provided the parents or caregivers are deemed reliable. Older children with fever without source also may be treated on an outpatient basis.

**Fever in the Elderly**

In the elderly, even slight elevations in temperature may indicate serious infection, most often caused by bacteria, or disease. This is because the elderly often have a lower baseline temperature (36.4°C [97.6°F] in one study) than younger persons, and although their temperature increases during an infection, it may fail to reach a level that is equated with significant fever. Therefore, it has been recommended that the definition of fever in the elderly be expanded to include an elevation of temperature of at least 1.1°C (2°F) above baseline values.

The absence of fever may delay diagnosis and initiation of antimicrobial treatment. Unexplained changes in functional capacity, worsening of mental status, weakness and fatigue, and weight loss are signs of infection in the elderly and should be viewed as possible signs of infection and sepsis when fever is absent. A thorough history and physical examination are critically important. The probable mechanisms for the blunted fever response include a disturbance in sensing of temperature by the thermoregulatory center in the hypothalamic system, alterations in release of endogenous pyrogens, and the failure to elicit responses such as vasoconstriction of skin vessels, increased heat production, and shivering that increase body temperature during a febrile response.

Another factor that may delay recognition of fever in the elderly is the method of temperature measurement. Oral temperature remains the most commonly used method, but research suggests that rectal and tympanic membrane methods are more effective in detecting fever in the elderly. This is because conditions such as mouth breathing, tongue tremors, and agitation often make it difficult to obtain accurate oral temperatures in the elderly.

**SUMMARY CONCEPTS**

- The systemic manifestations of inflammation include the effects of the acute-phase response, such as fever and lethargy; increased erythrocyte sedimentation rate (ESR), levels of C-reactive protein (CRP), other acute-phase proteins, and white blood cells; and enlargement of the lymph nodes that drain the affected area. In severe bacterial infections (sepsis), large quantities of microorganisms in the blood result in the production and release of enormous quantities of inflammatory cytokines and development of what is referred to as the systemic inflammatory response syndrome.
Fever, an elevation in body temperature, is one of the most prominent manifestations of the acute-phase response, especially if inflammation is caused by infection. It is produced in response to pyrogens that act by prompting the release of prostaglandin E₂ or fever-producing cytokines, which in turn resets the hypothalamic thermoregulatory center.

The reactions that occur during fever consist of four stages: a prodromal period with nonspecific complaints, such as mild headache and fatigue; a chill, during which the temperature rises; a flush, during which the skin becomes warm and flushed; and a defervescent stage, which is marked by the initiation of sweating.

The approach to fever in children varies depending on the age of the child. Infants and young children have decreased immunologic function and are more commonly infected with virulent organisms.

The elderly tend to have a lower baseline temperature, so that serious infections may go unrecognized because of the perceived lack of a significant fever.

**REVIEW EXERCISES**

1. A 15-year-old boy presents with abdominal pain, a temperature of 38°C (100.5°F), and an elevated white blood cell count of 13,000/µL, with an increase in neutrophils. A tentative diagnosis of appendicitis is made.
   - A. Explain the significance of pain as it relates to the inflammatory response.
   - B. What is the cause of the fever and elevated white blood cell count?
   - C. What would be the preferred treatment for this boy?

2. Aspirin and other nonsteroidal anti-inflammatory drugs are often used to control the manifestations of chronic inflammatory disorders such as arthritis.
   - A. Explain their mechanism of action in terms of controlling the inflammatory response.

3. Persons with long-standing ulcerative colitis, an inflammatory bowel disease, have a higher risk of colorectal cancer than the general population.
   - A. Hypothesize on cancer-producing mechanisms of this chronic inflammatory disease.

4. A 3-year-old child is seen in a pediatric clinic with a temperature of 39°C (103°F). Her skin is warm and flushed, her pulse is 120 beats per minute, and her respirations are shallow and rapid at 32 breaths per minute. Her mother states that she has complained of a sore throat and has refused to drink or take medications to bring her fever down.
   - A. Explain the physiologic mechanisms of fever generation.
   - B. Are the warm and flushed skin, rapid heart rate, and respirations consistent with this level of fever?
   - C. After receiving an appropriate dose of acetaminophen, the child begins to sweat, and the temperature drops to 37.2°C. Explain the physiologic mechanisms responsible for the drop in temperature.

**REFERENCES**

issue repair, which overlaps the inflammatory process that was discussed in Chapter 3, refers to the restoration of tissue structure and function after an injury. Tissue repair can take the form of regeneration, in which injured cells are replaced with cells of the same type, sometimes leaving no residual trace of previous injury; or it can take the form of replacement by connective (fibrous) tissue, which leads to scar formation or fibrosis in organs such as the liver or lung. For many types of common injuries, both regeneration and connective tissue replacement contribute to tissue repair. This chapter is divided into two parts. The first part discusses cell proliferation and regeneration, the cell cycle, the role of stem cells, growth factors, and the extracellular matrix in tissue renewal. The second focuses on connective tissue repair, cutaneous wound healing, factors that affect wound healing, and the effect of aging on wound healing.

Cell Proliferation and Tissue Regeneration

Tissue repair involves the proliferation of various cells, and close interactions between cells and the extracellular matrix (ECM). Body organs and tissues are composed of two types of tissues: parenchymal and stromal. The parenchymal tissues consist of the functioning cells of an organ or body part: whereas, the stromal tissues contain the supporting connective tissues, blood vessels, fibroblasts, nerve fibers, and extracellular matrix.

Cell Proliferation Versus Differentiation

Cell proliferation refers to the process of increasing cell numbers by mitotic division. Cell differentiation is the process whereby a cell becomes more specialized in

terms of structure and function. Stem cells are undifferentiated cells that have the capacity to generate multiple cell types (to be discussed). In normal tissue the size of the cell population is determined by a balance of cell proliferation, death by apoptosis (see Chapter 2), and emergence of newly differentiated cells from stem cells (Fig. 4-1). Several cell types proliferate during tissue repair including remnants of injured parenchymal tissue cells, vascular endothelial cells, and fibroblasts. The proliferation of these cell types is driven by proteins called growth factors. The production of growth factors and the ability of these cells to respond and expand in sufficient numbers are important determinants of the repair process.

All of the different cell types in the body originate from a single cell—the fertilized ovum. As the embryonic cells increase in number, they differentiate, facilitating the development of all the different cells and organs of the body. The process of differentiation is regulated by a combination of internal processes involving the expression of specific genes and external stimuli provided by neighboring cells, the ECM, and a variety of growth factors. The process occurs in orderly steps, with each progressive step being exchanged for a loss of ability to develop different cell characteristics. As a cell becomes more highly specialized, the stimuli that are able to induce mitosis become more limited. Neurons, which are highly specialized cells, lose their ability to proliferate once development of the nervous system is complete. In other, less-specialized tissues, such as the skin and mucosal lining of the gastrointestinal tract, a high degree of cell renewal continues throughout life. Even in these continuously renewing cell populations, the more specialized cells are unable to divide. Many of these cell populations rely on progenitor or parent cells of the same lineage. Progenitor cells are sufficiently differentiated so that their daughter cells are limited to the same cell line, but they have not reached the point of differentiation that precludes the potential for active proliferation. Some cell populations have self-renewing multipotent stem cells, such as the epithelial stem cells, that can differentiate into the different cell types throughout life.

The Cell Cycle

In order to understand cell proliferation, whether physiologic (as in tissue regeneration and repair) or pathologic (as in cancer), it is important to learn about the cell cycle, an orderly sequence of events in which a cell duplicates its genetic contents and divides. During the cell cycle, the duplicated chromosomes are appropriately aligned for distribution between two genetically identical daughter cells.

The cell cycle is divided into four distinct phases referred to as G1, S, G2, and M. Gap 1 (G1) is the postmitotic phase during which deoxyribonucleic acid (DNA) synthesis ceases while ribonucleic acid (RNA) and protein synthesis and cell growth take place (see Understanding the Cell Cycle). During the S phase, DNA synthesis occurs, giving rise to two separate sets of chromosomes, one for each daughter cell. G2 is the premitotic phase and is similar to G1 in that DNA synthesis ceases while RNA and protein synthesis continue. Collectively, G1, S, and G2 are referred to as interphase. The M phase is the phase of nuclear division and cytokinesis. Continually dividing cells, such as the stratified squamous epithelium of the skin, continue to cycle from one mitotic division to the next. When environmental conditions are adverse, such as nutrient or growth factor unavailability, or cells become terminally differentiated (i.e., highly specialized), cells may exit the cell cycle, becoming mitotically quiescent and reside in a special resting state known as G0. Cells in G0 may reenter the cell cycle in response to extracellular nutrients, growth factors, hormones, and other signals such as blood loss or tissue injury that trigger cell renewal. Highly specialized and terminally differentiated cells, such as neurons, may permanently stay in G0.

Within the cell cycle are checkpoints where pauses or arrests can be made if the specific events in the phases of the cell cycle have not been completed. There are also opportunities for ensuring the accuracy of DNA replication. These DNA damage checkpoints allow for any defects to be edited and repaired, thereby ensuring that each daughter cell receives a full complement of genetic information, identical to that of the parent cell.

The cyclins are a family of proteins that control the entry and progression of cells through the cell cycle. Cyclins bind to (thereby activating) proteins called cyclin-dependent kinases (CDKs). Kinases are enzymes that phosphorylate proteins. The CDKs phosphorylate specific target proteins and are expressed continuously during the cell cycle but in an inactive form, whereas the cyclins are synthesized during specific phases of the cell cycle and then degraded once their task is completed. Different arrangements of cyclins and CDKs are associated with each stage of the cell cycle. For example, cyclin B and CDK1 control the transition from G2 to M. As the cell moves into G2, cyclin B is synthesized and binds to CDK1. The cyclin B–CDK1 complex then directs the
events leading to mitosis, including DNA replication and assembly of the mitotic spindle. Although each phase of the cell cycle is monitored carefully, the transition from $G_2$ to $M$ is believed to be one of the most important checkpoints in the cell cycle. In addition to the synthesis and degradation of the cyclins, the cyclin–CDK complexes are regulated by the binding of CDK inhibitors. The CDK inhibitors are particularly important in regulating cell cycle checkpoints during which mistakes in DNA replication are repaired. The finding that the cell cycle can be reactivated by removing CDK inhibitors in quiescent and nonproliferating cells has potential implications for tissue repair and cell replacement therapy.4

**Proliferative Capacity of Tissues**

The capacity for regeneration varies with the tissue and cell type. Body tissues are divided into three types depending on the ability of their cells to undergo regeneration: (1) continuously dividing, (2) stable, and (3) permanent tissues.1,2

*Continuously dividing or labile* tissues are those in which the cells continue to divide and replicate throughout life, replacing cells that are continually being destroyed. They include the surface epithelial cells of the skin, oral cavity, vagina, and cervix; the columnar epithelium of the gastrointestinal tract, uterus, and fallopian tubes; the transitional epithelium of the urinary tract; and bone marrow cells. These tissues can readily regenerate after injury as long as a pool of stem cells is preserved. Bleeding, for example, stimulates the rapid proliferation of replacement cells by the blood-forming progenitor cells of the bone marrow.

*Stable* tissues contain cells that normally stop dividing when growth ceases. Cells in these tissues remain quiescent in the $G_0$ stage of the cell cycle. However, these cells are capable of undergoing regeneration when confronted with an appropriate stimulus; thus, they are capable of reconstituting the tissue of origin. Stable cells constitute the parenchyma of solid organs such as the liver and kidney. They also include smooth muscle cells, vascular endothelial cells, and fibroblasts, the proliferation of which is particularly important to wound healing.

The cells in *permanent* tissues do not proliferate. The cells in these tissues are considered to be terminally differentiated and do not undergo mitotic division in postnatal life. The permanent cells include nerve cells, skeletal muscle cells, and cardiac muscle cells. These cells do not normally regenerate; once destroyed, they are replaced with *fibrous* scar tissue that lacks the functional characteristics of the destroyed tissue.

**S** **t** **e** **m** **C** **e** **l** **l** **s**

Another type of tissue cell, called a *stem cell*, remains incompletely differentiated throughout life.1,2,5 In most continuously dividing tissues, the mature cells are terminally differentiated and short lived. As mature cells die the tissue is replenished by the differentiation of cells generated from stem cells. Stem cells are reserve cells that remain quiescent until there is a need for cell replenishment, in which case they divide, producing other stem cells and cells that can carry out the functions of the differentiated cell. When a stem cell divides, one daughter cell retains the stem cell characteristics, and the other daughter cell becomes a progenitor cell that undergoes a more differentiated state, until they reach the stage where they are fully differentiated.

**FIGURE 4-2.** Mechanisms of stem cell-mediated cell replacement. Division of a stem cell with an unlimited potential for proliferation results in one daughter cell, which retains the characteristics of a stem cell, and a second daughter cell that differentiates into a progenitor or parent cell, with limited potential for differentiation and proliferation. As the daughter cells of the progenitor cell differentiate they become more differentiated, until they reach the stage where they are fully differentiated.
A cell reproduces by performing an orderly sequence of events called the cell cycle. The cell cycle is divided into four phases of unequal duration that include the (1) synthesis (S) and mitosis (M) phases that are separated by (2) two gaps (G₁ and G₂). There is also (3) a dormant phase (G₀) during which the cell may leave the cell cycle. Movement through each of these phases is mediated at (4) specific checkpoints that are controlled by specific enzymes and proteins called cyclins.

1. **Synthesis and Mitosis.** Synthesis (S) and mitosis (M) represent the two major phases of the cell cycle. The S phase, which takes about 10 to 12 hours, is the period of DNA synthesis and replication of the chromosomes. The M phase, which usually takes less than an hour, involves formation of the mitotic spindle and cell division with formation of two daughter cells.

2. **Gaps 1 and 2.** Because most cells require time to grow and double their mass of proteins and organelles, extra gaps (G) are inserted into the cell cycle. G₁ is the stage during which the cell is starting to prepare for DNA replication and mitosis through protein synthesis and an increase in organelle and cytoskeletal elements. G₂ is the premitotic phase. During this phase, enzymes and other proteins needed for cell division are synthesized and moved to their proper sites.
Gap 0. G₀ is the stage after mitosis during which a cell may leave the cell cycle and either remain in a state of inactivity or reenter the cell cycle at another time. Labile cells, such as blood cells and those that line the gastrointestinal tract, do not enter G₀ but continue cycling. Stable cells, such as hepatocytes, enter G₀ after mitosis but can reenter the cell cycle when stimulated by the loss of other cells. Permanent cells, such as neurons that become terminally differentiated after mitosis, leave the cell cycle and are no longer capable of cell renewal.

Checkpoints and Cyclins. In most cells there are several checkpoints in the cell cycle, at which time the cycle can be arrested if previous events have not been completed. For example, the G₁/S checkpoint monitors whether the DNA in the chromosomes is damaged by radiation or chemicals, and the G₂/M checkpoint prevents entry into mitosis if DNA replication is not complete.

The cyclins are a family of proteins that control entry and progression of cells through the cell cycle. They function by activating proteins called cyclin-dependent kinases (CDKs). Different combinations of cyclins and CDKs are associated with each stage of the cell cycle. In addition to the synthesis and degradation of the cyclins, the cyclin–CDK complexes are regulated by the binding of CDK inhibitors. The CDK inhibitors are particularly important in regulating cell cycle checkpoints during which mistakes in DNA replication are repaired.
In recent years, it has become useful to categorize stem cells into two basic categories: embryonic and adult stem cells. Embryonic stem cells are pluripotent cells derived from the inner cell mass of the blastocyst stage of the embryo. These pluripotent stem cells have the capacity to generate multiple cell lines. As mentioned earlier, unipotential stem cells are normally present in proliferative tissues and generate cell lineages specific to that tissue. It is now recognized, however, that stem cells with the capacity to generate multiple lineages are present in the bone marrow and several other tissues of adult individuals. These cells are called adult stem cells or tissue stem cells. Whether adult stem cells have a differentiation capacity similar to that of embryonic stem cells remains the subject of current debate and research. Thus far, bone marrow stem cells have been shown to have very broad differentiation capabilities, being able to generate not only blood cells, but also fat, cartilage, bone, endothelial, and muscle cells.

A new field of medicine—regenerative medicine—is mainly concerned with the regeneration and restoration of damaged organs using embryonic and adult stem cells. One of the most exciting prospects in this area is a type of stem cell therapy known as therapeutic clonning. Other potential therapeutic strategies that use stem cells involve the transplantation of stem cells into areas of injury, mobilization of stem cells from the bone marrow into injured tissues, and use of stem cell culture systems to produce large amounts of differentiated stem cells for transplantation into injured tissue.

**Influence of Growth Factors**

Cell proliferation can be triggered by chemical mediators including growth factors, hormones, and cytokines. The term *growth factor* is generally applied to small proteins that increase cell size and cell division. In addition to cell proliferation, most growth factors have other effects. They assist in regulating the inflammatory process; serve as chemoattractants for neutrophils, monocytes (macrophages), fibroblasts, keratinocytes, and epithelial cells; stimulate angiogenesis; and contribute to the generation of the ECM. Some growth factors stimulate the proliferation of some cells and inhibit the cycling of other cells. In fact, a growth factor can have opposite effects on the same cell depending on its changing concentration during the healing process.

Many of the growth factors are produced by leukocytes recruited to the site of injury or activated at the site by the inflammatory process. Other growth factors are produced by parenchymal cells or stromal cells in response to injury or loss. Growth factors are named for their tissue of origin (e.g., platelet-derived growth factor [PDGF], fibroblast growth factor [FGF]), their biologic activity (e.g., transforming growth factor [TGF]), or the cells on which they act (e.g., vascular endothelial growth factor [VEGF]). The sources and functions of selected growth factors are described in Table 4-1.

The signaling pathways for the growth factors are similar to those of other cellular receptors that recognize extracellular ligands. The binding of a growth factor to its receptor triggers a series of events by which extracellular signals are transmitted into the cell, leading to the stimulation or inhibition of gene expression. These genes typically have several functions—they relieve blocks on cell cycle progression (thus promoting cell proliferation), prevent apoptosis, and enhance synthesis of cellular proteins in preparation for mitosis. Signaling may occur in the cell producing the growth factor (autocrine signaling), in cells in the immediate vicinity of the cell releasing the growth factor (paracrine signaling), or in distant target cells through growth factors that are released into the bloodstream (endocrine signaling).

There is continued interest in developing growth factors as a means of increasing cell proliferation and enhancing wound healing as well as developing strategies to block growth factor signaling pathways that could be used to inhibit malignant cell proliferation in cancer.

**Extracellular Matrix and Cell–Matrix Interactions**

The understanding of tissue regeneration and repair has expanded over the past several decades to encompass the complex environment of the ECM. There are two basic forms of ECM: (1) the basement membrane, which surrounds epithelial, endothelial, and smooth muscle cells; and (2) the interstitial matrix, which is present in the spaces between cells in connective tissue and between the epithelium and supporting cells of blood vessels.

The ECM is secreted locally and assembles into a network of spaces surrounding tissue cells (see Chapter 1). There are three basic components of the ECM: fibrous structural proteins (e.g., collagen and elastin fibers), water-hydrated gels (e.g., proteoglycans and hyaluronic acid) that permit resilience and lubrication, and adhesive glycoproteins (e.g., fibronectin, laminin) that connect the matrix elements to one another and to cells (Fig. 4-3). Integrins are a family of transmembrane glycoproteins that are the main cellular receptors for ECM components such as fibronectin and laminin. They bind to many ECM components, initiating signaling cascades that affect cell proliferation and differentiation. Fibroblasts, which reside in close proximity to collagen fibers, are responsible for the synthesis of collagen, elastic, and reticular fibers, and complex carbohydrates in the ground substance.

The ECM provides turgor to soft tissue and rigidity to bone; it supplies the substratum for cell adhesion; it is involved in the regulation of growth, movement, and differentiation of the cells surrounding it; and it provides for the storage and presentation of regulatory molecules that control the repair process. The ECM also provides the scaffolding for tissue renewal. Although the cells in many tissues are capable of regeneration, injury does not always result in restoration of normal structure unless the ECM is intact. The integrity of the underlying basement membrane, in particular, is critical to the regeneration of tissue. When the basement membrane is disrupted, cells proliferate in a haphazard way, resulting in disorganized and nonfunctional tissues.

Critical to the process of wound healing are transitions in the composition of the ECM. In the transitional process, the ECM components are degraded by proteases (enzymes) that are secreted locally by a variety of cells (fibroblasts, macrophages, neutrophils, synovial cells, and epithelial cells). Some of the proteases, such as the collag enases, are highly specific, cleaving particular proteins at a small number of sites. This allows for the structural integrity of the ECM to be retained while healing occurs. Because of their potential to produce havoc in tissues, the actions of the proteases are tightly controlled. They are typically produced in an inactive form that must be activated by certain chemicals likely to be present at the site of injury, and they are rapidly inactivated by tissue inhibitors. Recent research has focused on the unregulated action of the proteases in disorders such as cartilage matrix breakdown in arthritis and neuroinflammation in multiple sclerosis.

**SUMMARY CONCEPTS**

- The process of tissue growth and repair involves proliferation of functioning parenchymal cells of an organ or body part and its supporting connective tissues and extracellular matrix.

- Cell proliferation refers to the process of increasing cell numbers by mitotic division. Cell differentiation is the process whereby a cell becomes more specialized in terms of structure and function. The periodic biochemical and structural events occurring during cell proliferation are called the cell cycle.

- Body cells are divided into types according to their ability to regenerate. Labile cells, such as the epithelial cells of the skin and gastrointestinal tract, are those that continue to regenerate throughout life. Stable cells, such as those in the liver, are those that normally do not divide but are capable of regeneration when confronted with an appropriate stimulus. Permanent or fixed cells are
Healing by Connective Tissue Repair

The primary objective of the healing process is to fill the gap created by tissue destruction and to restore the structural continuity of the injured part. Tissue regeneration refers to the restoration of injured tissue to its normal structure and function by proliferation of adjacent surviving cells. As discussed earlier in the chapter, cell renewal occurs continuously in labile tissues such as gastrointestinal epithelium and skin. Regeneration can also occur in parenchymal organs with stable cell populations but, with the exception of the liver, is usually a limited process. It should be pointed out that extensive regeneration can occur only if the residual tissue is structurally and functionally intact. If the tissue is damaged by infection or inflammation, regeneration is incomplete and accomplished by replacement with scar tissue.

When regeneration cannot occur, healing by replacement with a connective (fibrous) tissue occurs, a process that terminates in scar formation. The term fibrosis is often used to describe the extensive deposition of collagen that occurs in organs that are incapable of regeneration. When this occurs, fibrous tissue grows into the area of damage, converting it to a mass of fibrous tissue, a process called organization. It can also occur in serous cavities (pleura, peritoneum) when excessive exudate accumulates and cannot be cleared. In the pericardium, fibroblasts secrete and organize collagen within fibrous strands, thereby binding the visceral and parietal pericardia together (Fig. 4-4). Fibrous strands sometimes become organized within the peritoneal cavity following abdominal surgery or peritonitis. These strands of collagen, called adhesions, can trap loops of bowel and cause obstruction.

Phases of Repair

Repair by connective tissue deposition can be divided into three phases: (1) hemostasis, angiogenesis, and ingrowth of granulation tissue; (2) emigration of fibroblasts and deposition of extracellular matrix; and (3) maturation and reorganization of the fibrous tissue (remodeling). It usually begins within 24 hours of injury and is evidenced by the migration of fibroblasts and the induction of fibroblast and endothelial cell proliferation. By 3 to 5 days, a special type of tissue called granulation tissue is apparent. The granulation tissue then progressively accumulates connective tissue, eventually resulting in the formation of a scar, which is then remodeled.

Angiogenesis and Ingrowth of Granulation Tissue

Granulation tissue is a glistening red, moist connective tissue that fills the injured area while necrotic debris is removed. It is composed of newly formed capillaries, proliferating fibroblasts, and residual inflammatory cells. The development of granulation tissue involves the growth of new capillaries (angiogenesis). Angiogenesis is a tightly regulated process that includes migration of endothelial cells to the site of tissue injury,
formation of capillary buds, and proliferation of endothelial cells, followed by fusion and remodeling of the endothelial cells into capillary tubes. Several growth factors induce angiogenesis, but the most important are VEGF and basic FGF-2. In angiogenesis, VEGF stimulates both proliferation and motility of endothelial cells, thus initiating the process of capillary sprouting. FGF-2 participates in angiogenesis mainly by stimulating the proliferation of endothelial cells. During angiogenesis, new blood vessels are leaky because of incompletely formed interendothelial cell junctions and because VEGF increases vascular permeability. This leakiness explains the edematous appearance of granulation tissue and accounts in part for the swelling that may persist in healing wounds long after the acute inflammation has subsided.

Emigration of Fibroblasts and Deposition of Extracellular Matrix

Scar formation builds on the granulation tissue framework of new vessels and loose ECM. The process occurs in two phases: emigration and proliferation of fibroblasts into the site of injury, and deposition of extracellular matrix by these cells. The recruitment and proliferation of fibroblasts is mediated by a number of growth factors including FGF-2 and TGF-β. These growth factors are released from endothelial cells and from inflammatory cells that are present at the site of injury.

As healing progresses, the number of proliferating fibroblasts and formation of new vessels decrease and there is increased synthesis and deposition of collagen. Collagen synthesis is important to the development of strength in the healing wound site. Ultimately, the granulation tissue scaffold evolves into a scar composed of largely inactive spindle-shaped fibroblasts, dense collagen fibers, fragments of elastic tissue, and other ECM components. As the scar matures, vascular degeneration eventually transforms the highly vascular granulation tissue into a pale, largely avascular scar.

Maturation and Remodeling of the Fibrous Tissue

The transition from granulation to scar tissue involves shifts in the modification and remodeling of the ECM. The outcome of the repair process is, in part, a balance between previously discussed ECM synthesis and degradation. The rate of collagen synthesis diminishes until it reaches equilibrium with collagen degradation. The degradation of collagen and other ECM proteins is achieved through a family of metalloproteinases, which require zinc for their activity. The metalloproteinases are produced by a variety of cell types (fibroblasts, macrophages, synovial cells, and some epithelial cells), and their synthesis and secretion are regulated by growth factors, cytokines, and other agents. Their synthesis may be suppressed pharmacologically by corticosteroids. Metalloproteinases are typically released as inactive precursors that require activation by enzymes, such as proteases, that are present at sites of injury.

Cutaneous Wound Healing

Thus far, this chapter has focused on general aspects of tissue repair and wound healing. The following section specifically addresses healing of skin wounds (cutaneous wound healing). This is a process that involves both epithelial cell regeneration and connective tissue scar formation, and thus is illustrative of general principles that apply to all tissues.

Healing by Primary and Secondary Intention

Depending on the extent of tissue loss, wound closure and healing occur by primary or secondary intention (Fig. 4-6). A sutured surgical incision is an example of healing by primary intention. Larger wounds (e.g., burns and large surface wounds) that have a greater loss of tissue and contamination heal by secondary intention. Healing by secondary intention is slower than healing by primary intention and results in the formation of larger
Phases of Healing

Cutaneous wound healing is commonly divided into three phases: (1) the inflammatory phase, (2) the proliferative phase, and (3) the remodeling phase. The duration of the phases is fairly predictable in wounds healing by primary intention. In wounds healing by secondary intention, the process depends on the extent of injury and the healing environment.

Inflammatory Phase. The inflammatory phase of wound healing begins at the time of injury and is a critical period because it prepares the wound environment for healing. It includes hemostasis (see Chapter 12) and the vascular and cellular phases of inflammation. Hemostatic processes are activated immediately at the time of injury. There is constriction of injured blood vessels and initiation of blood clotting by way of platelet activation and aggregation and deposition of fibrin. After a brief period of constriction, these same vessels dilate and capillaries increase their permeability, allowing plasma and blood components to leak into the injured area. In small surface wounds, the clot loses fluid and becomes a hard, desiccated scab that protects the area.

The cellular phase of inflammation follows and is evidenced by the migration of phagocytic white blood cells that digest and remove invading organisms, fibrin, extracellular debris, and other foreign matter. The neutrophils arrive within minutes and are usually gone by day 3 or 4. They ingest bacteria and cellular debris. Within 24 to 48 hours, macrophages, which are larger phagocytic cells, enter the wound area and remain for an extended period. These cells, arising from blood monocytes, are essential to the healing process. Their functions include phagocytosis and release of growth factors that stimulate epithelial cell growth, angiogenesis, and attraction of fibroblasts. When a large wound occurs in deeper tissues, neutrophils and macrophages are required to remove the debris and facilitate closure. Although a wound may heal in the absence of neutrophils, it cannot heal in the absence of macrophages.

Proliferative Phase. The proliferative phase of healing usually begins within 2 to 3 days of injury and may last as long as 3 weeks in wounds healing by primary intention. The primary processes during this time focus on the building of new tissue to fill the wound space. The key cell during this phase is the fibroblast. The fibroblast is a connective tissue cell that synthesizes and secretes collagen and other intercellular elements needed for wound healing. Fibroblasts also produce numerous growth factors that induce angiogenesis and endothelial cell proliferation and migration.

As early as 24 to 48 hours after injury, fibroblasts and vascular endothelial cells begin proliferating to form the granulation tissue that serves as the foundation for scar tissue development. This tissue is fragile and bleeds easily because of the numerous, newly developed capillary buds. Wounds that heal by secondary intention have more necrotic debris and exudate that must be removed, and they involve larger amounts of granulation tissue. The newly formed blood vessels are leaky and allow plasma proteins and white blood cells to leak into the tissues.

The final component of the proliferative phase is epithelialization, which is the migration, proliferation, and differentiation of the epithelial cells at the wound edges to form a new surface layer that is similar to that destroyed by the injury. In wounds that heal by primary intention, these epithelial cells proliferate and seal the wound within 24 to 48 hours. Because epithelial cell migration requires a moist vascular wound surface and is impeded by a dry or necrotic wound surface, epithelialization is delayed in open wounds until a bed of granulation tissue has formed. When a scab has formed on the wound, the epithelial cells migrate between it and the underlying viable tissue; when a significant portion of the wound has been covered with epithelial tissue, the scab lifts off.

At times, excessive granulation tissue, sometimes referred to as proud flesh, may form and extend above the edges of the wound, preventing reepithelialization from taking place. Surgical removal or chemical cauterization of the defect allows healing to proceed.

As the proliferative phase progresses, there is continued accumulation of collagen and proliferation of fibroblasts. Collagen synthesis reaches a peak within 5 to 7 days and continues for several weeks, depending on wound size. By the second week, the white blood cells have largely left the area, the edema has diminished, and the wound begins to blanch as the small blood vessels become thrombosed and degenerate.
Remodeling Phase. The third phase of wound healing, the remodeling process, begins approximately 3 weeks after injury and can continue for 6 months or longer, depending on the extent of the wound. As the term implies, there is continued remodeling of scar tissue by simultaneous synthesis of collagen by fibroblasts and lysis by collagenase enzymes. As a result of these two processes, the architecture of the scar becomes reoriented to increase the tensile strength of the wound.

Most wounds do not regain the full tensile strength of unwounded skin after healing is completed. Carefully sutured wounds immediately after surgery have approximately 70% of the strength of unwounded skin, largely because of the placement of the sutures. This allows persons to move about freely after surgery without fear of wound separation. When the sutures are removed, usually at the end of the 1st week, wound strength is approximately 10%. It increases rapidly over the next 4 weeks and then slows, reaching a plateau of approximately 70% to 80% of the tensile strength of unwounded skin at the end of 3 months. An injury that heals by secondary intention undergoes wound contraction during the proliferative and remodeling phases. As a result, the scar that forms is considerably smaller than the original wound. Cosmetically, this may be desirable because it reduces the size of the visible defect. However, contraction of scar tissue over joints and other body structures tends to limit movement and cause deformities. As a result of loss of elasticity, scar tissue that is stretched fails to return to its original length.

An abnormality in healing by scar tissue repair is keloid formation. Keloids are benign tumor-like masses caused by excess production of scar tissue (Fig. 4-7). They tend to develop in genetically predisposed individuals and are more common in African Americans and other dark skinned people. The majority of keloids lead to considerable cosmetic defects, but can grow to sufficient size to become symptomatic by causing deformity or limiting joint mobility. Thus far the majority of keloid research has focused on growth factors and signaling pathways, but unfortunately, reliable preventative or treatment measures have yet to be established.

Factors That Affect Wound Healing

Although many local and systemic factors impair healing, science has found only a few ways to promote wound repair. Among the causes of impaired wound healing are malnutrition; impaired blood flow and oxygen delivery; impaired inflammatory and immune responses; infection, wound separation, and foreign bodies; and age effects.

Nutritional Status

Successful wound healing depends in part on adequate stores of proteins, carbohydrates, fats, vitamins, and minerals. It is well recognized that malnutrition slows the healing process, causing wounds to heal inadequately or incompletely. Protein deficiencies prolong the inflammatory phase of healing and impair fibroblast proliferation, collagen and protein matrix synthesis, angiogenesis, and wound remodeling. Carbohydrates are needed as an energy source for white blood cells. Carbohydrates also have a protein-sparing effect and help to prevent the use of amino acids for fuel when they are needed for the healing process. Fats are essential constituents of cell membranes and are needed for the synthesis of new cells.

Although most vitamins are essential cofactors for the daily functions of the body, vitamins play an essential role in the healing process. Vitamin C is needed for collagen synthesis. In vitamin C deficiency, improper sequencing of amino acids occurs, proper linking of amino acids does not take place, the by-products of collagen synthesis are not removed from the cell, new wounds do not heal properly, and old wounds may pull apart. Administration of vitamin C rapidly restores the healing process to normal. Vitamin A functions in stimulating and supporting epithelization, capillary formation, and collagen synthesis. Vitamin A also has been shown to counteract the anti-inflammatory effects of corticosteroid drugs and can be used to reverse these effects in persons who are on chronic steroid therapy. The B vitamins are important cofactors in enzymatic reactions that contribute to the wound-healing process. All are water soluble and must be replaced daily, with the exception of vitamin B₁₂, which is stored in the liver and must be replaced daily. Vitamin K plays an indirect role in wound healing by preventing bleeding disorders that contribute to hematoma formation and subsequent infection.

(text continues on page 83)
Wound healing involves the restoration of the integrity of injured tissue. The healing of skin wounds, which are commonly used to illustrate the general principles of wound healing, is generally divided into three phases: (1) the inflammatory phase, (2) the proliferative phase, and (3) the wound contraction and remodeling phase. Each of these phases is mediated through cytokines and growth factors.

**Inflammationary Phase.** The inflammatory phase begins at the time of injury with the formation of a blood clot and the migration of phagocytic white blood cells into the wound site. The first cells to arrive, the neutrophils, ingest and remove bacteria and cellular debris. After 24 hours, the neutrophils are joined by macrophages, which continue to ingest cellular debris and play an essential role in the production of growth factors for the proliferative phase.

**Proliferative Phase.** The primary processes during this phase focus on the building of new tissue to fill the wound space. The key cell during this phase is the fibroblast, a connective tissue cell that synthesizes and secretes the collagen, proteoglycans, and glycoproteins needed for wound healing. Fibroblasts also produce a family of growth factors that induce angiogenesis (growth of new blood vessels) and endothelial cell proliferation and migration. The final component of the proliferative phase is epithelialization, during which epithelial cells at the wound edges proliferate to form a new surface layer that is similar to that which was destroyed by the injury.
Wound Contraction and Remodeling Phase. This phase begins approximately 3 weeks after injury with the development of the fibrous scar, and can continue for 6 months or longer, depending on the extent of the wound. During this phase, there is a decrease in vascularity and continued remodeling of scar tissue by simultaneous synthesis of collagen by fibroblasts and lysis by collagenase enzymes. As a result of these two processes, the architecture of the scar becomes reoriented to increase its tensile strength, and the scar shrinks so it is less visible.

The role of minerals in wound healing is less clearly defined. The major minerals, including sodium, potassium, calcium, and phosphorus, as well as trace minerals such as copper and zinc, must be present for normal cell function. Zinc is a cofactor in a variety of enzyme systems responsible for cell proliferation. In animal studies, zinc has been found to aid in reepithelialization.

Blood Flow and Oxygen Delivery

Impaired healing due to poor blood flow and hypoxia may occur as a result of wound conditions (e.g., swelling) or preexisting health problems. Arterial disease and venous pathology are well-documented causes of impaired wound healing. In situations of trauma, a decrease in blood volume may cause a reduction in blood flow to injured tissues.

For healing to occur, wounds must have adequate blood flow to supply the necessary nutrients and to remove the resulting waste, local toxins, bacteria, and other debris. Molecular oxygen is required for collagen synthesis and killing of bacteria by phagocytic white blood cells. It has been shown that even a temporary lack of oxygen can result in the formation of less-stable collagen. Wounds in ischemic tissue become infected more frequently than wounds in well-vascularized tissue. Neutrophils and macrophages require oxygen for destruction of microorganisms that have invaded the area. Although these cells can accomplish phagocytosis in a relatively anoxic environment, they cannot digest bacteria. Oxygen also contributes to signaling systems that support wound healing. Recent research suggests that almost all cells in the wound environment are fitted with specialized enzymes to convert oxygen to reactive oxygen species (ROS). These ROS function as cellular messengers that support wound healing, stimulating cytokine action, angiogenesis, cell motility, and extracellular matrix formation.

The availability of respired oxygen to wound tissues depends on vascular supply, vasomotor tone, the partial pressure of oxygen (PO\textsubscript{2}) in arterial blood, and the diffusion distance for oxygen (see Chapter 21). The central area of a wound has the lower oxygen level, with dermal wounds ranging from a PO\textsubscript{2} of 0 to 10 mm Hg centrally to 60 mm Hg in the periphery, while the PO\textsubscript{2} of arterial blood is approximately 100 mm Hg. Transcutaneous oxygen sensors are available for use in measuring wound oxygenation. From a therapeutic standpoint oxygen can be given systemically or administered locally using a topical device. Although topical oxygen therapy is not likely to diffuse into the deeper tissues, it does have the advantage of oxygenating superficial areas of the wound not supported by intact vasculature. Hyperbaric oxygen therapy delivers 100% oxygen at two to three times the normal atmospheric pressure at sea level. The goal of hyperbaric oxygen therapy is to increase oxygen delivery to tissues by increasing the partial pressure of oxygen dissolved in...
the plasma. Hyperbaric oxygen is currently reserved for the treatment of problem wounds in which hypoxia and infection interfere with healing.

**Impaired Inflammatory and Immune Responses**

Inflammatory and immune mechanisms function in wound healing. Inflammation is essential to the first phase of wound healing, and immune mechanisms prevent infections that impair wound healing. Among the conditions that impair inflammation and immune function are disorders of phagocytic function, diabetes mellitus, and therapeutic administration of corticosteroid drugs.

Phagocytic disorders may be divided into extrinsic and intrinsic defects. Extrinsic disorders are those that impair attraction of phagocytic cells to the wound site, prevent engulfment of bacteria and foreign agents by the phagocytic cells (i.e., opsonization), or cause suppression of the total number of phagocytic cells (e.g., immunosuppressive agents). Intrinsic phagocytic disorders are the result of enzymatic deficiencies in the metabolic pathway for destroying the ingested bacteria by the phagocytic cell. The intrinsic phagocytic disorders include chronic granulomatous disease, an X-linked inherited disease in which there is a deficiency of myeloperoxidase and nicotinamide adenine dinucleotide peroxidase (NADPH)-dependent oxidase enzyme. Deficiencies of these compounds prevent generation of hydrogen superoxide and hydrogen peroxide needed for killing bacteria.

Wound healing is a problem in persons with diabetes mellitus, particularly those who have poorly controlled blood glucose levels. Studies have shown delayed wound healing, poor collagen formation, and poor tensile strength in diabetic animals. Of particular importance is the effect of hyperglycemia on phagocytic function. Neutrophils, for example, have diminished chemotactic and phagocytic function, including engulfment and intracellular killing of bacteria, when exposed to altered glucose levels. Small blood vessel disease is also common among persons with diabetes mellitus, impairing the delivery of inflammatory cells, oxygen, and nutrients to the wound site.

The therapeutic administration of corticosteroid drugs decreases the inflammatory process and may delay the healing process. These hormones decrease capillary permeability during the early stages of inflammation, impair the phagocytic property of the leukocytes, and inhibit fibroblast proliferation and function.

**Infection, Wound Separation, and Foreign Bodies**

Wound contamination, wound separation, and foreign bodies delay wound healing. Infection impairs all dimensions of wound healing. It prolongs the inflammatory phase, impairs the formation of granulation tissue, and inhibits proliferation of fibroblasts and deposition of collagen fibers. All wounds are contaminated at the time of injury. Although body defenses can handle the invasion of microorganisms at the time of wounding, badly contaminated wounds can overwhelm host defenses. Trauma and existing impairment of host defenses also can contribute to the development of wound infections.

Approximation of the wound edges (i.e., suturing of an incision type of wound) greatly enhances healing and prevents infection. Epithelialization of a wound with closely approximated edges occurs within 1 to 2 days. Large, gaping wounds tend to heal more slowly because it is often impossible to effect wound closure with this type of wound. Mechanical factors such as increased local pressure or tension can cause wounds to pull apart, or dehisce.

Foreign bodies tend to invite bacterial contamination and delay healing. Fragments of wood, steel, glass, and other compounds may have entered the wound at the site of injury and can be difficult to locate when the wound is treated. Sutures are also foreign bodies, and although needed for the closure of surgical wounds, they are an impediment to healing. This is why sutures are removed as soon as possible after surgery. Wound infections are of special concern in persons with implantation of foreign bodies such as orthopedic devices (e.g., pins, stabilization devices), cardiac pacemakers, and shunt catheters. These infections are difficult to treat and may require removal of the device.

**Wound Healing in the Elderly**

A number of structural and functional changes have been reported to occur in aging skin, including a decrease in dermal thickness, a decline in collagen content, and a loss of elasticity. The observed changes in skin that occur with aging are complicated by the effects of sun exposure. Since the effects of sun exposure are cumulative, older persons show more changes in skin structure.

Wound healing is thought to be progressively impaired with aging. The elderly have alterations in wound-healing phases including hemostasis and inflammation, cell proliferation, and resolution. Keratinocytes, fibroblasts, and vascular endothelial cells display a reduced rate of proliferation. There is also a reported decrease in angiogenesis and collagen synthesis, impaired wound contraction, and slower reepithelialization of open wounds. Although wound healing may be delayed, most wounds heal, even in the debilitated elderly patient undergoing major surgical procedures.

The elderly are more vulnerable to chronic wounds, chiefly pressure, diabetic, and ischemic ulcers, than younger persons, and these wounds heal more slowly. However, these wounds are more likely due to other disorders such as immobility, diabetes mellitus, or vascular disease, rather than aging.
SUMMARY CONCEPTS

- Tissue repair involves regeneration with the same cell type, or when regeneration cannot restore the injured tissue, by replacement with fibrous (scar) tissue.

- Cutaneous wound healing occurs by primary and secondary intention and is commonly divided into three phases: inflammatory, proliferative, and remodeling. In wounds healing by primary intention, such as occurs in a sutured surgical incision, the duration of the healing phases is fairly predictable and the edges of the wound are closely approximated. Larger wounds that have a greater loss of tissue heal by secondary intention, a process that is more unpredictable and results in formation of larger amounts of scar tissue.

- Wound healing can be impaired or complicated by factors such as malnutrition, poor blood flow, diminished inflammatory and immune responses, infection, wound separation, and the presence of foreign bodies.

REVIEW EXERCISES

1. Following a heart attack, the area of heart muscle that has undergone necrosis because of a lack of blood supply heals by replacement with scar tissue.
   A. Compare the functioning of the heart muscle that has been replaced by scar tissue with that of the normal surrounding heart muscle.

2. A 35-year-old man comes in with a large abscess on his leg. He tells you he injured his leg while doing repair work on his house and he thinks there might be a wood sliver in the infected area.
   A. Explain the events that lead to formation of an abscess.
   B. He is told that incision and drainage of the lesion will be needed so healing can take place. Explain.
   C. He is reluctant to have the procedure done and asks whether an antibiotic would work as well. Explain why antibiotics alone are usually not effective in eliminating the microorganisms contained in an abscess.

Our hereditary information is stored in the chemical structure of deoxyribonucleic acid (DNA), an extremely stable macromolecule. Deoxyribonucleic acid contains within its structure the basic information needed to direct the function of our cells, influence our appearance, and how we respond to our environment, and serve as the unit of inheritance that is passed on from generation to generation. Our DNA can also influence disease susceptibility and how we react to drugs.

A gene is a locatable segment or segments of DNA sequence that encodes a set of functional products, typically proteins. Genetics is the study of genes. An understanding of the role that genetics plays in the pathogenesis of disease has expanded greatly over the past century. It is now apparent that many diseases, including cancer, diabetes, and cardiovascular diseases, have a genetic component. At the same time, genetic advances have led to new methods for early detection and more effective treatment. Advances in immunogenetics have made compatible blood transfusion and organ transplants a reality, and recombinant DNA technology has provided the methods for producing human insulin, growth hormone, and clotting factors. Perhaps the most extensive use of gene technology involved the Human Genome Project, begun in 1990 and completed in 2003. The goal of this international effort was to sequence the human genome and map all of its genes.

This chapter includes discussions of genetic control of cell function, chromosomes, patterns of inheritance, and gene technology.

Genetic Control of Cell Function

The genetic instructions for protein synthesis are encoded in the DNA contained in the cell nucleus. Because of its stable structure, the genetic information carried in DNA can survive the many stages of cell division involved in the day-to-day process of cell renewal and tissue growth. Its stable structure also allows the information to survive the many processes of reduction...
division involved in gamete (i.e., ovum and sperm) formation, the fertilization process, and the mitotic cell divisions involved in the formation of a new organism from the single-celled fertilized ovum called the zygote.

Although genes have gotten a lot of attention, it is the proteins that the genes encode that make up the majority of cellular structures and contribute to their function. Proteins are responsible for the functional diversity of cells, they perform most biologic functions, and it is at their level that many regulatory processes take place, many disease processes occur, and most drug targets are found. The term proteome is a relatively new term, created to define the complete set of proteins encoded by a genome. Proteomics, the study of the proteome, uses highly sophisticated technologic methods to examine the molecular and biochemical events in a cell.

DNA Structure and Function

The DNA molecule that stores the genetic information in the nucleus is a long, double-stranded, helical structure. Deoxyribonucleic acid is composed of nucleotides, which consist of phosphoric acid, a five-carbon sugar called deoxyribose, and one of four nitrogenous bases. These nitrogenous bases carry the genetic information and are divided into two groups: the pyrimidine bases, thymine (T) and cytosine (C), which have one nitrogen ring; and the purine bases, adenine (A) and guanine (G), which have two. The backbone of DNA consists of alternating groups of sugar and phosphoric acid, with the paired bases projecting inward from the sides of the sugar molecule.

Double Helix and Base Pairing

The native structure of DNA, as elucidated by James Watson and Frances Crick in 1953, is that of a spiral staircase, with the paired bases representing the steps (Fig. 5-1). A precise complementary pairing of purine and pyrimidine bases occurs in the double-stranded DNA molecule in which A is paired with T and G is paired with C. Each nucleotide in a pair is on one strand of the DNA molecule, with the bases on opposite DNA strands bound together by hydrogen bonds that are extremely stable under normal conditions. The double-stranded structure of DNA molecules allows them to replicate precisely by separation of the two strands, followed by synthesis of two new complementary strands. Similarly, the base complementary pairing allows for efficient and correct repair of damaged DNA molecules.

Several hundred to almost 1 million base pairs can represent a gene, the size being proportional to the protein product it encodes. Of the two DNA strands, only one is used in transcribing the information for the cell’s protein-building machinery. The genetic information of one strand is meaningful and is used as a template for transcription; the complementary code of the other strand does not make sense and is ignored. Both strands, however, are involved in DNA duplication. Before cell division, the two strands of the helix separate and a complementary molecule is duplicated next to each original strand. Two strands become four strands. During mitotic cell division, the newly duplicated double-stranded molecules are separated and placed in each daughter cell by the mechanics of mitosis. As a result, each of the daughter cells again contains the meaningful strand and the complementary strand joined together as a double helix. In 1958, Meselson and Stahl characterized this replication of DNA as semiconservative replication, as opposed to conservative replication, in which the parental strands reassociate when the two strands are brought together (Fig. 5-2).

Although scientific discussion regarding the structure and functioning of a gene goes into explicit detail, it does not really address the question of what a gene is. Many scientists are now in agreement that the proteins encoded by DNA know no boundaries. This means that nucleotides from one part of the genome can combine with nucleotides from other regions at extreme distances on the DNA molecule. It is also proposed that the functions of some genes are controlled by regulatory regions, also at a distance. Moreover, researchers now recognize that many thousands of genes in the human genome do not code for protein assembly, but rather for segments of ribonucleic
acid (RNA). These and other current findings have put to rest the old hypothesis of “one gene–one protein.”

Packaging of DNA

The genome is distributed in chromosomes, discrete bundles made up of one continuous, linear DNA helix. Each human somatic cell (cells other than the gametes) has 23 pairs of different chromosomes, with one chromosome of each pair derived from the individual’s mother and the other from the father. One of the chromosome pairs consists of the sex chromosomes. Genes are arranged linearly along each chromosome. When unraveled, the DNA in the longest chromosome is more than 7 cm in length. If the DNA of all 46 chromosomes were placed end to end, the total DNA would span a distance of about 2 m (more than 6 feet).

Because of their enormous length, the DNA double helices are tightly coiled in a complex called chromatin, which consists of proteins called histones along with other less well-characterized proteins that appear to be critical for ensuring normal chromosome behavior and appropriate gene expression. The histones play a critical role in proper packaging of chromatin. They form a core around which a segment of DNA double helix winds, like thread around a spool (Fig. 5-3). About 140 base pairs of DNA are associated with each histone core, making about two turns around the core. After a short “spacer” segment of DNA, the next core DNA complex forms, and so on, giving chromatin the appearance of beads on a string. Each complex of DNA with a histone core is called a nucleosome, which is the basic structural unit of chromatin. Each chromosome contains several hundred to over a million nucleosomes.

Although solving the structural problem of how to fit a huge amount of DNA into the nucleus, the chromatin fiber, when complexed with histones and packaged into various levels of compaction, makes the DNA inaccessible during the processes of replication and gene expression. To accommodate these processes, chromatin must be induced to change its structure, a process called chromatin remodeling. Several chemical interactions are now known to affect this process. One of these involves the acetylation of a histone amino acid group that is linked to opening of the chromatin fiber and gene activation. Another important chemical modification involves the methylation of histone amino acids, which is correlated with gene inactivation.

Genetic Code

Four bases—guanine, adenine, cytosine, and thymine—make up the alphabet of the genetic code. A sequence of three of these bases forms the fundamental triplet code for one of the 20 amino acids used in protein synthesis in humans. This triplet code is called a codon. The molecular link between the DNA code of genes and the amino acid sequence of proteins is RNA, a macromolecule similar in structure to DNA, except that uracil (U) replaces thymine (T) as one of the four bases. An example is the nucleotide sequence GCU (guanine, cytosine, and uracil), which is an RNA codon for the amino
acid alanine (Table 5-1). Start and stop codons, which signal the beginning or end of a protein molecule, are also present.

Although there are only 20 amino acids, plus the start and stop codons, mathematically, the four bases can be arranged in 64 different combinations. As shown in Table 5-1, several triplets code for the same amino acid; therefore, the genetic code is said to be redundant. For example, there are four codons for the amino acid valine. Codons that specify the same amino acid are synonymous. Synonymous codons usually have the same first two bases but differ in the third base. Because the genetic code is a universal language used by most living cells, the codons for an amino acid are the same whether that amino acid is found in a bacterium, plant, or human being. Also notice that AUG is the codon for the start signal as well as the codon for the amino acid methionine.

DNA Repair

Accidental errors in the replication of DNA do arise. These errors are called mutations. Mutations can result from the substitution of one base pair for another, the loss or addition of one or more base pairs, or rearrangements of base pairs. Many of these mutations occur spontaneously through normal endogenous processes, whereas others occur because of exogenous or environmental agents such as chemical and radiation. Mutations may arise in somatic cells or in germ cells. Only those DNA changes that occur in germ cells can be inherited.

Considering the millions of base pairs that must be duplicated in each cell division, it is not surprising that random changes in replication occur. Most of these defects are corrected by DNA repair mechanisms. Several repair mechanisms exist, and each depends on specific enzymes called endonucleases that recognize distortions of the DNA helix, cleave the abnormal chain, and remove the distorted region. The gap is then filled when the correct nucleotides, identified by a DNA polymerase using the intact complementary strand as a template, are added to the cleaved DNA. The newly synthesized end of the segment is then joined to the remainder of the DNA strand by a DNA ligase. The normal regulation of these gene repair mechanisms is under the control of DNA repair genes. Loss of these gene functions renders the DNA susceptible to accumulation of mutations, which can play a role in cancer (see Chapter 7).

Genetic Variability

As the Human Genome Project progressed, it became evident that the human genome sequence is almost exactly (99.9%) the same in all people. It is the small DNA sequence variation (one in every 1000 base pairs) that is thought to account for the individual differences in physical traits, behaviors, and disease susceptibility. These variations are sometimes referred to as single nucleotide polymorphisms (from the existence of more than one morphologic form in a population), or SNPs. An international effort has been organized to develop a genome-wide map of these variations as haplotypes (a combination of SNPs at adjacent locations which are inherited together) with the intent of providing a link between genetic variations and common complex diseases such as cancer, heart disease, diabetes, and some forms of mental disease (the International HapMap Project is discussed in the section under gene technology).

Mitochondrial DNA
In addition to nuclear DNA, part of the DNA of a cell resides in the mitochondria. Mitochondrial DNA (mtDNA) is inherited from the mother (i.e., matrilineal inheritance). It is a double-stranded closed circle containing 37 genes, 24 of which are needed for mtDNA translation and 13 of which are needed for oxidative metabolism. Replication of mtDNA depends on enzymes encoded by nuclear DNA. Thus, the protein-synthesizing apparatus and molecular components for oxidative metabolism are jointly derived from nuclear and mitochondrial genes. Genetic disorders of mtDNA, although rare, commonly affect tissues such as those of the neuromuscular system that have a high requirement for oxidative metabolism (see Chapter 6).

From Genes to Proteins
Although DNA determines the type of biochemical product that is needed by the cell and directs its synthesis, it is RNA, through the process of transcription and translation, which is responsible for the actual assembly of the products.

RNA Structure and Function
RNA, like DNA, is a large molecule made up of a long string of nucleotides. However, it differs from DNA in three aspects of its structure. First, RNA is a single-stranded rather than a double-stranded molecule. Second, the sugar in each nucleotide of RNA is ribose instead of deoxyribose. Third, the pyrimidine base thymine in DNA is replaced by uracil in RNA.

Cells contain three types of RNA: messenger RNA (mRNA), ribosomal RNA (rRNA), and transfer RNA (tRNA). All three types of RNA are synthesized in the nucleus by RNA polymerase enzymes and then moved into the cytoplasm, where protein synthesis takes place. See Understanding DNA-Directed Protein Synthesis.

Messenger RNA. Messenger RNA is the template for protein synthesis. It is a long molecule containing several hundred to several thousand nucleotides. Each group of three nucleotides forms a codon that is exactly complementary to a nucleotide triplet of the DNA molecule. Messenger RNA is formed by a process called transcription. In this process, the weak hydrogen bonds of DNA are broken so that free RNA nucleotides can pair with their exposed DNA counterparts on the meaningful strand of the DNA molecule (see Fig. 5-1). As with the base pairing of the DNA strands, complementary RNA bases pair with the DNA bases.

Ribosomal RNA. The ribosome is the physical structure in the cytoplasm where protein synthesis takes place. Ribosomal RNA forms 60% of the ribosome, with the remainder of the ribosome composed of the structural proteins and enzymes needed for protein synthesis. Unlike the two other types of RNA, rRNA is produced in a specialized nuclear structure called the nucleolus.

The formed tRNA combines with ribosomal proteins in the nucleus to produce the ribosome, which is then transported into the cytoplasm. On reaching the cytoplasm, most ribosomes become attached to the endoplasmic reticulum and begin the task of protein synthesis.

Transfer RNA. Transfer RNA is a clover-shaped molecule containing only 80 nucleotides, making it the smallest RNA molecule. Its function is to deliver the activated form of an amino acid to the protein that is being synthesized in the ribosomes. At least 20 different types of tRNA are known, each of which recognizes and binds to only one type of amino acid. Each tRNA molecule has two recognition sites: the first is complementary for the mRNA codon, the second for the amino acid itself. Each type of tRNA carries its own specific amino acid to the ribosomes, where protein synthesis is taking place; there it recognizes the appropriate codon on the mRNA and delivers the amino acid to the newly forming protein molecule.

Transcription
Transcription occurs in the cell nucleus and involves the synthesis of RNA from a DNA template (Fig. 5-4B). Genes are transcribed by enzymes called RNA polymerases that generate a single-stranded RNA identical in sequence (with the exception of U in place of T) to one of the strands of DNA. It is initiated by the assembly of a transcription complex composed of RNA polymerase and other associated factors. This complex binds to the double-stranded DNA at a specific site called the promoter region. Within the promoter region is the so-called “TATA box” that contains the crucial thymine-adenine-thymine-adenine sequence that RNA polymerase recognizes and binds to, starting the replication process (Fig. 5-4A). The RNA polymerase continues to copy the meaningful DNA strand as it travels along the length of the gene, stopping only when it reaches a termination site with a stop codon. On reaching the stop signal, the RNA polymerase leaves the gene and releases the RNA strand. The RNA strand then is processed.

Processing involves the addition of certain nucleic acids at the ends of the RNA strand and cutting and splicing of certain internal sequences. Splicing often involves the removal of stretches of RNA (Fig. 5-5). Because of the splicing process, the final mRNA sequence is different from the original DNA template. The retained protein-coding regions of the mRNA sequences are called exons and the regions between exons are called introns. The functions of the introns are unknown. They are thought to be involved in the activation or deactivation of genes during various stages of development.

Splicing permits a cell to produce a variety of mRNA molecules from a single gene. By varying the splicing segments of the initial mRNA, different mRNA molecules are formed. For example, in a muscle cell, the original tropomyosin mRNA is spliced in as many as 10 different ways, yielding distinctly different protein products. This permits different proteins to be expressed from a single gene and reduces the amount of DNA contained in the genome.

(text continues on page 93)
Understand → DNA-Directed Protein

Deoxyribonucleic acid (DNA) directs the synthesis of the many thousands of proteins that are contained in the different cells of the body. Although some of the proteins are structural proteins, the majority are enzymes that catalyze the different chemical reactions in the cell. Because DNA is located in the cell’s nucleus and protein synthesis takes place in the cytoplasm, a second type of nucleic acid—ribonucleic acid (RNA)—participates in the actual assembly of the proteins. There are three types of RNA: messenger RNA (mRNA), ribosomal RNA (rRNA), and transfer RNA (tRNA) that participate in (1) the transcription of the DNA instructions for protein synthesis and (2) the translation of those instructions into the assembly of the polypeptides that make up the various proteins.

1. Transcription. Transcription involves copying the genetic code containing the instructions for protein synthesis from DNA to a complementary strand of mRNA. Once mRNA has been processed, it diffuses through the nuclear pores into the cytoplasm, where it controls protein synthesis.
**Synthesis**

**Translation.** The process of translation involves taking the instructions transcribed from DNA to mRNA and transferring them to the rRNA of ribosomes located in the cytoplasm. It is the recognition of the mRNA codon by the tRNA anticodon that ensures the proper sequence of amino acids in a synthesized protein. In order to be functional, the newly synthesized protein must be folded into its functional form, modified further, and then routed to its final position in the cell.

(text continued from page 91)

**Translation.**

Proteins are made from a standard set of amino acids, which are joined end to end to form the long polypeptide chains of protein molecules. Each polypeptide chain may have as few as 100 to more than 300 amino acids in it. The process of protein synthesis is called translation because the genetic code is translated into the language of this polypeptide assembly.

Translation requires the coordinated actions of all three forms of RNA. It begins when mRNA contacts and passes through the ribosome, where it binds to tRNA. As the RNA complex passes through the ribosome, tRNA translates its codons into complementary anticodons, which determine which amino acids it then delivers to the rRNA of ribosomes for attachment to the growing polypeptide chain. The long mRNA strand usually travels through and directs protein synthesis in more than one ribosome.

---

**FIGURE 5-4. Transcription of messenger RNA (mRNA) from DNA double helix.** (A) Transcription of mRNA involves attachment of RNA polymerase along with transcription factors to a specific nucleotide sequence, the TATA (thymine-adenosine-thymine-adenosine) region on the promoter region of the DNA. Transcription moves along the transcription unit and terminates at the stop codon. (B) Transcription creates a complementary copy mRNA from one of the DNA strands in the double helix. DNA, deoxyribonucleic acid; RNA, ribonucleic acid.
specific amino acid sequence or to split the molecule into smaller chains. As an example, the two chains that make up the circulating active insulin molecule, one containing 21 and the other 30 amino acids, were originally part of an 82-amino-acid proinsulin molecule.

**Regulation of Gene Expression**

Only about 2% of the genome encodes instructions for synthesis of proteins. Although researchers are still learning about the functions of the other 98% of DNA, it is now believed to consist of sequences that code for the production of certain types of regulatory RNA, including RNA involved in the splicing process discussed earlier. Some of the remaining genes are involved in regulation of other genes; whereas others may play a role in regulating various nuclear or cytoplasmic functions. The degree to which a gene or particular group of genes is active is called gene expression. A phenomenon termed induction is an important process by which gene expression is increased. Gene repression is a process by which a regulatory gene acts to reduce or prevent gene expression. Activator and repressor sites commonly monitor levels of the synthesized product and regulate gene transcription through a negative feedback mechanism. Whenever product levels decrease, gene transcription is increased, and when product levels increase, gene transcription is repressed.

Although control of gene expression can occur in multiple steps, many regulatory events occur at the transcription level. As noted earlier, the initiation and regulation of transcription require the collaboration of a battery of proteins collectively termed transcription factors. After binding to their own specific DNA region, transcription factors can function to increase or decrease transcriptional activity of the genes. The role of transcription factors in gene expression explains why neurons and liver cells that have the same DNA in their nuclei nevertheless have completely different structures and functions. Moreover, some transcription factors activate genes only at specific stages of development. For example, the PAX family of transcription factors is involved in the development of such embryonic tissues as the eye and portions of the nervous system.

**SUMMARY CONCEPTS**

- Genes are the fundamental unit of information storage in the cell. They code for the assembly of the proteins made by the cell and therefore control inheritance and day-to-day cell function.
- Although every cell in the body contains the same basic genetic information, cells from our body express their genetic information differently, and can therefore differ vastly in their appearance, structure, and function.
Most genetic information of a cell is organized, stored, and retrieved in discrete bundles of DNA called chromosomes. Although the chromosomes are visible only in dividing cells, they retain their integrity between cell divisions. The chromosomes are arranged in pairs: one member of the pair is inherited from the mother, the other from the father. The maternal and paternal chromosomes of a pair are called homologous chromosomes (homologs). Humans have 23 pairs of chromosomes (46 total). Of the 23 pairs, 22 are called autosomes. These have the same appearance in all individuals, males and females, and each has been given a numeric designation for classification purposes (Fig. 5-6). The sex chromosomes, which make up the 23rd pair of chromosomes, determine the sex of a person. All males have an X and Y chromosome (i.e., an X chromosome from the mother and a Y chromosome from the father); all females have two X chromosomes (i.e., one from each parent). The much smaller Y chromosome contains the male-specific region (MSY) that determines sex. This region comprises more than 90% of the length of the Y chromosome.

Only one X chromosome in the female is active in controlling the expression of genetic traits; however, both X chromosomes are activated during gametogenesis. In the female, the active X chromosome is invisible, but the inactive X chromosome can be visualized with appropriate nuclear staining. This inactive chromatin mass is called a Barr body. The genetic sex of a child can be determined by microscopic study of cell or tissue samples for the presence of a Barr body. For example, the cells of a normal female have one Barr body and therefore a total of two X chromosomes. A normal male has no Barr bodies. Males with Klinefelter syndrome (one Y, an inactive X, and an active X chromosome) exhibit one Barr body.
Cell Division

Cells reproduce by duplicating their chromosomes and dividing in two. There are two types of cell division: mitosis and meiosis. Mitosis is the cell cycle process in which non-germ cells are replicated. It provides a way for the body to replace cells that have a limited life span, such as skin and blood cells; increase tissue mass during periods of growth; and repair tissue, such as in wound healing.

Meiosis is limited to replicating germ cells and takes place only once in a cell line. It results in the formation of gametes or reproductive cells (i.e., ovum and sperm), each of which has only a single set of 23 chromosomes. Meiosis is typically divided into two distinct phases: meiosis I and meiosis II (Fig. 5-7). During meiosis I, homologous chromosomes pair up, forming a double-structured chromosome containing four chromatids (four strands) and therefore called a tetrad (two chromatids per chromosome). They are also sometimes called bivalents. The X and Y chromosomes are not homologs and do not form bivalents. While in meiosis I, an interchange of chromatid segments can occur (Fig. 5-8). This process, called crossing over, allows for new combinations of genes, increasing genetic variability.

After cell division I, each of the two daughter cells contains one member of each homologous pair of chromosomes and a sex chromosome (23 double-stranded chromosomes). No DNA synthesis occurs before meiotic division II. During cell division II, the 23 double-stranded chromosomes (two chromatids) of each of the two daughter cells from meiosis I divide at their centromeres (central regions where the chromatids meet). Each subsequent daughter cell receives 23 single-stranded chromatids. Thus, a total of four daughter cells are formed by a meiotic division of one cell.

Chromosome Structure

Cytogenetics is the study of the structure and numeric characteristics of the cell's chromosomes. Chromosome studies can be done on any tissue or cell that grows and divides in culture. Lymphocytes from venous blood are frequently used for this purpose. After the cells have been cultured, a drug called colchicine is used to arrest mitosis before the chromosomes separate. A chromosome spread is prepared by fixing and spreading the chromosomes on a slide. Subsequently, appropriate staining techniques show the chromosomal banding patterns so they can be identified. The chromosomes are imaged, and the photographs of each of the chromosomes are cut out and arranged in 23 pairs according to a standard classification system (see Fig. 5-6). The completed picture is called a karyotype, and the procedure for preparing the picture is called karyotyping.

While the chromosomes are aligned on the equatorial plate of the cell, each chromosome takes the form of chromatids to form an "X" or "wishbone" pattern. Human chromosomes are divided into three types according to the position of the centromere (Fig. 5-9).
If the centromere is in the center and the arms are of approximately the same length, the chromosome is said to be metacentric; if it is not centered and the arms are of clearly different lengths, it is submetacentric; and if it is near one end, it is acrocentric. The short arm of the chromosome is designated as “p” for “petite,” and the long arm is designated as “q” for no other reason than it is the next letter of the alphabet. The arms of the chromosome are indicated by the chromosome number followed by the p or q designation (e.g., 1p). Chromosomes 13, 14, 15, 21, and 22 have small masses of chromatin called satellites attached to their short arms by narrow stalks.

The banding patterns of a chromosome are used in describing the geographic position of a gene on a chromosome, which can be useful, for example, in communicating the location of genes involved in genetic diseases. Each arm of a chromosome is divided into regions, which are numbered from the centromere outward (e.g., 1, 2). The regions are further divided into bands, which are also numbered (Fig. 5-10). These numbers are combined to designate the position of a gene; for example, Xp22 refers to band 2, region 2 of the short arm (p) of the X chromosome.

**SUMMARY CONCEPTS**

- The genetic information in a cell is organized, stored, and retrieved as small structures called chromosomes. There are 46 chromosomes arranged in 23 pairs, 22 of which are alike for males and females, and 1 pair of sex chromosomes, with XX pairing in females and XY pairing in males.
- Cell division involves the duplication of the chromosomes. Duplication of chromosomes in somatic cell lines involves mitosis, in which each daughter cell receives 23 pairs of chromosomes. Meiosis is limited to replicating germ cells (ovum and sperm) and results in formation of a single set of 23 chromosomes.
- A karyotype is an image of a person’s chromosomes. It is prepared by special laboratory techniques in which body cells are cultured, fixed, and then stained to display identifiable banding patterns. A photomicrograph is then made. Often the individual chromosomes are cut out and regrouped according to chromosome number.
Patterns of Inheritance

The characteristic traits that persons inherit from their parents are inscribed in gene pairs found along the length of the chromosomes. Alternate forms of the same gene are possible (i.e., one inherited from the mother and the other from the father), and each may produce a different aspect of a trait.

Definitions

Genetics has its own set of definitions. The genotype of a person is the genetic information stored in the base sequence triplet code. The phenotype refers to the recognizable traits, physical or biochemical, associated with a specific genotype. Often, the genotype is not evident by available detection methods. More than one genotype may have the same phenotype. Some brown-eyed persons carry one copy of the gene that codes for blue eyes, and other brown-eyed persons do not. Phenotypically, these two types of brown-eyed persons are the same, but genotypically they are different.

With regard to a genetic disorder, not all persons with a mutant gene are affected to the same extent. Expressivity refers to the manner in which the gene is expressed in the phenotype, which can range from mild to severe. Penetrance represents the ability of a gene to express its function. Seventy-five percent penetrance means 75% of persons of a particular genotype present with a recognizable phenotype. Syndactyly (webbed fingers or toes) and blue sclera are genetic mutations that often do not exhibit 100% penetrance.

The position of a gene on a chromosome is called its locus. Because each chromosome is paired, each gene is paired, and the two copies of a gene at the same locus are called alleles. When only one pair of alleles is involved in the transmission of information, the term single-gene trait is used. For example, the inheritance of freckles is governed by the alleles (the two copies) of a single gene. Single-gene traits follow the mendelian laws of inheritance (to be discussed).

Polygenic inheritance involves multiple genes at different loci, with each gene exerting a small additive effect in determining a trait. Most human traits are determined by multiple pairs of genes, many with alternate codes, accounting for some dissimilar forms that occur with certain genetic disorders. Polygenic traits are predictable, but with less reliability than single-gene traits. Multifactorial inheritance is similar to polygenic inheritance in that multiple genes at different loci affect the outcome; however, environmental effects on the genes also affect the outcome.

Many other gene–gene interactions are known. These include epistasis, in which a gene in one locus masks the phenotypic effects of a gene at a different locus; multiple alleles, in which more than one allele affects the same trait (e.g., ABO blood types); complementary genes, in which each gene is mutually dependent on the other; and collaborative genes, in which two different genes influencing the same trait interact to produce a phenotype neither gene alone could produce.

Mendel Laws

A main feature of inheritance is predictability: given certain conditions, the likelihood of the occurrence or recurrence of a specific trait is remarkably predictable. The units of inheritance are the genes, and the pattern of single-gene expression can often be predicted using the laws of genetic transmission elucidated by the Czech monk Gregor Mendel. Techniques and discoveries since Gregor Mendel’s original work was published in 1865 have led to some modification of his original laws.

During maturation, the primordial germ cells (i.e., sperm and ovum) of both parents undergo meiosis, or reduction division, in which the number of chromosomes is divided in half (from 46 to 23). At this time, the two alleles from a gene locus separate so that each germ cell receives only one allele from each parent. The alleles from the different gene loci segregate independently and recombine randomly in the zygote. Offspring in whom the two alleles of a given pair are the same are called homozygotes. For example, a plant may have two alleles for wrinkled peas. Heterozygotes have different alleles at a gene locus. For example, a plant may have one allele for wrinkled peas and one allele for round peas. In the latter case, what would the peas look like? Mendel discovered that the allele for round peas was dominant; that is, the trait it encodes is expressed in either a homozygous or a heterozygous pairing. The trait for wrinkled peas is recessive. It is expressed only in a homozygous pairing. All offspring with a dominant allele manifest that trait. In human genetics, a carrier is a person who is heterozygous for a recessive trait and does not manifest the trait. For example, the gene for the genetic disorder cystic fibrosis is recessive. Therefore, only persons with a genotype having two alleles for cystic fibrosis have the disease. In most cases, neither parent manifests the disease; however, both must be carriers.

Mendel labeled dominant factors “A” and recessive factors “a.” Geneticists continue to use capital letters to designate dominant traits and lowercase letters to identify recessive traits. The possible combinations that can occur with transmission of single-gene dominant and recessive traits can be illustrated by constructing a figure called a Punnett square using capital and lowercase letters (Fig. 5-11).

A pedigree is a graphic method for portraying a family history of an inherited trait. It is constructed from a carefully obtained family history and is useful for tracing the pattern of inheritance for a particular trait.

Genetic Imprinting

According to Mendel the phenotype of an individual is established by whether a given allele is inherited from the mother or father. Recently, however, it has become increasingly apparent that this is not always true. For
some human genes one of the alleles is transcriptional inactive (no RNA produced), depending on the parent from whom the allele is inherited. For example, an allele from the mother would be active and that from the father would be inactive. This process of gene silencing was given the name *genomic imprinting* by Helen Crouse in 1960. It is now more commonly known as *genetic imprinting*. In humans, it is estimated that approximately 100 genes exhibit genetic imprinting. Evidence suggests that a genetic conflict occurs in the developing embryo: the male genome attempts to establish larger offspring, whereas the female genome favors smaller offspring to conserve her energy for the current and subsequent pregnancies.

It was the pathologic analysis of ovarian teratomas (tumors made up of various cell types derived from an undifferentiated germ cell) and hydatidiform moles (gestational tumors) that yielded the first evidence of genetic imprinting. All ovarian teratomas were found to have a 46,XX karyotype. The results of detailed chromosomal polymorphism analysis confirmed that these tumors developed without the paternally derived genome. Conversely, analysis of hydatidiform moles suggested that they were tumors of paternal origin.

A related chromosomal disorder is *uniparental disomy*. This occurs when two chromosomes of the same number are inherited from one parent. Normally, this is not a problem except in cases where a chromosome has been imprinted by a parent. If an allele is inactivated by imprinting, the offspring will have only one working copy of the chromosome, resulting in possible problems.

**FIGURE 5-11.** The Punnett square showing all possible combinations for transmission of a single gene trait (dimples cheeks). The example shown is when both parents are heterozygous (dD) for the trait. The alleles carried by the mother are on the left and those carried by the father are on the top. The D allele is dominant and the d allele is recessive. The DD and Dd offspring have dimples and the dd offspring does not.

**SUMMARY CONCEPTS**

- The transmission of information from one generation to the next is vested in genetic material transferred from each parent at the time of conception.
- Inheritance represents the likelihood of the occurrence or recurrence of a specific genetic trait.
- The genotype is the total sum of the genetic information that is stored in the genetic code of a person, whereas the phenotype represents the recognizable traits, physical and biochemical, associated with the genotype.
- Expressivity refers to the expression of a gene in the phenotype, and penetrance is the ability of a gene to express its function. The point on the DNA molecule that controls the inheritance of a particular trait is called a gene locus.
- Alleles are the alternate forms of a gene (one from each parent), and the locus is the position that they occupy on the chromosome. The alleles at a gene locus may carry recessive or dominant traits.
- Mendelian, or single-gene, patterns of inheritance include autosomal dominant and recessive traits that are transmitted from parents to their offspring in a predictable manner. A recessive trait is one expressed only when two copies (homozygous) of the recessive allele are present. Dominant traits are expressed with either homozygous or heterozygous pairing of the alleles.
- Polygenic inheritance, which involves multiple genes, and multifactorial inheritance, which involves multiple genes as well as environmental factors, are less predictable.
- A pedigree is a graphic method for portraying a family history of an inherited trait.

**Gene Technology**

The past several decades have seen phenomenal advances in the field of genetics. These advances have included the assembly of physical and genetic maps through the Human Genome Project; the establishment of the International HapMap Project (http://hapmap.ncbi.nlm.nih.gov) to map the haplotypes of the many adjacent single-nucleotide polymorphisms in the human genome; the establishment of the 1000 Genomes Project (http://www.1000genomes.org), and the development of methods for applying the technology of these projects to the diagnosis and treatment of disease.
Gene Mapping

Genetic mapping is the assignment of genes to specific chromosomes or parts of the chromosome. Another type of mapping strategy, the haplotype map, focuses on identifying the slight variations in the human genome that influence an individual’s susceptibility to disease and responses to environmental factors such as microbes, toxins, and drugs.

There are two types of gene maps: genetic maps and physical maps. Genetic maps are like highway maps. They use linkage studies (e.g., dosage, hybridization) to estimate the distances between chromosomal landmarks (i.e., gene markers). Physical maps are similar to a surveyor’s map. They make use of cytogenetic and molecular techniques to determine the actual physical locations of genes on chromosomes. Genetic mapping has been refined over the decades. The earliest mapping efforts localized genes on the X chromosome. The initial assignment of a gene to a particular chromosome was made in 1911 for the color blindness gene inherited from the mother (i.e., following the X-linked pattern of inheritance).

The Human Genome Project

The Human Genome Project, initiated in 1990, sought to sequence and identify all the genes in the human genome. The international project was charged with developing genetic and physical maps that allowed the precise location of genes. Some of what was revealed was quite unexpected, including the fact that humans have a mere approximately 21,000 genes, rather than the initially estimated 100,000, and that any two individuals share 99.9% of their DNA sequence, indicating that the remarkable diversity among individuals is vested in about 0.1% of our DNA.

To date, the locations of approximately 21,000 genes have been mapped to a specific chromosome, and most of them to a specific region on the chromosome. However, genetic mapping is continuing so rapidly that these numbers are constantly being updated. An excellent source of articles regarding specific chromosome sequencing in humans is the National Center for Biotechnology Information (NCBI) (www.ncbi.nlm.nih.gov/index.html). Another source is the Genome Database, a central database for mapped genes and an international repository for most mapping information.

Genetic Mapping Methods

Many methods have been used for developing genetic maps. The most important ones are family linkage studies, gene dosage methods, and hybridization studies. Often, the specific assignment of a gene is made using information from several mapping techniques.

Linkage Studies. Linkage studies assume that genes occur in a linear array along the chromosomes. During meiosis, the paired chromosomes of the diploid germ cell exchange genetic material because of the crossing-over phenomenon (see Fig. 5-8). This exchange usually involves more than one gene; large blocks of genes (representing large portions of the chromosome) are usually exchanged. Although the point at which one block separates from another occurs randomly, the closer together two genes are on the same chromosome, the greater the chance is that they will be passed on together to the offspring. When two inherited traits occur together at a rate greater than would occur by chance alone, they are said to be linked.

Several methods take advantage of the crossing over and recombination of genes to map a particular gene. In one method, any gene that has already been assigned to a chromosome can be used as a marker to assign other linked genes. For example, it was found that an extra long chromosome 1 and the Duffy blood group were inherited as a dominant trait, placing the position of the blood group gene close to the extra material on chromosome 1. Color blindness has been linked to classic hemophilia A (i.e., lack of factor VIII) in some pedigrees; hemophilia A has been linked to glucose-6-phosphate dehydrogenase deficiency in others; and color blindness has been linked to glucose-6-phosphate dehydrogenase deficiency in still others. Because the gene for color blindness is found on the X chromosome, all three genes must be found in a small section of the X chromosome. Linkage analysis can be used clinically to identify affected persons in a family with a known genetic defect. Males, because they have one X and one Y chromosome, are said to be hemizygous for sex-linked traits. Females can be homozygous (normal or mutant) or heterozygous for sex-linked traits. Heterozygous females are known as carriers for X-linked defects.

One autosomal recessive disorder that has been successfully diagnosed prenatally by linkage studies using amniocentesis is congenital adrenal hyperplasia (due to 21-hydroxylase deficiency), which is linked to an immune response gene (human leukocyte antigen [HLA] type). Postnatal linkage studies have been used in diagnosing hemochromatosis, which is closely linked to another HLA type. Persons with this disorder are unable to metabolize iron, and it accumulates in the liver and other organs. It cannot be diagnosed by conventional means until irreversible damage has been done. Given a family history of the disorder, HLA typing can determine if the gene is present, and if it is present, dietary restriction of iron intake may be used to prevent organ damage.

Gene Dosage Studies. Dosage studies involve measuring enzyme activity. Autosomal genes are normally arranged in pairs, and normally both are expressed. If both alleles are present and are expressed, the activity of the enzyme should be 100%. If one member of the gene pair is missing, only 50% of the enzyme activity is present, reflecting the activity of the remaining normal allele.

Hybridization Studies. A recent biologic discovery revealed that two somatic cells from different species, when grown together in the same culture, occasionally fuse to form a new hybrid cell. Two types of hybridization methods are used in genomic studies: somatic cell hybridization and in situ hybridization.

Somatic cell hybridization involves the fusion of human somatic cells with those of a different species (typically, the mouse) to yield a cell containing the
chromosomes of both species. Because these hybrid cells are unstable, they begin to lose chromosomes of both species during subsequent cell divisions. This makes it possible to obtain cells with different partial combinations of human chromosomes. The enzymes of these cells are then studied with the understanding that for an enzyme to be produced, a certain chromosome must be present and, therefore, the coding for the enzyme must be located on that chromosome.

In situ hybridization involves the use of specific sequences of DNA or RNA to locate genes that do not express themselves in cell culture. Deoxyribonucleic acid and RNA can be chemically tagged with radioactive or fluorescent markers. These chemically tagged DNA or RNA sequences are used as probes to detect gene location. The probe is added to a chromosome spread after the DNA strands have been separated. If the probe matches the complementary DNA of a chromosome segment, it hybridizes and remains at the precise location (therefore the term in situ) on a chromosome. Radioactive or fluorescent markers are used to find the location of the probe.

Haplotype Mapping
As work on the Human Genome Project progressed, many researchers reasoned that identifying the common patterns of DNA sequence variations in the human genome would be possible. An international project, known as the International HapMap Project, was organized with the intent of developing a haplotype map of these variations. One of the findings of the Human Genome Project was that the genome sequence was 99.9% identical for all people. It is anticipated that the 0.1% variation may greatly affect an individual's response to drugs, toxins, and predisposition to various diseases. Sites in the DNA sequence where individuals differ at a single DNA base are called single-nucleotide polymorphisms (SNPs, pronounced “snips”). A haplotype consists of the many closely linked SNPs on a single chromosome that generally are passed as a block from one generation to another in a particular population. One of the motivating factors behind the HapMap project was the realization that the identification of a few SNPs was enough to uniquely identify the haplotypes in a block. The specific SNPs that identify the haplotypes are called tag SNPs. A HapMap is a map of these haplotype blocks and their tag SNPs. This approach should prove useful in reducing the number of SNPs required to examine an entire genome and make genome scanning methods much more efficient in finding regions with genes that contribute to disease development.

Recent improvements in sequencing technology (“Next-Gen” sequencing platforms) have dramatically reduced the cost of sequencing. The goal of the 1000 Genomes Project is to sequence the genomes of a large number of people and provide a comprehensive high resolution resource for human genetic variation (www.1000genomes.org). It is anticipated that the HapMap Project and the 1000 Genomes Project will provide a useful tool for disease diagnosis and management. Much attention has focused on the use of SNPs to decide whether a genetic variant is associated with a higher risk of disease susceptibility in one population versus another. Pharmacogenetics addresses the variability of drug response due to inherited characteristics in individuals. With the availability of SNPs, it may soon be possible to identify persons who can be expected to respond favorably to a drug and those who can be expected to experience adverse reactions. This would result in safer, more effective, and more cost-efficient use of medications.

Recombinant DNA Technology
The term recombinant DNA refers to a combination of DNA molecules that are not found together in nature. Recombinant DNA technology makes it possible to identify the DNA sequence in a gene and produce the protein encoded by a gene. The specific nucleotide sequence of a DNA fragment can often be identified by analyzing the amino acid sequence and mRNA codon of its protein product. Short sequences of base pairs can be synthesized, radioactively labeled, and subsequently used to identify their complementary sequence. In this way, identifying normal and abnormal gene structures is possible.

Gene Isolation and Cloning
The gene isolation and cloning methods used in recombinant DNA technology rely on the fact that the genes of all organisms, from bacteria through mammals, are based on a similar molecular organization. Gene cloning requires cutting a DNA molecule apart, modifying and reassembling its fragments, and producing copies of the modified DNA, its mRNA, and its gene product. The DNA molecule is cut apart using a bacterial enzyme, called a restriction enzyme, that binds to DNA wherever a particular short sequence of base pairs is found and cleaves the molecule at a specific nucleotide site. In this way, a long DNA molecule can be broken down into smaller, discrete fragments, one of which presumably contains the gene of interest. Many restriction enzymes are commercially available that cut DNA at different recognition sites.

The restrictive fragments of DNA can often be replicated through insertion into a unicellular organism, such as a bacterium (Fig. 5-12). To do this a plasmid, which is a cloning vector such as a bacterial virus or a small DNA circle that is found in most bacteria, is used. Viral and plasmid vectors replicate autonomously in the host bacterial cell. During gene cloning, a bacterial vector and the DNA fragment are mixed and joined by a special enzyme called a DNA ligase. The recombinant vectors formed are then introduced into a suitable culture of bacteria, and the bacteria are allowed to replicate and express the recombinant vector gene. Sometimes, mRNA is taken from a tissue that expresses a high level of the gene and is used to produce a complementary DNA molecule that can be used in the cloning process. Because the fragments of the entire DNA molecule are used in the cloning process, additional steps are taken to identify and separate the clone that contains the gene of interest.
Pharmaceutical Applications

Recombinant DNA technology has also made it possible to produce proteins that have therapeutic properties. One of the first products to be produced was human insulin. Recombinant DNA corresponding to the A chain of human insulin was isolated and inserted into plasmids that were in turn used to transform *Escherichia coli*. The bacteria then synthesized the insulin chain. A similar method was used to obtain the B chains. The A and B chains were then mixed and allowed to fold and form disulfide bonds, producing active insulin molecules. Human growth hormone has also been produced in *E. coli*. More complex proteins are produced in mammalian cell culture using recombinant DNA techniques. These include erythropoietin, which is used to stimulate red blood cell production; factor VIII, which is used to treat hemophilia; and tissue plasminogen activator (tPA), which is frequently administered after a heart attack to dissolve the thrombi that are obstructing coronary blood flow.

DNA Fingerprinting

The technique of DNA fingerprinting is based in part on those techniques used in recombinant DNA technology and on those originally used in medical genetics to detect slight variations in the genomes of different individuals. Using restriction enzymes, DNA is cleaved at specific regions (Fig. 5-13). The DNA fragments are separated...
Genetic Control of Cell Function and Inheritance

According to size by electrophoresis. The single-stranded DNA is then transferred to nitrocellulose paper, baked to attach the DNA to the paper, and treated with a series of radioactive probes. After the radioactive probes have been allowed to bond with the denatured DNA, radiography is used to reveal the labeled DNA fragments.

When used in forensic pathology, this procedure is applied to specimens from the suspect and the forensic specimen. Banding patterns are then analyzed to see if they match. With conventional methods of analysis of blood and serum enzymes, a 1 in 100 to 1000 chance exists that the two specimens match because of chance. With DNA fingerprinting, these odds are 1 in 100,000 to 1 million.

When necessary, the polymerase chain reaction (PCR) can be used to amplify specific segments of DNA (see Chapter 14). It is particularly suited for amplifying regions of DNA for clinical and forensic testing procedures because only a small sample of DNA is required as the starting material. Regions of DNA can be amplified from a single hair or drop of blood or saliva.

Gene Therapy

Although quite different from inserting genetic material into a unicellular organism such as bacteria, techniques are available for inserting genes into the genome of intact multicellular plants and animals. The adenoviruses are promising delivery vehicles for these genes. These viruses are ideal vehicles because their DNA does not become integrated into the host genome; however, repeated inoculations are often needed because the body’s immune system usually targets cells expressing adenovirus proteins. Sterically stable liposomes also show promise as DNA delivery mechanisms. This type of therapy is one of the more promising methods for the treatment of genetic disorders such as cystic fibrosis, certain cancers, and a number of infectious diseases.

Two main approaches are used in gene therapy: transferred genes can replace defective genes or they can selectively inhibit deleterious genes. Cloned DNA sequences are usually the compounds used in gene therapy. However, the introduction of the cloned gene into the multicellular organism can influence only the few cells that get the gene. An answer to this problem would be the insertion of the gene into a sperm or ovum; after fertilization, the gene would be replicated in all of the differentiating cell types. Even so, techniques for cell insertion are limited. Not only are moral and ethical issues involved, but these techniques cannot direct the inserted DNA to attach to a particular chromosome or supplant an existing gene by knocking it out of its place.

To date, gene therapy has been used successfully to treat children with severe combined immunodeficiency disease (see Chapter 16) and in a suicide gene transfer to facilitate treatment of graft-versus-host disease after donor lymphocyte infusion.

RNA Interference Technology

One method of gene therapy focuses on the previously described replacement of missing or defective genes. However, several genetic disorders are not due to missing genes, but to faulty gene activity. With this in mind, some scientists are approaching the problem by using RNA interference (RNAi) to stop genes from making unwanted disease proteins. RNA interference is a naturally occurring process in which small pieces of double-stranded RNA (small interfering RNA [siRNA]) suppress gene expression. Scientists believe that RNAi may have originated as a defense against viral infections and potentially harmful genomic invaders. In viral infections, RNAi would serve to control the infection by preventing the synthesis of viral proteins.

With the continued refinement of techniques to silence genes, RNAi has already had a major impact on molecular biology. For example, it has given scientists the ability to practice reverse genomics, in which a gene’s function can be inferred through silencing its expression. Increasingly, pharmacologic companies are using RNAi to identify disease-related drug targets. There also is considerable interest in harnessing RNAi for therapeutic purposes, including the treatment of human immunodeficiency virus (HIV) infection and hepatitis C.

Before this can occur, however, the therapeutic methods must be shown to be safe and effective, and obstacles to delivering RNAi into targeted cells must be overcome. It is difficult for RNA to cross the cell membrane, and it is quickly broken down by enzymes in the blood.

### Summary Concepts

- The genome is the gene complement of an organism. Genomic mapping is a method used to assign genes to particular chromosomes or parts of a chromosome. The most important methods used are family linkage studies, gene dosage methods, and hybridization studies. Linkage studies assign a chromosome location to genes based on their close association with other genes of known location. Dosage studies involve measuring enzyme activity to determine if both members of a gene pair are present and functioning normally. Hybridization studies involve the fusion of human somatic cells with those of a different species to study gene location on chromosomes.

- Recombinant DNA studies involve the extraction of specific types of mRNA used in the synthesis of complementary DNA strands. The complementary DNA strands, labeled with a radioisotope, bind with the genes for which they are complementary and are used as gene probes.

- Genetic engineering has provided the methods for manipulating nucleic acids and recombining genes (recombinant DNA) into hybrid molecules that can be inserted into unicellular organisms.
SUMMARY CONCEPTS (continued)
and reproduced many times over. As a result, proteins that formerly were available only in small amounts (e.g., human insulin) can now be made in large quantities once their respective genes have been isolated. Deoxyribonucleic acid fingerprinting, which relies on recombinant DNA technologies and those of genetic mapping, is often used in forensic investigations.

- A newer strategy for management of genetic disorders focuses on gene silencing by using ribonucleic acid interference (RNAi) technology to stop genes from making unwanted disease proteins.

REVIEW EXERCISES

1. The Human Genome Project has revealed that humans have only approximately 21,000 genes. Only about 2% of the genome encodes instructions for protein synthesis, whereas 50% consist of repeat sequences that do not code proteins.

A. Use this information to explain how this small number of protein-encoding genes is able to produce the vast array of proteins needed for organ and structural development in the embryo, as well as those needed for normal function of the body in postnatal life.

2. A child about to undergo surgery is typed for possible blood transfusions. His parents are told that he is type O positive. Both his mother and father are type A positive.

A. How would you go about explaining this variation in blood type to the parents?

3. The posttranslational folding of proteins is essential to their proper functioning and degradation.

A. Hypothesize on how age-related changes in the folding of proteins in the central nervous system could contribute to the development of neurofibrillary tangles that are characteristic of Alzheimer disease.

4. More than 100,000 people die of adverse drug reactions each year; another 2.2 million experience serious reactions; whereas others fail to respond at all to the therapeutic actions of drugs.

A. Explain how the use of information about single-nucleotide polymorphisms might be used to map individual variations in drug responses.

5. Human insulin, prepared by recombinant DNA technology, is now available for the treatment of diabetes mellitus.

A. Explain the techniques used for the production of a human hormone using this technology.

6. Cystic fibrosis is a disorder of the cell membrane chloride channel that causes the exocrine glands of the body to produce abnormally thick mucus resulting in the development of chronic obstructive lung disease, pancreatitis, and infertility in men.

A. Explain how a single mutant gene can produce such devastating effects.

B. The disease is transmitted as a single-gene recessive trait. Describe the inheritance of the disorder using Figure 5-11.

7. Adult polycystic kidney disease is transmitted as an autosomal dominant trait.

A. Explain the parent-to-child transmission of this disorder.

B. Although the disease is transmitted as an autosomal dominant trait, some people who inherit the gene may develop symptoms early in life, others may develop them later in life, and still others may never develop significant symptoms of the disease. Explain.

BIBLIOGRAPHY

Congenital disorders are abnormalities of a body structure, function, or metabolism that are present at birth. They affect about a quarter of a million babies in the United States each year and are the leading cause of infant death. Congenital disorders may be caused by defective genes (single-gene or multifactorial inheritance), chromosomal aberrations, or environmental factors that are active during embryonic or fetal development (e.g., maternal exposure to infection or toxic chemicals during pregnancy). Although all congenital disorders are by definition present at birth, genetic disorders may make their appearance later in life.

The scientific understanding of congenital disorders has advanced significantly over the past three decades, largely as a result of the Human Genome Project. In fact, the molecular basis for many single-gene disorders is now known or will likely be known within the next few years. Such research has led to new and exciting insights not only in genetics, but also in the basic pathophysiology of disease.

This chapter provides an overview of genetic and other congenital disorders. It concludes with a brief survey of prenatal screening and diagnostic methods.
person’s father and the other from the person’s mother. The term *allele* refers to different forms or DNA sequences that a gene may have in a population. If the members of a gene pair are identical (i.e., code the exact same gene product), the person is *homozygous*, and if the two members are different, the person is *heterozygous*. The genetic composition of a person is called a *genotype*, whereas the *phenotype* is the observable expression of a genotype in terms of morphologic, biochemical, or molecular traits. If the trait is expressed in the heterozygote (i.e., only one member of the gene pair codes for the trait), it is said to be *dominant*; if it is expressed only in the homozygote (i.e., both members of the gene pair code for the trait), it is *recessive*. Although gene expression usually follows a dominant or recessive pattern, it is possible for both alleles of a gene pair to be fully expressed in the heterozygote, a condition called *codominance*. Many genes have only one normal version, which geneticists call the *wild-type* allele. Other genes have more than one normal allele (alternate forms) at the same locus. This is called *polymorphism*. Blood group inheritance (e.g., AO, BO, AB) is an example of codominance and polymorphism.

A *gene mutation* is a biochemical event that results in a change in the DNA sequence of a gene. Mutations can involve the substitution of a single-nucleotide base (point mutation) or insertion or deletion of one or two base pairs. Those that affect the germ cells (ovum or spermatozoa) are transmitted to the progeny and may give rise to inherited diseases. Mutations in somatic (body) cells are not transmitted to the progeny but are important in the causation of cancers and some congenital disorders.

### Single-Gene Disorders

Single-gene disorders are caused by a single defective or mutant gene. The defective gene may be present on an autosome or the X chromosome and may affect only one member of an autosomal gene pair (matched with a normal gene) or both members of the pair. Single-gene defects follow the mendelian pattern of inheritance (see Chapter 5) and are often called *mendelian disorders*.

A single mutant gene may be expressed in many different parts of the body. Marfan syndrome is a defect in connective tissue that has widespread effects involving skeletal, ocular, and cardiovascular structures. In other single-gene disorders, the same defect can be caused by mutations at several different loci. Childhood deafness can result from 16 different types of autosomal recessive mutations.

Virtually all single-gene disorders lead to formation of an abnormal protein or decreased production of a gene product. The disorder can result in a defective enzyme or decreased amounts of an enzyme, defects in receptor proteins and their function, alterations in nonenzyme proteins, or mutations resulting in unusual reactions to drugs. Table 6-1 lists some of the common single-gene disorders and their manifestations.

Autosomal Dominant Disorders

In autosomal dominant disorders, a single mutant allele from an affected parent is transmitted to an offspring regardless of sex. The affected parent has a 50% chance of transmitting the disorder to each offspring (Fig. 6-1). The unaffected relatives of the parent or unaffected siblings of the offspring do not transmit the disorder. In many conditions, the age of onset is delayed, and the signs and symptoms of the disorder do not appear until later in life, as in Huntington disease (see Chapter 37).

In some cases, the person with an autosomal dominant disorder does not have an affected parent. Such persons owe their disorder to new mutations involving either the ovum or sperm from which they were derived. Their siblings are neither affected nor at increased risk of developing the disease. Whether the mutation is passed on to the next generation depends on the affected person’s reproductive capacity. Many new autosomal dominant mutations are accompanied by reduced reproductive capacity; therefore, the defect is not perpetuated in future generations. If an autosomal defect is accompanied by a total inability to reproduce, essentially all new cases of the disorder will be due to new mutations. If the defect does not affect reproductive capacity, it is more likely to be inherited.

Although there is a 50% chance of inheriting a dominant genetic disorder from an affected parent, there can be wide variation in gene penetration and expression. When a person inherits a dominant mutant gene but fails to express it, the trait is described as having reduced penetrance. Penetrance is expressed in mathematical terms: a 50% penetrance indicates that a person who inherits the defective gene has a 50% chance of expressing the disorder. The person who has a mutant gene but does not express it is an important exception to the rule that unaffected persons do not transmit an autosomal dominant trait. These persons can transmit the gene to their descendants and so produce a skipped generation. Autosomal dominant disorders also can display variable expressivity, meaning that they can be expressed differently among individuals. Polydactyly or supernumerary digits, for example, may be expressed in either the fingers or the toes.

The gene products of autosomal dominant disorders usually are regulatory proteins involved in rate-limiting components of complex metabolic pathways or key components of structural proteins such as collagen. Two disorders of autosomal inheritance, Marfan syndrome and neurofibromatosis (NF), are discussed here.

Marfan Syndrome. Marfan syndrome is an autosomal dominant disorder with an estimated prevalence of 1 per 20,000. Approximately 75% of cases are of familial origin, with the rest arising from new mutations in the germ cells of parents. The pathogenesis of Marfan syndrome is related to mutations in a gene on chromosome 15 that codes for fibrillin, a major component of microfibrils found in the extracellular matrix. Microfibrils serve as scaffolding for deposition of elastin and are considered integral components of elastic fibers. These fibers are essential for maintaining the tissue architecture of various body structures, most notably tendons and other elastin–tissue–rich structures, such as heart valves and blood vessels.

Marfan syndrome affects several organ systems, including the ocular system (eyes), the cardiovascular system (heart and blood vessels), and the skeletal system (bones and joints). There is a wide range of variation in the expression of the disorder. Persons may have abnormalities of one or all three systems. The skeletal deformities, which are the most obvious features of the disorder, include a long, thin body with exceptionally long extremities and long, tapering fingers, sometimes called arachnodactyly or spider fingers; hyperextensible joints; and a variety of spinal deformities, including kyphosis and scoliosis (Fig. 6-2). Chest deformities, pectus excavatum (i.e., deeply depressed sternum), or pectus carinatum (pigeon chest) deformity often is present and may require surgery. The most common eye disorder is bilateral dislocation of the lens due to weakness of the suspensory ligaments. Myopia and predisposition to retinal detachment also are common, the result of increased optic globe length due to altered connective tissue support of ocular structures. The most life-threatening aspects of the disorder, however, are the cardiovascular defects, which include mitral valve prolapse, progressive dilation of the aortic valve ring, and weakness of the aorta and other arteries. Dissection and rupture of the aorta may lead to premature death. In women, the risk of aortic dissection is increased in pregnancy.

Treatment plans for Marfan syndrome include echocardiograms and electrocardiograms to assess the status of the cardiovascular system, periodic eye examinations, and evaluation of the skeletal system, especially in children and adolescents. Low to moderate activity levels are usually well tolerated. Strenuous activities such as contact sports, weight training, high-impact aerobics, and scuba diving should usually be avoided. Surgical treatment may become necessary in cases of progressive aortic dilation or acute aortic dissection.

Neurofibromatosis. Neurofibromatosis is a condition involving neurogenic tumors that arise from Schwann cells and other elements of the peripheral nervous system.
There are at least two genetically and clinically distinct forms of the disorder: type 1 NF (NF-1), also known as von Recklinghausen disease, and type 2 bilateral acoustic NF (NF-2). Both of these disorders result from a genetic defect in a tumor-suppressor gene that regulates cell differentiation and growth. The gene for NF-1 has been mapped to chromosome 17 and the gene for NF-2 to chromosome 22.

Type 1 NF is a relatively common disorder, with a frequency of 1 in 3500. Approximately 50% of cases have a family history of autosomal dominant transmission, and the remaining 50% appear to represent a new mutation. The disorder is characterized by multiple neural tumors (neurofibromas) dispersed anywhere on the body; numerous pigmented skin lesions, some of which are café au lait spots; and pigmented nodules (Lisch nodules) of the iris. The cutaneous neurofibromas, which vary in number from a few to many hundreds, manifest as soft, pedunculated lesions that project from the skin. They are the most common type of lesion, often are not apparent until puberty, and are present in greatest density over the trunk (Fig. 6-3). The subcutaneous lesions grow just below the skin; they are firm and round, and may be painful. Plexiform neurofibromas involve the larger peripheral nerves. They tend to form large tumors that cause severe disfigurement of the face, overgrowth of an extremity, or skeletal deformities such as scoliosis. Pigmented nodules of the iris (Lisch nodules), which are specific to NF-1, usually are present after 6 years of age. They do not present any clinical problem but are useful in establishing a diagnosis.

A second major component of NF-1 is the presence of large (usually ≥15 mm in diameter), flat cutaneous pigmentations, known as café au lait spots. They are usually a uniform light brown in whites and darker brown in persons of color, with sharply demarcated edges. Although small single lesions may be found in normal children, larger lesions or six or more spots larger than 1.5 cm in diameter suggest NF-1. The skin pigmentations become more evident with age as the melanosomes in the epidermal cells accumulate melanin.

Children with NF-1 are also susceptible to neurologic complications. There is an increased incidence of learning disabilities, attention deficit disorders, and abnormalities of speech. Complex partial and generalized tonic-clonic seizures are a frequent complication. Neurofibromatosis-1 is also associated with increased incidence of other neurogenic tumors, including meningiomas, optic gliomas, and pheochromocytomas.
Neurofibromatosis-2, which is characterized by tumors of the acoustic nerve and multiple menigiomas, is much less common than NF-1. The disorder is often asymptomatic through the first 15 years of life. The most frequent symptoms are headaches, hearing loss, and tinnitus (i.e., ringing in the ears). There may be associated intracranial and spinal menigiomas. The condition is often made worse by pregnancy, and oral contraceptives may increase the growth and symptoms of tumors. Persons with the disorder should be warned that severe disorientation may occur during diving or swimming underwater, and drowning may result. Surgery may be indicated for debulking or removal of the tumors.

**Autosomal Recessive Disorders**

Autosomal recessive disorders are manifested only when both members of the gene pair are affected. In this case, both parents may be unaffected but are carriers of the defective gene. Autosomal recessive disorders affect both sexes. The occurrence risks in each pregnancy are one in four for an affected child, two in four for a carrier child, and one in four for a normal (noncarrier, unaffected) homozygous child (Fig. 6-4). Consanguineous mating (mating of two related individuals), or inbreeding, increases the chance that two people who mate will be carriers of an autosomal recessive disorder.

With autosomal recessive disorders, the age of onset is frequently early in life; the symptomatology tends to be more uniform than with autosomal dominant disorders; and the disorders are characteristically caused by loss-of-function mutations, many of which impair or eliminate the function of an enzyme. In the case of a heterozygous carrier, the presence of a mutant gene usually does not produce symptoms because equal amounts of normal and defective enzymes are synthesized. This “margin of safety” ensures that cells with half their usual amount of enzyme function normally. By contrast, the inactivation of both alleles in a homozygote results in complete loss of enzyme activity. Although new mutations for recessive disorders do occur, they are rarely detected clinically because the affected person is an asymptomatic heterozygote. Several generations may pass before the descendants of such a person mate with other heterozygotes and produce affected offspring.

Autosomal recessive disorders include almost all inborn errors of metabolism. Enzyme disorders that impair catabolic pathways result in an accumulation of dietary substances (e.g., phenylketonuria) or cellular constituents (e.g., lysosomal storage diseases). Other disorders result from a defect in the enzyme-mediated synthesis of an essential protein (e.g., the cystic fibrosis transmembrane conductance regulator in cystic fibrosis [see Chapter 23]). Two examples of autosomal recessive disorders that are not covered elsewhere in this book are phenylketonuria and Tay-Sachs disease.

**Phenylketonuria.** Phenylketonuria (PKU, hyperphenylalaninemia) is a metabolic disorder caused by elevated levels of phenylalanine that are toxic to the brain. The incidence of PKU and hyperphenylalaninemia is 1 per 10,000 in the white and Asian population, but varies widely across geographic areas (e.g., 1 per 4500 in Ireland to less than 1 per 100,000 in Finland). In most cases, the hyperphenylalaninemia results from a deficiency of phenylalanine hydroxylase (PAH), a liver enzyme that converts the amino acid phenylalanine to tyrosine.

Phenylalanine is an essential amino acid derived solely from the diet. In normal children, less than 50% of the phenylalanine consumed in the diet is used for protein synthesis. The remainder is converted to tyrosine by PAH. When breakdown of phenylalanine is blocked because of a lack of PAH, other minor metabolic pathways are used, yielding several intermediates that are excreted in large amounts in the sweat and urine. These metabolites impart an unpleasant, strong, musty odor to affected infants. It is believed, however, that phenylalanine rather than its metabolites contributes to the brain damage in PKU. The lack of tyrosine, a precursor of melanin, is responsible for the light color of the hair and skin.

At the molecular level, approximately 400 mutant alleles for the PAH gene have been identified, some of which produce only mild deficiency while others produce severe deficiency. The severity of hyperphenylalaninemia depends on the degree of PAH deficiency and can be classified as classic PKU, mild PKU, or mild hyperphenylalaninemia based on blood concentrations of phenylalanine. Infants and children with classic and mild PKU require dietary protein restrictions to prevent intellectual impairment, microcephaly, and other signs of impaired neurologic development. Affected infants are normal at birth but within a few weeks begin to develop a rising phenylalanine level and signs of impaired brain development. Seizures, other neurologic abnormalities, decreased pigmentation of the hair and skin, and eczema often accompany the mental retardation in untreated infants.

Because the symptoms of untreated PKU develop gradually and would often go undetected until irreversible intellectual impairment had occurred, newborns are routinely screened for abnormal levels of serum phenylalanine.
Infants with hyperphenylalaninemia are treated with a special diet that restricts phenylalanine intake. The results of dietary therapy of children with PKU have been impressive. The diet can prevent intellectual impairment as well as other neurodegenerative effects of untreated PKU. However, dietary treatment must be started early in neonatal life to prevent brain damage. Infants with elevated phenylalanine levels should begin treatment by 7 to 10 days of age, indicating the need for early diagnosis. The duration of the dietary restriction remains controversial. Women with PKU who wish to have children require careful attention to their diet, both before conception and during pregnancy, as a means of controlling their phenylalanine levels.

**Tay-Sachs Disease.** Tay-Sachs disease is a variant of a class of lysosomal storage diseases, known as the gangliosidoses, in which there is failure of lysosomes to break down the GM$_2$ ganglioside of cell membranes. Tay-Sachs disease is inherited as an autosomal recessive trait and is predominantly a disorder of Eastern European (Ashkenazi) Jews, in whom a carrier rate of 1 in 30 has been reported.1–3

The GM$_2$ ganglioside accumulates in the lysosomes of all organs in Tay-Sachs disease, but is most prominent in the brain neurons and retina. Microscopic examination reveals neurons ballooned with cytoplasmic vacuoles, each of which constitutes a markedly distended lysosome filled with gangliosides. In time, there is progressive destruction of neurons within the brain substance, including the cerebellum, basal ganglia, brain stem, spinal cord, and autonomic nervous system. Involvement of the retina is detected by ophthalmoscopy as a cherry-red spot on the macula.

Infants with Tay-Sachs disease appear normal at birth but begin to manifest progressive weakness, muscle flaccidity, and decreased attentiveness at approximately 6 to 10 months of age. This is followed by rapid deterioration of motor and mental function, often with development of generalized seizures. Retinal involvement leads to visual impairment and eventual blindness. The disease is invariably fatal, and death usually occurs before 4 to 5 years of age. Although there is no cure for the disease, analysis of the blood serum for the lysosomal enzyme hexosaminidase A, which is deficient in Tay-Sachs disease, allows for accurate identification of genetic carriers for the disease.

**X-Linked Disorders**

Sex-linked disorders are almost always associated with the X, female, chromosome, and the inheritance pattern is predominantly recessive.1–4 Because of the presence of a normal paired X gene, female heterozygotes rarely experience the effects of a defective gene, whereas all males who receive the gene are typically affected. The common pattern of inheritance is one in which an unaffected mother carries one normal and one mutant allele on the X chromosome. This means that she has a 50% chance of transmitting the defective gene to her sons, and her daughters have a 50% chance of being carriers of the mutant gene (Fig. 6-5). When the affected son procreates, he transmits the defective gene to all of his daughters, who become carriers of the mutant gene. Because the genes of the Y chromosome are unaffected, the affected male does not transmit the defect to any of his sons, and they will not be carriers or transmit the disorder to their children. X-linked recessive disorders include glucose-6-phosphate dehydrogenase deficiency (see Chapter 13), hemophilia A (see Chapter 12), and X-linked agammaglobulinemia (see Chapter 16).

**Single-Gene Disorders with Atypical Patterns of Inheritance**

Several genetic disorders do not follow the mendelian pattern of inheritance. These include diseases caused by genomic imprinting, triplet repeat mutations, and mutations in mitochondrial genes.3

**Genomic Imprinting**

According to the mendelian pattern of inheritance, a mutant allele of an autosomal gene is equally likely to be transmitted from a parent to an offspring of either sex; similarly, a female is equally likely to transmit a mutated X-linked gene to either sex.2 Originally, little attention was paid to whether the sex of the parent had any effect on expression of the genes each parent transmits. It is now known that in some genetic disorders, such as Prader-Willi and Angelman syndromes, the expression of the disease phenotype depends on whether the mutant allele was inherited from the father or the mother, a phenomenon known as genomic imprinting. Both syndromes exhibit intellectual disability as a common feature, and both involve the same deletion in chromosome 15. However, when the deletion is inherited from the mother, the infant presents with Angelman...
(“happy puppet”) syndrome, which exhibits mental retardation along with paroxysms of laughter, ataxia, and seizures. In contrast, when the same deletion is inherited from the father, Prader-Willi syndrome results, and the child manifests intellectual impairment, uncontrolled appetite, obesity, and diabetes.

Figure 6-6 is a pedigree showing another inheritance pattern typical of genetic imprinting. In the example shown, gene expression is entirely “turned off” during spermatogenesis, so that any offspring who inherit the affected allele from the father will merely be carriers. Expression is “turned on” during oogenesis, however, so those who inherit the allele from the mother will express the disorder.

**Triplet Repeat Mutations: Fragile X Syndrome**

Fragile X syndrome is the prototype of disorders in which the mutation is characterized by a long repeating sequence of three nucleotides. Thus far, about 40 diseases associated with neurodegenerative changes, including Huntington disease and myotonic dystrophy, have been classified as triplet repeat mutations, in which the expansion of specific sets of three nucleotides within a gene disrupts its function.

Fragile X syndrome, an abnormality in the X chromosome, is the common cause of inherited intellectual disability. It is second only to Down syndrome as an identifiable cause of intellectual impairment. Because the syndrome is an X-linked disorder, it is more prevalent in males (1 in 4000) than females (1 in 8000).

In addition to intellectual disability, the fragile X syndrome is characterized by distinctive features including a large face, a large mandible, and large, everted ears. Hyperextensible joints, a high-arched palate, and mitral valve prolapse, which are observed in some cases, mimic a connective tissue disorder. Some physical abnormalities may be subtle or absent. The most distinctive feature, which is present in 90% of prepubertal boys, is macroorchiidism, or large testes. Because girls have two X chromosomes, they are more likely to have relatively normal cognitive development, or they may show a learning disability in a particular area, such as mathematics. Women with the disorder may also experience premature ovarian failure or begin menopause earlier than women who are not affected by fragile X syndrome.

The term fragile X stems from the cytogenetic observation of a constriction or fragile site on the long arm of the X chromosome. The fragile X syndrome results from a mutation in the *FMR1* (fragile X mental retardation 1) gene that has been mapped to this fragile site. The protein product of the FMR1 gene, the fragile X mental retardation protein (FMRP), is a widely expressed ribonucleic acid (RNA)-binding protein. The protein travels from the cytoplasm to the nucleus, where it binds specific messenger RNAs (mRNAs) and then transports them from the nucleus to the synaptic ends of axons and dendrites, where the FMRP–mRNA complexes perform critical roles in regulating the translation of mRNA.

The inheritance of the FMR1 gene follows the pattern of X-linked traits, with the father passing the gene on to all his daughters but not his sons. However, unlike other X-linked recessive disorders, approximately 20% of males who have been shown to carry the fragile X mutation are clinically and cytogenetically normal. These “carrier males” can transmit the disease to their grandsons through their phenotypically normal daughters. Another peculiarity is the presence of mental retardation in approximately 50% of carrier females. Both of these peculiarities have been related to the dynamic
nature of the mutation, which is sometimes maintained as a “premutation” (e.g., in carrier males) and sometimes advances to a full mutation (e.g., in affected males and carrier females who are nonetheless affected).

**Mitochondrial Gene Disorders**

The mitochondria contain their own DNA, which is distinct from the DNA contained in the cell nucleus. An understanding of the role of mitochondrial DNA (mtDNA) has evolved since 1988, when the first mutation of mtDNA was discovered.\(^{20-22}\) Since that time, more than 100 different disease-related rearrangements and point mutations have been identified. In contrast to the mendelian pattern of inheritance of nuclear DNA, disorders of mtDNA have a maternal form of inheritance. This reflects the fact that sperm mitochondria are generally eliminated from the embryo so that disorders of the mtDNA are almost always inherited entirely from the mother.\(^1\)

Mitochondrial DNA, which is packaged in a double-stranded circular chromosome located inside the mitochondria, is often referred to as the “other human genome.”\(^{20-22}\) It contains 37 genes: two ribosomal RNA (rRNA) genes; 22 transfer RNA (tRNA) genes; and 13 structural genes encoding subunits of the mitochondrial respiratory chain enzymes, which participate in oxidative phosphorylation and generation of adenosine triphosphate (ATP; see Chapter 1). Another 74 polypeptides that participate in oxidative phosphorylation are encoded by the nuclear genes. Although a rare disorder in nuclear encoded mitochondrial proteins has been described, most inherited defects in mitochondrial function result from mutations in the mitochondrial genome itself.

Mitochondrial DNA mutations generally affect tissues and organs that are highly dependent on oxidative phosphorylation to meet their high needs for metabolic energy. Thus, mitochondrial diseases frequently affect the brain and neuromuscular system and produce encephalomyopathies, retinal degeneration, loss of extracocular muscle function, lactic acidosis, and deafness.\(^{21-23}\) The mitochondrial myopathies are often associated with the so-called ragged red fibers, a histologic phenotype resulting from degeneration of muscle fibers and massive accumulation of abnormal mitochondria. The range of mitochondrial diseases is broad, however, and may include liver dysfunction, bone marrow failure, pancreatic islet cell dysfunction, and diabetes, as well as other disorders. Table 6-2 describes representative examples of disorders due to mutations in mtDNA.

### Multifactorial Inheritance Disorders

Multifactorial inheritance disorders are caused by multiple genes and, in many cases, environmental factors.\(^1-4\) The exact number of genes contributing to multifactorial traits is not known, and these traits do not follow the same clear-cut pattern of inheritance as single-gene disorders. Multifactorial inheritance has been described as a threshold phenomenon in which the factors contributing to the trait can be compared with water filling a glass.\(^24\) Using this analogy, it could be said that expression of the disorder occurs when the glass overflows. Disorders of multifactorial inheritance can be expressed during fetal life and be present at birth, or they may be expressed later in life. Congenital disorders that are thought to arise through multifactorial inheritance include cleft lip or palate, clubfoot, congenital dislocation of the hip, congenital heart disease, and urinary tract malformation. Environmental factors are thought to play a greater role in disorders of multifactorial inheritance that develop in adult life, such as coronary artery disease, diabetes mellitus, hypertension, cancer, and common psychiatric disorders such as bipolar disorder and schizophrenia.

Although multifactorial traits cannot be predicted with the same degree of accuracy as mendelian single-gene

</table>
mutations, characteristic patterns exist. First, multifactorial congenital malformations tend to involve a single organ or tissue derived from the same embryonic developmental field. Second, the risk of recurrence in future pregnancies is for the same or a similar defect. This means that parents of a child with a cleft palate defect have an increased risk of having another child with a cleft palate, but not with spina bifida. Third, the increased risk (compared with the general population) among first-degree relatives of the affected person is 2% to 7%, and among second-degree relatives, it is approximately one-half that amount. The risk increases with increasing incidence of the defect among relatives. This means that the risk is greatly increased when a second child with the defect is born to a couple. The risk also increases with severity of the disorder and when the defect occurs in the sex not usually affected by the disorder.

**Cleft Lip and Cleft Palate**

Cleft lip with or without cleft palate is one of the most common birth defects. It is also one of the more conspicuous, resulting in an abnormal facial appearance and defective speech. The incidence varies among ethnic groups, ranging from 2 per 1000 live births among Native Americans and Asians, 1 per 1000 among people of European ancestry, to 1 per 2500 among Africans. Cleft lip with or without cleft palate is more frequent among boys, whereas isolated cleft palate occurs in the midline and may involve only the uvula or may extend into or through the soft and hard palates.

Children with cleft lip or palate commonly have problems with feeding and speech. The immediate problem in an infant with cleft palate is feeding. Nursing at the breast or nipple depends on suction developed by pressing the nipple against the hard palate with the tongue. Although infants with cleft lip usually have no problems with feeding, those with cleft palate usually require specially constructed, soft artificial nipples with large openings or nipple depends on suction developed by pressing the nipple against the hard palate with the tongue. Although infants with cleft lip usually have no problems with feeding, those with cleft palate usually require specially constructed, soft artificial nipples with large openings and a squeezable bottle. A specially constructed plastic obturator that fits over the palate defect may be used to facilitate sucking for some infants. Cleft lip and palate can also cause speech defects. The muscles of the soft palate and the lateral and posterior walls of the nasopharynx constitute a valve that separates the nasopharynx from the oropharynx during swallowing and in the production of certain vocal sounds such as p, b, d, t, h, and y, or the sibilants s, sh, and ch.

A child with cleft lip or palate may require years of special treatment by health care professionals, including a plastic surgeon, pediatric dentist, orthodontist, speech therapist, and nurse specialist. Surgical closure of the lip is usually performed by 3 months of age, with closure of the palate usually done before 1 year of age. Depending on the extent of the defect, additional surgery may be required as the child grows. Displacement of the maxillary arches and malposition of the teeth usually require orthodontic correction.

![Figure 6-7: Cleft lip and cleft palate](image)

**Summary Concepts**

- Genetic disorders can be caused by single gene (mendelian) or multiple gene (polygenic) inheritance. In single gene disorders the defective gene may be present on an autosome or on the X chromosome and they may be expressed as a dominant or recessive trait. In autosomal dominant disorders, a single mutant allele from an affected parent is transmitted to an offspring regardless of sex. The affected parent has a 50% chance of transmitting the disorder to each offspring. Autosomal recessive disorders are manifested only when both members of the gene pair are affected. Usually, both parents are unaffected but are carriers of the defective gene. Their chances of having an affected child are one in four.
Chromosomal Disorders

Chromosomal disorders form a major category of genetic disease, accounting for a large proportion of reproductive wastage (early gestational abortions), congenital malformations, and intellectual disability. Specific chromosomal abnormalities can be linked to more than 60 identifiable syndromes that are present in 0.7% of all live births, 2% of all pregnancies in women older than 35 years of age, and 50% of all first-term abortions.

During cell division (i.e., mitosis) in nongerm cells, the chromosomes replicate so that each cell receives a full diploid number. In germ cells, a different form of division (i.e., meiosis) takes place (see Chapter 5). During meiosis, the double sets of 22 autosomes and the two sex chromosomes (normal diploid number) are reduced to single sets (haploid number) in each gamete. At the time of conception, the haploid number in the ovum and that in the sperm join and restore the diploid number of chromosomes.

Occasionally, mitotic errors during cleavage of the fertilized ovum or in somatic cells give rise to two or more cell lines characterized by distinctive karyotypes, a condition referred to as mosaicism. Sometimes mosaicism consists of an abnormal karyotype and a normal one, in which case the physical deformities caused by the abnormal cell line usually are less severe. Chromosomal abnormalities are commonly identified according to the shorthand description of the karyotype. In this system, the total number of chromosomes is given first, followed by the sex chromosome complement, and then the description of any abnormality. For example, a male with trisomy 21 is designated 47,XY,+21.

Structural Chromosomal Abnormalities

Aberrations in chromosome structure occur when there is a break in one or more of the chromosomes followed by rearrangement or deletion of the chromosome parts. Among the factors believed to cause chromosome breakage are exposure to radiation sources, such as x-rays; influence of certain chemicals; extreme changes in the cellular environment; and viral infections. Several patterns of chromosome breakage and rearrangement can occur (Fig. 6-8). There can be a deletion of the broken portion of the chromosome. One of the most common deletion disorders is 22q11.2 deletion syndrome (to be discussed). When one chromosome is involved, the broken parts may be inverted. Isochromosome formation occurs when the centromere, or central portion, of the chromosome separates horizontally instead of vertically. Ring formation results from a break involving both ends of a chromosome, deletion of the outermost fragments, and joining of the remaining centric portion of the chromatids to form a ring. Translocation occurs when there are simultaneous breaks in two chromosomes from different pairs, with exchange of chromosome parts. With a balanced reciprocal translocation, no genetic information is lost; therefore, persons with translocations usually are normal. However, these persons are translocation carriers and may have normal and abnormal children.

A special form of translocation called a centric fusion or Robertsonian translocation involves two chromosomes in which the centromere is near the end, most commonly chromosomes 13 and 14 or 14 and 21. Typically, the break occurs near the centromere, affecting the short arm in one chromosome and the long arm in the other. Transfer of the chromosome fragments leads to one unusually long and one extremely short fragment. The short fragment is usually lost during subsequent divisions. In this case, the person has only 45 chromosomes, but the amount of genetic material that is lost is so small that it often goes unnoticed. The chief clinical importance of this type of translocation is that carriers of a robertsonian translocation involving chromosome 21 are at risk for producing a child with Down syndrome (to be discussed).

The manifestations of aberrations in chromosome structure depend to a great extent on the amount of genetic material that is lost. Many cells sustaining...
unrestored breaks are eliminated within the next few mitoses because of deficiencies that may in themselves be fatal. This is beneficial because it prevents the damaged cells from becoming a permanent part of the organism or, if it occurs in the gametes, from giving rise to grossly defective, nonviable zygotes. Some altered chromosomes, such as those that occur with translocations, are passed on to the next generation.

22q11.2 Deletion Syndrome

The 22q11.2 deletion syndrome (22q11.2 DS) is a particularly common inheritable deletion syndrome. This autosomal dominant disease is caused by the deletion of a small piece of chromosome 22 and is characterized by a wide range of clinical phenotypes. While overall phenotypic penetrance for 22q11.2 DS is very high among deleted individuals, there are often marked phenotypic differences (variable expressivity) between related individuals with identical 22q11.2 microdeletions. Clinical findings are diverse and include psychosocial abnormalities, cognitive abnormalities, developmental delay, psychiatric illnesses, palatal abnormalities, parathyroid insufficiency, growth retardation, immune defects, congenital heart defects, renal anomalies, and abnormal craniofacial findings. Due to its highly variable phenotype, 22q11.2 DS has also been known by a variety of other names, including DiGeorge syndrome, velo-cardiofacial syndrome, conotruncal anomaly face syndrome, Shprintzen syndrome, and others. The most widely used approach to diagnose a patient with suspected 22q11.2 DS relies on the fluorescent in situ hybridization (FISH) cytogenetic test using a probe localized to the TUPLE1 gene. More recently, clinical cytogenetic reference labs employ microarrays that carry millions of probes to detect smaller microdeletions. The early diagnosis of 22q11.2 DS is critically important to effectively treat this disorder.

Numeric Disorders Involving Autosomes

A change in chromosome number is referred to as aneuploidy. Among the causes of aneuploidy is a failure of the chromosomes to separate during oogenesis or spermatogenesis. This can occur in either the autosomes or the sex chromosomes and is called nondisjunction (Fig. 6-9). Nondisjunction gives rise to germ cells that have an even number of chromosomes (22 or 24). The products of conception formed from this even number of chromosomes have an uneven number of chromosomes, 45 or 47. Monosomy refers to the presence of only one member of a chromosome pair. The defects associated with monosomy of the autosomes are severe and usually cause abortion. Monosomy of the X chromosome (45,X), or Turner syndrome, causes less severe defects. Polysomy, or the presence of more than two chromosomes to a set, occurs when a germ cell containing more than 23 chromosomes is involved in conception. A variety of trisomies involving autosomal chromosomes 13, 18, 21, and 22 have been described. With the exception of trisomy 21, most of these disorders are quite uncommon.
Down Syndrome

First described in 1866 by John Langon Down, trisomy 21, or Down syndrome, causes a combination of birth defects including some degree of intellectual disability characteristic facial features, and other health problems. According to the National Down Syndrome Association, it is the most common chromosomal disorder, occurring approximately once in every 691 births.

Approximately 95% of cases of Down syndrome are caused by nondisjunction or an error in cell division during meiosis, resulting in a trisomy of chromosome 21. A rare form of Down syndrome can occur in the offspring of persons in whom there has been a Robertsonian translocation (see Fig. 6-7) in which the long arm of another chromosome (most often 14 or 22) is added to the normal long arm of chromosome 21; therefore, the person with this type of Down syndrome has 46 chromosomes, but essentially has a trisomy of 21.

The risk of having a child with Down syndrome increases with maternal age. It begins to rise sharply at about age 30, reaching 1 in 25 births at 45 years of age. The reason for the correlation between maternal age and nondisjunction is unknown, but is thought to reflect some aspect of aging of the oocyte. Although men continue to produce sperm throughout their reproductive life, women are born with all the oocytes they will ever have. These oocytes may change as a result of the aging process. With increasing age, there is a greater chance of a woman having been exposed to damaging environmental agents such as drugs, chemicals, and radiation. Unlike trisomy 21, Down syndrome due to a translocation shows no relation to maternal age.

The physical features of a child with Down syndrome are distinctive, and therefore the condition usually is apparent at birth. These features include growth delay and a small and rather square head. There is a flatter facial profile, small nose, and somewhat depressed nasal bridge; small folds on the inner corners of the eyes (epicanthal folds) and upward slanting of the eyes; small, low-set, and malformed ears; a fat pad at the back of the neck; an open mouth; and a larger, protruding tongue (Fig. 6-10). The child’s hands usually are short and stubby, with fingers that curl inward, and there usually is only a single palmar (i.e., simian) crease. There is excessive space between the large and second toe. Hypotonia and joint laxity also are present in infants and young children. There often are

FIGURE 6-9. Nondisjunction as a cause of disorders of chromosomal numbers. (A) Normal distribution of chromosomes during meiosis I and II. (B) If nondisjunction occurs at meiosis I, the gametes contain either a pair of chromosomes or a lack of chromosomes. (C) If nondisjunction occurs at meiosis II, the affected gametes contain two copies of one parental chromosome or a lack of chromosomes.

FIGURE 6-10. Clinical features of a child with Down syndrome.
accompanying congenital heart defects and an increased risk of gastrointestinal malformations. Approximately 1% of persons with trisomy 21 Down syndrome have mosaicism (i.e., cell populations with the normal chromosome number and cell populations with trisomy 21); these persons may be less severely affected. Of particular concern is the much greater risk of development of acute leukemia among children with Down syndrome—10 to 20 times greater than that of other children. With increased life expectancy due to improved health care, it has also been found that there is an increased risk of Alzheimer disease among older persons with Down syndrome.

In the past few years, unprecedented breakthroughs have been made in the treatment of Down syndrome. These include the development of interventional and educational strategies to help affected individuals achieve their employment and independence goals based on their full potential. Several studies to determine safe and effective drugs to improve cognitive ability have been initiated (Down Syndrome Research and Treatment Foundation http://lumindfoundation.org/).

Several prenatal screening tests can help determine the risk of having a child with Down syndrome. The most commonly used are blood tests that measure maternal serum levels of α-fetoprotein, human chorionic gonadotropin (hCG), unconjugated estriol, inhibin A, and pregnancy-associated plasma protein A (PAPP-A, see section on prenatal screening and diagnosis). The results of three or four of these tests, together with the woman’s age, are used to determine the likelihood of a pregnant woman having a child with Down syndrome. Another test, fetal nuchal translucency (sonolucent space on the back of the fetal neck), uses ultrasonography and can be performed between 10 and 13 weeks of gestation. The fetus with Down syndrome tends to have a greater area of translucency compared with a chromosomally normal infant. The nuchal translucency test is usually used in combination with other screening tests. The current standard for determining the presence of Down syndrome in the fetus is through chromosome analysis using chorionic villus sampling, amniocentesis, or percutaneous umbilical blood sampling. More recently, non-invasive screening for fetal chromosomal abnormalities using cell-free DNA obtained through a maternal blood draw has become available.

### Numeric Disorders Involving Sex Chromosomes

Chromosomal disorders associated with the sex chromosomes are much more common than those related to the autosomes, save for trisomy 21. Furthermore, imbalances (excess or deletions) are much better tolerated than those involving the autosomes. This is related in large part to two factors that are peculiar to the sex chromosomes: (1) the inactivation of all but one X chromosome and (2) the modest amount of genetic material that is carried on the Y chromosome.

Although girls normally receive both a paternal and a maternal X chromosome, the clinical manifestations of X-chromosome abnormalities can be quite variable because in somatic cells of females only one X chromosome is transcriptionally active while the other chromosome is inactive. The process of X inactivation, which is random, occurs early in embryonic life and is usually complete at the end of the first week of development. After one X chromosome has become inactivated in a female, all cells descended from that cell have the same inactivated X chromosome. Although much of one X chromosome is inactivated in females, several regions contain genes that escape inactivation and continue to be expressed by both X chromosomes. These genes may explain some of the variations in clinical manifestations seen in cases of numerical abnormalities of the X chromosome, such as Turner syndrome.

#### Turner Syndrome

Turner syndrome describes an absence of all (45,X/0) or part of one of a female’s two X chromosomes. Some women may display a mosaicism with one or more additional cell lines. This disorder affects approximately 1 of every 5000 live births, and it has been estimated that almost all fetuses with the 45,X/0 karyotype are spontaneously aborted during the first trimester.

Characteristically, the girl with Turner syndrome is short in stature, but her body proportions are normal (Fig. 6-11). Because of the absence of the ovaries, she does not menstruate and shows no signs of secondary sex characteristics. There are variations in the

![FIGURE 6-11. Clinical features of Turner syndrome.](http://lumindfoundation.org/)
syndrome, with abnormalities ranging from essentially none to webbing of the neck with redundant skin folds, nonpitting lymphedema of the hands and feet, and congenital heart defects, particularly coarctation of the aorta and bicuspid aortic valve. There also may be abnormalities in kidney development (i.e., abnormal location, abnormal vascular supply, or double collecting system). There may be other abnormalities, such as changes in nail growth, high-arched palate, short fourth metacarpal, and strabismus. Although most women with Turner syndrome have normal intelligence, they may have problems with visuospatial organization (e.g., difficulty in driving, nonverbal problem-solving tasks such as mathematics, and psychomotor skills) and may have attention deficit disorder.

The diagnosis of Turner syndrome often is delayed until late childhood or early adolescence in girls who do not present with the classic features of the syndrome. Early diagnosis is an important aspect of treatment for Turner syndrome. It allows for counseling about the phenotypic characteristics of the disorder; screening for cardiac, renal, thyroid, and other abnormalities; and provision of emotional support for the girl and her family. Because of the potential for delay in diagnosis, it has been recommended that girls with unexplained short stature (height below the fifth percentile), webbed neck, peripheral lymphedema, coarctation of the aorta, or delayed puberty have chromosome studies done.40

The management of Turner syndrome begins during childhood and requires ongoing assessment and treatment. Growth hormone therapy is now standard treatment and can result in a gain of 6 to 10 cm in final height. Estrogen therapy, which is instituted around the normal age of puberty, is used to promote development and maintenance of secondary sexual characteristics.34–36

There are also health concerns for adult women with Turner syndrome.34–42 Until recently, females with Turner syndrome received intensive medical care during childhood but were discharged from specialty clinics after induction of puberty and attainment of final height. It is now known that women with Turner disease have increased morbidity due to cardiovascular disease and gastrointestinal, renal, and endocrine disorders. Adults with Turner syndrome continue to have reduced bone mass, and this has been associated with increased risk of fractures.

Klinefelter Syndrome

Klinefelter syndrome is a condition of testicular dysgenesis accompanied by the presence of one or more extra X chromosomes in excess of the normal male XY complement.2,43–47 Most males with Klinefelter syndrome have one extra X chromosome (47,XXY). In rare cases, there may be more than one extra X chromosome (48,XXXY). The presence of the extra X chromosome in the 47,XXY male results from nondisjunction during meiotic division in one of the parents.

Klinefelter syndrome is characterized by enlarged breasts, sparse facial and body hair, small testes, and the inability to produce sperm (Fig. 6-12).45–47 Regardless of the number of X chromosomes present, the male phenotype is retained. The condition often goes undetected at birth. The infant usually has normal male genitalia, with a small penis and small, firm testicles. At puberty, the intrinsically abnormal testes do not respond to stimulation from the gonadotropins and undergo degeneration. Low testosterone levels lead to tall stature with abnormal body proportions in which the lower part of the body is longer than the upper part. Later in life, the body build may become heavy, with a female distribution of subcutaneous fat and variable degrees of breast enlargement. There may be deficient secondary male sex characteristics, such as a voice that remains feminine in pitch and sparse beard and pubic hair. While the intellect usually is normal, most 47,XXY males have some degree of language impairment. They often learn to talk later than do other children and often have trouble with learning to read and write.
Based on studies conducted in the 1970s, including one sponsored by the National Institutes of Health and Human Development, it has been estimated that the 47,XXY syndrome is one of the most common genetic abnormalities known, occurring as frequently as 1 in 500 to 1000 male births. Although the presence of the extra chromosome is fairly common, the signs and symptoms of Klinefelter syndrome are relatively uncommon. Many men live their lives without being aware that they have an additional chromosome. For this reason, it has been suggested that the term Klinefelter syndrome be replaced with 47,XXY male.

Adequate management of Klinefelter syndrome requires a comprehensive neurodevelopmental evaluation. Men with Klinefelter syndrome have congenital hypogonadism, which results in inability to produce normal amounts of testosterone accompanied by an increase in hypothalamic gonadotrophic hormones (see Chapter 39). Androgen therapy is usually initiated when there is evidence of a testosterone deficit. This may begin as early as 12 to 14 years of age. Because gynecomastia predisposes to breast cancer, breast self-examination should be encouraged for men with Klinefelter syndrome. Infertility is common in men with Klinefelter syndrome due to a decrease in sperm count. If sperm are present, cryopreservation may be useful for future family planning.

**SUMMARY CONCEPTS**

- Chromosomal disorders result from a change in chromosome structure or number. They reflect events that occur at the time of meiosis, such as defective movement of an entire chromosome or breakage of a chromosome with loss, gain, or translocation of genetic material.

- A change in chromosome number is called aneuploidy. Monosomy involves the presence of only one member of a chromosome pair as is seen in Turner syndrome, in which there is monosomy of the X chromosome in females. Polysomy refers to the presence of more than two chromosomes in a set, as occurs in Klinefelter syndrome, which involves polysomy of the X chromosome in males. Trisomy 21 (i.e., Down syndrome) is the most common disorder of the autosomal chromosomes, and occurs in both sexes.

**Disorders Due to Environmental Influences**

The developing embryo is subject to many nongenetic influences. After conception, development is influenced by the environmental factors that the embryo shares with the mother. The physiologic status of the mother—her hormone balance, her general state of health, her nutritional status, and the drugs she takes—undoubtedly influences fetal development. For example, diabetes mellitus is associated with increased risk of congenital anomalies. Smoking is associated with lower than normal neonatal weight. Alcohol consumption can cause fetal abnormalities. Some agents cause early abortion. Measles and other infectious agents cause congenital malformations. Other agents, such as radiation, can cause chromosomal and genetic defects and produce developmental disorders. Chart 6-1 lists some common agents.

**Period of Vulnerability**

The embryo’s development is most easily disturbed during the period when differentiation and development of the organs are taking place. This time interval, which is often referred to as the period of organogenesis, extends from day 15 to day 60 after conception. Environmental influences during the first 2 weeks after fertilization may interfere with implantation and result in abortion or early resorption of the products of conception. Each organ has a critical period during which it is highly susceptible to environmental derangements (Fig. 6-13). Often, the effect is expressed at the biochemical level just before the organ begins to develop. The same agent may affect different organ systems that are developing at the same time.

**Teratogenic Agents**

A teratogenic agent is an environmental agent that produces abnormalities during embryonic or fetal development. Maternal disease or altered metabolic state also can affect the environment of the embryo or fetus. Theoretically, environmental agents can cause birth defects in three ways: by direct exposure of the pregnant woman and the embryo or fetus to the agent; through exposure of the soon-to-be-pregnant woman with an agent that has a slow clearance rate such that a teratogenic dose is retained during early pregnancy; or as a result of mutagenic effects of an environmental agent that occur before pregnancy, causing permanent damage to a woman’s (or a man’s) reproductive cells. The developing embryo is subject to many nongenetic influences. After conception, development is influenced by the environmental factors that the embryo shares with the mother.

**Radiation**

Radiation is teratogenic and mutagenic, and there is the possibility of effecting inheritable changes in genetic materials. Heavy doses of ionizing radiation have been shown to cause microcephaly, skeletal malformations, and intellectual disability. There is no evidence that diagnostic levels of radiation cause congenital anomalies. Because the question of safety remains, however, many agencies require that the day of a woman’s last menstrual
period be noted on all radiologic requisitions. Other institutions may require a pregnancy test before any extensive diagnostic x-ray studies are performed. Administration of therapeutic doses of radioactive iodine ($^{131}$I) during the 13th week of gestation, the time when the fetal thyroid is beginning to concentrate iodine, has been shown to interfere with thyroid development.

**Environmental Chemicals and Drugs**

Environmental chemicals and drugs can cross the placenta and cause damage to the developing embryo and fetus. Some of the best-documented environmental teratogens are the organic mercurials, which cause neurologic deficits and blindness. Sources of exposure to mercury include contaminated food (fish) and water. The precise mechanism by which chemicals and drugs exert their teratogenic effects is largely unknown. They may produce cytotoxic (cell-killing), antimitabolic, or growth-inhibiting properties. Often their effects depend on the time of exposure (in terms of embryonic and fetal development) and extent of exposure (dosage).

**Medications and Illicit Drugs.** Drugs top the list of chemical teratogens, probably because they are regularly used at elevated doses. Many drugs can cross the placenta and expose the fetus to both pharmacologic and teratogenic effects. Factors that affect placental drug transfer and drug effects on the fetus include the rate at which the drug crosses the placenta, the duration of exposure, and the stage of placental and fetal development at the time of exposure. Lipid-soluble drugs tend to cross the placenta more readily and enter the fetal circulation. The molecular weight of a drug also influences the rate of transfer and the amount of drug transferred across the placenta. Drugs with a molecular weight of less than 500 can cross the placenta easily, depending on lipid solubility and degree of ionization.
those with a molecular weight of 500 to 1000 cross the placenta with more difficulty; and those with a molecular weight of more than 1000 cross very poorly.

A number of drugs are suspected of being teratogens, but only a few have been identified with certainty. Perhaps the best known of these drugs is thalidomide, which has been shown to give rise to a full range of malformations, including phocomelia (i.e., short, flipperlike appendages) of all four extremities. Other drugs known to cause fetal abnormalities are the antimetabolites that are used in the treatment of cancer, the anticoagulant drug warfarin, several of the anticonvulsant drugs, ethyl alcohol, and cocaine. More recently, vitamin A and its derivatives (the retinoids) have been targeted for concern because of their teratogenic potential. Concern over the teratogenic effects of vitamin A derivatives became evident with the introduction of the acne drug isotretinoin (Accutane). Fetal abnormalities such as microcephaly, heart defects, retinal and optic nerve abnormalities, and central nervous system malformations were observed in women ingesting therapeutic doses of the drug during the first trimester of pregnancy.

In 1979, the U.S. Food and Drug Administration established a system for classifying drugs according to probable risks to the fetus. This system classifies all drugs approved after 1983 into five pregnancy risk categories: A, B, C, D, and X. Drugs in category A are the least dangerous, and categories B, C, and D are increasingly more dangerous. Those in category X are contraindicated during pregnancy because of proven teratogenicity.

Because many drugs are suspected of causing fetal abnormalities, and even those that were once thought to be safe are now being viewed critically, it is recommended that women in their childbearing years avoid unnecessary use of drugs. This pertains to nonpregnant women as well as pregnant women because many developmental defects occur early in pregnancy. As happened with thalidomide, the damage to the embryo may occur before pregnancy is suspected or confirmed. A drug that is often abused and can have deleterious effects on the fetus is alcohol.

**Alcohol**. The term fetal alcohol syndrome (FAS) refers to a constellation of physical, behavioral, and cognitive abnormalities resulting from maternal alcohol consumption. It has been estimated that out of the 4 million babies born each year, 4000 to 6000 will be born with FAS. Alcohol, which is lipid soluble and has a molecular weight between 600 and 1000, passes freely across the placental barrier; concentrations of alcohol in the fetus are at least as high as in the mother. Unlike other teratogens, alcohol exerts harmful effects that are not restricted to the sensitive period of early gestation but extend throughout pregnancy.

Alcohol has widely variable effects on fetal development, ranging from minor abnormalities to FAS. There may be prenatal or postnatal growth retardation; central nervous system (CNS) involvement, including neurologic abnormalities, developmental delays, behavioral dysfunction, intellectual impairment, and skull and brain malformation; and the characteristic set of facial features that include small palpebral fissures (i.e., eye openings), a thin vermillion (upper lip), and an elongated, flattened midface and philtrum (i.e., the groove in the middle of the upper lip) (Fig. 6-14). The facial features of FAS may not be as apparent in the newborn but become more prominent as the infant develops. As the children grow into adulthood, the facial features become more subtle, making diagnosis of FAS in older

individuals more difficult. Each of these defects can vary in severity, probably reflecting the timing of alcohol consumption in terms of the period of fetal development, amount of alcohol consumed, and hereditary and environmental influences.

In 2004, the National Task Force on Fetal Alcohol Syndrome and Fetal Alcohol Effects published guidelines for the referral and diagnosis of FAS. The criteria for FAS diagnosis require the documented presence of three of the following findings: (1) three facial abnormalities (smooth philtrum, thin vermillion, and small palpebral fissures), (2) growth defects (prenatal or postnatal height or weight, or both, below the 10th percentile), and (3) CNS abnormalities (e.g., head circumference below 10th percentile, global cognitive or intellectual deficits, motor functioning delays, problems with attention or hyperactivity).

The amount of alcohol that can be safely consumed during pregnancy is unknown. Even small amounts of alcohol consumed during critical periods of fetal development may be teratogenic. For example, if alcohol is consumed during the period of organogenesis, a variety of skeletal and organ defects may result. When alcohol is consumed later in gestation, when the brain is undergoing rapid development, there may be behavioral and cognitive disorders in the absence of physical abnormalities. Chronic alcohol consumption throughout pregnancy may result in a variety of effects, ranging from physical abnormalities to growth retardation and compromised CNS functioning. Evidence suggests that short-lived high concentrations of alcohol such as those that occur with binge drinking may be particularly significant, with abnormalities being unique to the period of exposure. Because of the possible effect on the fetus, it is recommended that women abstain from alcohol during pregnancy.

Infectious Agents

Many microorganisms cross the placenta and enter the fetal circulation, often producing multiple malformations. The acronym TORCH stands for toxoplasmosis, other, rubella (i.e., German measles), cytomegalovirus, and herpes, which are the agents most frequently implicated in fetal anomalies. Other infections include varicella-zoster virus infection, listeriosis, leptospirosis, Epstein-Barr virus infection, and syphilis. Human immunodeficiency virus (HIV) and human parvovirus (B19) have been suggested as additions to the list. The TORCH screening test examines the infant’s serum for the presence of antibodies to these agents. These infections tend to cause similar clinical manifestations, including microcephaly, hydrocephalus, defects of the eye, and hearing problems.

Toxoplasmosis is a protozoal infection caused by Toxoplasma gondii. The infection can be contracted by eating raw or inadequately cooked meat or food that has come in contact with infected meat. The domestic cat can carry the organism, excreting the protozoa in its feces. It has been suggested that pregnant women should avoid contact with excrement from the family cat. Although the introduction of the rubella vaccine has virtually eliminated congenital rubella syndrome in most developed countries, it remains endemic in many developing countries, where it is the major preventable cause of hearing impairment, blindness, and adverse neurodevelopmental outcome. The epidemiology of cytomegalovirus infection is largely unknown. Some infants are severely affected at birth, and others, although having evidence of the infection, have no symptoms. In some symptom-free infants, brain damage becomes evident over a span of several years. There also is evidence that some infants contract the infection during the first year of life, and in some of them the infection leads to retardation a year or two later. Herpes simplex virus type 2 infection is considered to be a genital infection and usually is transmitted through sexual contact. The infant acquires this infection in utero or in passage through the birth canal.

Nutrient Deficiencies

Although most birth defects are related to exposure to a teratogenic agent, deficiencies of nutrients and vitamins also may be a factor. Folic acid deficiency has been implicated in the development of neural tube defects (e.g., anencephaly, spina bifida, encephalocele). Studies have shown a reduction in neural tube defects when folic acid was taken before conception and continued during the first trimester of pregnancy. The Public Health Service recommends that all women of childbearing age should receive 400 micrograms (µg) of folic acid daily. These recommendations are particularly important for women who have previously had an affected pregnancy, for couples with a close relative with the disorder, and for women with diabetes mellitus and those taking anti-convulsant drugs who are at increased risk for having infants with birth defects.

Since 1998, all enriched cereal grain products in the United States have been fortified with folic acid. To achieve an adequate intake of folic acid, pregnant women should couple a diet that contains folate-rich foods (e.g., orange juice; dark, leafy green vegetables; and legumes) with sources of synthetic folic acid, such as fortified food products.
Prenatal Screening and Diagnosis

The purpose of prenatal screening and diagnosis is not just to detect fetal abnormalities. Rather, it has the following objectives: to provide parents with information needed to make an informed choice about having a child with an abnormality; to provide reassurance and reduce anxiety among high-risk groups; and to allow parents at risk for having a child with a specific defect, who might otherwise forgo having a child, to begin a pregnancy with the assurance that knowledge about the presence or absence of the disorder in the fetus can be confirmed by testing. Prenatal screening cannot be used to rule out all possible fetal abnormalities. It is limited to determining whether the fetus has (or probably has) designated conditions indicated by late maternal age, family history, or well-defined risk factors.

Screening and Diagnostic Methods

Among the methods used for prenatal screening and diagnosis are ultrasonography, maternal serum (blood) screening tests, amniocentesis, chorionic villus sampling, and percutaneous umbilical fetal blood sampling (Fig. 6-15).

Amniocentesis, chorionic villus sampling, percutaneous umbilical cord blood sampling, and fetal biopsy are invasive procedures that carry a small risk for the fetus.

Ultrasonography

Ultrasonography is a non-invasive diagnostic method that uses reflections of high-frequency sound waves to visualize soft tissue structures. Since its introduction in 1958, it has been used during pregnancy to determine the number of fetuses, fetal size and position, the amount of amniotic fluid, and placental location. It also is possible to assess fetal movement, breathing movements, and heart pattern. There is also good evidence that early ultrasonography (i.e., before 14 weeks) accurately determines gestational age.

Improved resolution and real-time units have enhanced the ability of ultrasound scanners to detect congenital anomalies. With this more sophisticated equipment, it is possible to obtain information such as measurements of hourly urine output in a high-risk fetus. Ultrasonography makes possible the in-utero diagnosis of hydrocephalus, spina bifida, facial defects, congenital heart defects, congenital diaphragmatic hernias, disorders of the gastrointestinal tract, and skeletal anomalies. Cardiovascular abnormalities are the most commonly missed malformation. A four-chamber view of the fetal heart improves the detection of cardiac malformations. Intrauterine diagnosis of congenital abnormalities permits planning of surgical correction shortly after birth, preterm delivery for early correction, selection of cesarean section to reduce fetal injury, and, in some cases, intratuterine therapy. When a congenital abnormality is suspected, a diagnosis made using ultrasonography usually can be obtained by weeks 16 to 18 of gestation.

Maternal Serum Markers

Maternal blood testing began in the early 1980s with the test for α-fetoprotein (AFP). Since that time, many serum factors have been studied as screening tests for fetal anomalies. Current maternal testing uses three distinct tests (AFP, human chorionic gonadotropin [hCG], and unconjugated estriol) to screen for trisomy syndromes in low-risk women while incorporating the detection of neural tube defects. The combined use of the three maternal serum markers between 15 and 22 weeks of pregnancy has been shown to detect as many as 60% of Down syndrome pregnancies. The use of ultrasound to verify fetal age can reduce the number of false-positive tests with this screening method.

α-Fetoprotein is a major fetal plasma protein and has a structure similar to the albumin that is found in postnatal life. AFP is made initially by the yolk sac, gastrointestinal tract, and liver. Fetal plasma levels peak at approximately 10 to 13 weeks' gestation and then decline progressively until term, while maternal levels peak in the third trimester. Maternal and amniotic fluid levels of AFP are elevated in pregnancies where the fetus has a neural tube defect (i.e., anencephaly and open spina bifida) or certain other malformations such as an anterior abdominal wall defect in which the fetal integument is not intact. Screening of maternal blood samples usually is done between weeks 16 and 18 of gestation. Although neural tube defects have been associated with elevated levels of AFP, decreased levels have been associated with Down syndrome.

A complex glycoprotein, hCG is produced exclusively by the outer layer of the trophoblast shortly after

SUMMARY CONCEPTS (continued)

- A number of environmental agents can be damaging to the unborn child, including radiation, environmental pollutants such as mercury, medications and illicit drugs, alcohol, and infectious agents. Because many of these agents have the potential for causing fetal abnormalities, often at an early stage of pregnancy, it is recommended that women of childbearing age avoid all unnecessary use of drugs and abstain from alcohol.
- The acronym TORCH stands for toxoplasmosis, other, rubella, cytomegalovirus, and herpes, which are the infectious agents most frequently implicated in fetal anomalies.
- It also has been shown that maternal folic acid deficiency can contribute to neural tube defects, and iodine deficiency can cause congenital hypothyroidism and impaired neurological development (cretinism).
implantation in the uterine wall. It increases rapidly in the first 8 weeks of gestation, declines steadily until 20 weeks, and then plateaus. The single maternal serum marker that yields the highest detection rate for Down syndrome is an elevated level of hCG.

Unconjugated estriol is produced by the placenta from precursors provided by the fetal adrenal glands and liver. It increases steadily throughout pregnancy to a higher level than that normally produced by the liver. Unconjugated estriol levels are decreased in Down syndrome and trisomy 18.

Other maternal serum markers include pregnancy-associated plasma protein A (PAPP-A) and inhibin A. PAPP-A, which is secreted by the placenta, has been shown to play an important role in promoting cell differentiation and proliferation in various body systems. In complicated pregnancies, the PAPP-A concentration increases with gestational age until term. Decreased PAPP-A levels in the first trimester (between 10 to 13 weeks) have been shown to be associated with Down syndrome. When used along with maternal age, free β-hCG, and ultrasound measurement of nuchal translucency, serum PAPP-A levels can reportedly detect 85% to 95% of affected pregnancies with a false-positive rate of approximately 5%. Inhibin A, which is secreted by the corpus luteum and fetoplacental unit, is also a maternal serum marker for fetal Down syndrome.

Non-Invasive Prenatal Testing (NIPT)
Circulating cell free DNA (cf-DNA) fragments are short fragments of DNA found in the blood. During pregnancy, there are cf-DNA fragments from both the mother and fetus in maternal circulation. It is possible to analyze cf-DNA from the maternal blood to detect common fetal trisomies such as Down syndrome as early as 10 weeks. Non-invasive prenatal testing using cf-DNA offers tremendous potential as a screening tool due to its increased accuracy over maternal serum markers and the nuchal translucency tests. The recent and rapid adoption of non-invasive prenatal screening in high-risk pregnancies in the United States suggests that NIPT may change the standard of care for genetic screening (ACOG 2013).
Invasive Testing

Amniocentesis. Amniocentesis involves the withdrawal of a sample of amniotic fluid from the pregnant uterus using either a transabdominal or transcervical approach (see Fig. 6-15). The procedure is useful in women older than 35 years of age, who have an increased risk of giving birth to an infant with Down syndrome; in parents who have another child with chromosomal abnormalities; and in situations in which a parent is known to be a carrier of an inherited disease. Ultrasound is used to gain additional information and to guide the placement of the amniocentesis needle. The amniotic fluid and cells that have been shed by the fetus are studied. Amniocentesis is performed on an outpatient basis typically at the 15th to 16th week after the first day of the last menstrual period. For chromosomal analysis, the fetal cells are grown in culture and the result is available in 10 to 14 days. The amniotic fluid also can be tested using various biochemical tests.

Chorionic Villus Sampling. Sampling of the chorionic villi usually is done after 10 weeks of gestation. Doing the test before that time is not recommended because of the danger of limb reduction defects in the fetus. The chorionic villi are the site of exchange of nutrients between the maternal blood and the embryo—the chorionic sac encloses the early amniotic sac and fetus, and the villi are the primitive blood vessels that develop into the placenta. The sampling procedure can be performed using either a transabdominal or transcervical approach (see Fig. 6-15). The tissue that is obtained can be used for fetal chromosome studies, DNA analysis, and biochemical studies. The fetal tissue does not have to be cultured, and fetal chromosome analysis can be made available in 24 hours. Deoxyribonucleic acid analysis and biochemical tests can be completed within 1 to 2 weeks.

Percutaneous Umbilical Cord Blood Sampling. Percutaneous umbilical cord blood sampling involves the transcutaneous insertion of a needle through the uterine wall and into the umbilical artery. It is performed under ultrasound guidance and can be done any time after 16 weeks of gestation. It is used for prenatal diagnosis of hemoglobinopathies, coagulation disorders, metabolic and cytogenetic disorders, and immunodeficiencies. Fetal infections such as rubella and toxoplasmosis can be detected through measurement of immunoglobulin M antibodies or direct blood cultures. Results from cytogenetic studies usually are available within 48 to 72 hours. Because the procedure carries a greater risk of pregnancy loss than amniocentesis, it usually is reserved for situations in which rapid cytogenetic analysis is needed or in which diagnostic information cannot be obtained by other methods.

Fetal Biopsy. Fetal biopsy is done with a fetoscope under ultrasound guidance. It is used to detect certain genetic skin defects that cannot be diagnosed with DNA analysis. It also may be done to obtain muscle tissue for use in diagnosis of Duchenne muscular dystrophy.

Cytogenetic and Biochemical Analyses

Amniocentesis and chorionic villus sampling yield cells that can be used for cytogenetic and DNA analyses. Biochemical analyses can be used to detect abnormal levels of AFP and abnormal biochemical products in the maternal blood and in specimens of amniotic fluid and fetal blood. Cytogenetic studies are used for fetal karyotyping to determine the chromosomal makeup of the fetus. They are done to detect abnormalities of chromosome number and structure. Karyotyping also reveals the sex of the fetus. This may be useful when an inherited defect is known to affect only one sex.

Analysis of DNA is done on cells extracted from the amniotic fluid, chorionic villus sampling, or fetal blood from percutaneous umbilical sampling to detect genetic defects such as inborn errors of metabolism. The defect may be established through direct demonstration of the molecular defect or through methods that break the DNA into fragments so that the fragments may be studied to determine the presence of an abnormal gene. Direct demonstration of the molecular defect is done by growing the amniotic fluid cells in culture and measuring the enzymes that the cultured cells produce. Many of the enzymes are expressed in the chorionic villi; this permits earlier prenatal diagnosis because the cells do not need to be subjected to prior culture. Deoxyribonucleic acid studies are used to detect genetic defects that cause inborn errors of metabolism, such as Tay-Sachs disease, glycogen storage diseases, and familial hypercholesterolemia.

SUMMARY CONCEPTS

- Prenatal diagnosis includes the use of ultrasonography, maternal blood screening, amniocentesis, chorionic villus sampling, and percutaneous umbilical fetal blood sampling.
- Ultrasonography is used for determination of fetal size and position and for the presence of structural anomalies.
- Maternal blood screening, which measures α-fetoprotein (AFP), unconjugated estriol, and chorionic gonadotropin (hCG), is used to assess for neural tube defects (AFP) and Down syndrome (AFP, unconjugated estriol, and hCG).
- Amniocentesis, chorionic villus sampling, and percutaneous umbilical blood sampling are used to obtain specimens for cytogenetic and biochemical studies.

## REVIEW EXERCISES

1. A 23-year-old woman with sickle cell disease and her husband want to have a child, but worry that the child will be born with the disease.
   - A. What is the mother’s genotype in terms of the sickle cell gene? Is she heterozygous or homozygous?
   - B. If the husband is found not to have the sickle cell gene, what is the probability of their child having the disease or being a carrier of the sickle cell trait?

2. A couple has a child who was born with a congenital heart disease.
   - A. Would you consider the defect to be the result of a single-gene or a polygenic trait?
   - B. Would these parents be at greater risk of having another child with a heart defect, or would they be at equal risk of having a child with a defect in another organ system, such as cleft palate?

3. A couple has been informed that their newborn child has the features of Down syndrome. It was suggested that genetic studies be performed.
   - A. The child is found to have trisomy 21. Use Figure 6-8 to describe the events that occur during meiosis to explain the origin of the third chromosome.
   - B. If the child had been found to have the robertsonian chromosome, how would you explain the origin of the abnormal chromosome?

4. A 26-year-old woman is planning to become pregnant.
   - A. What information would you give her regarding the effects of medications and drugs on the fetus? What stage of fetal development is associated with the greatest risk?
   - B. What is the rationale for ensuring that she has an adequate intake of folic acid before conception?
   - C. She and her husband have an indoor cat. What precautions should she use in caring for the cat?

Cancer is a major health problem in the United States and many other parts of the world. It is estimated that 1.66 million Americans were newly diagnosed with cancer in 2013 and 580,350 died of the disease. Cancer affects all age groups, and is the second leading cause of death among children ages 1 to 14 years. As age-adjusted cancer mortality rates increase and heart disease mortality decreases, it is predicted that cancer will soon become the leading cause of death. The good news, however, is that the survival rates have improved to the extent that almost 64% of people who develop cancer each year will be alive 5 years later.

Cancer is not a single disease. It can originate in almost any organ, with skin cancers being the most common site in persons in the United States. Excluding skin cancers, the prostate is the most common site in men and the breast is the most common site in women (Fig. 7-1). The ability of cancer to be cured varies considerably and depends on the type of cancer and the extent of the disease at the time of diagnosis. Cancers such as acute lymphoblastic leukemia, Hodgkin disease, testicular cancer, and osteosarcoma, which only a few decades ago had poor prognoses, are cured in many cases today. However, lung cancer, which is the leading cause of death in men and women in the United States, remains resistant to therapy.

This chapter is divided into five sections: characteristics of benign and malignant neoplasms, etiology of cancer, clinical manifestations, diagnosis and treatment, and childhood cancers and late effects on cancer survivors. Hematologic malignancies (lymphomas and leukemias) are presented in Chapter 11.
of programmed cell death that eliminates senescent cells, deoxyribonucleic acid (DNA), and damaged or unwanted cells. In adult tissues, the size of a population of cells is determined by the rates of cell proliferation and death by apoptosis. In malignant neoplasms, the accumulation of neoplastic cells may result not only from excessive and uncontrolled proliferation, but also from evasion of apoptosis.

All tumors—benign and malignant—are composed of two types of tissue: (1) *parenchymal* or specific functional cells of an organ or tissue, and (2) connective tissue that forms the supporting tissue framework or stroma. The *parenchymal* tissue, which is made up of the transformed or neoplastic cells of a tumor, determines its behavior and is the component for which the tumor is named. The supporting nonneoplastic stromal tissue component is made up of connective tissue, extracellular matrix, and blood vessels. It is essential to the growth of the tumor since it carries the blood supply and provides support for the parenchymal tumor cells.

### Terminology

Cancers are commonly referred to as *tumors* or *neoplasms*. Although defined in the medical literature as a swelling that can be caused by a number of conditions, including inflammation and trauma, the term *tumor* is increasingly being used to describe a neoplasm. *Onkology*, from the Greek term *onkos*, for a “swelling,” refers to the study or science of neoplasms. *Clinical oncology* deals with neoplastic disorders in the clinical setting, primarily in terms of diagnosis and treatment.

Benign tumors usually are named by adding the suffix *-oma* to the parenchymal tissue type from which the growth originated. Thus, a benign epithelial neoplasm of glandular tissue is called an *adenoma*, and a benign tumor arising in fibrous tissue is called a *fibroma*. The term *carcinoma* is used to designate a malignant tumor of epithelial tissue origin. In the case of malignancies that originate from glandlike structures, the term *adenocarcinoma* is used, and for those that originate from squamous cells, the term *squamous cell carcinoma* is used. Malignant tumors of mesenchymal origin are called *sarcomas*. A cancer of fibrous tissue is a *fibrosarcoma* and a malignant tumor composed of chondrocytes is a *chondrosarcoma*.

*Papillomas* are benign microscopic or macroscopic fingerlike projections that grow on any surface. A *polyp* is a growth that projects from a mucosal surface, such as the intestine. Although the term usually implies a benign neoplasm, some malignant tumors also appear as polyps. Adenomatous polyps are considered precursors to adenocarcinomas of the colon.

### Biology of Benign and Malignant Tumors

The differences between benign and malignant tumors are determined by (1) the characteristics of the tumor cells, (2) the rate of growth, (3) local invasion, and (4) the ability to metastasize. The characteristics of benign and malignant neoplasms are summarized in Table 7-1.
Benign Neoplasms

Benign tumors are composed of well-differentiated cells that resemble the cells of the tissues of origin and are generally characterized by a slow, progressive rate of growth that may come to a standstill or regress.\textsuperscript{2,3} For unknown reasons, benign tumors have lost the ability to suppress the genetic program for cell proliferation but have retained the program for normal cell differentiation. They grow by expansion and remain localized to their site of origin and do not have the capacity to infiltrate, invade, or metastasize to distant sites. Because they expand slowly, they develop a surrounding rim of compressed connective tissue called a fibrous capsule.\textsuperscript{3} The capsule is responsible for a sharp line of demarcation between the benign tumor and the adjacent tissues, a factor that facilitates surgical removal.

Malignant Neoplasms

In contrast to benign tumors, malignant neoplasms tend to grow rapidly, invade and infiltrate nearby tissue, and spread to other parts of the body. They lack a well-defined capsule and their margins are not clearly separated from the normal surrounding tissue. Because of their rapid rate of growth, malignant tumors may compress blood vessels and outgrow their blood supply, causing ischemia and tissue injury. Some malignancies secrete hormones and/or cytokines, liberate enzymes and toxins, and/or induce an inflammatory response that injures normal tissue as well as the tumor itself.

There are two categories of malignant neoplasms—solid tumors and hematologic cancers. Solid tumors initially are confined to a specific tissue or organ. As the growth of the primary solid tumor progresses, cells detach from the original tumor mass, invade the surrounding tissue, and enter the blood and lymph system to spread to distant sites, a process termed metastasis. Hematologic cancers involve cells normally found within the blood and lymph, thereby making them disseminated diseases from the beginning.

Cancer in situ is a localized preinvasive lesion. For example, in ductal carcinoma in situ of the breast, the malignant cells have not crossed the basement membrane. Depending on its location, an in situ lesion usually can be removed surgically or treated so that the chances of recurrence are small. For example, cancer in situ of the cervix is essentially 100% curable.

Tumor Cell Characteristics

Whether a tumor is benign or malignant is determined by an examination of its cells. Typically, such an examination includes macroscopic (naked eye) inspection to determine the presence or absence of a tumor capsule and invasion of the surrounding tissue, supplemented by microscopic examination of histologic sections of the tumor. Additional information may be obtained from electron microscopy, immunochemistry techniques, chromosomal studies, and DNA analysis. The growth and behavior of tumor cells may be studied using culture techniques.

Differentiation and Anaplasia. Differentiation refers to the extent to which the parenchymal (specific organ versus supportive tissue) cells of a tumor resemble their normal forerunners morphologically and functionally. Malignant neoplasms that are composed of poorly differentiated or undifferentiated cells are described as being anaplastic, anaplasia literally means to “form backward” to an earlier dedifferentiated state. On histologic examination, benign tumors are composed of cells that resemble the tissue from which they have arisen. By contrast, the cells of malignant tumors are characterized by wide changes of parenchymal cell differentiation from well differentiated to completely undifferentiated.

Undifferentiated cancer cells are marked by a number of morphologic changes. Both the cells and nuclei display variations in size and shape, a condition referred to as pleomorphism. Their nuclei are variable in size and bizarre in shape, their chromatin is coarse and clumped, and their nucleoli are often considerably larger than normal (Fig. 7-2A). Characteristically, the nuclei contain an abundance of DNA and are extremely dark staining. The cells of undifferentiated tumors usually display a large number of mitoses, reflecting a higher rate of proliferation. They also display atypical, bizarre mitotic figures, sometimes producing tripolar, tetrapolar, or multipolar spindles (Fig. 7-2B). Highly anaplastic cancer cells, whatever their tissue of origin, begin to resemble undifferentiated or embryonic cells more than they do their tissue of origin.

Some cancers display only slight anaplasia and others marked anaplasia. The cytologic/histologic grading of tumors is based on the degree of differentiation and the number of proliferating cells. The closer the tumor cells resemble comparable normal tissue cells, both morphologically (structurally) and functionally, the lower the
grade. Accordingly, on a scale ranging from grade I to IV, grade I neoplasms are well differentiated and grade IV are poorly differentiated and display marked anaplasia.2

Genetic Instability and Chromosomal Abnormalities. Most cancer cells exhibit a characteristic called genetic instability that is often considered to be a hallmark of cancer.3,4 The concept came about after the realization that uncorrected mutations in normal cells are rare due to many cellular mechanisms to prevent them. To account for the high frequency of mutations in cancer cells, it is thought that cancer cells have a genotype that is highly divergent from the genotype of normally transformed cells. Characteristics of genetic instability are alterations in growth regulatory genes and genes involved in cell cycle progression and arrest.

Genomic instability most commonly results in gross chromosomal abnormalities. Benign tumors usually have a normal number of chromosomes. By contrast, malignant cells often display a feature called aneuploidy, in which they have an abnormal number of chromosomes.2,4 The chromosomes may be structurally abnormal due to insertions, deletions, amplifications, or translocations of parts of their arms (see Chapter 6). They may also display microsatellite instability, which involves short repetitive sequences of DNA, and point mutations.

Growth Properties. The characteristics of altered proliferation and differentiation are associated with a number of growth and behavioral changes that distinguish cancer cells from their normal counterparts. These include growth factor independence, lack of cell density–dependent inhibition, impaired cohesiveness and adhesion, loss of anchorage dependence, faulty cell-to-cell communication, and an indefinite cell life span or immortality.

Cell growth in test tubes or culture dishes is referred to as in vitro cell culture because the first containers used for these cultures were made of glass (vitrum, meaning “glass” in Latin). It is assumed that the in vivo (in the body) growth of tumor cells mimics that of in vitro studies. Most normal cells require a complex growth medium and survive for only a limited time in vitro. In the case of cancer cells, the addition of serum, which is rich in growth factors, is unnecessary for the cancers to proliferate. Some cancer cells produce their own growth factors and secrete them into the culture medium, while others have abnormal receptors or signaling proteins that may inappropriately activate growth-signaling pathways within the cells. Breast cancer cells that do not express estrogen receptors are an example. These cancer cells grow even in the absence of estrogen, which is the normal growth stimulus for breast duct epithelial cells.

Normal cells that are grown in culture tend to display a feature called cell density–dependent inhibition, in which they stop dividing after the cell population reaches a particular density.1 This is sometimes referred to as contact inhibition since cells often stop growing when they come into contact with each other. In wound healing, for example, contact inhibition causes fibrous tissue growth to cease at the point where the edges of a wound come together. Malignant cells show no such contact inhibition and grow rampantly without regard for adjacent tissue. There is also a reduced tendency of cancer cells to stick together (i.e., loss of cohesiveness and adhesiveness) owing, in part, to a loss of cell surface adhesion molecules. This permits shedding of the tumor’s surface cells; these cells appear in the surrounding body fluids or secretions and often can be detected using cytologic examination.

Cancer cells also display a feature called anchorage independence.5,6 Studies in culture show that normal cells, with the exception of hematopoietic cells, will not grow and proliferate unless they are attached to a solid surface such as the extracellular matrix. For some cell types, including epithelial tissue cells, even survival depends on such attachments. If normal epithelial cells become detached, they often undergo a type of apoptosis known as anoikis due to not having a “home.” In contrast to normal cells, cancer cells often survive in microenvironments different from those of the normal cells. They frequently remain viable and multiply without normal attachments to other cells and the extracellular matrix. Another characteristic of cancer cells is faulty cell-to-cell communication, a feature that may contribute to the growth and survival of cancer cells. Impaired cell-to-cell communication may interfere with formation of intercellular connections and responsiveness to membrane-derived signals. For example, changes in gap junction proteins, which enable cytoplasmic continuity and communication between cells, have been described in some types of cancer.7 Cancer cells also differ from normal cells by being immortal; that is, they have an unlimited life span. If normal noncancerous cells are harvested from the body and grown under culture conditions, most cells divide a limited number of times, usually about 50 population doublings, then achieve senescence and fail to divide further. In contrast, cancer cells may divide an infinite number of times, and hence achieve immortality. Telomeres are short, repetitive nucleotide sequences at the outermost extremities of chromosome arms (see Chapter 2). Most cancer cells maintain high levels of telomerase, an enzyme that prevents telomere shortening, which keeps telomeres from aging and attaining a critically short length that is associated with cellular replicative senescence.

Functional Features. Because of their lack of differentiation, cancer cells tend to function on a more primitive level than normal cells, retaining only those functions that are essential for their survival and proliferation. They may also acquire some new features and become quite different from normal cells. For example, many transformed cancer cells revert to earlier stages of gene expression and produce antigens that are immunologically distinct from the antigens that are expressed by cells of the well-differentiated tissue from which the cancer originated. Some cancers may elaborate fetal antigens that are not produced by comparable cells in the adult. Tumor antigens may be clinically useful as markers to indicate the presence, recurrence, or progressive growth of a cancer. Response to treatment can also be evaluated based on an increase or decrease in tumor antigens.

Cancers may also engage in the abnormal production of substances that affect body function. For example,
cancer cells may produce procoagulant materials that affect the clotting mechanisms, or tumors of nonendocrine origin may assume the ability to engage in hormone synthesis. These conditions are often referred to as paraneoplastic syndromes (to be discussed).

**Tumor Growth**

The rate of growth in normal and cancerous tissue depends on three factors: (1) the number of cells that are actively dividing or moving through the cell cycle, (2) the duration of the cell cycle, and (3) the number of cells that are being lost relative to the number of new cells being produced. One of the reasons cancerous tumors often seem to grow so rapidly relates to the size of the cell pool that is actively engaged in cycling. It has been shown that the cell cycle time of cancerous tissue cells is not necessarily shorter than that of normal cells. Rather, cancer cells do not die on schedule and growth factors prevent cells from exiting the cell cycle and entering the G0 or noncycling phase (see Chapter 4, Understanding the Cell Cycle). Thus, a greater percentage of cancer cells are actively engaged in cycling as compared to cells in normal tissue.

The ratio of dividing cells to resting cells in a tissue mass is called the growth fraction. The doubling time is the length of time it takes for the total mass of cells in a tumor to double. As the growth fraction increases, the doubling time decreases. When normal tissues reach their adult size, an equilibrium between cell birth and cell death is reached. Cancer cells, however, continue to divide until limitations in blood supply and nutrients inhibit their growth. When this occurs, the doubling time for cancer cells decreases. If tumor growth is plotted against time on a semilogarithmic scale, the initial growth rate is exponential and then tends to decrease or flatten out over time. This characterization of tumor growth is called the Gompertzian model.

By conventional radiographic methods, a tumor usually is undetectable until it has doubled 30 times and contains more than 1 billion \((10^9)\) cells. At this point, it is approximately 1 cm in size (Fig. 7-3). Methods to identify tumors at smaller sizes are under investigation; in some cases the application of ultrasound and magnetic resonance imaging (MRI) enable detection of tumors less than 1 cm. After 35 doublings, the mass contains more than 1 trillion \((10^{12})\) cells, which is a sufficient number to kill the host.

**Invasion**

The word cancer is derived from the Latin word meaning crablike because cancers grow and spread by sending crablike projections into the surrounding tissues. Unlike benign tumors, which grow by expansion and usually are surrounded by a capsule, cancer spreads by direct invasion into surrounding tissues, seeding of cancer cells in body cavities, and metastatic spread.

Most cancers synthesize and secrete enzymes that break down proteins and contribute to the infiltration, invasion, and penetration of the surrounding tissues. The lack of a sharp line of demarcation separating them from the surrounding tissue makes the complete surgical removal of malignant tumors more difficult than removal of benign tumors. Often it is necessary for the surgeon to excise portions of seemingly normal tissue bordering the tumor for the pathologist to establish that cancer-free margins are present around the excised tumor and to ensure that the remaining tissue is cancer free.

---

**FIGURE 7-3.** Growth curve of a hypothetical tumor on arithmetic coordinates. Notice the number of doubling times before the tumor reaches an appreciable size. (Adapted from Collins VP, Loeffler RK, Tivey H. Observations of growth rates of human tumors. Am J Roentgenol Radium Ther Nucl Med. 1956;76(5):988–1000.)
The seeding of cancer cells into body cavities occurs when a tumor erodes and sheds cells into these spaces.\(^2,3\) Most often, the peritoneal cavity is involved, but other spaces such as the pleural cavity, pericardial cavity, and joint spaces may be involved. Seeding into the peritoneal cavity is particularly common with ovarian cancers. Similar to tissue culture, tumors in these sites grow in masses and often produce fluid (e.g., ascites, pleural effusion).\(^2\) The seeding of cancers is often a concern during the surgical removal of cancers, where it is possible to inadvertently introduce free cancer cells into a body cavity such as the peritoneal cavity.\(^4\)

**Metastatic Spread**

The term *metastasis* is used to describe the development of a secondary tumor in a location distant from the primary tumor.\(^2,3\) Metastatic tumors frequently retain many of the microscopic characteristics of the primary tumor from which they were derived. Because of this, it usually is possible to determine the site of the primary tumor from the cellular characteristics of the metastatic tumor. Some tumors tend to metastasize early in their developmental course, while others do not metastasize until later. Occasionally, a metastatic tumor will be found far advanced before the primary tumor becomes clinically detectable.

Malignant tumors disseminate by one of two pathways: lymph channels (lymphatic spread) or blood vessels (hematogenous spread).\(^2\) Lymphatic spread is more typical of carcinomas, whereas hematogenous spread is favored by sarcomas.

**Lymphatic Spread.** In many types of cancer, the first evidence of disseminated disease is the presence of tumor cells in the lymph nodes that drain the tumor area.\(^2\) When metastasis occurs by way of the lymphatic channels, the tumor cells lodge first in the initial lymph node that receives drainage from the tumor site. Once in this lymph node, the cells may die because of the lack of a proper environment, remain dormant for unknown reasons, or grow into a discernible mass (Fig. 7-4). If they survive and grow, the cancer cells may spread from more distant lymph nodes to the thoracic duct, and then gain access to the blood vasculature. Furthermore, cancer cells may gain access to the blood vasculature from the initial node and more distant lymph nodes by way of tumor-associated blood vessels that may infiltrate the tumor mass.

The term *sentinel node* is used to describe the initial lymph node to which the primary tumor drains.\(^10\) Because the initial metastasis in breast cancer is almost always lymphatic, lymphatic spread and, therefore, extent of disease may be determined through lymphatic mapping and sentinel lymph node biopsy. This is done by injecting a radioactive tracer and blue dye into the tumor to determine the first lymph node in the route of lymph drainage from the cancer. Once the sentinel lymph node is identified, it is examined to determine the presence or absence of cancer cells. The procedure is also used to map the spread of melanoma and other cancers that have their initial metastatic spread through the lymphatic system.

**Hematogenous Spread.** With hematogenous spread, cancer cells commonly invade capillaries and venules, whereas thicker-walled arterioles and arteries are relatively resistant. With venous invasion, blood-borne neoplastic cells follow the venous flow draining the site of the neoplasm, often stopping in the first capillary bed they encounter. Since venous blood from the gastrointestinal tract, pancreas, and spleen is routed through the portal vein to the liver, and all vena caval blood flows to the lungs, the liver and lungs are the most frequent metastatic sites for hematogenous spread.\(^2,3\)

Although the site of hematologic spread usually is related to vascular drainage of the primary tumor, some tumors metastasize to distant and unrelated sites. For example, prostatic cancer preferably spreads to bone, bronchogenic cancer to the adrenals and brain, and neuroblastomas to the liver and bones. The selective nature of hematologic spread indicates that metastasis is a finely orchestrated and multistep process, in which only a small, select clone of cancer cells has the right combination of gene products to perform all of the steps needed for establishment of a secondary tumor (Fig. 7-5). To metastasize, a cancer cell must be able to break loose from the primary tumor, invade the surrounding extracellular matrix, gain access to a blood vessel, survive its passage in the bloodstream, emerge from the bloodstream at a favorable location, invade the surrounding tissue, and begin to grow and establish a blood supply.

Considerable evidence suggests that cancer cells capable of metastasis secrete enzymes that break down the surrounding extracellular matrix, allowing them to
move through the degraded matrix and gain access to a blood vessel. Once in the circulation, the tumor cells are vulnerable to destruction by host immune cells. Some tumor cells gain protection from the antitumor host cells by aggregating and adhering to circulating blood components, particularly platelets, to form tumor emboli. Exit of the tumor cells from the circulation involves adhesion to the vascular endothelium followed by movement through the capillary wall into the site of secondary tumor formation by mechanisms similar to those involved in invasion.

Once in the distant site, the process of metastatic tumor development depends on the establishment of blood vessels and specific growth factors that promote proliferation of the tumor cells. Tumor cells as well as other cells in the microenvironment secrete factors that enable the development of new blood vessels within the tumor, a process termed angiogenesis (to be discussed).11–13 The presence of stimulatory or inhibitory growth factors correlates with the site-specific pattern of metastasis. For example, a potent growth-stimulating factor has been isolated from lung tissue, and stromal cells in bone have been shown to produce a factor that stimulates growth of prostatic cancer cells.

Recent evidence indicates that chemoattractant cytokines called chemokines that regulate the trafficking of leukocytes (white blood cells) and other cell types under a variety of inflammatory and noninflammatory conditions may play a critical role in cancer invasion and metastasis.14,15 Tumor cells have been shown to express functional chemokine receptors, which can sustain cancer cell proliferation, angiogenesis, and survival and promote organ-specific localization of metastasis. Insights into the presence and role of chemokines in cancer spread and metastasis provide directions for development of future diagnostic and treatment methods. The implications include methods to diminish metastasis by blocking the action of selected chemokines and/or their receptors.

SUMMARY CONCEPTS

- The term neoplasm refers to an abnormal mass of tissue in which the uncontrolled proliferation of cells exceeds and is uncoordinated with that of the normal tissues. Differentiation refers to the extent to which neoplastic cells resemble their normal counterparts.
- Neoplasms are commonly classified as being either benign or malignant. Benign neoplasms are well-differentiated tumors that resemble their tissues of origin, but have lost the ability to control cell proliferation. They grow by expansion, are enclosed in a fibrous capsule, and do not cause death unless their location is such that it interrupts vital body functions. Malignant neoplasms are less–well-differentiated tumors that have lost the ability to control both cell proliferation and differentiation. They grow in a disorganized and uncontrolled manner, invade surrounding tissues, have cells that break loose and travel to distant sites to form metastases, and inevitably cause suffering and death unless their growth can be controlled through treatment.
- Anaplasia is the loss of cell differentiation in cancerous tissue. Undifferentiated cancer cells are marked by a number of morphologic changes, referred to as pleomorphism. The characteristics of altered proliferation and differentiation are associated with a number of other changes including genetic instability, growth factor independence, loss of cell density–dependent inhibition, loss of cohesiveness, and anchorage dependence, faulty cell-to-cell communication, an indefinite cell life span (immortality), and expression of fetal antigens not produced by their normal adult counterparts, and abnormal production of hormones and substances that affect body function.
- The rate of growth of cancerous tissue depends on the ratio of dividing to resting cells (growth fraction) and the time it takes for the total mass of cells in the tumor to double (doubling time). A tumor is usually undetectable until it has doubled 30 times and contains more than a billion cells.
The spread of cancer occurs through three pathways: direct invasion and extension, seeding of cancer cells in body cavities, and metastatic spread through lymphatic or vascular pathways. Only a proportionately small clone of cancer cells is capable of metastasis. To metastasize, a cancer cell must be able to break loose from the primary tumor, invade the surrounding extracellular matrix, gain access to a blood vessel, survive its passage in the bloodstream, emerge from the bloodstream at a favorable location, and invade the surrounding tissue. Once in the distant tissue site, the metastatic process depends on the establishment of blood vessels and specific growth factors that promote proliferation of the tumor cells.

Etiology of Cancer

The cause or causes of cancer can be viewed from two perspectives: (1) the genetic and molecular mechanisms that characterize the transformation of normal cells into cancer cells and (2) the external and more contextual factors such as age, heredity, and environmental agents that contribute to its development and progression. Together, both mechanisms contribute to a multidimensional web of causation by which cancers develop and progress over time.

Genetic and Molecular Basis of Cancer

The pathogenesis of most cancers is thought to originate from genetic damage or mutation with resultant changes that transform a normally functioning cell into a cancer cell. Epigenetic factors that involve silencing of a gene or genes may also be involved. In recent years, the role of cancer stem cells in the pathogenesis of cancer has been identified. Finally, the cellular microenvironment that involves the extracellular matrix and a complex milieu of cytokines, growth factors, and other cell types is also recognized as an important contributor to cancer development and its growth and progression.

Cancer-Associated Genes

Most cancer-associated genes can be classified into two broad categories based on whether gene overactivity or underactivity increases the risk for cancer. The category associated with gene overactivity involves proto-oncogenes, which are normal genes that become cancer-causing genes if mutated. Proto-oncogenes encode for normal cell proteins such as growth factors, growth factor receptors, transcription factors that promote cell growth, cell cycle proteins (cyclins or cyclin-dependent proteins), and inhibitors of apoptosis. The category of cancer-associated underactivity genes includes the tumor-suppressor genes, which, by being less active, create an environment in which cancer is promoted.

Genetic Events Leading to Oncogene Formation or Activation. There are a number of genetic events that can cause or activate oncogenes. A common event is a point mutation in which there is a single nucleotide base change due to an insertion, deletion, or substitution. An example of an oncogene caused by point mutations is the ras oncogene, which has been found in many cancers. Members of the ras proto-oncogene family are important signal-relaying proteins that transmit growth signals to the cell nucleus. Hence, activation of the ras oncogene can increase cell proliferation.

Chromosomal translocations have traditionally been associated with cancers such as Burkitt lymphoma and chronic myeloid leukemia. In Burkitt lymphoma the c-myc gene, which encodes a growth signal protein, is translocated from its normal position on chromosome 8 to chromosome 14, placing it at the site of an immunoglobulin gene. The outcome of the translocation in chronic myeloid leukemia is the appearance of the so-called Philadelphia chromosome involving chromosomes 9 and 22 and the formation of an abnormal fusion protein that promotes cell proliferation (see Chapter 11, Fig. 11-6). Recent advances in biotechnology and genomics are enabling the identification and increased understanding of how gene translocations, even within the same chromosome, contribute to the development of cancer.

Another genetic event that is common in cancer is gene amplification. Multiple copies of certain genes may cause overexpression with higher than normal levels of proteins that increase cell proliferation. For example, the human epidermal growth factor receptor-2 (HER-2/neu) gene is amplified in up to 30% of breast cancers and indicates a tumor that is aggressive with a poor prognosis. One of the agents used in treatment of HER-2/neu overexpressing breast cancers is trastuzumab (Herceptin), a monoclonal antibody that selectively binds to HER-2, thereby inhibiting the proliferation of tumor cells that overexpress HER-2.

Genetic Events Leading to Loss of Tumor-Suppressor Gene Function. Normal cells have regulatory genetic mechanisms that protect them against activated or newly acquired oncogenes. These genes are called tumor-suppressor genes. When this type of gene is inactivated, a genetic signal that normally inhibits cell proliferation is removed, thereby causing unregulated growth to begin. Mutations in tumor-suppressor genes are generally recessive, in that cells tend to behave normally until there is homologous deletion, inactivation, or silencing of both the maternal and paternal genes.

Two of the best-known tumor-suppressor genes are the p53 and retinoblastoma (RB) genes. The p53 gene, named after the molecular weight of the protein it encodes, is the most common target for genetic alteration in...
human cancers. Mutations in the p53 gene can occur in virtually every type of cancer including lung, breast, and colon cancer—the three leading causes of cancer death. Sometimes called the “guardian of the genome,” the p53 gene acts as a molecular police officer that prevents the propagation of genetically damaged cells. Located on the short arm of chromosome 17, the p53 gene normally senses DNA damage and assists in DNA repair by causing arrest of the cell cycle in G1 and inducing DNA repair or initiating apoptosis in a cell that cannot be repaired. With homologous loss of p53 gene activity, DNA damage goes unrepaired and mutations occur in dividing cells leading to malignant transformations. The p53 gene also appears to initiate apoptosis in radiation- and chemotherapy-damaged tumor cells. Thus, tumors that retain normal p53 function are more likely to respond to such therapy than tumors that carry a defective p53 gene.

The RB gene was isolated in studies involving a malignant tumor of the eye known as retinoblastoma. The tumor occurs in a hereditary and sporadic form and becomes evident in early life. Approximately 60% of cases are sporadic, and the remaining 40% are hereditary, inherited as an autosomal dominant trait. Known as the “two hit” hypothesis of carcinogenesis, both normal alleles of the RB gene must be inactivated for the development of retinoblastoma (Fig. 7-6). In hereditary cases, one genetic change (“first hit”) is inherited from an affected parent and is therefore present in all somatic cells of the body, whereas the second mutation (“second hit”) occurs in one of the retinal cells (which already carries the first mutation). In sporadic (non-inherited) cases, both mutations (“hits”) occur within a single somatic cell, whose progeny then form the cancer.

The RB gene represents a model for other genes that act similarly. In persons carrying an inherited mutation, such as a mutated RB allele, all somatic cells are perfectly normal, except for the risk of developing cancer. That person is said to be heterozygous or carrying one mutated gene at the gene locus. Cancer develops when a person becomes homozygous with two defective genes for the mutant allele, a condition referred to as loss of heterozygosity. For example, loss of heterozygosity is known to occur in hereditary cancers, in which a mutated gene is inherited from a parent and other conditions (e.g., radiation exposure) are present that cause mutation of the companion gene, making an individual more susceptible to cancer.

**Epigenetic Mechanisms**

In addition to mechanisms that involve DNA and chromosomal structural changes, there are molecular and cellular mechanisms termed “epigenetic” mechanisms that involve changes in the patterns of gene expression without a change in the DNA. Epigenetic mechanisms may “silence” genes, such as tumor-suppressor genes, so that even if the gene is present, it is not expressed and a cancer-suppressing protein is not made. One such mechanism of epigenetic silencing is by methylation of the promoter region of the gene, a change that prevents transcription and causes gene inactivity. Genes silenced by hypermethylation can be inherited, and epigenetic silencing of genes can be considered a “first hit” in the “two hit” hypothesis described earlier.

MicroRNAs (miRNA) are small, noncoding, single-stranded ribonucleic acids (RNAs), about 22 nucleotides in length, which function at the post-transcriptional level as negative regulators of gene expression. miRNAs pair with messenger RNA (mRNA) containing a nucleotide sequence that complements the sequence of the microRNA, and through the action of the RNA-induced silencing, mediate post-transcriptional gene silencing. miRNAs have been shown to undergo changes in expression in cancer cells, and frequent amplifications and deletions of miRNA loci have been identified in a number of human cancers, including those of the lung, breast, colon, pancreas, and hematopoietic systems. They can participate in neoplastic transformation by increasing the expression of oncogenes or reducing the expression of tumor suppressor genes. For example, down-regulation or deletion of certain miRNAs in some leukemias and lymphomas results in increased expression of BCL2, an
anti-apoptotic protein that protects tumor cells from apoptosis.

**Molecular and Cellular Pathways**

Numerous molecular and cellular mechanisms with a myriad of associated pathways and genes are known or suspected to facilitate the development of cancer. These mechanisms include defects in DNA repair mechanisms, disorders in growth factor signaling pathways, evasion of apoptosis, development of sustained angiogenesis, and evasion of metastasis.

Mechanisms and genes that regulate repair of damaged DNA have been implicated in the process of oncogenesis (Fig. 7-7). The DNA repair genes affect cell proliferation and survival indirectly through their ability to repair nonlethal damage in other genes including proto-oncogenes, tumor-suppressor genes, and the genes that control apoptosis. These genes have been implicated as the principal targets of genetic damage occurring during the development of a cancer cell. Such genetic damage may be caused by the action of chemicals, radiation, or viruses, or it may be inherited in the germ line. Significantly, it appears that the acquisition of a single-gene mutation is not sufficient to transform normal cells into cancer cells.

Instead, cancerous transformation appears to require the activation of many independently mutated genes.

A relatively common pathway by which cancer cells gain autonomous growth is by mutations in genes that control signaling pathways between growth factor receptors on the cell membrane and their targets in the cell nucleus. Under normal conditions, cell proliferation involves the binding of a growth factor to its receptor on the cell membrane, activation of the growth factor receptor on the inner surface of the cell membrane, transfer of the signal across the cytosol to the nucleus via signal-transducing proteins that function as second messengers, induction and activation of regulatory factors that initiate DNA transcription, and entry of the cell into the cell cycle (Fig. 7-8). Many of the proteins involved in the signaling pathways that control the action of growth factors in cancer cells exert their effects through enzymes called kinases that phosphorylate proteins. In some types of cancer such as chronic myeloid leukemia, mutation in a proto-oncogene controlling tyrosine kinase activity occurs, causing unregulated cell growth and proliferation.
The accumulation of cancer cells may result not only from the activation of growth-promoting oncogenes or inactivation of tumor-suppressor genes, but also from genes that regulate cell death through apoptosis or programmed cell death. Faulty apoptotic mechanisms have an important role in cancer. The failure of cancer cells to undergo apoptosis in a normal manner may be due to a number of problems. There may be altered cell survival signaling, down-regulation of death receptors, stabilization of the mitochondria, or inactivation of proapoptotic proteins. Alterations in apoptotic and antiapoptotic pathways have been found in many cancers. One example is the high levels of the antiapoptotic protein BCL2 that occur secondary to a chromosomal translocation in certain B-cell lymphomas. The mitochondrial membrane is a key regulator of the balance between cell death and survival. Proteins in the BCL2 family reside in the inner mitochondrial membrane and are either proapoptotic or antiapoptotic. Since apoptosis is considered a normal cellular response to DNA damage, loss of normal apoptotic pathways may contribute to cancer by enabling DNA-damaged cells to survive.

Even with all the genetic abnormalities described earlier, tumors cannot enlarge unless angiogenesis occurs and supplies them with the blood vessels necessary for survival. Angiogenesis is required not only for continued tumor growth, but also for metastasis. The molecular basis for the angiogenic switch is unknown, but it appears to involve increased production of angiogenic factors or loss of angiogenic inhibitors. These factors may be produced directly by the tumor cells themselves or by inflammatory cells (e.g., macrophages) or other stromal cells associated with the tumors. In normal cells, the p53 gene can stimulate expression of antiangiogenic molecules and repress expression of proangiogenic molecules, such as vascular endothelial growth factor (VEGF). Thus, loss of p53 activity in cancer cells both promotes angiogenesis and removes an antiangiogenic switch. Because of the crucial role of angiogenic factors in tumor growth, much interest is focused on the development of antiangiogenesis therapy.

Finally, multiple genes and molecular and cellular pathways are known to be involved in tumor invasion and metastasis. Evidence suggests that genetic programs that are normally operative in stem cells during embryonic development may become operative in cancer stem cells, enabling them to detach, cross tissue boundaries, escape death by anoikis or apoptosis, and colonize new tissues. The MET proto-oncogene, which is expressed in cancer stem cells, is a key regulator of invasive growth. Recent findings suggest that adverse conditions such as tissue hypoxia, which are commonly present in cancerous tumors, trigger this invasive behavior by activating the MET tyrosine kinase receptor.

**Tumor Cell Transformation**

The process by which carcinogenic agents cause normal cells to become cancer cells is hypothesized to be a multistep mechanism that can be divided into three stages: initiation, promotion, and progression (Fig. 7-9). **Initiation** involves the exposure of cells to appropriate doses of a carcinogenic agent; promotion, the unregulated and accelerated growth of the mutated cells; and progression, the acquisition of malignant characteristics by the tumor cells.

![Figure 7-9](image-url)
Host and Environmental Factors

Because cancer is not a single disease, it is reasonable to assume that it does not have a single cause. More likely, cancers develop because of interactions among host and environmental factors. Among the host factors that have been linked to cancer are heredity, hormonal factors, obesity, and immunologic mechanisms. Environmental factors include chemical carcinogens, radiation, and microorganisms.

Heredity

The genetic predisposition for development of cancer has been documented for a number of cancerous and precancerous lesions that follow mendelian inheritance patterns. Two tumor suppressor genes, called BRCA1 (breast carcinoma 1) and BRCA2 (breast carcinoma 2), have been implicated in a genetic susceptibility to breast cancer. These genes have also been associated with an increased risk of ovarian, prostate, pancreatic, colon, and other cancers.

Several cancers exhibit an autosomal dominant inheritance pattern that greatly increases the risk of developing a tumor. The inherited mutation is usually a point mutation occurring in a single allele of a tumor-suppressor gene. Persons who inherit the mutant gene are born with one normal and one mutant copy of the gene. In order for cancer to develop, the normal allele must be inactivated, usually through a somatic mutation. As previously discussed, retinoblastoma is an example of a cancer that follows an autosomal dominant inheritance pattern. Approximately 40% of retinoblastomas are inherited, and carriers of the mutant RB suppressor gene have a 10,000-fold increased risk of developing retinoblastoma, usually with bilateral involvement. Familial adenomatous polyposis of the colon also follows an autosomal dominant inheritance pattern. In people who inherit this gene, hundreds of adenomatous polyps may develop, some of which inevitably become malignant.

Hormones

Hormones have received considerable research attention with respect to cancer of the breast, ovary, and endometrium in women and of the prostate and testis in men. Although the link between hormones and the development of cancer is unclear, it has been suggested that it may reside with the ability of hormones to drive the cell division of a malignant phenotype. Because of the evidence that endogenous hormones affect the risk of these cancers, concern exists regarding the effects on cancer risk if the same or closely related hormones are administered for therapeutic purposes.

Obesity

Obesity has been associated with insulin resistance and increased production of pancreatic insulin, both of which can have a carcinogenic effect. Insulin enhances insulin-like growth factor-1 (IGF-1) synthesis and its bioavailability. Both insulin and IGF-1 are anabolic molecules that can promote tumor development by stimulating cell proliferation and inhibiting apoptosis. Obesity has also been associated with increased levels of sex hormones (androgens and estrogens), which act to stimulate cell proliferation, inhibit apoptosis, and therefore increase the chance of malignant cell transformation, particularly of endometrial and breast tissue, and possibly of other organs (e.g., prostate and colon cancer). And lastly, obesity has been related to a condition of chronic inflammation characterized by abnormal production of inflammatory cytokines that can contribute to the development of malignancies.

Immunologic Mechanisms

There is substantial evidence for the participation of the immune system in resistance against the progression and spread of cancer. The central concept, known as the immune surveillance hypothesis, which was first proposed by Paul Ehrlich in 1909, postulates that the immune system plays a central role in protection against the development of tumors. In addition to cancer–host interactions as a mechanism of cancer development, immunologic mechanisms provide a means for the detection, classification, and prognostic evaluation of cancers and a potential method of treatment. Immunotherapy (discussed later in this chapter) is a cancer treatment modality designed to heighten the patient’s general immune responses so as to increase tumor destruction.

The immune surveillance hypothesis suggests that the development of cancer might be associated with impairment or decline in the surveillance capacity of the immune system. For example, increases in cancer incidence have been observed in people with immunodeficiency diseases and in those with organ transplants who are receiving immunosuppressant drugs. The incidence of cancer also is increased in the elderly, in whom there is a known decrease in immune activity. The association of Kaposi sarcoma with acquired immunodeficiency syndrome (AIDS) further emphasizes the role of the immune system in preventing malignant cell proliferation (discussed in Chapter 16).

It has been shown that most tumor cells have molecular configurations that can be specifically recognized by immune cells or antibodies. These configurations are therefore called tumor antigens. Some tumor antigens are found only on tumor cells, whereas others are found on both tumor cells and normal cells; however, quantitative and qualitative differences in the tumor antigens permit the immune system to distinguish tumor from normal cells. Virtually all of the components of the immune system have the potential for eradicating cancer cells, including T and B lymphocytes, natural killer (NK) cells, and macrophages (see Chapter 15). The T-cell response, which is responsible for direct killing of tumor cells and for activation of other components of the immune system, is
one of the most important host responses for controlling the growth of tumor cells. The finding of tumor-reactive antibodies in the serum of people with cancer supports the role of the B lymphocyte as a member of the immune surveillance team. Antibodies cause destruction of cancer cells through complement-mediated mechanisms or through antibody-dependent cellular cytotoxicity, in which the antibody binds the cancer cell to another effector cell, such as the NK cell, that does the actual killing of the cancer cell. NK cells do not require antigen recognition and can lyse a wide variety of target cells.

**Chemical Carcinogens**

A carcinogen is an agent capable of causing cancer. The role of environmental agents in causation of cancer was first noted in 1775 by Sir Percivall Pott, an English physician who related the high incidence of scrotal cancer in chimney sweeps to their exposure to coal soot.

Coal tar has since been found to contain potent polycyclic aromatic hydrocarbons. Since then, many chemicals have been suspected of being carcinogens. Some have been found to cause cancers in animals, and others are known to cause cancers in humans (Chart 7-1).

Chemical carcinogens can be divided into two groups: (1) direct-reacting agents, which do not require activation in the body to become carcinogenic, and (2) indirect-reacting agents, called *procarcinogens* or *initiators*, which become active only after metabolic conversion. Direct- and indirect-acting initiators form highly reactive species (such as free radicals) that bind with residues on DNA, RNA, or cellular proteins. They then prompt cell mutation or disrupt protein synthesis in a way that alters cell replication and interferes with cell regulatory controls. The carcinogenicity of some chemicals is augmented by agents called *promoters* that, by themselves, have little or no cancer-causing ability. It is believed that promoters, in the presence of these carcinogens, exert their effect by altering gene expression, increasing DNA synthesis, enhancing gene amplification (i.e., number of gene copies that are made), and altering intercellular communication.

Exposure to many carcinogens, such as those contained in cigarette smoke, is associated with a lifestyle risk for development of cancer. Cigarette smoke contains both procarcinogens and promoters. It is directly associated with lung and laryngeal cancer and has been linked with cancers of the mouth, nasal cavities, pharynx, esophagus, pancreas, liver, kidney, uterus, cervix, and bladder and myeloid leukemias. Not only is the smoker at risk, but others passively exposed to cigarette smoke are at risk. Chewing tobacco increases the risk of cancers of the oral cavity and esophagus.

Occupational exposure to industrial chemicals is another significant risk factor for cancer. These include polycyclic aromatic hydrocarbons, which are metabolized in the liver. For example, long-term exposure to vinyl chloride, the simple two-carbon molecule that is widely used in the plastics industry, increases the risk for hepatic angiosarcoma.

There is also strong evidence that certain elements in the diet contain chemicals that contribute to cancer risk. Most known dietary carcinogens occur either naturally in plants (e.g., *aflatoxins*) or are produced during food preparation. The polycyclic aromatic hydrocarbons are of particular interest because they are produced during several types of food preparation, including frying foods in animal fat that has been reused multiple times; grilling or charcoal-broiling meats; and smoking meats and fish. Nitrosamines, which are powerful carcinogens, are formed in foods that are smoked, salted, cured, or pickled using nitrates or nitrites as preservatives. Formation of these nitrosamines may be inhibited by the presence of antioxidants such as vitamin C found in fruits and vegetables. Cancer of the colon has been associated with a high dietary intake of fat and red meat and a low intake of dietary *fiber*. A high-fat diet is thought to be carcinogenic because it increases the flow of primary bile acids that are converted to secondary bile acids in the presence of anaerobic bacteria in the colon, producing carcinogens or promoters.

Heavy or regular alcohol consumption is associated with a variety of cancers. The first and most toxic metabolite of ethanol is acetaldehyde, a known carcinogen that interferes with DNA synthesis and repair and that causes point mutations in some cells. The carcinogenic effect of cigarette smoke can be enhanced...
by concomitant consumption of alcohol; persons who smoke and drink considerable amounts of alcohol are at increased risk for development of cancer of the oral cavity, larynx and esophagus.

The effects of carcinogenic agents usually are dose dependent—the larger the dose or the longer the duration of exposure, the greater the risk that cancer will develop. Some chemical carcinogens may act in concert with other carcinogenic influences, such as viruses or radiation, to induce neoplasia. There usually is a time delay ranging from 5 to 30 years from the time of chemical carcinogen exposure to the development of overt cancer. This is unfortunate because many people may have been exposed to the agent and its carcinogenic effects before the association was recognized.

**Radiation**

The effects of ionizing radiation in carcinogenesis have been well documented in atomic bomb survivors, in patients diagnostically exposed, and in industrial workers, scientists, and physicians who were exposed during employment. Malignant epitheliomas of the skin and leukemia were significantly elevated in these populations. Between 1950 and 1970, the death rate from leukemia alone in the most heavily exposed population groups of the atomic bomb survivors in Hiroshima and Nagasaki was 147 per 100,000 persons, 30 times the expected rate.

The type of cancer that developed depended on the dose of radiation, the sex of the person, and the age at which exposure occurred. The length of time between exposure and the onset of cancer is related to the age of the individual. For example, children exposed to ionizing radiation in utero have an increased risk for developing leukemias and childhood tumors, particularly 2 to 3 years after birth. Therapeutic irradiation to the head and neck can give rise to thyroid cancer years later. The carcinogenic effect of ionizing radiation is related to its mutagenic effects in terms of causing chromosomal breakage, translocations, and, less frequently, point mutations.

The association between sunlight and the development of skin cancer (see Chapter 46) has been reported for more than 100 years. Ultraviolet radiation emits relatively low-energy rays that do not deeply penetrate the skin. The evidence supporting the role of ultraviolet radiation in the cause of skin cancer includes skin cancer that develops primarily on the areas of skin more frequently exposed to sunlight (e.g., the head and neck, arms, hands, and legs), a higher incidence in light-complexioned individuals who lack the ultraviolet-filtering skin pigment melanin, and the fact that the intensity of ultraviolet exposure is directly related to the incidence of skin cancer, as evidenced by higher rates occurring in Australia and the American Southwest. There also are studies that suggest that intense, episodic exposure to sunlight, particularly during childhood, is more important in the development of melanoma than prolonged low-intensity exposure. As with other carcinogens, the effects of ultraviolet radiation usually are additive, and there usually is a long delay between the time of exposure and the time that cancer can be detected.

**Viral and Microbial Agents**

An oncogenic virus is one that can induce cancer. Many DNA and RNA viruses have proved to be oncogenic in animals. However, only four DNA viruses have been implicated in human cancers: the human papilloma virus (HPV), Epstein-Barr virus (EBV), hepatitis B virus (HBV), and human herpesvirus 8 (HHV-8) (discussed in Chapter 29). There are over 70 genetically different types of HPV. Some types (i.e., types 1, 2, 4, 7) have been shown to cause benign squamous papillomas (i.e., warts). By contrast, high-risk HPVs (e.g., types 16 and 18) are implicated in the pathogenesis of squamous cell carcinoma of the cervix and anogenital region. Thus, cervical cancer can be viewed as a sexually transmitted disease, caused by transmission of HPV. In addition, at least 20% of oropharyngeal cancers are associated with high-risk HPVs. A vaccine to protect against HPV types 6, 11, 16, and 18 is now available (see Chapter 40).

Epstein-Barr virus is a member of the herpesvirus family. It has been implicated in the pathogenesis of several human cancers, including Burkitt lymphoma, a tumor of B lymphocytes. In persons with normal immune function, the EBV-driven B-cell proliferation is readily controlled and the person becomes asymptomatic or experiences a self-limited episode of infectious mononucleosis (see Chapter 11). However, in regions of the world where Burkitt lymphoma is endemic, such as parts of East Africa, concurrent malaria or other infections cause impaired immune function, allowing sustained B-lymphocyte proliferation. Epstein-Barr virus is also associated with B-cell lymphomas in immunosuppressed individuals, such as those with AIDS or with drug-suppressed immune systems (e.g., individuals with transplanted organs).

There is strong epidemiologic evidence linking chronic HBV and hepatitis C virus (HCV) infection with hepatocellular carcinoma (discussed in Chapter 30). It has been estimated that 70% to 85% of hepatocellular cancers worldwide are due to infection with HBV or HCV. The precise mechanism by which these viruses induce hepatocellular cancer has not been fully determined. It seems probable that the oncogenic effects are multifactorial, with immunologically mediated chronic inflammation leading to persistent liver damage, regeneration, and genomic damage. The regeneration process is mediated by a vast array of growth factors, cytokines, chemokines, and bioactive substances produced by immune cells that promote cell survival, tissue remodeling, and angiogenesis.

Although a number of retroviruses (RNA viruses) cause cancer in animals, human T-cell leukemia virus-1
(HTLV-1) is the only known retrovirus to cause cancer in humans. Human T-cell leukemia virus-1 is associated with a form of T-cell leukemia that is endemic in certain parts of Japan and some areas of the Caribbean and Africa, and is found sporadically elsewhere, including the United States and Europe. Similar to the AIDS virus, HTLV-1 is attracted to the CD4+ T cells, and this subset of T cells is therefore the major target for malignant transformation. The virus requires transmission of infected T cells by way of sexual intercourse, infected blood, or breast milk.

**Clinical Manifestations**

There probably is not a single body function left unaffected by the presence of cancer. Even the presenting signs and symptoms may be localized or widespread.

**Local and Regional Manifestations**

Because tumor cells replace normally functioning parenchymal cells, the initial manifestations of cancer usually reflect the function of the primary site of involvement. For example, lung cancer initially produces impairment of respiratory function; as the tumor grows and metastasizes, other body structures become affected. Cancer has no regard for normal anatomic boundaries; as it grows, it invades and compresses adjacent structures. Abdominal cancer, for example, may compress the viscera and cause bowel obstruction. Growing tumors may also compress and erode blood vessels, causing ulceration and necrosis along with frank bleeding and sometimes hemorrhage.

The development of effusions (i.e., fluid) in the pleural, pericardial, or peritoneal spaces may be the presenting sign of some tumors. Direct involvement of the serous surface seems to be the most significant inciting factor, although many other mechanisms such as obstruction of lymphatic flow may play a role. Most persons with pleural effusions are symptomatic at presentation with chest pain, shortness of breath, and cough. More than any other malignant neoplasms, ovarian cancers are associated with the accumulation of fluid in the peritoneal cavity. Complaints of abdominal discomfort, swelling and a feeling of heaviness, and increase in abdominal girth, which reflect the presence of peritoneal effusions or ascites, are the most common presenting symptoms in ovarian cancer, occurring in up to 65% of women with the disease.

**Systemic Manifestations**

Cancer also produces systemic manifestations such as anemia, anorexia and cachexia, and fatigue and sleep disorders. Many of these manifestations are compounded by the side effects of methods used to treat the disease. In its late stages, cancer often causes pain (see Chapter 35). Pain is probably one of the most dreaded aspects of cancer, and pain management is one of the major treatment concerns for persons with incurable cancers. Although research has produced amazing insights into the causes and cures for cancer, only recently have efforts focused on the associated side effects of the disease.

**Anemia**

Anemia is common in persons with various types of cancers. It may be related to blood loss, iron deficiency, hemolysis, impaired red cell production, or treatment effects. For example, drugs used in treatment of cancer are cytotoxic and can decrease red blood cell production. Also, there are many mechanisms through which erythrocyte production can be impaired in persons with malignancies including nutritional deficiencies, bone marrow failure, a blunted erythropoietin response to hypoxia, and an iron deficiency. Inflammatory cytokines generated in response to tumors decrease erythropoietin synthesis, resulting in a decrease in erythrocyte production. Iron deficiency may
be due, in part, to a dysregulation of iron metabolism, leading to a functional iron deficiency.\(^\text{37}\)

Cancer-related anemia is associated with reduced treatment effectiveness, increased mortality, increased transfusion requirements, and reduced performance and quality of life. Hypoxia, a characteristic feature of advanced solid tumors, has been recognized as a critical factor in promoting tumor resistance to radiotherapy and some chemotherapeutic agents.

Cancer-related anemia is often treated with iron supplementation and recombinant human erythropoietin (rHuEPO, epoetin alfa).\(^\text{37}\) Since iron deficiency may result in failure to respond to erythropoietin, it has been suggested that iron parameters be measured before initiation of erythropoietin therapy. When treatment with supplemental iron is indicated, it has been suggested that it be given intravenously, since oral iron has been shown to be largely ineffective in persons with cancer.\(^\text{37}\)

### Anorexia and Cachexia

Many cancers are associated with weight loss and wasting of body fat and muscle tissue, accompanied by profound weakness, anorexia, and anemia. This wasting syndrome is often referred to as the cancer anorexia–cachexia syndrome.\(^\text{38–40}\) It is a common manifestation of most solid tumors with the exception of breast cancer. The condition is more common in children and elderly persons and becomes more pronounced as the disease progresses. Persons with cancer cachexia also respond less well to chemotherapy and are more prone to toxic side effects.

The cause of the cancer anorexia–cachexia syndrome is probably multifactorial, resulting from a persistent inflammatory response in conjunction with production of specific cytokines and catabolic factors by the tumor. Although anorexia, reduced food intake, and abnormalities of taste are common in people with cancer and often are accentuated by treatment methods, the extent of weight loss and protein wasting cannot be explained in terms of diminished food intake alone. There also is a disparity between the size of the tumor and the severity of cachexia, which supports the existence of other mediators in the development of cachexia. It has been demonstrated that tumor necrosis factor (TNF-\(\alpha\)) and other cytokines including interleukin-1 (IL-1) and IL-6 can produce the wasting syndrome in experimental animals.\(^\text{3}\) High serum levels of these cytokines have been observed in persons with cancer, and their levels appear to correlate with progress of the tumor. Tumor necrosis factor-\(\alpha\), secreted primarily by macrophages in response to tumor cell growth or gram-negative bacterial infections, was the first identified cytokine associated with cachexia and wasting. It causes anorexia by suppressing satiety centers in the hypothalamus and increasing the synthesis of lipoprotein lipase, an enzyme that facilitates the release of fatty acids from lipoproteins so that they can be used by tissues. IL-1 and IL-6 share many of the features of TNF-\(\alpha\) in terms of the ability to initiate cachexia.

### Fatigue and Sleep Disorders

Fatigue and sleep disturbances are two of the side effects most frequently experienced by persons with cancer.\(^\text{41–45}\)

Cancer-related fatigue is characterized by feelings of tiredness, weakness, and lack of energy and is distinct from the normal tiredness experienced by healthy individuals in that it is not relieved by rest or sleep. It occurs both as a consequence of the cancer itself and as a side effect of cancer treatment. Cancer-related fatigue may be an early symptom of malignant disease and has been reported by as many as 40\% of patients at the time of diagnosis.\(^\text{42}\) Furthermore, the symptom often remains for months or even years after treatment.

The cause of cancer-related fatigue is largely unknown but is probably multifactorial and involves the dysregulation of several interrelated physiologic, biochemical, and psychological systems. The basic mechanisms of fatigue have been broadly categorized into two components: peripheral and central. Peripheral fatigue, which has its origin in the neuromuscular junction and muscles, results from the inability of the peripheral neuromuscular apparatus to perform a task in response to central stimulation. Mechanisms implicated in peripheral fatigue include a lack of adenosine triphosphate (ATP) and the buildup of metabolic by-products such as lactic acid. Central fatigue arises in the central nervous system (CNS) and is often described as the difficulty in initiating or maintaining voluntary activities. One hypothesis proposed to explain cancer-related fatigue is that cancer and cancer treatments result in dysregulation of brain serotonin (5-HT) levels or function. There is also evidence that proinflammatory cytokines, such as TNF-\(\alpha\), can influence 5-HT metabolism.

### Paraneoplastic Syndromes

In addition to signs and symptoms at the sites of primary and metastatic disease, cancer can produce manifestations in sites that are not directly affected by the disease. Such manifestations are collectively referred to as paraneoplastic syndromes.\(^\text{46,47}\) Some of these manifestations are caused by the elaboration of hormones by cancer cells, and others result from the production of circulating factors that produce hematopoietic, neurologic, and dermatologic syndromes (Table 7-3). These syndromes are most commonly associated with lung, breast, and hematologic malignancies.\(^\text{2}\)

A variety of peptide hormones are produced by both benign and malignant tumors. Although not normally expressed, the biochemical pathways for the synthesis and release of peptide hormones are present in most cells.\(^\text{47}\) The three most common endocrine syndromes associated with cancer are the syndrome of inappropriate antidiuretic hormone (ADH) secretion (see Chapter 8), Cushing syndrome due to ectopic adrenocorticotropic hormone (ACTH) production (see Chapter 32), and hypercalcemia (see Chapter 8). Hypercalcemia also can be caused by osteolytic processes induced by cancer such as multiple myeloma or bony metastases from other cancers.

Some paraneoplastic syndromes are associated with the production of circulating mediators that produce...
hematologic complications. For example, a variety of cancers may produce procoagulation factors that contribute to an increased risk for venous thrombosis and nonbacterial thrombotic endocarditis. Sometimes, unexplained thrombotic events are the first indication of an undiagnosed malignancy. The precise relationship between coagulation disorders and cancer is still unknown. Several malignancies, such as mucin-producing adenocarcinomas, release thromboplastin and other substances that activate the clotting system.

The symptomatic paraneoplastic neurologic disorders are relatively rare with the exception of the Lambert-Eaton myasthenic syndrome, which affects about 3% of persons with small cell lung cancer, and myasthenia gravis, which affects about 15% of people with thymoma. The Lambert-Eaton syndrome, or reverse myasthenia gravis, is seen almost exclusively in small cell lung cancer. It produces muscle weakness in the limbs rather than the initial mouth and eye muscle weakness seen in myasthenia gravis. The origin of paraneoplastic neurologic disorders is thought to be immune mediated. The altered immune response is initiated by the production of onconeural antigens (e.g., antigens normally expressed in the nervous system) by the cancer cells. The immune system, in turn, recognizes the onconeural antigens as foreign and mounts an immune response. In many cases, the immune attack controls the growth of the cancer.

The paraneoplastic syndromes may be the earliest indication that a person has cancer, and should be regarded as such. They may also represent significant clinical problems, may be potentially lethal in persons with cancer, and may mimic metastatic disease and confound treatment. Diagnostic methods focus on both identifying the cause of the disorder and locating the malignancy responsible. Techniques for precise identification of minute amounts of polypeptides may allow for early diagnosis of curable malignancies in asymptomatic individuals. The treatment of paraneoplastic syndromes involves concurrent treatment of the underlying cancer and suppression of the mediator causing the syndrome.

### SUMMARY CONCEPTS

- There probably is no single body function left unaffected by the presence of cancer. Because tumor cells replace normally functioning parenchymal tissue, the initial manifestations of cancer usually reflect the primary site of involvement.
- Cancer compresses blood vessels, obstructs lymph flow, disrupts tissue integrity, invades serous cavities, and compresses visceral organs. It may result in development of effusions (i.e., fluid) in the pleural, pericardial, or peritoneal spaces.
- Systemic manifestations of cancer include anorexia and cachexia; fatigue and sleep disorders; and anemia.
- Cancer may also produce paraneoplastic syndromes that arise from the ability of neoplasms to elaborate hormones and other chemical mediators to produce endocrine, hematopoietic, neurologic, and dermatologic syndromes. Many of these manifestations are compounded by the side effects of methods used to treat the disease.
Screening, Diagnosis, and Treatment

Advances in the screening, diagnosis, and treatment of cancer have boosted 5-year survival rates to nearly 64%. When treatment cannot cure the disease, it may be used to slow its progression or provide palliative care.

Screening

Screening represents a secondary prevention measure for the early recognition of cancer in an otherwise asymptomatic population.\(^{50,51}\) Screening can be achieved through observation (e.g., skin, mouth, external genitalia), palpation (e.g., breast, thyroid, rectum and anus, prostate, lymph nodes), and laboratory tests and procedures (e.g., Papanicolaou [Pap] smear, colonoscopy, mammography). It requires a test that will specifically detect early cancers or premalignancies, is cost effective, and results in improved therapeutic outcomes. For most cancers, stage at presentation is related to curability, with the highest rates reported when the tumor is small and there is no evidence of metastasis. For some tumors, however, metastasis tends to occur early, even from a small primary tumor. Unfortunately, no reliable screening methods are currently available for many cancers.

Cancers for which current screening or early detection has led to improvement in outcomes include cancers of the breast (breast self-examination and mammography, discussed in Chapter 40), cervix (Pap smear, Chapter 40), colon and rectum (rectal examination, fecal occult blood test, and flexible sigmoidoscopy and colonoscopy, Chapter 29), prostate (prostate-specific antigen testing and transrectal ultrasonography, Chapter 39), and malignant melanoma (self-examination, Chapter 46). While not as clearly defined, it is recommended that screening for other types of cancers such as cancers of the thyroid, testicles, ovaries, lymph nodes, and oral cavity be done at the time of periodic health examinations.

Diagnostic Methods

The methods used in the diagnosis and staging of cancer are determined largely by the location and type of cancer suspected. They include blood tests for tumor markers, cytologic studies, tissue biopsy, and gene profiling techniques as well as medical imaging, which is discussed with specific cancers later in this text.

Tumor Markers

Tumor markers are antigens expressed on the surface of tumor cells or substances released from normal cells in response to the presence of tumor.\(^2\) Some substances, such as hormones and enzymes, that are normally produced by the involved tissue become overexpressed as a result of cancer. Tumor markers are used for screening, establishing prognosis, monitoring treatment, and detecting recurrent disease. Table 7-4 identifies some of the more commonly used tumor markers and summarizes their source and the cancers associated with them.

</table>
The serum markers that have proven most useful in clinical practice are the human chorionic gonadotropin (hCG), prostate-specific antigen (PSA), CA-125, α-fetoprotein (AFP), CD blood cell antigens, and carcinoembryonic antigen (CEA). The hCG is a hormone normally produced by the placenta. It is used as a marker for diagnosing, prescribing treatment, and following the disease course in persons with high-risk gestational trophoblastic tumors. Prostate-specific antigen (PSA) is used as a marker in prostate cancer, and CA-125 is used as a marker in ovarian cancer. Markers for leukemia and lymphomas are grouped by so-called clusters of differentiation (CD) antigens (see Chapter 15). The CD antigens help to distinguish among T and B lymphocytes, monocytes, granulocytes, and natural killer cells and immature variants of these cells.

Some cancers express fetal antigens that are normally present only during embryonal development and induced to reappear as a result of neoplasia. The two that have proved most useful as tumor markers are alpha fetoprotein (AFP) and CEA. α-fetoprotein is synthesized by the fetal liver, yolk sac, and gastrointestinal tract and is the major serum protein in the fetus. Elevated levels are encountered in people with primary liver cancers and have also been observed in some testicular, ovarian, pancreatic, and stomach cancers. Carcinoembryonic antigen normally is produced by embryonic tissue in the gut, pancreas, and liver and is elaborated by a number of different cancers, including colorectal carcinomas, pancreatic cancers, and gastric and breast tumors. As with most other tumor markers, elevated levels of AFP and CEA are found in other, noncancerous conditions, and elevated levels of both depend on tumor size so that neither is useful as an early test for cancer.

As diagnostic tools, tumor markers have limitations. Nearly all markers can be elevated in benign conditions, and most are not elevated in the early stages of malignancy. Furthermore, they are not in themselves specific enough to permit a diagnosis of a malignancy, but once a malignancy has been diagnosed and shown to be associated with elevated levels of a tumor marker, the marker can be used to assess progress of the disease. Extremely elevated levels of a tumor marker can indicate a poor prognosis or the need for more aggressive treatment. Perhaps the greatest value of tumor markers is in monitoring therapy in people with widespread cancer. The level of most cancer markers tends to decrease with successful treatment and increase with recurrence or spread of the tumor.

Cytologic, Histologic, and Gene-Profiling Methods

Cytologic and histologic studies are laboratory methods used to examine tissues and cells. Several sampling approaches are available including cytologic smears, tissue biopsies, and needle aspiration.

**Papanicolaou Smear.** The Pap smear is a cytologic method that consists of a microscopic examination of a properly prepared slide by a cytotecnologist or pathologist for the purpose of detecting the presence of abnormal cells. The usefulness of the Pap smear relies on the fact that cancer cells lack the cohesive properties and intercellular junctions that are characteristic of normal tissue; without these characteristics, cancer cells tend to exfoliate and become mixed with secretions surrounding the tumor growth. Although the Pap smear is widely used as a screening test for cervical cancer, it can be performed on other body secretions, including nipple drainage, pleural or peritoneal fluid, and gastric washings.

**Tissue Biopsy.** Tissue biopsy involves the removal of a tissue specimen for microscopic study. It is of critical importance in designing the treatment plan should cancer cells be found. Biopsies are obtained in a number of ways, including needle biopsy; endoscopic methods, such as bronchoscopy or cystoscopy, which involve the passage of an endoscope through an orifice and into the involved structure; and laparoscopic methods.

Fine needle aspiration involves withdrawing cells and attendant fluid with a small-bore needle. The method is most widely used for assessment of readily palpable lesions in sites such as the thyroid, breast, and lymph nodes. Modern imaging techniques have also enabled the method to be extended to deeper structures such as the pelvic lymph nodes and pancreas.

In some instances, a surgical incision is made from which biopsy specimens are obtained. Excisional biopsies are those in which the entire tumor is removed. The tumors usually are small, solid, palpable masses. If the tumor is too large to be completely removed, a wedge of tissue from the mass can be excised for examination. A quick frozen section may be done and examined by a pathologist to determine the nature of a mass lesion or evaluate the margins of an excised tumor to ascertain that the entire neoplasm has been removed.

**Immunohistochemistry.** Immunohistochemistry involves the use of monoclonal antibodies to facilitate the identification of cell products or surface markers. For example, certain anaplastic carcinomas, malignant lymphomas, melanomas, and sarcomas look very similar under the microscope, but must be accurately identified because their treatment and prognosis are quite different.

Immunohistochemistry can also be used to determine the site of origin of metastatic tumors. Many cancer patients present with metastasis. In cases in which the origin of the metastasis is obscure, immunohistological detection of tissue-specific or organ-specific antigens can often help to identify the tumor source. Immunohistochemistry can also be used to detect molecules that have prognostic or therapeutic significance. For example, detection of estrogen receptors on breast cancer cells is of prognostic and therapeutic significance because these tumors respond to antiestrogen therapy.

**Microarray Technology.** Microarray technology has the advantage of analyzing a large number of molecular changes in cancer cells to determine overall patterns of behavior that would not be available by conventional means. The technique uses “gene chips” that can perform
miniature assays to detect and quantify the expression of large numbers of genes at the same time. DNA arrays are now commercially available to assist in making clinical decisions regarding breast cancer treatment. In addition to identifying tumor types, microarrays have been used for predicting prognosis and response to therapy, examining tumor changes after therapy, and classifying hereditary tumors.

Staging and Grading of Tumors

The two basic methods for classifying cancers are grading according to the histologic or cellular characteristics of the tumor and staging according to the clinical spread of the disease. Both methods are used to determine the course of the disease and aid in selecting an appropriate treatment or management plan.

Grading of tumors involves the microscopic examination of cancer cells to determine their level of differentiation and the number of mitoses. The closer the tumor cells resemble comparable normal tissue cells, both morphologically and functionally, the lower the grade. Accordingly, on a scale ranging from grade I to IV, grade I neoplasms are well differentiated and grade IV are poorly differentiated and display marked anaplasia.

The clinical staging of cancers uses methods to determine the extent and spread of the disease. It is useful in determining the choice of treatment for individual patients, estimating prognosis, and comparing the results of different treatment regimens. The significant criteria used for staging that vary with different organs include the size of the primary tumor, its extent of local growth (whether within or outside the organ), lymph node involvement, and presence of distant metastasis. This assessment is based on clinical and radiographic examination (CT and MRI) and, in some cases, surgical exploration. Two methods of staging are currently in use: the TNM system (T for primary tumor, N for regional lymph node involvement, and M for metastasis), which was developed by the Union for International Cancer Control, and the American Joint Committee (AJC) system. In the TNM system, T1, T2, T3, and T4 describe tumor size, N0, N1, N2, and N3, lymph node involvement; and M0 or M1, the absence or presence of metastasis. In the AJC system, cancers are divided into stages 0 to IV incorporating the size of the primary lesions and the presence of nodal spread and distant metastasis.

Cancer Treatment

The goals of cancer treatment methods fall into three categories: curative, control, and palliative. The most common modalities are surgery, radiation, chemotherapy, hormonal therapy, and biotherapy. The treatment of cancer involves the use of a carefully planned program that combines the benefits of multiple treatment modalities and the expertise of an interdisciplinary team of specialists including medical, surgical, and radiation oncologists; clinical nurse specialists; nurse practitioners; pharmacists; and a variety of ancillary personnel.

Surgery

Surgery is used for diagnosis, staging of cancer, tumor removal, and palliation (i.e., relief of symptoms) when a cure cannot be achieved. The type of surgery to be used is determined by the extent of the disease, the location and structures involved, the tumor growth rate and invasiveness, the surgical risk to the patient, and the quality of life the patient will experience after the surgery. If the tumor is small and has well-defined margins, the entire tumor often can be removed. If, however, the tumor is large or involves vital tissues, surgical removal may be difficult if not impossible.

Radiation Therapy

Radiation can be used as the primary method of treatment, as preoperative or postoperative treatment, with chemotherapy, or along with chemotherapy and surgery. It can also be used as a palliative treatment to reduce symptoms in persons with advanced cancers. It is effective in reducing the pain associated with bone metastasis and, in some cases, improves mobility. Radiation also is used to treat several oncologic emergencies, such as spinal cord compression, bronchial obstruction, and hemorrhage.

Radiation therapy exerts its effects through ionizing radiation, which affects cells by direct ionization of molecules or, more commonly, by indirect ionization. Indirect ionization produced by x-rays or gamma rays causes cellular damage when these rays are absorbed into tissue and give up their energy by producing fast-moving electrons. These electrons interact with free or loosely bonded electrons of the absorber cells and subsequently produce free radicals that interact with critical cell components (see Chapter 2). It can immediately kill cells, delay or halt cell cycle progression, or, at dose levels commonly used in radiation therapy, cause damage to the cell nucleus, resulting in cell death after replication. Cell damage can be sublethal, in which case a single break in the strand can repair itself before the next radiation insult. Double-stranded breaks in DNA are generally believed to be the primary damage that leads to cell death. Cells with un repaired DNA damage may continue to function until they undergo cell mitosis, at which time the genetic damage causes cell death.

The therapeutic effects of radiation therapy derive from the fact that the rapidly proliferating and poorly differentiated cells of a cancerous tumor are more likely to be injured by radiation therapy than are the more slowly proliferating cells of normal tissue. To some extent, however, radiation is injurious to all rapidly proliferating cells, including those of the bone marrow and the mucosal lining of the gastrointestinal tract. This results in many of the common adverse effects of radiation therapy, including infection, bleeding, and anemia due to loss of blood cells, and nausea and vomiting due to loss of gastrointestinal tract cells. In addition to its lethal effects, radiation also produces sublethal injury. Recovery from sublethal doses of radiation occurs in the interval between the first dose of radiation and subsequent doses. This is why large total doses of radiation
can be tolerated when they are divided into multiple smaller, fractionated doses. Normal tissue is usually able to recover from radiation damage more readily than is cancerous tissue.

Therapeutic radiation can be delivered in one of three ways: external beam or teletherapy, with beams generated by a linear accelerator or cobalt-60 machine at a distance and aimed at the patient's tumor; brachytherapy, in which a sealed radioactive source is placed close to or directly in the tumor site; and systemic therapy, in which radioisotopes with a short half-life are given by mouth or injected into the tumor site.

**Chemotherapy**

Cancer chemotherapy has evolved as one of the major systemic treatment modalities. Unlike surgery and radiation, cancer chemotherapy is a systemic treatment that enables drugs to reach the site of the tumor as well as distant sites. Chemotherapeutic drugs may be used as the primary form of treatment, or they may be used as part of a multimodal treatment plan. Chemotherapy is the primary treatment for most hematologic and some solid tumors, including chorionic carcinoma, testicular cancer, acute and chronic leukemia, Burkitt lymphoma, Hodgkin disease, and multiple myeloma.

Most cancer drugs are more toxic to rapidly proliferating cells than to those incapable of replication or in phase G0 of the cell cycle. Because of their mechanism of action, they are more effective against tumors with a high growth fraction. By the time many cancers reach a size that is clinically detectable, the growth fraction has decreased considerably. In this case, reduction in tumor size through the use of surgical debulking procedures or radiation therapy often causes tumor cells residing in G0 to reenter the cell cycle. Thus, surgery or radiation therapy may be used to increase the effectiveness of chemotherapy, or chemotherapy may be given to patients with no overt evidence of residual disease after local treatment (e.g., surgical resection of a primary breast cancer).

For most chemotherapy drugs, the relationship between tumor cell survival and drug dose is exponential, with the number of cells surviving being proportional to drug dose, and the number of cells at risk for exposure being proportional to the destructive action of the drug. Exponential killing implies that a proportion or percentage of tumor cells is killed, rather than an absolute number (Fig. 7-10). This proportion is a constant percentage of the total number of cells. For this reason, multiple courses of treatment are needed if the tumor is to be eradicated.

A major problem in cancer chemotherapy is the development of cellular resistance. Acquired resistance develops in a number of drug-sensitive tumor types. Experimentally, drug resistance can be highly specific to a single agent and is usually based on genetic changes in a given tumor cell type. In other instances, a multidrug-resistant phenomenon affecting anticancer drugs with differing structures occurs. This type of resistance often involves the increased expression of transmembrane transporter genes involved in drug efflux.

Cancer chemotherapy drugs may be classified as either cell cycle specific or cell cycle nonspecific (see Understanding—The Cell Cycle, Chapter 4). Drugs are cell cycle specific if they exert their action during a specific phase of the cell cycle. For example, methotrexate, an antimetabolite, acts by interfering with DNA synthesis and thereby interrupts the S phase of the cell cycle. Cell cycle–nonspecific drugs exert their effects throughout all phases of the cell cycle. The alkylating agents, which are cell cycle nonspecific, act by disrupting DNA when cells are in the resting state as well as when they are dividing. The site of action of chemotherapeutic drugs varies. Chemotherapy drugs that have similar structures and effects on cell function usually are grouped together, and these drugs usually have similar side effect profiles. Because chemotherapy drugs differ in their mechanisms of action, cell cycle–specific and cell cycle–nonspecific agents are often combined to treat cancer.

Combination chemotherapy has been found to be more effective than treatment with a single drug. With this method, several drugs with different mechanisms of action, metabolic pathways, times of onset of action and recovery, side effects, and onset of side effects are
used. Drugs used in combinations are individually effective against the tumor and synergistic with each other. The maximum possible drug doses usually are used to ensure the maximum cell kill within the range of toxicity tolerated by the host for each drug. Routes of administration and dosage schedules are carefully designed to ensure optimal delivery of the active forms of the drugs to the tumor during the sensitive phase of the cell cycle.

**Chemotherapy Side Effects.** Unfortunately, chemotherapy drugs affect both cancer cells and the rapidly proliferating cells of normal tissue, producing undesirable side effects. Some side effects appear immediately or after a few days (acute), some within a few weeks (intermediate), and others months to years after chemotherapy administration (long term).

Most chemotherapeutic drugs suppress bone marrow function and formation of blood cells, leading to anemia, neutropenia, and thrombocytopenia. With neutropenia, there is risk for developing serious infections, whereas thrombocytopenia increases the risk for bleeding. The availability of hematopoietic growth factors (e.g., granulocyte colony-stimulating factor [G-CSF]; erythropoietin, which stimulates red blood production; and IL-11, which stimulates platelet production) has shortened the period of myelosuppression, thereby reducing the need for hospitalizations due to infection and decreasing the need for blood products.

Anorexia, nausea, and vomiting are common problems associated with cancer chemotherapy. The severity of the vomiting is related to the emetic potential of the particular drug. These symptoms can occur within minutes or hours of drug administration and are thought to be due to stimulation of the chemoreceptor trigger zone in the medulla that stimulates vomiting (see Chapter 28). The chemoreceptor trigger zone responds to the level of chemicals circulating in the blood. The acute symptoms usually subside within 24 to 48 hours and often can be relieved by antiemetic drugs. The pharmacologic approaches to prevent chemotherapy-induced nausea and vomiting have greatly improved over several decades. The development of serotonin (5-HT₃) receptor antagonists has facilitated the use of highly emetic chemotherapy drugs by more effectively reducing the nausea and vomiting induced by these drugs.

Alopecia or hair loss results from impaired proliferation of the hair follicles and is a side effect of a number of cancer drugs; it usually is temporary, and the hair tends to regrow when treatment is stopped. The rapidly proliferating structures of the reproductive system are particularly sensitive to the action of cancer drugs. Women may experience changes in menstrual flow or have amenorrhea. Men may have a decreased sperm count (i.e., oligospermia) or absence of sperm (i.e., azoospermia). Many chemotherapeutic agents also may have teratogenic or mutagenic effects leading to fetal abnormalities.

Chemotherapy drugs are toxic to all cells. Because they are potentially mutagenic, carcinogenic, and teratogenic, special care is required when handling or administering the drugs. Drugs, drug containers, and administration equipment require special disposal as hazardous waste.  

**Hormone and Antihormone Therapy**

Hormonal therapy consists of administration of drugs designed to deprive the cancer cells of the hormonal signals that otherwise would stimulate them to divide. It is used for cancers that are responsive to or dependent on hormones for growth and have specific hormone receptors. Among the tumors that are known to be responsive to hormonal manipulation are those of the breast, prostate, and endometrium. Other cancers, such as Kaposi sarcoma and renal, liver, ovarian, and pancreatic cancer, are also responsive to hormonal manipulation, but to a lesser degree.

The therapeutic options for altering the hormonal environment in the woman with breast cancer or the man with prostate cancer include surgical and pharmacologic measures. Surgery involves the removal of the organ responsible for the hormone production that is stimulating the target tissue (e.g., ovaries in women or testes in men). Pharmacologic methods focus largely on reducing circulating hormone levels or changing the hormone receptors so that they no longer respond to the hormone. Pharmacologic suppression of circulating hormone levels can be effected through pituitary desensitization, as with the administration of androgens, or through the administration of gonadotropin-releasing hormone (GnRH) analogs that act at the level of the hypothalamus to inhibit gonadotropin production and release. Another class of drugs, the aromatase inhibitors, is used to treat breast cancer; these drugs act by interrupting the biochemical processes that convert the adrenal androgen androstenedione to estrone.

Hormone receptor function can be altered by the administration of pharmacologic doses of exogenous hormones that act by producing a decrease in hormone receptors or by antihormone drugs (antiestrogens and antiandrogens) that bind to hormone receptors, making them inaccessible to hormone stimulation. Initially, patients often respond favorably to hormonal treatments, but eventually the cancer becomes resistant to hormonal manipulation, and other approaches must be sought to control the disease.

**Biotherapy**

Biotherapy involves the use of immunotherapy and biologic response modifiers as a means of changing a person’s immune response and modifying tumor cell biology. It involves the use of monoclonal antibodies, cytokines, and adjuvants.

**Monoclonal Antibodies.** Recent advances in the ability to manipulate the genes of immunoglobulins have resulted in the development of a wide array of monoclonal antibodies directed against tumor-specific antigens as well as signaling molecules. These include chimeric human-murine (mouse) antibodies with human constant region and murine-variable regions (see Chapter 15, Figure 15-10),
humanized antibodies in which the murine regions that bind antigen have been grafted into human immunoglobulin (Ig) G molecules, and entirely human antibodies derived from transgenic expressing immunoglobulin genes. Some monoclonal antibodies are directed to block major pathways central to tumor cell survival and proliferation, whereas others are modified to deliver toxins, radioisotopes, cytokines, or other cancer drugs.

Currently approved monoclonal antibodies include rituximab (Rituxan), a chimeric IgG monoclonal antibody that targets the CD20 antigen on B cells and is used in the treatment of nonHodgkin lymphoma; bevacizumab (Avastin), a humanized IgG monoclonal antibody that targets vascular endothelial growth factor (VEGF) to inhibit blood vessel growth (angiogenesis) and is approved for treatment of colorectal, lung, renal, and breast cancer; and cetuximab (Erbitux), a chimeric monoclonal antibody that targets the epidermal growth factor receptor (EGFR) to inhibit tumor cell growth and is approved for treatment of colorectal cancer and squamous cell cancer of the head and neck.

Cytokines. The biologic response modifiers include cytokines such as the interferons and interleukins. The interferons appear to inhibit viral replication and also may be involved in inhibiting tumor protein synthesis, prolonging the cell cycle, and increasing the percentage of cells in the G0 phase. Interferons stimulate NK cells and T-lymphocyte killer cells. There are three major types of interferons, alpha (α), beta (β), and gamma (γ), with members of each group differing in terms of their cell surface receptors. Interferon-γ has been approved for the treatment of hairy cell leukemia, AIDS-related Kaposi sarcoma, and chronic myelogenous leukemia, and as adjuvant therapy for patients at high risk for recurrent melanoma. Interferon-α has been used to treat some solid tumors (e.g., renal cell carcinoma, colorectal cancer, carcinoid tumors, ovarian cancer) and hematologic neoplasms (e.g., B-cell and T-cell lymphomas, cutaneous T-cell lymphoma, and multiple myeloma). Research now is focusing on combining interferons with other forms of cancer therapy and establishing optimal doses and treatment protocols.

The interleukins (ILs) are cytokines that provide communication between cells by binding to receptor sites on the cell surface membranes of the target cells. Of the 18 known interleukins (see Chapter 15), IL-2 has been the most widely studied. A recombinant human IL-2 (rIL-2, aldesleukin) has been approved by the U.S. Food and Drug Administration (FDA) and is currently being used for the treatment of metastatic renal cell carcinoma and metastatic melanoma.

Adjuvants. Adjuvants are substances such as Bacillus Calmette-Guérin (BCG) that nonspecifically stimulate or indirectly augment the immune system. Instillations of BCG, an attenuated strain of the bacterium that causes bovine tuberculosis, are used to treat noninvasive bladder cancer after surgical ablation. It is assumed that BCG acts locally to stimulate an immune response, thereby decreasing the relapse rate.

Targeted Therapy
Researchers have been working diligently to produce drugs that selectively attack malignant cells while leaving normal cells unharmed. The characteristics and capabilities of cancer cells have been used to establish a framework for the development of such targeted therapies, including those that disrupt molecular signaling pathways, inhibit angiogenesis, and harness the body’s immune system. The first targeted therapies were the monoclonal antibodies. Researchers are now working to design drugs that can disrupt molecular signaling pathways, such as those that use the protein tyrosine kinases. The protein tyrosine kinases are intrinsic components of the signaling pathways for growth factors involved in the proliferation of lymphocytes and other cell types. Imatinib mesylate is a protein tyrosine kinase inhibitor indicated in the treatment of chronic myeloid leukemia (see Chapter 11). Angiogenesis is also being explored as a target for targeted cancer therapy. One of the newer antiangiogenic agents, bevacizumab, targets and blocks VEGF, which is released by many cancers to stimulate proliferation of new blood vessels.

SUMMARY CONCEPTS
- The methods used in the detection and diagnosis of cancer vary with the type of cancer and its location. Because many cancers are curable if diagnosed early, health care practices designed to promote early detection, such as screening, are important.
- Diagnostic methods include laboratory tests for the presence of tumor markers, cytologic and histologic studies using cells or tissue specimens, and gene profiling methods, in addition to medical imaging.
- There are two basic methods of classifying tumors: grading according to the histologic or tissue characteristics, and clinical staging according to spread of the disease. The Tumor, Node, Metastasis (TNM) system for clinical staging of cancer uses tumor size, lymph node involvement, and presence of metastasis.
- Treatment of cancer can include surgery, radiation, or chemotherapy. Other therapies include hormonal, immunologic, and biologic therapies, as well as molecularly targeted agents that disrupt molecular signaling pathways, inhibit angiogenesis, and harness the body’s immune system. Treatment plans that use more than one type of therapy are providing cures for a number of cancers that a few decades ago had a poor prognosis, and are increasing the life expectancy in other types of cancer.
Childhood Cancers and Late Effects on Cancer Survivors

Despite progressively improved 5-year survival rates, from 56% in 1974 to 75% in 2000, cancer remains the leading cause of disease-related deaths among children between 1 to 14 years in the United States. Leukemia (discussed in Chapter 11) accounts for one-third of cases of cancer in children ages 1 to 14 years. Cancer of the brain and other parts of the nervous system are the second most common, followed by tissue sarcoma, neuroblastoma, renal cancer (Wilms tumor, discussed in Chapter 26), and non-Hodgkin and Hodgkin lymphoma (discussed in Chapter 11).

Incidence and Types of Childhood Cancers

The spectrum of cancers that affect children differs markedly from those that affect adults. Although most adult cancers are of epithelial cell origin (e.g., lung cancer, breast cancer, colorectal cancers), childhood cancers usually involve the hematopoietic system (leukemia), brain and other parts of the nervous system, soft tissues, kidneys (Wilms tumor), and bone.

The incidence of childhood cancers is greatest during the first years of life, decreases during middle childhood, and then increases during puberty and adolescence. During the first 2 years of life, embryonal tumors such as neuroblastoma, retinoblastoma, and Wilms tumor are among the most common types of tumors. Acute lymphocytic leukemia has a peak incidence in children 2 to 5 years of age. As children age, especially after they pass puberty, bone malignancies, lymphoma, gonadal germ cell tumors (testicular and ovarian carcinomas), and various carcinomas such as thyroid cancer and malignant melanoma increase in incidence.

A number of the tumors of infancy and early childhood are embryonal in origin, meaning that they exhibit features of organogenesis similar to that of embryonic development. Because of this characteristic, these tumors are frequently designated with the suffix “-blastoma” (e.g., nephroblastoma [Wilms tumor], retinoblastoma, neuroblastoma). Wilms tumor (discussed in Chapter 25) and neuroblastoma are particularly illustrative of this type of childhood tumor.

Biology of Childhood Cancers

As with adult cancers, there probably is no one cause of childhood cancer. Although a number of genetic conditions are associated with childhood cancer, such conditions are relatively rare, suggesting an interaction between genetic susceptibility and environmental exposures. The most notable heritable conditions that impart susceptibility to childhood cancer include Down syndrome (20- to 30-fold increased risk of acute lymphoblastic leukemia), neurofibromatosis (NF) type 1 (neurofibromas, optic gliomas, brain tumors), NF type 2 (acoustic neuroma, meningiomas), xeroderma pigmentosum (skin cancer), ataxia-telangiectasia (lymphoma, leukemia), and the Beckwith-Wiedemann syndrome (Wilms tumor).

While constituting only a small percentage of childhood cancers, the biology of a number of these tumors illustrates several important biologic aspects of neoplasms, such as the two-hit theory of recessive tumor-suppressor genes (e.g., RB gene mutation in retinoblastoma); defects in DNA repair; and the histologic similarities between embryonic organogenesis and oncogenesis. Syndromes associated with defects in DNA repair include xeroderma pigmentosum, in which there is increased risk of skin cancers due to defects in repair of DNA damaged by ultraviolet light. The development of childhood cancers has also been linked to genetic imprinting, which is characterized by selective inactivation of one of the two alleles of a certain gene (discussed in Chapter 5). The inactivation is determined by whether the gene is inherited from the mother or father. For example, normally the maternal allele for the insulin-like growth factor-2 (IGF-2) gene is inactivated (imprinted). The Beckwith-Wiedemann syndrome is an overgrowth syndrome characterized by organomegaly, macroglossia (enlargement of the tongue), hemihypertrophy (muscular or osseous hypertrophy of one side of the body or face), renal abnormalities, and enlarged adrenal cells. The syndrome, which reflects changes in the imprinting of IGF-2 genes located on chromosome 11, is also associated with increased risk of Wilms tumor, hepatoblastoma, rhabdomyosarcoma, and adrenal cortical carcinoma.

Diagnosis and Treatment

Because many childhood cancers are curable, early detection is imperative. In addition, there are several types of cancers for which less therapy is indicated than for more advanced disease. Therefore, early detection often minimizes the amount and duration of treatment required for cure.
Unfortunately, there are no early warning signs or screening tests for cancer in children.\textsuperscript{70,71} Prolonged fever, persistent lymphadenopathy, unexplained weight loss, growing masses (especially in association with weight loss), and abnormalities of central nervous system function should be viewed as warning signs of cancer in children. Because these signs and symptoms of cancer are often similar to those of common childhood diseases, they are frequently attributed to other causes.

Diagnosis of childhood cancers involves many of the same methods that are used in adults. Histologic examination is usually an essential part of the diagnostic procedure. Accurate disease staging is especially beneficial in childhood cancers, in which the potential benefits of treatment must be carefully weighed against potential long-term treatment effects.

The treatment of childhood cancers is complex and continuously evolving. It usually involves appropriate multidisciplinary and multimodal therapy, as well as the evaluation for recurrent disease and late effects of the disease and therapies used in its treatment. The treatment program should include specialized teams of health care providers.\textsuperscript{72}

Several modalities are frequently used in the treatment of childhood cancer, with chemotherapy being the most widely used, followed in order of use by surgery, radiotherapy, and biologic agent therapy. Chemotherapy is more widely used in treatment of children with cancer than in adults because children better tolerate the acute adverse effects, and in general, pediatric tumors are more responsive to chemotherapy than adult cancers.

Radiation therapy is generally used sparingly in children because they are more vulnerable to the late adverse effects. As with care of adults, adequate pain management is critical.

**Survivors of Childhood Cancers**

With improvement in treatment methods, the number of children who survive childhood cancer is continuing to increase.\textsuperscript{73–76} As a result of cancer treatment, almost 80% of children and adolescents with a diagnosis of cancer become long-term survivors.\textsuperscript{72} Unfortunately, radiation and chemotherapy may produce late sequelae, such as impaired growth, neurologic dysfunction, hormonal dysfunction, cardiomyopathy, pulmonary fibrosis, and risk for second malignancies (Table 7-5). There is a special risk of second cancers in children with the retinoblastoma gene. Thus, one of the growing challenges is providing appropriate health care to survivors of childhood and adolescent cancers.

Children reaching adulthood after cancer therapy may have reduced physical stature because of the therapy they received, particularly radiation, which retards the growth of normal tissues along with cancer tissue. The younger the age and the higher the radiation dose, the greater the deviation from normal growth.

There is concern about the effect that CNS radiation has on cognition and hormones that are controlled by the hypothalamic-pituitary axis. Children younger than 6 years of age at the time of radiation and those receiving

the highest radiation doses are most likely to have subsequent cognitive difficulties.\textsuperscript{73–75} Growth hormone deficiency in adults is associated with increased prevalence of dyslipidemia, insulin resistance, and cardiovascular mortality.\textsuperscript{77} Moderate doses of cranial radiation therapy (CRT) are also associated with obesity, particularly in female patients. For many years, whole-brain radiation or cranial irradiation was the primary method of preventing CNS relapse in children with acute lymphocytic leukemia. Because of cognitive dysfunction associated with CRT, other methods of CNS prophylaxis are now being used.

Delayed sexual maturation in both boys and girls can result from chemotherapy with alkylating agents or from irradiation of the gonads. Cranial irradiation may result in premature menarche in girls, with subsequent early closure of the epiphyses and a reduction in final growth achieved. Data related to fertility and health of the offspring of childhood cancer survivors is just becoming available.

Vital organs such as the heart and lungs may be affected by cancer treatment. Children who received anthracyclines (i.e., doxorubicin or daunorubicin) may be at risk for developing cardiomyopathy and congestive heart failure. Pulmonary irradiation may cause lung dysfunction and restrictive lung disease. Drugs such as bleomycin, methotrexate, and busulfan also can cause lung disease.

**SUMMARY CONCEPTS**

- Although most adult cancers are of epithelial cell origin, most childhood cancers involve the hematopoietic system, nervous system, or connective tissue.
- Heritable forms of cancer tend to have an earlier age of onset, a higher frequency of multifocal lesions in a single organ, and bilateral involvement of paired organs or multiple primary tumors.
- The early diagnosis of childhood cancers often is overlooked because the signs and symptoms mimic those of other childhood diseases.
- With improvement in treatment methods, the number of children who survive childhood cancer is continuing to increase. As these children approach adulthood, there is continued concern that the life-saving therapy they received during childhood may produce late effects, such as impaired growth, cognitive dysfunction, hormonal dysfunction, cardiomyopathy, pulmonary fibrosis, and risk for second malignancies.

**REVIEW EXERCISES**

1. A 30-year-old woman has experienced heavy menstrual bleeding and is told she has a uterine tumor called a leiomyoma. She is worried she has cancer.
   A. What is the difference between a leiomyoma and leiomyosarcoma?
   B. How would you go about explaining the difference to her?

2. Among the characteristics of cancer cells are the lack of cell differentiation, impaired cell–cell adhesion, and loss of anchorage dependence.
   A. Explain how each of these characteristics contributes to the usefulness of the Pap smear as a screening test for cervical cancer.

3. A 12-year-old boy is seen in the pediatric cancer clinic with osteosarcoma. His medical history reveals that his father had been successfully treated for retinoblastoma as an infant.
   A. Relate the genetics of the retinoblastoma (RB) gene and “two hit” hypothesis to the development of osteosarcoma in this boy.

4. A 48-year-old man presents at his health care clinic with complaints of leg weakness. He is a heavy smoker and has had a productive cough for years. Subsequent diagnostic tests reveal he has a small cell lung cancer with brain metastasis. His proposed plan of treatment includes chemotherapy and radiation therapy.
   A. What is the probable cause of the leg weakness and is it related to the lung cancer?
   B. Relate this man’s smoking history to the development of lung cancer.
   C. Explain the mechanism of cancer metastasis.
   D. Explain the mechanisms whereby chemotherapy and irradiation are able to destroy cancer cells while having less or no effect on normal cells.

5. A 17-year-old girl is seen by a guidance counselor at her high school because of problems in keeping up with assignments in her math and science courses. She tells the counselor that she had leukemia when she was 2 years old and was given radiation treatment to her brain. She confides that she has always had more trouble with learning than her classmates and thinks it might be due to the radiation. She also relates that she is shorter than her classmates and this has been bothering her.
   A. Explain the relationship between cranial radiation therapy and decreased cognitive function and short stature.
   B. What other neuroendocrine problems might this girl have as a result of the radiation treatment?
REFERENCES

Fluids and electrolytes are present in body cells, in the tissue spaces between the cells, and in the blood that fills the vascular compartment. Body fluids transport gases, nutrients, and wastes; help generate the electrical activity needed to power body functions; take part in the transforming of food into energy; and otherwise maintain the overall function of the body. Although fluid volume and composition remain relatively constant in the presence of a wide range of changes in intake and output, conditions such as environmental stresses and disease can impair intake, increase losses, and otherwise interfere with mechanisms that regulate their volume, composition, and distribution.

This chapter is divided into five sections: composition and compartmental distribution of body fluids; disorders of sodium and water balance; disorders of potassium balance; disorders of calcium, phosphorus, and magnesium balance; and disorders of acid–base balance.

Composition and Compartmental Distribution of Body Fluids

Body fluids are distributed between the intracellular and extracellular fluid compartments. The intracellular fluid (ICF) compartment, which consists of the

(continued on page 160)
fluid contained within all of the trillions of cells in the body, contains about two thirds of the body water in healthy adults. The remaining one third is in the extra-cellular fluid (ECF) compartment, which contains all the fluids outside the cells, including those in the interstitial or tissue spaces and the plasma in the blood vessels (Fig. 8-1).

The composition of the ECF and ICF are strikingly different. The ECF contains large amounts of sodium and chloride, moderate amounts of bicarbonate, but only small quantities of potassium, magnesium, calcium, and phosphate. In contrast, the ICF contains almost no calcium; small amounts of sodium, chloride, bicarbonate, and phosphate; moderate amounts of magnesium; and large amounts of potassium (Table 8-1). Although blood levels usually are representative of the total body levels of an electrolyte, this is not always the case, particularly with potassium, which is approximately 28 times more concentrated inside the cell than outside.

Movement of Body Fluids and Electrolytes Between Compartments

The lipid bilayer and transport proteins serve as the primary barriers to the movement of substances across the cell membrane that separates the ECF and ICF compartments (see Chapter 1, Fig. 1-11). Lipid-soluble substances (e.g., oxygen \([O_2]\) and carbon dioxide \([CO_2]\)), which dissolve in the lipid layer of the cell membrane, pass directly through the membrane. Many ions (e.g., sodium \([Na^+]\) and potassium \([K^+]\)) rely on transport proteins located in the cell membrane for movement across the membrane, accounting for the compartmental difference in their concentrations. Water crosses the cell membrane by osmosis using special transmembrane protein channels called aquaporins.

Dissociation of Electrolytes

Electrolytes are substances that dissociate in solution to form charged particles, or ions. For example, the sodium chloride (NaCl) molecule dissociates to form a positively charged Na\(^+\) and a negatively charged Cl\(^-\) ion. Particles that do not dissociate into ions such as glucose and urea are called nonelectrolytes. Positively charged ions are called cations because they are attracted to the cathode of a wet electric cell, and negatively charged ions are called anions because they are attracted to the anode. The ions found in body fluids carry one charge (i.e., monovalent ion) or two charges (i.e., divalent ion). Because of their attraction forces, positively charged cations are always accompanied by negatively charged anions. Thus, both the ICF and ECF contain equal amounts of anions and cations. Cations and anions may be exchanged for one another, providing they carry the same charge. For example, a positively charged hydrogen ion (H\(^+\)) may be exchanged for a positively charged K\(^+\), and a negatively charged bicarbonate ion (HCO\(_3\)^-) may be exchanged for a negatively charged chloride ion (Cl\(^-\)).

The concentration of electrolytes in the ICF and ECF can be expressed in several ways; for example, milligrams per deciliter (mg/dL), milliequivalents per liter (mEq/L), or millimoles per liter (mmol/L) (Box 8-1).
Osmosis and Tonicity

Despite the remarkable difference in the concentration of individual molecules in the ICF and ECF, the total concentration gradient is the same in both compartments because of the osmotic movement of water. Osmosis refers to the movement of water across a semipermeable membrane (i.e., one that is permeable to water but impermeable to most solutes). As with solute particles, water diffuses down its concentration gradient, moving from the side of the membrane with a greater concentration of water and lesser concentration of solute particles to the side with a lesser concentration of water and greater concentration of solute particles (Fig. 8-2). As water moves across the semipermeable membrane, it generates a pressure called the osmotic pressure. The magnitude of the osmotic pressure represents the hydrostatic pressure (measured in millimeters of mercury [mm Hg]) needed to oppose the movement of water across the membrane.

**Box 8-1** Measurement Units

Laboratory measurements of electrolytes in body fluids are expressed as a concentration or amount of solute in a given volume of fluid, such as milligrams per deciliter (mg/dL), milliequivalents per liter (mEq/L), or millimoles per liter (mmol/L).

The use of milligrams (mg) per deciliter expresses the weight of the solute in one tenth of a liter (dL). The concentration of electrolytes such as calcium, phosphate, and magnesium is often expressed in mg/dL.

The milliequivalent is used to express the charge equivalency for a given weight of an electrolyte: 1 mEq of sodium has the same number of charges as 1 mEq of chloride, regardless of molecular weight. The number of milliequivalents of an electrolyte in a liter of solution can be derived from the following equation:

\[
\text{mEq} = \frac{\text{mg} \times 10}{100 \times \text{valence}} \times \frac{1}{\text{atomic weight}}
\]

The Système Internationale (SI) units express electrolyte concentration in millimoles per liter (mmol/L). A millimole is one thousandth of a mole, or the molecular weight of a substance expressed in milligrams. The number of millimoles of an electrolyte in a liter of solution can be calculated using the following equation:

\[
\text{mmol/L} = \frac{\text{mEq/L}}{\text{valence}}
\]

**Figure 8-2.** Movement of water across a semipermeable membrane. Water moves from the side that has fewer nondiffusible particles to the side that has more. The osmotic pressure is equal to the hydrostatic pressure needed to oppose water movement across the membrane.
The osmotic activity that nondiffusible particles exert in pulling water from one side of the semipermeable membrane to the other is measured by a unit called an osmole. In the clinical setting, osmotic activity usually is expressed in milliosmoles (one thousandth of an osmole) per liter. Each nondiffusible particle, large or small, is equally effective in its ability to pull water through a semipermeable membrane. Thus, it is the number, rather than the size, of the nondiffusible particles that determines the osmotic activity of a solution.

The osmotic activity of a solution may be expressed in terms of either its osmolarity or osmolality. Osmolarity refers to the osmolar concentration in 1 L of solution (mOsm/L H₂O) and osmolality to the osmolar concentration in 1 kg of water (mOsm/kg H₂O). Osmolarity is often used when referring to fluids outside the body and osmolality for describing fluids inside the body. Because 1 L of water weighs 1 kg, the terms osmolarity and osmolality are often used interchangeably.

Serum osmolality, which is largely determined by Na⁺ and its attendant anions (Cl⁻ and HCO₃⁻), normally ranges between 275 and 295 mOsm/kg H₂O. Blood urea nitrogen (BUN) and glucose, which also are osmotically active, usually account for less than 5% of the total osmotic pressure in the ECF compartment. However, this can change, such as when blood glucose levels are elevated in persons with diabetes mellitus or when BUN levels change rapidly in persons with chronic kidney disease.

The term tonicity refers to the tension or effect that a solution with impermeable solutes exerts on cell size because of water movement across the cell membrane. Solutions to which body cells are exposed can be classified as isotonic, hypotonic, or hypertonic depending on whether they cause cells to swell or shrink (Fig. 8-3A). Cells placed in an isotonic solution, which has the same effective osmolality as the ICF, neither shrink nor swell. An example of an isotonic solution is 0.9% sodium chloride. When cells are placed in a hypotonic solution, which has a lower osmolality than the ICF, they swell as water moves into the cell (Fig. 8-3B). When they are placed in a hypertonic solution, which has a greater osmolality than the ICF, they shrink as water is pulled out of the cell (Fig. 8-3C).

**Compartmental Distribution of Body Fluids**

Body water, which constitutes about 60% of body weight in the adult, is distributed between the ICF and ECF compartments. The fluid in the ICF compartment constitutes approximately 40% of body weight, and that in the ECF approximately 20% of body weight. The fluid in the ECF compartment is further divided into two major subdivisions: the plasma compartment, which constitutes approximately 5% of body weight, and the interstitial compartment, which constitutes approximately 14% of body weight (Fig. 8-4). The fluid in the interstitial compartment acts as a transport vehicle for gases, nutrients, wastes, and other materials that move between the vascular compartment and body cells. The interstitial fluid compartment also provides a reservoir from which vascular volume can be maintained during periods of hemorrhage or loss of vascular volume. An interstitial gel, which is a sponge-like material supported by collagen fibers, fills the tissue spaces and aids in even distribution of interstitial fluid.

Normally, most of the fluid in the interstitium is in gel form. The interstitial gel, which has a firmer consistency than water, opposes the outflow of water from the capillaries, preventing the accumulation of free water in the interstitial spaces.

![FIGURE 8-3](image_url) Tonicity: Red cells undergo no change in size in isotonic solutions (A), they increase in size in hypotonic solutions (B) and decrease in size in hypertonic solutions (C).

![FIGURE 8-4](image_url) Approximate size of body compartments in a 70-kg adult.
A third, usually minor, subdivision of the ECF compartment is the transcellular compartment. It includes the cerebrospinal fluid and fluid contained in the various body spaces, such as the peritoneal, pleural, and pericardial cavities, and joint spaces. Normally, only about 1% of ECF is in the transcellular space. This amount can increase considerably in conditions such as ascites, in which large amounts of fluid are sequestered in the peritoneal cavity. When the transcellular fluid compartment becomes considerably enlarged, it is referred to as a third space, because this fluid is not readily available for exchange with the rest of the ECF.

Capillary/Interstitial Fluid Exchange

The transfer of water between the vascular and interstitial compartments occurs at the capillary level. There are four main forces that control the movement of water between the capillary and interstitial spaces: (1) the capillary filtration pressure, which pushes water out of the capillary into the interstitial spaces; (2) the capillary colloidal osmotic pressure, which pulls water back into the capillary; (3) the interstitial or tissue hydrostatic pressure, which opposes the movement of water out of the capillary; and (4) the interstitial colloidal osmotic pressure, which pulls water out of the capillary into the interstitial spaces. Normally, the combination of these four forces is such that only a small excess of fluid remains in the interstitial compartment. This excess fluid is removed from the interstitium by the lymphatic system and returned to the systemic circulation.

Capillary filtration refers to the movement of water through capillary pores because of hydrostatic pressure, rather than an osmotic force. The capillary filtration pressure (about 30 to 40 mm Hg at the arterial end, 10 to 15 mm Hg at the venous end, and 25 mm Hg in the middle) is the pressure pushing water out of the capillary into the interstitial spaces. It reflects the arterial and venous pressures, the precapillary (arterioles) and postcapillary (venules) resistances, and the force of gravity. A rise in arterial or venous pressure increases capillary pressures throughout the body, whereas the force of gravity increases the capillary pressure in the dependent or lower parts of the body. In a person who is standing absolutely still, the weight of blood in the vascular column causes an increase of 1 mm Hg pressure for every 13.6 mm of distance from the heart. Since this pressure results from the weight of water, it is called hydrostatic pressure. In the adult who is standing absolutely still, the pressure in the veins of the feet can reach 90 mm Hg.

The capillary colloidal osmotic or oncotic pressure (about 28 mm Hg) is the osmotic pressure generated by the plasma proteins that are too large to pass through the pores of the capillary wall. The term colloidal osmotic pressure differentiates this type of osmotic pressure from the osmotic pressure that develops at the cell membrane from the presence of electrolytes and nonelectrolytes.

Because plasma proteins do not normally penetrate the capillary pores and because their concentration is greater in the plasma than in the interstitial fluids, it is capillary colloidal osmotic pressure that pulls fluids back into the capillary.

The interstitial fluid pressure (about −3 mm Hg) and interstitial colloidal osmotic pressure (about 8 mm Hg) contribute to movement of water into and out of the interstitial spaces. The interstitial hydrostatic pressure, which is normally negative, contributes to the outward movement of water into the interstitial spaces. The interstitial colloidal osmotic pressure, which reflects the small amount of plasma proteins that normally escape into the interstitial spaces from the capillary, also pulls water out of the capillary into the tissue spaces.

The lymphatic system represents an accessory route whereby fluid from the interstitial spaces can return to the circulation. More importantly, the lymphatic system provides a means for removing plasma proteins and osmotically active particulate matter from the tissue spaces, neither of which can be reabsorbed into the capillaries.

Edema

Edema can be defined as palpable swelling produced by an increase in interstitial fluid volume. The physiologic mechanisms that contribute to edema formation include factors that: (1) increase the capillary filtration pressure, (2) decrease the capillary colloidal osmotic pressure, (3) increase capillary permeability, or (4) produce obstruction to lymph flow. The causes of edema are summarized in Chart 8-1.

(text continues on page 165)
Movement of fluid between the vascular compartment and the interstitial fluid compartment surrounding the body cells occurs at the capillary level. The direction and amount of fluid that flows across the capillary wall are determined by: (1) the hydrostatic pressure of the two compartments, (2) the colloidal osmotic pressures of the two compartments, and (3) the removal of excess fluid and osmotically active particles from the interstitial spaces by the lymphatic system.

1. **Hydrostatic Pressure.** The hydrostatic pressure is the pushing force exerted by a fluid. Inside the capillaries, the hydrostatic pressure is the same as the capillary filtration pressure, about 30 mm Hg at the arterial end and 10 mm Hg at the venous end. The interstitial fluid pressure is the force of fluid in the interstitial spaces pushing against the outside of the capillary wall. Evidence suggests that the interstitial pressure is slightly negative (−3 mm Hg), contributing to the outward movement of fluid from the capillary.

2. **Colloidal Osmotic Pressure.** The colloidal osmotic pressure is the pulling force created by the presence of evenly dispersed particles, such as the plasma proteins, that cannot pass through the pores of the capillary membrane. The capillary colloidal osmotic pressure is normally about 28 mm Hg throughout the length of the capillary bed. The interstitial colloidal osmotic pressure (about 8 mm Hg) represents the pulling pressure exerted by the small amounts of plasma proteins that leak through the pores of the capillary wall into the interstitial spaces. The capillary colloidal osmotic pressure, which is greater than both the hydrostatic pressure at the venous end of the capillary and the interstitial colloidal osmotic pressure, is largely responsible for the movement of fluid back into the capillary.

Lymphatic vessel

Lymph Drainage. The lymphatic system represents an accessory system by which fluid can be returned to the circulatory system. Normally the forces moving fluid out of the capillary into the interstitium are greater than those returning fluid to the capillary. Any excess fluids and osmotically active plasma proteins that may have leaked into the interstitium are picked up by vessels of the lymphatic system and returned to the circulation. Without the function of the lymphatic system, excessive amounts of fluid would accumulate in the interstitial spaces.

Increased Capillary Filtration Pressure. Edema due to increased capillary filtration pressure is usually the result of increased vascular volume. It is commonly seen in conditions such as congestive heart failure that produce fluid retention and venous congestion (see Chapter 20). Edema does not usually become evident until the interstitial volume has been increased by 2.5 to 3 L. Dependent edema describes an accumulation of fluid in the lower parts of the body. Because of the effects of gravity, edema that results from increased capillary pressure commonly causes dependent edema. For example, edema of the ankles and feet becomes more pronounced during prolonged periods of standing. Lower extremity edema due to an increase in venous pressure is a common complication of venous insufficiency resulting from thrombophlebitis (development of a blood clot in one of the deep leg veins).

Decreased Capillary Colloidal Osmotic Pressure. Plasma proteins exert the osmotic force needed to pull fluid back into the capillary from the tissue spaces. The plasma proteins constitute a mixture of albumin, globulins, and fibrinogen. Albumin, the smallest of the plasma proteins, has a molecular weight of 69,000; globulins have molecular weights of approximately 140,000; and fibrinogen has a molecular weight of 400,000. Because of its lower molecular weight, 1 g of albumin has approximately twice as many osmotically active molecules as 1 g of globulin and almost six times as many as 1 g of fibrinogen. Also, the concentration of albumin (approximately 4.5 g/dL) is greater than that of the globulins (2.5 g/dL) and fibrinogen (0.3 mg/dL). Therefore, albumin has the greatest effect on the colloidal osmotic pressure.

Edema caused by decreased capillary colloidal osmotic pressure usually is the result of inadequate production or excessive loss of plasma proteins, mainly albumin. The plasma proteins are synthesized in the liver. In persons with severe liver failure, the impaired synthesis of albumin results in a decrease in colloidal osmotic pressure. In starvation and malnutrition, edema develops because there is a lack of amino acids for plasma protein synthesis. The most common site of plasma protein loss is the kidney. In kidney diseases such as nephrotic syndrome, the glomerular capillaries become permeable to the plasma proteins, particularly albumin (see Chapter 25). When this occurs, large amounts of albumin are filtered out of the blood and lost in the urine. An excessive loss of plasma proteins also occurs when large areas of skin are injured or destroyed, such as occurs during the early stages of a burn.

Because the plasma proteins are evenly distributed throughout the body and are not affected by the force of gravity, edema that is caused by a decrease in capillary colloidal osmotic pressure tends to produce generalized edema involving the face as well as the legs and feet.

Increased Capillary Permeability. When the capillary pores become enlarged or the integrity of the capillary wall is damaged, capillary permeability is increased. When this occurs, plasma proteins and other osmotically active particles leak into the interstitial spaces, pulling fluid out of the capillary into the interstitium. Among the conditions that increase
capillary permeability are burn injury, inflammation, and immune responses.

Obstruction of Lymphatic Flow. Osmotically active plasma proteins and other large particles that cannot be reabsorbed through the pores in the capillary membrane rely on the lymphatic system for movement back into the circulatory system. Edema due to impaired lymph flow is commonly referred to as lymphedema. Malignant involvement of lymph structures and removal of lymph nodes during cancer surgery are common causes of lymphedema. Another cause of lymphedema is infection and trauma involving the lymphatic channels and lymph nodes.

Manifestations. The effects of edema are determined largely by its location. Edema of the brain, larynx, and lungs are acute, life-threatening conditions. Non–life-threatening edema may interfere with movement, limiting joint motion. Swelling of the ankles and feet often is insidious in onset and may or may not be associated with disease. At the tissue level, edema increases the distance for diffusion of oxygen, nutrients, and wastes. Thus, edematous tissues usually are more susceptible to injury and development of ischemic tissue damage, including pressure ulcers. Edema can also compress blood vessels. For example, the skin of a severely swollen finger can act as a tourniquet, shutting off the blood flow. Edema can also be disfiguring, causing psychological effects and disturbances in self-concept, as well as making it difficult to obtain proper-fitting clothing and shoes.

Pitting edema occurs when the accumulation of interstitial fluid exceeds the absorptive capacity of the tissue gel. In this form of edema, the tissue water becomes mobile and can be translocated with pressure exerted by a finger. Nonpitting edema in which the swollen area becomes firm and discolored, occurs when plasma proteins have accumulated in the tissue spaces and coagulated. It is most commonly seen in areas of localized infection or trauma.

Assessment and Treatment. Methods for assessing edema include daily weight (1 L of water weighs 2.2 pounds), visual assessment, measurement of the affected part, and application of finger pressure to assess for pitting edema. Daily weight measurements taken at the same time each day with the same amount of clothing would provide a useful index of water gain due to edema. Visual inspection and measurement of the circumference of an extremity can also be used to assess the degree of swelling. This is particularly useful when swelling is due to thrombophlebitis. Finger pressure can be used to assess the degree of pitting edema. If an indentation remains after the finger has been removed, pitting edema is identified. It is evaluated on a scale of +1 (minimal) to +4 (severe) (Fig. 8-5).

Distinguishing lymphedema from other forms of edema can be challenging, especially early in its course. Papillomatosis, a characteristic honeycomb appearance of the skin due to dilated lymph vessels that are enveloped in fibrotic tissue, distinguishes lymphedema from other forms of edema. Computed tomography (CT) or magnetic resonance imaging (MRI) may be used to confirm the diagnosis.

Treatment of edema usually is directed toward maintaining life when the swelling involves vital structures, correcting or controlling the cause, and preventing tissue injury. Edema of the lower extremities may respond to simple measures such as elevating the feet. Diuretic therapy commonly is used to treat edema associated with an increase in ECF volume. Serum albumin levels can be measured, and albumin administered intravenously to raise the plasma colloidal osmotic pressure when edema is caused by hypoalbuminemia.

Elastic support stockings and sleeves increase interstitial fluid pressure and resistance to outward movement of fluid from the capillary into the tissue spaces. These support devices typically are prescribed for patients with conditions such as venous or lymphatic obstruction and are most efficient if applied before the tissue spaces have filled with fluid—for example, in the morning before the effects of gravity have caused fluid to move into the ankles. Moderate to severe lymphedema is usually treated with light-pressure massage designed to increase lymph flow by encouraging opening and closing of lymph vessel valves; compression garments or pneumatic compression pumps; range-of-motion exercises; and scrupulous skin care to prevent infection.

Third-Space Accumulation

Third spacing represents the loss or movement and trapping of ECF in a transcompartmental space. The serous cavities, which are part of the transcompartmental compartment (i.e., third space) located in strategic body areas where there is continual movement of body structures—the pericardial sac, the peritoneal cavity, and the pleural cavity. The serous cavities, which are closely linked with
lymphatic drainage systems, use the same mechanisms for interstitial fluid exchange as other areas of the body. The milking action of the moving structures, such as the lungs, continually forces fluid and plasma proteins back into lymphatic channels, helping to keep these cavities empty. Thus any obstruction of lymph flow causes fluid to accumulate in the serous cavities. Although the accumulation of third-space fluids produces a gain in body weight, it does not contribute to the body's fluid reserve or function.

The prefix hydro- may be used to indicate the presence of excessive fluid in one of the serous cavities, with hydrothorax referring to fluid in the pleural cavity. An accumulation of fluid in the peritoneal cavity as ascites and the transudation of fluid into the serous cavities is referred to as effusion. Effusion can contain blood, plasma proteins, inflammatory cells (i.e., pus), and extracellular fluid.

### SUMMARY CONCEPTS

- **Body Fluids**, which contain water and electrolytes, are distributed between the intracellular fluid (ICF) and extracellular fluid (ECF) compartments of the body, with two thirds being contained in the ICF and one third in the ECF.

- The cell membrane serves as a selective barrier to the movement of substances between the ICF and ECF. Lipid-soluble substances (e.g., oxygen \( \text{O}_2 \) and carbon dioxide \( \text{CO}_2 \)), which dissolve in the lipid layer of the cell membrane, pass directly through the membrane. Electrolytes, such as sodium \( [\text{Na}^+] \) and potassium \( [\text{K}^-] \), rely on transport proteins located in the cell membrane for movement across the membrane, accounting for the compartmental difference in their concentrations.

- Water moves across a semipermeable membrane by osmosis moving from the side with the greater concentration of water and lesser concentration of solute particles to the side having the lesser water concentration and greater solute concentration. Osmolarity refers to the osmotic activity that nondiffusible particles exert in pulling water from one side of a semipermeable membrane to the other and to the tension or effect that the osmotic pressure of a solution that has an osmolality greater than the ICF and shrinks when placed in a hypertonic solution that has an osmolality greater than the ICF.

- Edema represents the accumulation of fluid volume in the interstitial spaces of the ECF resulting from: (1) an increase in capillary filtration pressure, (2) a decrease capillary colloid osmotic pressure, (3) an increase in capillary permeability, or (4) obstructed lymphatic flow. The effect that edema exerts on body function is determined by its location, with edema of the brain, larynx, or lungs representing an acute life-threatening situation.

- Third spacing represents the loss or trapping of ECF in the transcellular space, such as in the pericardial sac, the peritoneal cavity, or the pleural cavity.

### Water and Sodium Balance

The distribution of body fluids between the ICF and ECF compartments relies on the concentration of ECF water and sodium. Water provides approximately 90% to 93% of the volume of body fluids and sodium salts approximately 90% to 95% of ECF solutes. Normally, equivalent changes in sodium and water are such that the volume and osmolality of ECF are maintained within a normal range. Positive water balance (intake greater than output) results in a decrease in body fluid osmolality and ECF sodium concentration due to diluting effects of the excess water. Likewise, a negative water balance (intake less than output) results in an increase in body fluid osmolality and ECF sodium concentration.

### Regulation of Water Balance

Total body water (TBW) accounts for a large percentage of body weight. In young men, TBW accounts for approximately 60% of body weight and decreases to approximately 52% in elderly men. Because women usually have less lean muscle mass than men, TBW accounts for only about 50% of body weight in young women and decreases to approximately 46% in elderly women. Obesity decreases TBW, with levels sometimes as low as 30% to 40% of body weight in adults.

Infants normally have more TBW than older children or adults. Total body water constitutes approximately 75% to 80% of body weight in full-term infants and an even greater percentage in premature infants. In addition to having a greater percentage of body water than adults, infants have more than half of their TBW in their ECF compartment, as compared...
to adults who have only about a third in their ECF compartment. The greater ECF water content of an infant can be explained in terms of a higher metabolic rate, larger surface area in relation to its body mass, and inability to concentrate urine because of immature kidney structures. Because ECF is more readily lost from the body, infants are more vulnerable to fluid deficit than are older children and adults. As an infant grows older, TBW decreases, and by the second year of life, the percentages and distribution of body water approach those of an adult.

The main source of water gain is through oral intake and metabolic processes. Oral intake, including that obtained from liquids and solid foods, is absorbed from the gastrointestinal tract. The amount of water gained from metabolic processes is much less than from oral intake, varying from 150 to 300 mL/day, depending on the metabolic rate.

Normally, the largest loss of water occurs through the kidneys, with lesser amounts being lost through the skin, lungs, and gastrointestinal tract. Even when oral or parenteral fluids are withheld, the kidneys continue to produce urine as a means of ridding the body of metabolic wastes. The urine output that is required to eliminate these wastes is called the obligatory urine output. Water losses that occur through evaporative losses from skin and to moisten the air in the respiratory system are referred to as insensible water losses because they occur without a person’s awareness. The amount of water lost from the skin through sweating varies depending on physical activity and environmental temperature. The sources of body water gains and losses are summarized in Table 8-2.

### Regulation of Sodium Balance

Sodium is the most plentiful electrolyte in the ECF compartment, with a concentration ranging from 135 to 145 mEq/L (135 to 145 mmol/L). Sodium does not readily cross the cell membrane; as a result, only a small amount (10 to 15 mEq/L [10 to 15 mmol/L]) is located in the ICF compartment. As the major cation in the ECF compartment, Na⁺ and its attendant Cl⁻ and HCO₃⁻ anions account for approximately 90% to 95% of the osmotic activity in the ECF. Thus, serum osmolality usually varies with changes in serum sodium concentration.

Sodium normally enters the body through the gastrointestinal tract, being derived from dietary sources. Although body needs for sodium usually can be met by as little as 500 mg/day, dietary intake frequently exceeds that amount. As package labels indicate, many commercially prepared foods and soft drinks contain considerable amounts of sodium.

Most sodium losses occur through the kidney. The kidneys are extremely efficient in regulating sodium output. When sodium intake is limited or conservation of sodium is needed, the kidneys are able to reabsorb almost all the Na⁺ that has been filtered in the glomerulus, resulting in essentially sodium-free urine.

Usually, less than 10% of sodium intake is lost through the gastrointestinal tract and skin. Sodium losses increase with conditions such as vomiting, diarrhea, and gastrointestinal suction, all of which can remove sodium from the stomach or small intestine. Sodium leaves the skin by way of the sweat glands, which secrete a hypotonic solution containing both sodium and chloride. Although sodium losses due to sweating are usually negligible, they can increase greatly during heavy exercise and periods of exposure to a hot environment.

### Mechanisms of Water and Sodium Regulation

There are two major physiologic mechanisms for regulating body levels of water: thirst, which is primarily a regulator of water intake, and the antidiuretic hormone (ADH), which controls the output of water by the kidney. Thirst and ADH function in the maintenance of
the effective circulating volume, which can be described as that portion of the ECF that fills the vascular compartment and is “effectively” perfusing the tissues. The effective circulating volume is monitored by sensors that are located both in the vascular system and the kidney.

While thirst and ADH are the main regulators of water intake and output, the sympathetic nervous system and the renin-angiotensin-aldosterone system function in the regulation of sodium balance by the kidneys (see Chapter 18). The sympathetic nervous system responds to changes in arterial pressure and blood volume by adjusting the glomerular filtration rate and the rate at which sodium is filtered from the blood. Sympathetic activity also regulates renal reabsorption of sodium and renin release. The renin-angiotensin-aldosterone system exerts its action through angiotensin II and aldosterone. Angiotensin II acts directly on the renal tubules to increase sodium reabsorption. It also acts to constrict renal blood vessels, thereby decreasing the glomerular filtration rate and slowing renal blood flow so that less sodium is filtered and more is reabsorbed. Angiotensin II is also a powerful regulator of aldosterone, a hormone secreted by the adrenal cortex. Aldosterone acts to increase sodium reabsorption by the kidneys, while increasing potassium elimination.

**Thirst and Disorders of Thirst**

Like appetite and eating, thirst and drinking are two separate entities. Thirst is the conscious sensation of the need to obtain and drink fluids high in water content. Drinking water or other fluids often occurs as the result of habit or for reasons other than those related to thirst. Most people drink without being thirsty, and water is consumed before it is needed. As a result, thirst is basically an emergency response. It usually occurs only when the need for water has not been anticipated.

Thirst is controlled by the thirst center in the hypothalamus. There are two stimuli for true thirst based on water need: (1) cellular dehydration caused by an increase in ECF osmolality, and (2) a decrease in the effective circulating volume, which may or may not be associated with a decrease in serum osmolality. Sensory neurons, called osmoreceptors, which are located in or near the thirst center in the hypothalamus, respond to changes in ECF osmolality by swelling or shrinking (Fig. 8-7). Thirst normally develops when there is as little as a 1% to 2% change in serum osmolality. Stretch receptors in the vascular system that monitor the effective circulating volume also aid in the regulation of thirst. Thus, thirst is one of the earliest symptoms of hemorrhage and is often present before other signs of blood loss appear.

A third stimulus, the production of angiotensin II by the renin-angiotensin mechanism in the kidney, functions in the production of nonosmotic thirst. Angiotensin II increases in response to low blood volume and low blood pressure. This system is considered a backup system for thirst should other systems fail. Because it is a backup system, it probably does not contribute to the regulation of normal thirst. However, elevated levels of angiotensin II may lead to thirst in conditions such as congestive heart failure and chronic kidney disease, in which a decrease in renal blood flow leads to increased renin levels.

**Hypodipsia.** Hypodipsia represents a decrease in the ability to sense thirst. Water deficit is commonly associated with lesions in the area of the hypothalamus (e.g., head trauma, meningiomas, occult hydrocephalus, subarachnoid hemorrhage). There is also evidence that thirst is decreased and water intake reduced in elderly persons, despite higher...
serum sodium and osmolality levels. The inability to perceive and respond to thirst is compounded in elderly persons who have had a stroke and may be further influenced by confusion, sensory deficits, and motor disturbances.

**Polydipsia.** Polydipsia, or excessive thirst, is normal when it accompanies conditions of water deficit, but abnormal when it results in excess water intake. Increased thirst and drinking behavior can be classified into two categories: (1) inappropriate or false thirst that occurs despite normal levels of body water and serum osmolality, and (2) compulsive water drinking. *Inappropriate or excessive thirst* may persist despite adequate hydration. It is a common complaint in persons with congestive heart failure and chronic kidney disease. Although the cause of thirst in these people is unclear, it may result from increased angiotensin II levels. Thirst is also a common complaint in those with dry mouth caused by decreased salivary function or treatment with drugs with an anticholinergic action (e.g., antihistamines, atropine) that lead to decreased salivary flow.

*Psychogenic polydipsia* involves compulsive water drinking and is usually seen in persons with psychiatric disorders, most commonly schizophrenia. Persons with the disorder drink large amounts of water and excrete large amounts of urine. The cause of excessive water drinking in these persons is uncertain. It has been suggested that it may share the same pathology as the psychosis because persons with the disorder often increase their water drinking during periods of exacerbation of their psychotic symptoms. The condition may be compounded by antipsychotic medications that increase ADH levels and interfere with water excretion by the kidneys. Cigarette smoking, which is common among persons with psychiatric disorders, also stimulates ADH secretion. Excessive water ingestion coupled with impaired water excretion (or rapid ingestion at a rate that exceeds renal excretion) in persons with psychogenic polydipsia can lead to water intoxication (see section on hyponatremia). Treatment usually consists of water restriction and behavioral measures aimed at decreasing water consumption. Measurements of body weight can be used to provide an estimate of water consumption.

**Antidiuretic Hormone and Disorders of Antidiuretic Hormone**

The antidiuretic hormone, also known as vasopressin, controls the reabsorption of water by the kidneys. Antidiuretic hormone is a small peptide, nine amino acids in length, that is synthesized by cells in the supraoptic and paraventricular nuclei of the hypothalamus and then transported along a neural pathway (i.e., hypothalamic-hypophyseal tract) to the posterior pituitary gland, where it is stored. When the supraoptic and paraventricular nuclei in the hypothalamus are stimulated by increased serum osmolality or other factors, nerve impulses travel down the hypothalamic-hypophyseal tract to the posterior pituitary gland, causing the stored ADH to be released into the circulation (see Fig. 8-7).

As with thirst, ADH levels are controlled by ECF volume and osmolality. Osmoreceptors in the hypothalamus sense changes in ECF osmolality and stimulate the production and release of ADH (see Fig. 8-7). A small increase in serum osmolality of 1% is sufficient to cause ADH release. Stretch receptors that are sensitive to changes in blood pressure and the effective circulating volume also contribute to the regulation of ADH release (i.e., nonosmotic ADH secretion). A blood volume decrease of 5% to 10% produces a maximal increase in ADH levels. As with many other homeostatic mechanisms, acute conditions produce greater changes in ADH levels than do chronic conditions.

Antidiuretic hormone exerts its effects through vasopressin receptors located in the collecting tubules of the kidney. In the presence of ADH, highly permeable water channels called aquaporins are inserted into the tubular membrane. The increased water permeability allows water from the urine filtrate to be reabsorbed into the blood, making the urine more concentrated (see understanding urine concentration, Chapter 24).

The abnormal synthesis and release of ADH occurs in a number of stress situations including severe pain, nausea, trauma, surgery, certain anesthetic agents, and some narcotics (e.g., morphine and meperidine). Among other drugs that affect ADH are nicotine, which stimulates its release, and alcohol, which inhibits it. Two important conditions that alter ADH levels are diabetes insipidus and the syndrome of inappropriate secretion of ADH.

**Diabetes Insipidus.** Diabetes insipidus (DI) is caused by a deficiency of ADH or a decreased renal response to ADH. Persons with DI are unable to concentrate their urine during periods of water restriction and they excrete large volumes of urine, usually 3 to 20 L/day, depending on the degree of ADH deficiency or renal insensitivity to ADH. This large urine output is accompanied by excessive thirst. As long as the thirst mechanism is normal and fluid is readily available, there is little or no alteration in the fluid levels of persons with DI. The danger arises when the condition develops in someone who is unable to communicate the need for water or is unable to secure the needed water. In such cases, inadequate fluid intake rapidly leads to increased serum osmolality and hypertonic dehydration.

There are two types of DI: neurogenic or central DI, which occurs because of a defect in the synthesis or release of ADH, and nephrogenic DI, which occurs because the kidneys do not respond to ADH. Most cases of neurogenic DI are caused by inflammatory, autoimmune, or vascular diseases that affect the hypothalamic-neurohypophyseal system, with less than 10% attributed to hereditary forms of the disorder. In nephrogenic DI, loss of 80% of ADH-secreting neurons is necessary before polyuria becomes evident.
persons with neurogenic DI have an incomplete form of the disorder and retain some ability to concentrate their urine. Temporary neurogenic DI may follow traumatic head injury or surgery near the hypothalamic hypophyseal tract. Nephrogenic DI is characterized by impairment of urine-concentrating ability and free-water conservation. Congenital nephrogenic DI, which is present at birth, is caused by defective expression of the renal vasopressin receptors or vasopressin insensitive water channels. Acquired forms of the disorder may occur with pyelonephritis, lithium toxicity, and electrolyte disorders, such as potassium depletion or chronic hypercalcemia, that interfere with the actions of ADH on the collecting tubules of the kidney.

The manifestations of DI include complaints of intense thirst, a craving for ice water, and polyuria or excessive urination. The volume of ingested fluids may range from 2 to 20 L daily with corresponding large urine volumes. Partial DI usually presents with less-intense thirst and should be suspected in persons with enuresis or bed-wetting. DI may present with hypernatremia and dehydration, especially in persons without free access to water, or with damage to the hypothalamic thirst center and altered thirst sensation.

The management of central or neurogenic DI depends on the cause and severity of the disorder. Many persons with incomplete neurogenic DI maintain near-normal water balance when permitted to ingest water in response to thirst. Pharmacologic preparations of ADH (e.g., nasal and oral forms of desmopressin acetate [DDAVP]) are available for persons who cannot be managed by conservative measures. Both neurogenic and nephrogenic forms of DI respond partially to the thiazide diuretics (e.g., hydrochlorothiazide). These diuretics are thought to act by increasing sodium excretion by the kidneys, leading to ECF volume contraction, a decrease in the glomerular filtration, and an increase in sodium and water reabsorption.

Syndrome of Inappropriate Antidiuretic Hormone. The syndrome of inappropriate ADH (SIADH) results from a failure of the negative feedback system that regulates the release and inhibition of ADH. In persons with this syndrome, ADH secretion continues even when serum osmolality is decreased, causing marked water retention and dilutional hyponatremia.

The SIADH can occur as an acute transient condition or as a chronic condition. Stimuli such as surgery, pain, stress, and temperature changes are capable of stimulating ADH through the CNS. Drugs induce SIADH in different ways; some drugs are thought to increase hypothalamic production and release of ADH, and others are believed to act directly on the renal tubules to enhance the action of ADH. More chronic forms of SIADH may result from lung tumors, chest lesions, and CNS disorders. Tumors, particularly bronchogenic carcinomas and cancers of the lymphoid tissue, prostate, and pancreas, are known to produce and release ADH independent of normal hypothalamic control mechanisms (described in Chapter 7). Other intrathoracic conditions, such as advanced tuberculosis, severe pneumonia, and positive-pressure breathing, can also cause SIADH. The suggested mechanism for SIADH in positive-pressure ventilation is activation of baroreceptors that respond to marked changes in intrathoracic pressure. Disease and injury to the CNS can cause direct pressure on or direct involvement of the hypothalamic–posterior pituitary structures. Examples include brain tumors, hydrocephalus, head injury, meningitis, and encephalitis. Human immunodeficiency virus (HIV) infection is an established cause of SIADH (e.g., related to associated infections, tumors, drugs).

The manifestations of SIADH are those of dilutional hyponatremia (to be discussed). Urine output decreases despite adequate or increased fluid intake. Urine osmolality is high and serum osmolality low. Hematocrit, serum sodium, and BUN levels are decreased because of the dilutional effects of an expanded blood volume. The severity of symptoms is usually related to the extent of sodium depletion and water intoxication.

The treatment of SIADH depends on its severity. In mild cases, treatment consists of fluid restriction. If fluid restriction is not sufficient, diuretics such as mannitol and furosemide (Lasix) may be given to promote diuresis and free-water clearance. Lithium and the antibiotic demeclocycline inhibit the action of ADH on the renal collecting ducts and sometimes are used in treating the disorder. In cases of severe water intoxication, a hypertonic (e.g., 3%) sodium chloride solution may be administered intravenously.

Disorders of Water and Sodium Balance

Disorders of water and sodium can be divided into two main categories: (1) isotonic contraction or expansion of the ECF volume brought about by proportionate changes in sodium and water, and (2) hypotonic dilution or hypertonic concentration of the ECF brought about by disproportionate changes in sodium and water (Fig. 8-8).

Isotonic disorders usually are confined to the ECF compartment, producing a contraction (fluid volume deficit) or expansion (fluid volume excess) of the interstitial and vascular fluids. Disorders of sodium concentration produce a change in the osmolality of the ECF with movement of water from the ECF compartment into the ICF compartment (hyponatremia) or from the ICF compartment into the ECF fluid compartment (hypernatremia).

Isotonic Fluid Volume Deficit

Fluid volume deficit is characterized by a decrease in the ECF, including the circulating blood volume. Isotonic fluid volume deficit, which results when water and electrolytes are lost in isotonic proportions, is almost always caused by a loss of body fluids and is often accompanied by a decrease in fluid intake. This form of volume loss may follow a variety of disorders, including the loss of
gastrointestinal fluids such as occurs with severe vomiting, diarrhea, or gastrointestinal suction; excessive urinary losses, such as occurs with osmotic diuresis or injudicious use of diuretic therapy; excessive sweating due to fever and exercise; or endocrine disorders, such as adrenal insufficiency, in which reduced levels of aldosterone cause excessive sodium loss in the urine (see Chapter 32). Third-space losses cause sequestering of ECF in the serous cavities or extracellular spaces of injured tissue.

Isotonic fluid volume deficit is manifested by a decrease in ECF volume, as evidenced by a decrease in body weight. A mild ECF deficit exists when weight loss equals 2% of body weight. A moderate deficit equates to a 5% loss in weight and a severe deficit to an 8% or greater loss in weight (Table 8-3). Because the ECF is trapped in the transcellular compartment of persons with third-space losses, their body weight may not decrease.

Thirst is a common symptom of fluid deficit, although it is not always present in early stages of isotonic fluid deficit. Urine output decreases and urine osmolality and specific gravity increase as ADH levels rise because of a decrease in vascular volume. Although there is an isotonic loss of fluid from the vascular compartment, blood components such as red blood cells and BUN become more concentrated.

The fluid content of body tissues decreases as fluid is removed from the interstitial spaces. The eyes assume a sunken appearance and feel softer than normal as the fluid content in the anterior chamber of the eye decreases. Fluids add resiliency to the skin and underlying tissues that is referred to as tissue turgor. Tissue turgor is assessed by pinching a fold of skin between the thumb and forefinger (Fig. 8-9). The skin should immediately return to its original configuration when the fingers are released. A loss of 3% to 5% of body water in children causes the resiliency of the skin to be lost, and the tissue remains elevated for several seconds. Decreased tissue turgor is less predictive of fluid deficit in older persons (>65 years) because of the loss of tissue elasticity. In infants, fluid deficit may be evidenced by depression of the anterior fontanel due to a decrease in cerebrospinal fluid.

Arterial and venous volumes decline during periods of fluid deficit, as does filling of the capillary circulation, which can be assessed by applying pressure to a fingernail for 5 seconds and then releasing the pressure and observing the time (normally 1 to 2 seconds) that it takes for the color to return to normal (capillary refill time). As the volume in the arterial system declines, the blood pressure decreases, the heart rate increases, and the pulse becomes weak and thready. Postural hypotension (a drop in blood pressure on standing) is an early sign of fluid deficit. On the venous side of the circulation, the veins become less prominent. When volume depletion becomes severe, signs of hypovolemic shock and vascular collapse appear (see Chapter 20).

Treatment of fluid volume deficit consists of fluid replacement and measures to correct the underlying cause. Usually, isotonic electrolyte solutions are used for fluid replacement. Acute hypovolemia and hypovolemic shock can cause renal damage; therefore, prompt
assessment of the degree of fluid deficit and adequate measures to resolve the deficit and treat the underlying cause are essential.

**Isotonic Fluid Volume Excess**

Isotonic fluid volume excess, which represents an isotonic expansion of the ECF compartment with increases in both interstitial and vascular volumes, usually results from an increase in total body sodium that is accompanied by a proportionate increase in body water. Although it can occur as the result of excessive sodium intake, it is most commonly caused by a decrease in sodium and water elimination by the kidney. Among the causes of decreased sodium and water elimination are disorders of renal function, heart failure, liver failure, and corticosteroid hormone excess. A condition called *circulatory overload* results from an increase in blood volume; it can occur during infusion of intravenous fluids or transfusion of blood if the amount or rate of administration is excessive.

Heart failure produces a decrease in the effective circulating volume and renal blood flow and a compensatory increase in sodium and water retention (see Chapter 20). Persons with severe congestive heart failure maintain a precarious balance between sodium and water intake and output. Even small increases in sodium intake can precipitate a state of fluid volume excess and a worsening of heart failure. Liver failure (e.g., cirrhosis of the liver) impairs aldosterone metabolism and decreases effective circulating volume and renal perfusion, leading to increased salt and water retention.

ADH, antidiuretic hormone.
The corticosteroid hormones also increase sodium reabsorption by the kidneys; therefore, persons being treated with these medications and those with Cushing syndrome or disease often have problems with sodium retention (see Chapter 32).

Isotonic fluid volume excess is manifest by an increase in interstitial and vascular fluids, and is characterized by weight gain over a short period of time. Mild fluid volume excess represents a 2% gain in weight; moderate fluid volume excess, a 5% gain in weight; and severe fluid volume excess, a gain of 8% or more in weight (see Table 8-3).3 The presence of edema is characteristic of isotonic fluid excess. When the fluid excess accumulates gradually, as often happens in debilitating diseases and starvation, edema may mask the loss of tissue mass. As vascular volume increases, central venous pressure increases, leading to distended neck veins, slow-empting peripheral veins, a full and bounding pulse, and an increase in central venous pressure. There is often a dilutional decrease in hematocrit and BUN levels due to expansion of the plasma volume. When excess fluid accumulates in the lungs (i.e., pulmonary edema), there are complaints of shortness of breath and difficult breathing, respiratory crackles, and a productive cough. Ascites and pleural effusion may occur with severe fluid volume excess.

The treatment of fluid volume excess focuses on providing a more favorable balance between sodium and water intake and output. A sodium-restricted diet is often prescribed as a means of decreasing extracellular sodium and water levels. Diuretic therapy is commonly used to increase sodium elimination. When there is a need for intravenous fluid administration or transfusion of blood components, the procedure requires careful monitoring to prevent circulatory overload.

**Hyponatremia**

Hyponatremia is usually defined as a serum sodium concentration of less than 135 mEq/L (135 mmol/L).3 It is one of the most common electrolyte disorders seen in hospitalized patients and is also common in the outpatient population, particularly in the elderly. A number of age-related events make the elderly population more vulnerable to hyponatremia, including a decrease in renal function accompanied by limitations in sodium conservation. Although older people maintain body fluid homeostasis under most circumstances, the ability to withstand environmental, drug-related, and disease-associated stresses often becomes progressively limited.

Hyponatremia can present as a hypovolemic, euvolemic, or hypervolemic state. Hyponatremia can also present as a hypertonic hyponatremia resulting from an osmotic shift of water from the ICF to the ECF, such as occurs with hyperglycemia. In this situation, the sodium in the ECF becomes diluted as water moves out of body cells in response to the osmotic effects of the elevated blood glucose level.21,22

**Hypovolemic hypotonic hyponatremia** is the most common type of hyponatremia. It occurs when water is used to replace the loss of iso-osmotic body fluids. Among the causes of hypovolemic hyponatremia is excessive sweating in hot weather, particularly during heavy exercise, which leads to loss of salt and water. Hyponatremia develops when water, rather than electrolyte-containing liquids, is used to replace fluids lost in sweating. Iso-osmotic fluid loss, such as occurs in vomiting or diarrhea, does not usually lower serum sodium levels unless these losses are replaced with disproportionate amounts of orally ingested or parenterally administered water. Gastrointestinal fluid loss and ingestion of excessively diluted formula are common causes of acute hyponatremia in infants and children. Hypovolemic hypotonic hyponatremia is also a common complication of adrenal insufficiency, in which a lack of aldosterone increases renal losses of sodium and a cortisol deficiency leads to increased release of ADH with water retention.

**Euvolemic or normovolemic hypotonic hyponatremia** represents retention of water with dilution of sodium while maintaining the effective circulatory volume within a normal range. It is usually the result of SIADH. The risk of normovolemic hyponatremia is increased during the postoperative period. During this time ADH levels are often high, producing an increase in water reabsorption by the kidney. The hyponatremia becomes exaggerated when electrolyte-free fluids (e.g., 5% glucose in water) are used for intravenous fluid replacement.

**Hypervolemic hypotonic hyponatremia** occurs in edematous states such as decompensated heart failure, advanced liver disease, and renal disease. Although the total body sodium is increased in heart failure, the baroreceptors often sense the effective circulatory volume as inadequate, resulting in fluid retention. Abuse of methylenedioxyxymethamphetamine (MDMA), also known as “ecstasy,” can lead to severe neurologic symptoms, including seizures, brain edema, and herniation due to severe hyponatremia. MDMA and its metabolites have been shown to produce enhanced release of ADH from the hypothalamus.3,22

**Manifestations.** The manifestations of hyponatremia depend on the rapidity of onset and the severity of the sodium dilution. The signs and symptoms may be acute (refers to onset within 48 hours), as in severe water intoxication, or more insidious in onset and less severe, as in chronic hyponatremia. Because of water movement, hyponatremia produces an increase in intracellular water, which is responsible for many of the clinical manifestations of the disorder. Muscle cramps, weakness, and fatigue reflect the effects of hyponatremia on skeletal muscle function and are often early signs of hyponatremia. These effects commonly are observed in persons with hyponatremia that occurs during heavy exercise in hot weather. Gastrointestinal manifestations such as nausea and vomiting, abdominal cramps, and diarrhea may also occur (Table 8-4).

The cells of the brain and nervous system are the most seriously affected by increases in intracellular water.22-25
Symptoms include apathy, lethargy, and headache, which can progress to disorientation, confusion, gross motor weakness, and depression of deep tendon reflexes. Seizures and coma occur when serum sodium levels reach extremely low levels. These severe effects, which are caused by cerebral edema, may be irreversible.

**Treatment.** The treatment of hyponatremia is determined by the underlying cause, severity, and timing of onset. When hyponatremia is caused by water intoxication, limiting water intake or discontinuing medications that contribute to SIADH may be sufficient. The administration of a saline solution orally or intravenously may be needed when hyponatremia is caused by sodium deficiency. Symptomatic hyponatremia (i.e., neurologic manifestations) may be treated with hypertonic saline solution and a loop diuretic, such as furosemide, to increase water elimination. This combination allows for correction of serum sodium levels while ridding the body of excess water. The vasopressin receptor antagonists (vaptans) may be used in the treatment of euvolemic hyponatremia.

The treatment of severe hyponatremia varies depending on the timing of the onset of the disorder. Cells, particularly those in the brain, tend to defend against changes in cell volume caused by changes in ECF osmolality by increasing or decreasing their concentration of organic osmotically active molecules (called osmolytes) that can’t cross the cell membrane. In the case of prolonged water intoxication (greater than 48 hours), brain cells reduce their concentration of osmolytes as a means of preventing an increase in cell volume. It takes several days for brain cells to restore the osmolytes lost during hyponatremia. Thus, treatment measures that produce rapid changes in serum osmolality may cause a dramatic decrease in brain cell volume. One of the reported effects of rapid treatment of hyponatremia, called the osmotic demyelination syndrome, is characterized by destruction of the myelin sheath of the axons passing through the brain stem. This syndrome can cause serious neurologic injury and sometimes death. In persons with acute-onset hyponatremia (i.e., onset within 48 hours), in whom cerebral adaptation has not had time to occur, rapid correction is less likely to result in osmotic demyelination.

**Hypernatremia**

Hypernatremia is characterized by a serum sodium level above 145 mEq/L (145 mmol/L) and a serum osmolality greater than 295 mOsm/kg H2O. Because sodium and its attendant anion is functionally an impermeable solute, hypernatremia increases ECF tonicity, causing movement of water out of the ICF, resulting in cellular dehydration.

As with hyponatremia, hypernatremia can present as an euvolemic state, in which water from the ICF is
pulled into the ECF preventing a change in volume; as a hypovolemic state, in which water loss is greater than sodium loss; or as a hypervolemic state if there is an addition of a hypertonic solution containing both sodium and water.  

All forms of hyponatremia represent a hypovolemic state with an increase in intracellular osmolality that causes activation of the thirst mechanism and an increased ability of the kidneys to conserve water by producing concentrated urine. Thirst is highly effective in preventing hyponatremia. Therefore, hyponatremia is more likely to occur in infants and in persons who do not experience or cannot express their thirst or obtain water to drink. Hypodipsia is particularly prevalent among the elderly. A defect in thirst or inability to obtain or drink water can interfere with water intake. An increase in the intracellular osmolality normally leads to an increase in ADH levels with increased reabsorption of water by the kidneys. Hyponatremia develops when there is impaired ability of the kidneys to conserve water by producing concentrated urine, most commonly due to acute or chronic renal failure.

Net water loss can occur through the urine, gastrointestinal tract, lungs, or skin. It can result from increased losses from the respiratory tract during fever or strenuous exercise, or from the gastrointestinal tract due to watery diarrhea or when highly osmotic tube feedings are given with inadequate amounts of water. With pure water loss, both the ICF and ECF compartments lose an equal percentage of their volume. Because ICF contains a greater percentage of water than the ECF, more actual water volume is lost from the ICF than the ECF compartment. The therapeutic administration of excess amounts of sodium-containing solutions may also cause hyponatremia.

**Manifestations.** The clinical manifestations of hyponatremia caused by water loss are largely those of ECF loss and cellular dehydration (see Table 8-4). The severity of signs and symptoms is greatest when the increase in serum sodium is large and occurs rapidly. Body weight is decreased in proportion to the amount of water that has been lost. Because blood plasma is roughly 90% to 93% water, the concentrations of blood cells and other blood components increase as ECF water decreases.

Thirst is an early symptom of water deficit, occurring when water losses are equal to 0.5% of body water. Urine output is decreased and urine osmolality increased because of renal water-conserving mechanisms. Body temperature frequently is elevated, and the skin becomes warm and flushed. Hyponatremia produces an increase in serum osmolality and results in water being pulled out of body cells. As a result, the skin and mucous membranes become dry, and salivation and lacrimation are decreased. The mouth becomes dry and sticky, and the tongue becomes rough and fissured. Swallowing is difficult. The subcutaneous tissues assume a firm, rubbery texture. Most significantly, movement of water out of the CNS causes decreased reflexes, agitation, headache, and restlessness. Coma and seizures may develop as hyponatremia progresses.

**Treatment.** Treatment of hyponatremia includes measures to treat the underlying cause of the disorder and fluid replacement therapy to treat the accompanying dehydration. Replacement fluids can be given orally or intravenously. Oral glucose-electrolyte replacement solutions are widely available in grocery stores and pharmacies for use in the treatment of acute hyponatremia due to diarrhea and other dehydrating disorders in infants and young children (see Chapter 29). Oral replacement therapy is less expensive than intravenous therapy and has a lower complication rate. Intravenous therapy may be required for children and adults with severe dehydration.

One of the serious aspects of sustained hyponatremia is dehydration of brain and nerve cells. The treatment of sustained hyponatremia requires controlled gradual correction of sodium and water levels to avoid serious neurologic complications. As with severe hyponatremia, brain cells protect against changes in cell volume by changing their concentration of organic osmolytes, increasing their concentration in hyponatremia to prevent water from being pulled into the ECF. If hyponatremia is corrected too rapidly—before the osmolytes have had a chance to dissipate—the plasma may become relatively hypotonic in relation to brain cell osmolality. When this occurs, water moves into the brain cells, causing cerebral edema and potentially severe neurologic impairment.
Potassium Balance

Potassium (K+) is the second most abundant cation in the body, with 98% located in the intracellular compartment, primarily in skeletal muscle. Of the remaining 2% that is in the extracellular compartment, only about 0.4% is measurable in the plasma. This tiny amount is maintained at a fairly narrow serum concentration of 3.5 to 5.0 mEq/L (3.5 to 5.0 mmol/L).

Regulation of Potassium Balance

Potassium balance is normally regulated by dietary intake, urine output, and transcompartmental shifts between the ICF and ECF compartments. The kidneys are the main source of potassium loss. Approximately 80% to 90% of potassium loss occurs in the urine, with the remainder being lost in the stools from the gastrointestinal tract and in sweat from the skin.

Potassium is filtered in the glomerulus, reabsorbed along with sodium and water in the proximal tubule and with sodium and chloride in the thick ascending loop of Henle, and then secreted into the late distal and collecting tubules for elimination in the urine. In contrast to other electrolytes, the regulation of potassium elimination by the kidney is mainly controlled by its secretion from the blood into the tubular filtrate rather than through its reabsorption from the tubular filtrate into the blood (see Chapter 24).

Aldosterone plays an essential role in regulating potassium elimination in the distal tubule of the kidney. In the presence of aldosterone, Na+ is transported back into the blood and K+ is secreted in the tubular filtrate for elimination in the urine. There is also a potassium/hydrogen exchange mechanism in the collecting tubules of the kidney. When serum potassium levels increase, K+ is secreted into the urine and H+ is reabsorbed, leading to a decrease in pH and metabolic acidosis; when potassium levels are low, K+ is reabsorbed and H+ is secreted in the urine, leading to an increase in pH and metabolic alkalosis.

Among the factors that influence the ECF/ICF shift in potassium are serum osmolality, acid–base balance, insulin, and increased sympathetic nervous system activity (Fig. 8-10). An acute increase in serum osmolality causes water to move out of the cell; this in turn prompts an increase in K+ concentration that causes it to move out into the ECF. Acid–base disorders rely on an ECF to ICF cation shift for buffering of the H+ ion. In metabolic acidosis, for example, H+ moves into body cells for buffering, causing K+ to leave and move into the ECF. Both insulin and epinephrine (a β-adrenergic sympathetic neurotransmitter) increase cellular uptake of K+ by increasing the activity of the Na+/K+-adenosine triphosphatase (ATPase) membrane pump. Normally, it takes 6 to 8 hours for the kidneys to eliminate half of potassium that has been ingested in the diet. After a meal, insulin release not only serves to regulate blood glucose levels, but also serves to control serum potassium levels by temporarily shifting the excess into cells until it can be eliminated by the kidneys.

Exercise can also produce compartmental shifts in potassium. Repeated muscle contraction causes potassium to be released into the ECF. Although the increase usually is small with modest exercise, it can be considerable during exhaustive exercise. Even the repeated clenching and unclenching of the fist during a blood draw can cause potassium to move out of cells causing an artificial elevation in serum potassium levels.
Disorders of Potassium Balance

As the major intracellular cation, potassium is critical to many body functions, including maintenance of the osmotic integrity of cells, acid–base balance, and the intricate chemical reactions that transform carbohydrates into energy and convert amino acids to proteins. Potassium also plays a critical role in conducting nerve impulses and controlling the excitability of skeletal, cardiac, and smooth muscle. It does this by regulating the resting membrane potential, the opening of sodium channels that control the flow of current during the action potential, and the rate of repolarization. Changes in nerve and muscle excitability are particularly important in the heart, where alterations in serum potassium levels can produce serious cardiac arrhythmias and conduction defects. Changes in serum potassium levels also affect the electrical activity of skeletal muscles and the smooth muscle in the blood vessels and gastrointestinal tract.

The resting membrane potential is determined by the ratio of ECF to ICF potassium concentration (see Chapter 1, “Understanding Membrane Potentials”). A decrease in the ECF potassium concentration (hypokalemia) causes the resting membrane potential to become more negative, moving it further from the threshold for excitation (Fig. 8-11). Thus, it takes a greater stimulus to reach the threshold potential and open the sodium channels that are responsible for the action potential. An increase in serum potassium (hyperkalemia) has the opposite effect; it causes the resting membrane potential to become more positive, moving it closer to the threshold. With severe hyperkalemia, the resting membrane potential approaches the threshold potential, causing sustained subthreshold depolarization with a resultant inactivation of the sodium channels and net decrease in excitability. The rate of repolarization (return of the membrane potential toward its resting potential so it can undergo another action potential) also varies with serum potassium levels. It is more rapid in hyperkalemia and delayed in hypokalemia.

Hypokalemia

Hypokalemia refers to a decrease in serum potassium levels below 3.5 mEq/L (3.5 mmol/L). The causes of potassium deficit can be grouped into three categories: inadequate intake; excessive gastrointestinal, renal, and skin losses; and a shift between the ICF and ECF compartments.

Inadequate dietary intake is a frequent cause of hypokalemia. Insufficient dietary intake may result from the inability to obtain or ingest food or from a diet that is low in potassium-containing foods. Potassium intake is often inadequate in persons on fad diets and those who have eating disorders. Elderly persons are particularly likely to have potassium deficits.

Excessive renal losses of potassium occur with diuretic therapy, metabolic alkalosis, magnesium depletion, trauma and stress, and an increase in aldosterone levels. Diuretic therapy, with the exception of potassium-sparing diuretics, is the most common cause of hypokalemia. Both thiazide and loop diuretics increase the loss of potassium in the urine. Magnesium depletion, which often coexists with potassium depletion due to diuretic therapy, produces additional urinary losses. Renal losses of potassium are accentuated by aldosterone. Primary aldosteronism, caused by either a tumor or hyperplasia of the cells of the adrenal cortex that secrete aldosterone, can produce severe losses by increasing potassium secretion in the distal renal tubule (see Chapter 32).

Although potassium losses from the skin and the gastrointestinal tract usually are minimal, these losses can become excessive under certain conditions. For example, burns increase surface losses of potassium. Intestinal secretions contain relatively large amounts of potassium (e.g., 85 to 90 mEq/L), thus diarrhea can produce large losses of potassium.

Hypokalemia can also be caused by intracellular shifting of potassium from the ECF compartment (see Fig. 8-10). A wide variety of β2-adrenergic agonist drugs (e.g., decongestants and bronchodilators) produce an intracellular shift in potassium, causing a transient decrease in serum potassium levels. Insulin also increases the movement of potassium into the cell. Because insulin increases the movement of glucose and potassium into cells, potassium deficit often develops during treatment of diabetic ketoacidosis.

Manifestations. The manifestations of hypokalemia include alterations in neuromuscular, gastrointestinal, renal, and cardiovascular function (Table 8-5). These manifestations reflect the effects of hypokalemia on the electrical activity of excitable tissues such as those of the neuromuscular systems as well as the body’s
attempt to regulate ECF potassium levels within a more normal range. The signs and symptoms of hypokalemia seldom develop until serum potassium levels have fallen to less than 3.0 mEq/L (3.0 mmol/L). They are typically gradual in onset, and therefore the disorder may go undetected for some time.

The renal mechanisms that serve to conserve potassium during hypokalemia interfere with the kidney's ability to concentrate urine. Urine output and plasma osmolality are increased, urine specific gravity is decreased, and complaints of polyuria, nocturia, and thirst are common. Metabolic alkalosis and renal chloride wasting are signs of severe hypokalemia.

There are numerous signs and symptoms associated with gastrointestinal function, including anorexia, nausea, and vomiting. Atony of the gastrointestinal smooth muscle can cause constipation, abdominal distention, and, in severe hypokalemia, paralytic ileus. When gastrointestinal symptoms occur gradually and are not severe, they often impair potassium intake and exaggerate the condition.

Complaints of weakness, fatigue, and muscle cramps, particularly during exercise, are common in moderate hypokalemia (serum potassium 2.5 to 3.0 mEq/L [2.5 to 3.0 mmol/L]). Muscle paralysis with life-threatening respiratory insufficiency can occur with severe hypokalemia. Leg muscles, particularly the quadriceps, are most prominently affected. Some people complain of muscle tenderness and paresthesias rather than weakness. In chronic potassium deficiency, muscle atrophy may contribute to muscle weakness.

The most serious effects of hypokalemia are on the heart. Hypokalemia produces a decrease in the resting membrane potential, causing prolongation of the PR interval (see Chapter 17). It also prolongs the rate of ventricular repolarization and lengthens the relative refractory period, causing depression of the ST segment, flattening of the T wave, and appearance of a prominent U wave. Although these ECG changes usually are not serious, they may predispose to reentry ventricular arrhythmias. Hypokalemia also increases the risk of digitalis toxicity in persons being treated with the drug, and there is an increased risk of ventricular arrhythmias, particularly in persons with underlying heart disease. The dangers associated with digitalis toxicity are compounded in persons who are receiving diuretics that increase urinary losses of potassium.

In a rare genetic condition, called hypokalemic familial periodic paralysis, episodes of hypokalemia cause attacks of flaccid paralysis that last 6 to 48 hours if untreated. The paralysis may be precipitated by situations that cause severe hypokalemia by producing an intracellular shift in potassium, such as ingestion of a high-carbohydrate meal or administration of insulin, epinephrine, or glucocorticoid drugs. The paralysis often can be reversed by potassium replacement therapy.
**Treatment.** When possible, hypokalemia caused by a potassium deficit is treated by increasing the intake of foods high in potassium content—meats, dried fruits, fruit juices (particularly orange juice), and bananas. Oral potassium supplements are prescribed for persons whose intake of potassium is insufficient in relation to losses. This is particularly useful in persons who are receiving diuretic therapy and those who are taking digitalis.

Potassium may be given intravenously when the oral route is not tolerated or when rapid replacement is needed. Magnesium deficiency may impair potassium correction; in such cases, magnesium replacement is indicated. The rapid infusion of a concentrated potassium solution can cause death from cardiac arrest. Health personnel who assume responsibility for administering intravenous solutions that contain potassium should be fully aware of all the precautions pertaining to their dilution and flow rate.

**Hyperkalemia**

Hyperkalemia refers to an increase in serum levels of potassium in excess of 5.5 mEq/L (5.5 mmol/L). It seldom occurs in healthy persons because the body is extremely effective in preventing excess potassium accumulation in the extracellular fluid.

There are three main causes of hyperkalemia: (1) decreased renal elimination, (2) a shift in potassium from the ICF to ECF compartment, and (3) excessively rapid rate of administration. The most common cause of serum potassium excess is decreased renal function. Chronic hyperkalemia is almost always associated with chronic kidney disease. Some kidney disorders, such as sickle cell nephropathy, lead nephropathy, and systemic lupus nephritis, can selectively impair tubular secretion of potassium without causing kidney failure.

A mineralocorticoid (aldosterone) deficiency, which increases tubular reabsorption of potassium in the distal renal tubule, is another cause of hyperkalemia. It can result from adrenal insufficiency, depression of aldosterone release due to a decrease in renin or angiotensin II, or impaired ability of the kidneys to respond to aldosterone. Potassium-sparing diuretics can produce hyperkalemia by means of the latter mechanism. Because of their ability to decrease aldosterone levels, the angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers can also produce an increase in serum potassium levels.

A shift in potassium from the ICF to the ECF also can lead to elevated serum potassium levels. Acidosis tends to increase serum potassium levels by causing potassium to move from the ICF to the ECF. Tissue injury also causes release of intracellular potassium into the ECF compartment. For example, burns and crushing injuries cause cell death and release of potassium into the extracellular fluids. The same injuries often diminish renal function, which contributes to the development of hyperkalemia. Transient hyperkalemia may occur during exhaustive exercise or seizures, when muscle cells are permeable to potassium.

Potassium excess can also result from excessive oral ingestion or intravenous administration of potassium. Normally it is difficult to increase potassium intake to the point of causing hyperkalemia when renal function is adequate and the aldosterone Na+/K+ exchange system is functioning. An exception to this rule is the intravenous route of administration. In some cases, severe and fatal incidents of hyperkalemia have occurred when intravenous potassium solutions were infused too rapidly. Because the kidneys control potassium elimination, the administration of intravenous solutions that contain potassium should not be initiated until urine output has been assessed and renal function has been deemed to be adequate.

**Manifestations.** The signs and symptoms of potassium excess are closely related to a decrease in neuromuscular excitability (see Table 8-5). The neuromuscular manifestations of potassium excess usually are absent until the serum concentration exceeds 6 mEq/L (6 mmol/L). The first symptom associated with hyperkalemia typically is paresthesia (a feeling of numbness and tingling). There may be complaints of generalized muscle weakness or dyspnea secondary to respiratory muscle weakness.

The most serious effect of hyperkalemia is on the heart. Hyperkalemia decreases membrane excitability, producing a delay in atrial and ventricular depolarization, and it increases the rate of ventricular repolarization. As the serum potassium concentration rises, there is a characteristic sequence of changes in the ECG that are due to the effects of hyperkalemia on atrial and ventricular depolarization (represented by the P wave and QRS complex) and repolarization (represented by the T wave and QRS complex). The earliest ECG changes are peaked and narrowed T waves and a shortened QT interval, which reflect abnormally rapid repolarization (Fig. 8-12). The alteration in T-wave configuration typically becomes prominent when the serum potassium concentration exceeds 6 mEq/L (6 mmol/L). If serum potassium levels continue to rise, delayed depolarization of the atria and ventricles produces further changes in the ECG. There is a prolongation of the PR interval; widening of the QRS complex with no change in its configuration; and decreased amplitude, widening, and eventual disappearance of the P wave. The heart rate may be slow. Ventricular fibrillation and cardiac arrest are terminal events. Detrimental effects of hyperkalemia on the heart are most pronounced when the serum potassium level rises rapidly.

**Treatment.** The treatment of potassium excess varies with the degree of increase in serum potassium and whether there are ECG and neuromuscular manifestations. On an emergent basis, calcium antagonizes the potassium-induced decrease in membrane excitability, restoring excitability toward normal. The protective effect of calcium administration is usually short lived (15 to 30 minutes) and must be accompanied by other therapies to decrease the ECF potassium concentration. The redistribution of potassium from the ECF into the
ICF compartment can be accomplished by the administration of sodium bicarbonate, β-agonists (e.g., nebulized albuterol), or insulin to rapidly decrease the ECF concentration.

Less-emergent measures focus on decreasing or curtailing potassium intake or absorption, increasing renal excretion, and increasing cellular uptake. Decreased intake can be achieved by restricting dietary sources of potassium. The major ingredient in most salt substitutes is potassium chloride, and such substitutes should not be given to persons with kidney problems. Increasing potassium output often is more difficult. Persons with kidney failure may require hemodialysis or peritoneal dialysis to reduce serum potassium levels.

Calcium, phosphorus, and magnesium balance

Calcium, phosphorus, and magnesium are the major divalent cations in the body. Most of these cations are deposited in bone, with only a small amount in the ECF. Homeostatic mechanisms that regulate serum calcium and phosphorus levels involve three organs—the intestine, kidney, and bone, principally through the complex interaction of parathyroid hormone and vitamin D \(^{35-37}\) (Fig. 8-13).

The main function of parathyroid hormone (PTH) is to maintain ECF calcium concentrations.\(^ {35,37}\) It does this by stimulating the release of calcium and phosphorus from bone into the ECF; increasing renal reabsorption of calcium and excretion of phosphorus; and enhancing the gastrointestinal absorption of calcium and phosphorus through its effects on vitamin D synthesis. *Vitamin D* \(_3\), which functions as a hormone, is synthesized by the skin and converted to its active form, *calcitriol*, in the kidney. The active form of vitamin D has several effects on the intestines, kidneys, and bone that increase serum levels of calcium and phosphorus and contribute to their

**SUMMARY CONCEPTS**

- Potassium is the second most abundant cation in the body, with 98% being located in the intracellular fluid (ICF) compartment. The high ICF concentration is required for many cell functions, including maintenance of the osmotic integrity of cells and acid–base balance, intricate chemical reactions that transform carbohydrates into energy, changing glucose into glycogen, and converting amino acids to proteins. Potassium also plays a critical role in conducting nerve impulses and controlling the excitability of skeletal, cardiac, and smooth muscles.

- Potassium is ingested in the diet and eliminated in the urine, with ICF and extracellular (ECF) levels being regulated by compartmental shifts between the ICF and ECF, and mechanisms that adjust renal excretion with dietary ingestion of potassium.

- Hypokalemia, or potassium deficit, can result from inadequate intake, excessive losses, or redistribution from the ECF to the ICF compartments. It is manifested by alterations in kidney, skeletal muscle, gastrointestinal, and cardiac function, reflecting the crucial role of potassium in cell metabolism and neuromuscular function.

- Hyperkalemia, or potassium excess, can result from decreased elimination of potassium by the kidney, a transcellular shift in potassium from the ICF into the ECF compartment, or excessively rapid intravenous administration of potassium. It is manifested by alterations in neuromuscular and cardiac function, the most serious being the development of serious and even fatal cardiac arrhythmias.
feedback regulation. It stimulates the absorption of calcium, and to a lesser extent phosphorus, from the intestine; it increases calcium and phosphorus reabsorption by the renal tubules; and it inhibits PTH synthesis by the parathyroid glands. The role of PTH and vitamin D on the skeleton is discussed further in Chapters 42 and 43.

Disorders of Calcium Balance
Calcium is the major divalent cation in the body. Approximately 99% of body calcium is found in bone, where it provides strength and stability for the skeletal system and serves as an exchangeable source to maintain ECF calcium levels. Most of the remaining calcium (approximately 1%) is located in the ICF, and only 0.1% to 0.2% (approximately 8.5 to 10.5 mg/dL [21 to 26 mmol/L]) of the remaining calcium is present in the ECF.

Extracellular calcium exists in three forms: (1) protein bound, (2) complexed, and (3) ionized (Fig. 8-14). Approximately 40% of serum calcium is bound to plasma proteins, mainly albumin. Another 10% is complexed (i.e., chelated) with substances such as citrate, phosphorus, and sulfate. The remaining 50% of serum calcium is present in the ionized form. Only the ionized form of calcium (Ca++) is free to leave the vascular compartment and participate in cellular functions. Since most of the protein-bound calcium combines with albumin, total serum calcium is significantly altered by serum albumin levels. As a general rule, a decrease in serum albumin of 1.0 g/dL below normal will decrease total serum Ca++ by 0.8 mg/dL. Ionized Ca++ levels are inversely affected by the pH of the blood. For example, when the arterial pH increases in alkalosis, more calcium becomes bound to protein. Although the total serum calcium remains unchanged, the ionized portion decreases.

Ionized Ca++ serves a number of functions. It participates in many enzyme reactions; exerts an important effect on membrane potentials and neuronal excitability; is necessary for contraction in skeletal, cardiac, and smooth muscle; participates in the release of hormones, neurotransmitters, and other chemical messengers; influences cardiac contractility and automaticity by way of slow calcium channels; and is essential for blood coagulation (see Chapter 12).

Regulation of Calcium Balance
Calcium enters the body through the gastrointestinal tract, is absorbed from the intestine under the influence of vitamin D, excreted by the kidney, and stored in bone. Approximately 35% of dietary calcium is absorbed from the duodenum and upper jejunum; the remainder is eliminated in the stool.

Calcium is stored in bone and excreted by the kidney. The ionized form of Ca++ is filtered from the plasma into the glomerulus and then selectively reabsorbed back into the blood. The distal convoluted

**FIGURE 8-13.** Regulation of serum calcium concentration by parathyroid hormone.

**FIGURE 8-14.** Distribution of body calcium between the bone and the intracellular fluid (ICF) and extracellular fluid (ECF) compartments. The percentages of free, complexed, and protein-bound calcium in extracellular fluids are indicated.
Hypocalcemia has also been associated with many drugs, including those that inhibit bone resorption (e.g., bisphosphonates), cause vitamin D deficiency or resistance (e.g., antiepileptics), increase urinary losses of calcium (loop diuretics), or decrease calcium absorption through reduced gastric acid production (proton-pump inhibitors, histamine 2-blockers). Citrate, which is used as an anticoagulant in blood transfusion, can also produce a decrease in Ca++ if transfused too rapidly. Hypocalcemia is seen more commonly during the transfusion of plasma and platelets, which have high citrate concentrations.3

**Manifestations.** Hypocalcemia can manifest as an acute or chronic condition. Most persons with mild hypocalcemia are asymptomatic, whereas large or abrupt changes in ionized calcium lead to increased neuromuscular excitability and cardiovascular effects (Table 8-6). 3,35,36,38

Ionized calcium stabilizes neuromuscular excitability, thereby making nerve cells less sensitive to stimuli. Nerves exposed to low ionized calcium levels show decreased thresholds for excitation, repetitive responses to a single stimulus, and, in extreme cases, continuous activity. The severity of the manifestations depends on the underlying cause, rapidity of onset, accompanying electrolyte disorders, and extracellular pH. Increased neuromuscular excitability can manifest as paresthesias (i.e., tingling around the mouth and in the hands and feet), tetany (i.e., muscle spasms of the muscles of the face, hands, and feet), and, in severe hypocalcemia, laryngeal spasm and seizures.3,35,38

Chvostek and Trousseau tests can be used to assess for increased neuromuscular excitability (Fig. 8-15). 3,38

Chvostek sign is elicited by tapping the face just below the temple at the point where the facial nerve emerges. Tapping the face over the facial nerve causes spasm of the lip, nose, or face when the test result is positive. An inflated blood pressure cuff is used to test for Trousseau sign. The cuff is inflated 10 mm Hg above systolic blood pressure for 3 minutes. Contraction of the fingers and hands (i.e., carpopedal spasm) indicates the presence of tetany.

Cardiovascular effects of acute hypocalcemia include hypotension, cardiac insufficiency, cardiac arrhythmias (particularly heart block and ventricular fibrillation), and failure to respond to drugs such as digitalis, noradrenaline, and dopamine that act through calcium-mediated mechanisms.3

**Treatment.** Acute hypocalcemia is an emergency situation, requiring prompt treatment. An intravenous infusion containing calcium (e.g., calcium gluconate, calcium chloride) is used when tetany or acute symptoms are present or anticipated because of a decrease in the serum calcium level.3,35,38

Chronic hypocalcemia is treated with oral intake of calcium. Oral calcium supplements of carbonate, gluconate, or lactate salts may be used.3 Long-term treatment may require the use of vitamin D preparations, especially in persons with hypoparathyroidism and chronic
kidney disease. The active form of vitamin D is administered when the liver or kidney mechanisms needed for hormone activation are impaired. Synthetic PTH (1–34) can be administered by subcutaneous injection as replacement therapy in hypoparathyroidism.

Hypercalcemia

Hypercalcemia represents a total serum calcium concentration greater than 10.5 mg/dL (2.6 mmol/L). Falsely elevated levels of calcium can result from prolonged drawing of blood with an excessively tight tourniquet. Increased serum albumin levels may also elevate the total serum calcium but not affect the ionized calcium.

Hypercalcemia occurs when calcium movement into the circulation overwhelms calcium regulatory hormones or the ability of the kidney to remove excess calcium ions. The two most common causes of hypercalcemia are increased bone resorption due to hyperparathyroidism and neoplasms. Hypercalcemia is a common complication of malignancy, occurring in approximately 20% to 30% of persons with advanced disease. A number of malignant tumors, including carcinoma of the lung, have been associated with hypercalcemia. Some tumors destroy the bone, while others produce humoral agents that stimulate bone resorption or inhibit bone formation.

Less common causes of hypercalcemia include prolonged immobilization, increased intestinal absorption of calcium, excessive doses of vitamin D, or the effects of drugs such as lithium and thiazide diuretics. Prolonged immobilization and lack of weight bearing cause demineralization of bone and release of calcium into the bloodstream. Intestinal absorption of calcium can be increased by excessive doses of vitamin D or as the result of a condition called the milk-alkali syndrome.
The milk-alkali syndrome is caused by the ingestion of calcium (often in the form of milk) and absorbable antacids, particularly calcium carbonate. The condition is characterized by hypercalcemia, hyperphosphatemia, alkalosis, and progressive renal failure. Because of the availability of nonabsorbable antacids, the condition is seen less frequently than in the past, but it may occur in women who are overzealous in taking calcium preparations for osteoporosis prevention. Discontinuation of the antacid repairs the alkalosis and increases calcium elimination.

A variety of drugs elevate calcium levels. The use of lithium to treat bipolar disorders has been shown to cause hyperparathyroidism and hypercalcemia in some people. The thiazide diuretics increase calcium reabsorption in the distal convoluted tubule of the kidney. Although the thiazide diuretics seldom cause hypercalcemia, they can unmask hypercalcemia from other causes such as underlying bone disease and conditions that increase bone resorption.

**Manifestations.** The signs and symptoms of calcium excess reflect a decrease in neural excitability, alterations in cardiac and smooth muscle function, and exposure of the kidneys to high concentrations of calcium (see Table 8-6). There may be a dulling of consciousness, stupor, weakness, and muscle flaccidity. Behavioral changes may range from subtle alterations in personality to acute psychoses. The heart responds to elevated levels of calcium with increased contractility and ventricular arrhythmias. Digitalis accentuates these responses. Gastrointestinal symptoms include constipation, anorexia, nausea, and vomiting, reflecting a decrease in smooth muscle activity. Bone pain can occur with hyperparathyroidism or malignancy. Excess PTH can lead to bone resorption with development of bone cysts or osteoporosis.

High calcium concentrations in the urine filtrate impair the ability of the kidneys to concentrate urine by interfering with the action of ADH (an example of nephrogenic DI). This causes salt and water diuresis and an increased sensation of thirst. Hypercalcuria also predisposes to the development of renal calculi. Pancreatitis is another potential complication of hypercalcemia and is probably related to stones in the pancreatic ducts.

**Hypercalcemic crisis** describes an acute life-threatening increase in the serum calcium level. Hyperparathyroidism and malignant disease are the major causes of hypercalcemic crisis. Manifestations reflect those of severe hypercalcemia including polyuria, excessive thirst, dehydration, excessive muscle weakness, cardiac arrhythmias, disturbed mental state, and altered levels of consciousness.

**Treatment.** Treatment of calcium excess usually is directed toward rehydration and use of measures to increase urinary excretion of calcium and inhibit release of calcium from bone. Fluid replacement is needed in situations of volume depletion. The excretion of sodium is accompanied by calcium excretion. Diuretics and sodium chloride can be administered to increase urinary elimination of calcium after the ECF volume has been restored. Loop diuretics commonly are used rather than thiazide diuretics, which increase calcium reabsorption.

The initial lowering of calcium levels is followed by measures to inhibit bone resorption. Drugs that are used to inhibit calcium mobilization include bisphosphonates, calcitonin, and corticosteroids. The bisphosphonates, which act mainly by inhibiting osteoclastic activity, provide a significant reduction in calcium levels with relatively few side effects. Calcitonin inhibits osteoclastic activity, thereby decreasing bone resorption. The corticosteroids inhibit the conversion of vitamin D to its active form and are used to treat hypercalcemia due to vitamin D toxicity and hematologic malignancies.

**Disorders of Phosphorus Balance**

Phosphorus is mainly located in bone (about 85%) and in the ICF (about 14%). Only about 1% is in the ECF compartment, and of that, only a minute proportion is in the plasma. In the adult, the normal serum phosphorus level ranges from 2.5 to 4.5 mg/dL (0.8 to 1.45 mmol/L). Levels in children are greater, probably because of increased levels of growth hormone and decreased levels of gonadal hormones.

**Regulation of Phosphorus Balance**

Phosphorus is ingested in the diet and eliminated in the urine. It is derived from many dietary sources, including milk and meats. About 50% to 65% of ingested phosphorus is absorbed in the intestine, primarily in the jejunum. Absorption is diminished by concurrent ingestion of substances that bind phosphorus, including calcium, magnesium, and aluminum. Renal elimination of phosphate is then regulated by an overflow mechanism in which the amount of phosphate lost in the urine is directly related to phosphate concentrations in the blood.

Phosphorus exists in two forms within the body—inorganic and organic. The inorganic form (phosphate \( \text{H}_2\text{PO}_4^- \) or \( \text{HPO}_4^{2-} \)) is the principal circulating form of phosphorus and is the form that is routinely measured (and reported as phosphorus) for laboratory purposes. Most of the intracellular phosphorus is in the organic form (e.g., nucleic acids, phospholipids, adenosine triphosphate [ATP]).

Phosphorus is essential to many bodily functions. It plays a major role in bone formation; is essential to a number of metabolic processes, including the formation of ATP and the enzymes needed for glucose, fat, and protein metabolism; is a necessary component of several vital parts of the cell, being incorporated into the nucleic acids of DNA and RNA and the phospholipids of the cell membrane; and serves as an acid–base buffer in the ECF and in the kidney. Delivery of oxygen by the red blood cell depends on organic phosphorus in ATP and 2,3-diphosphoglycerate (2,3-DPG). Phosphorus is
also needed for normal function of white blood cells and platelets.

**Hypophosphatemia**

Hypophosphatemia is commonly defined by a serum phosphorus level of less than 2.5 mg/dL (0.81 mmol/L) in adults; and is considered severe at a concentration of less than 1.0 mg/dL (0.32 mmol/L). Hypophosphatemia may occur despite normal body phosphorus stores as a result of movement from the ECF into the ICF compartment. Serious depletion of phosphorus may exist with low, normal, or high plasma concentrations.

The most common causes of hypophosphatemia are depletion of phosphorus because of insufficient intestinal absorption, transcompartmental shifts, and increased renal losses. Often, more than one of these mechanisms is active. Unless food intake is severely restricted, dietary intake and intestinal absorption of phosphorus are usually adequate. Intestinal absorption may be inhibited by administration of glucocorticoids, high dietary levels of magnesium, and hypothyroidism. Prolonged ingestion of antacids may also interfere with intestinal absorption. Antacids that contain aluminum hydroxide, aluminum carbonate, and calcium carbonate bind with phosphate, causing increased phosphate losses in the stool. Because of their ability to bind phosphate, calcium-based antacids are sometimes used therapeutically to decrease plasma phosphate levels in persons with chronic kidney disease.

Malnutrition increases phosphate excretion and phosphorus loss from the body. Refeeding of malnourished persons increases the incorporation of phosphorus into nucleic acids and phosphorylated compounds in the cell. The catabolic events that occur with diabetic ketoacidosis also deplete phosphorus stores. Usually the hypophosphatemia does not become apparent, however, until insulin and fluid replacement have reversed the dehydration and glucose has started to move back into the cell. Chronic alcohol use is a common cause of hypophosphatemia. Contributing factors include poor food intake and the effect that chronic alcohol use has on the renal threshold for phosphate reabsorption, causing more phosphate to be eliminated in the urine. Administration of hyperalimentation solutions without adequate phosphorus can cause a rapid influx of phosphorus into the body’s muscle mass, particularly if treatment is initiated after a period of tissue catabolism. Respiratory alkalosis due to prolonged hyperventilation can produce hypophosphatemia through increased PTH levels and increased phosphate excretion. Clinical conditions associated with hyperventilation include sepsis, withdrawal from chronic alcoholism, fever, and primary hyperventilation.

**Manifestations.** Many of the manifestations of phosphorus deficiency result from a decrease in cellular energy stores associated with a deficiency in ATP and impaired oxygen transport due to a decrease in red blood cell 2,3-diphosphoglycerate (2,3-DPG). The decrease in cellular energy can cause altered neural function, disturbed musculoskeletal function, and hematologic disorders (Table 8-7).

Red blood cell metabolism is impaired by phosphorus deficiency; causing the cells to become rigid, undergo increased hemolysis, and have diminished ATP and 2,3-DPG levels (see Chapter 14). The chemotactic and phagocytic functions of white blood cells and the hemostatic functions of the platelets are also impaired. Anorexia and dysphagia can occur. Neural manifestations (intention tremors, paresthesias, hyporeflexia, stupor, coma, and seizures) are uncommon but serious manifestations.

Chronic phosphorus depletion interferes with mineralization of newly formed bone matrix. In growing children, this process causes abnormal endochondral growth and clinical manifestations of rickets. In adults,

the condition leads to joint stiffness, bone pain, and skeletal deformities consistent with osteomalacia (see Chapter 44).

**Treatment.** The treatment of hypophosphatemia is usually directed toward prophylaxis. This may be accomplished with dietary sources high in phosphorus (one glass of milk contains approximately 250 mg of phosphorus) or with oral or intravenous replacement solutions. Phosphorus supplements usually are contraindicated in hyperparathyroidism, chronic kidney disease, and hypercalciemia because of the increased risk of extracellular calcifications.

**Hyperphosphatemia**

Hyperphosphatemia represents a serum phosphorus concentration in excess of 4.5 mg/dL (1.45 mmol/L) in adults. Moderate hyperphosphatemia exists when serum phosphate is in the range of 4.6 to 6.0 mg/dL (1.49 to 1.94 mmol/L) and severe hyperphosphatemia when serum phosphate levels are greater than 6.0 (1.94 mmol/L).³

Hyperphosphatemia can result from failure of the kidneys to excrete excess phosphate, rapid redistribution of intracellular phosphate to the ECF compartment, or high phosphate intake.³,⁴² Because phosphorus is primarily eliminated by the kidneys, hyperphosphatemia due to impaired renal function is a common electrolyte disorder in persons with chronic kidney disease (see Chapter 26). Release of intracellular phosphorus can result from conditions such as massive tissue injury, rhabdomyolysis (muscle dissolution), heat stroke, potassium deficiency, and seizures. The administration of excess phosphate-containing antacids, laxatives, or enemas can be another cause of hyperphosphatemia, especially when there is a decrease in vascular volume and a reduced glomerular filtration rate. Phosphate-containing laxatives and enemas predispose to hypovolemia and a decreased glomerular filtration rate by inducing diarrhea, thereby increasing the risk of hyperphosphatemia. Serious and even fatal hyperphosphatemia has reportedly resulted from administration of phosphate enemas.⁴⁷

**Manifestations.** Many of the signs and symptoms of a phosphate excess are related to a calcium deficit (see Table 8-7). Because of the reciprocal relationship between calcium and phosphate levels, a high serum phosphate level tends to lower serum calcium levels, which can lead to tetany and other signs of hypocalcemia.³ Inadequately treated hyperphosphatemia in chronic kidney disease can lead to renal bone disease, and extracellular calcifications in soft tissues (see Chapter 26). A secondary effect of hyperphosphatemia in chronic kidney disease is stimulation of nodular hyperplasia of the parathyroid glands that results in a secondary hyperparathyroidism.⁴⁶

**Treatment.** The treatment of hyperphosphatemia is directed at the cause of the disorder. Dietary restriction of foods that are high in phosphorus may be used. Calcium-based phosphate binders are useful in chronic hyperphosphatemia. Sevelamer, a recently approved calcium- and aluminum-free phosphate binder, is as effective as a calcium-based binder, but lacks its adverse effects.³ Hemodialysis is used to reduce phosphate levels in persons with chronic kidney disease.

**Disorders of Magnesium Balance**

Magnesium is the second most abundant intracellular divalent cation.⁴⁸–⁵⁰ Although the average adult has approximately 24 g of magnesium distributed throughout the body, only an estimated 2% is distributed in the ECF.⁵¹ The normal serum concentration of magnesium is 1.3 to 2.1 mg/dL (0.65 to 1.1 mmol/L).³

**Regulation of Magnesium Balance**

Magnesium is ingested in the diet, absorbed from the intestine, and excreted by the kidneys. Intestinal absorption is not closely regulated, and only about 30% to 50% of dietary magnesium is absorbed.⁴⁸ The kidney is the principal organ of magnesium regulation. The kidneys filter about 80% of the serum magnesium and only about 3% is excreted in the urine, although this amount can be influenced by other conditions and medications.⁴⁸ Renal reabsorption is stimulated by PTH and is decreased in the presence of increased serum levels of magnesium and calcium.

Magnesium is a cofactor in hundreds of metabolic reactions in the body. It is required for cellular energy metabolism, functioning of the Na⁺/K⁺-ATPase membrane pump, membrane stabilization, nerve conduction, and ion transport. It also acts as a cofactor in many intracellular enzyme reactions, including the transfer of high-energy phosphate groups in the generation of ATP from adenosine diphosphate (ADP). It is essential to all reactions that require ATP, for every step related to replication and transcription of DNA, and for translation of messenger RNA.³,⁴⁸–⁵⁰

Magnesium also participates in potassium and calcium channel activity. Magnesium blocks the outward movement of potassium in cardiac cells, preventing the development of cardiac arrhythmias.⁵¹ It also acts as a smooth muscle relaxant by altering calcium levels that are responsible for muscle contraction. Because of its smooth muscle relaxing effect, there has been a recent interest in the use of magnesium in the treatment of severe bronchial asthma.⁵⁶ In addition, it has been suggested that magnesium may have an anticonvulsant effect. Currently, it is the first-line drug in the prevention and treatment of seizures associated with eclampsia in pregnant women (see Chapter 18).⁵²

**Hypomagnesemia**

Magnesium deficiency refers to depletion of total body stores and hypomagnesemia to a low serum concentration of less than 1.3 mg/dL (0.65 mmol/L).³ It is seen in conditions that limit intake or increase intestinal or
renal losses, and it is a common finding in patients in emergency departments and critical care units.

Magnesium deficiency can result from insufficient intake, excessive losses, or movement between the ECF and ICF compartments. It can result from conditions that directly limit intake, such as malnutrition, starvation, or prolonged use of magnesium-free parenteral nutrition. Other conditions, such as diarrhea, malabsorption syndromes, prolonged nasogastric suction, or laxative abuse, decrease intestinal absorption. Another common cause of magnesium deficiency is chronic alcoholism. Many factors contribute to hypomagnesemia in alcoholism, including low intake and gastrointestinal losses from diarrhea. There have also been recent reports of hypomagnesemia associated with prolonged use of proton-pump inhibitor medications, presumably due to decreased intestinal absorption of magnesium.

Although the kidneys are able to defend against hypomagnesemia, they are less able to conserve magnesium and prevent hypomagnesemia. Urine losses are increased in diabetic ketoacidosis, hyperparathyroidism, and hyperaldosteronism. Some drugs increase renal losses of magnesium, including both loop and thiazide diuretics, nephrotoxic drugs such as aminoglycoside antibiotics, cyclosporine, cisplatin, and amphotericin B.

Relative hypomagnesemia may also develop in conditions that promote movement of magnesium between the ECF and ICF compartments, including rapid administration of glucose, insulin-containing parenteral solutions, and alkalosis. Although transient, these conditions can cause serious alterations in body function.

**Manifestations.** Signs of magnesium deficiency are not usually apparent until the serum magnesium is less than 1.0 mEq/L (0.4 mmol/L). Hypomagnesemia is characterized by an increase in neuromuscular excitability as evidenced by hyperactive deep tendon reflexes, paresthesias (i.e., numbness, pricking, tingling sensation), muscle fasciculations, and tetanic muscle contractions (Table 8-8). A positive Chvostek or Trousseau sign may be present, especially if the abnormal serum magnesium level is associated with hypocalcemia. Other manifestations may include ataxia, vertigo, disorientation, depression, and psychotic symptoms.

Cardiovascular manifestations include tachycardia, hypertension, and ventricular arrhythmias. There may be ECG changes such as widening of the QRS complex, appearance of peaked T waves, prolongation of the PR interval, T-wave inversion, and appearance of U waves. Ventricular arrhythmias, particularly in the presence of digitalis, may be difficult to treat unless magnesium levels are normalized.

Magnesium deficiency often occurs in conjunction with hypocalcemia and hypokalemia, producing a number of related neurologic and cardiovascular manifestations. Hypocalcemia is typical of severe hypomagnesemia. Most persons with hypomagnesemia-related hypocalcemia have decreased PTH levels, probably as a result of impaired magnesium-dependent mechanisms that control PTH synthesis and release. The resultant hypocalcemia is corrected with calcium replacement until the magnesium is normalized. Hypokalemia is also a typical feature of hypomagnesemia. It leads to a reduction in intracellular potassium and impairs the ability of the kidneys to conserve potassium. When hypomagnesemia is present, hypokalemia remains unresponsive to potassium replacement therapy.

**Treatment.** The treatment of hypomagnesemia consists of magnesium replacement. The route of administration depends on the severity of the condition. Symptomatic moderate to severe magnesium deficiency is treated by parenteral administration. Treatment must be continued for several days to replace stored and serum levels. In conditions of chronic intestinal or renal loss, maintenance support with oral magnesium may be required.

Magnesium often is used therapeutically to treat cardiac arrhythmia, myocardial infarct, angina, bronchial asthma, and pregnancy complicated by preeclampsia or eclampsia. Caution is needed to prevent hypomagnesemia in persons with any degree of chronic kidney disease.

Hypermagnesemia

Hypermagnesemia represents an increase in total body magnesium and a serum magnesium concentration in excess of 2.5 mg/dL (1.1 mmol/L). Because of the ability of the normal kidney to excrete magnesium, hypermagnesemia is rare.

When hypermagnesemia does occur, it usually is related to renal insufficiency and the injudicious use of magnesium-containing medications such as antacids, mineral supplements, or laxatives. The elderly are particularly at risk because they have age-related reductions in kidney function and tend to consume more magnesium-containing medications, including antacids and laxatives. Magnesium sulfate is used to treat toxemia of pregnancy and labor; in these cases, careful monitoring of serum magnesium levels and observation for signs of hypermagnesemia are essential. Neonatal hypermagnesemia may also occur, but usually the blood levels of magnesium are lower in the infant than in the mother.

Manifestations. The signs and symptoms occur only when serum magnesium levels exceed 4.0 mg/dL (2.0 mmol/L). Because magnesium tends to suppress PTH secretion, hypocalcemia may accompany hypermagnesemia.

Hypermagnesemia affects neuromuscular and cardiovascular function and releases acetylcholine at the myoneural junction, causing hyporeflexia and muscle weakness. Cardiovascular effects are related to the calcium channel–blocking effects of magnesium. Blood pressure is decreased, and the ECG shows an increase in the PR interval, a shortening of the QT interval, T-wave abnormalities, and prolongation of the QRS and PR intervals. Severe hypermagnesemia is associated with muscle and respiratory paralysis, complete heart block, and cardiac arrest.

Treatment. The treatment of hypermagnesemia includes cessation of magnesium administration. Calcium is a direct antagonist of magnesium, and intravenous administration of calcium may be used. Peritoneal dialysis or hemodialysis may be required.

Disorders of Parathyroid Hormone

Both calcium and phosphate homeostasis are impacted by disorders of PTH. Parathyroid hormone is secreted by the four parathyroid glands located adjacent to the thyroid gland in the neck. The hormone is synthesized as a preprohormone, converted to a prohormone and then to PTH, and finally packaged into secretory granules for release into the circulation. The dominant regulator of PTH secretion is the serum calcium concentration (see Fig. 8-13). A unique ECF calcium-sensing receptor on the parathyroid cell membrane responds rapidly to changes in serum calcium levels. When the serum calcium level is high, the secretion of PTH is inhibited, and serum calcium is deposited in the bones. When the level is low, PTH secretion is increased, and calcium is mobilized from the bones and released into the blood.

The synthesis and release of PTH from the parathyroid gland are also influenced by magnesium. Magnesium serves as a cofactor in the generation of cellular energy and is important in the function of second messenger systems. Magnesium’s effects on the synthesis and release of PTH are thought to be mediated through these mechanisms. Because of its function in regulating PTH release, severe and prolonged hypomagnesemia can markedly inhibit PTH levels.

The central function of PTH is to regulate ionized Ca$^{++}$ levels through three target organs: bone, kidney, and intestine absorption. Parathyroid hormone stimulates the release of calcium from bone, and it increases calcium reabsorption by the kidney, while increasing the activation of vitamin D by the kidney; which in turn, increases the intestinal reabsorption of calcium.

Hypoparathyroidism

Hypoparathyroidism reflects deficient PTH secretion, resulting in low serum levels of ionized calcium. Parathyroid hormone deficiency may occur because of a congenital absence of all of the parathyroid glands, as in DiGeorge syndrome (see Chapter 16), or because of an acquired disorder due to inadvertent removal or irreversible damage to the glands during thyroidectomy, parathyroidectomy, or radical neck dissection for cancer. A transient form of PTH deficiency may occur after thyroid surgery owing to parathyroid gland suppression. Hypoparathyroidism also may have an autoimmune origin. Antiparathyroid antibodies have been detected in some persons with hypoparathyroidism, particularly those with multiple autoimmune disorders such as type 1 diabetes mellitus or Graves disease. Other causes of hypoparathyroidism include heavy metal damage such as occurs with Wilson disease and metastatic tumors. Functional impairment of parathyroid function occurs with magnesium deficiency. Correction of the hypomagnesemia results in rapid disappearance of the condition.

Manifestations. Manifestations of acute hypoparathyroidism, which result from a decrease in serum calcium, include tetany with muscle cramps, carpopedal spasm, and convulsions (see section on hypocalcemia). Paresthesias, such as tingling of the circumoral area and in the hands and feet, are almost always present. Low calcium levels may cause prolongation of the QT interval on the ECG, resistance to digitalis, hypotension, and refractory heart failure. Symptoms of chronic PTH deficiency include lethargy, an anxiety state, and personality changes. There may be blurring of vision because of cataracts, which develop over a number of years. Extrapyramidal signs, such as those seen with Parkinson disease, may occur because of calcification of the basal ganglia. Teeth may be defective if the disorder occurs during childhood.
Pseudohypoparathyroidism is a rare familial disorder characterized by target tissue resistance to PTH. It is characterized by hypocalcemia, increased parathyroid function, and a variety of congenital defects in the growth and development of the skeleton, including short stature and short metacarpal and metatarsal bones. There are variants of the disorder, with some persons having the pseudohypoparathyroidism along with the congenital defects and others having the congenital defects with normal calcium and phosphorus levels. The manifestations of the disorder are due primarily to chronic hypocalcemia.

**Treatment.** The goals of therapy focus on the control of symptoms while minimizing complications. Acute hypoparathyroid tetany, which usually occurs after surgery, is treated with intravenous calcium gluconate followed by oral administration of calcium salts and vitamin D. Magnesium supplementation is used when the disorder is caused by magnesium deficiency. Persons with chronic hypoparathyroidism are treated with oral calcium and vitamin D. Levels of serum calcium, phosphorus, and creatinine (to check kidney function) are monitored at regular intervals as a means of maintaining serum calcium within a slightly low but asymptomatic range.

**Hyperparathyroidism**

Hyperparathyroidism is characterized by increased levels of PTH. It can manifest as a primary disorder caused by hyperplasia or tumors of the parathyroid glands, or as a secondary disorder in persons with chronic kidney disease or chronic malabsorption of calcium.

**Manifestations.** Primary hyperparathyroidism is a leading cause of hypercalcemia in the outpatient department. It is seen more commonly after 50 years of age and is more common in women than men. Primary hyperparathyroidism causes an elevation in ionized serum calcium and increased urinary excretion of both calcium and phosphorus. The increased urinary concentration of calcium and phosphorus may prompt the development of kidney stones. Chronic bone resorption may produce diffuse demineralization, pathologic fractures, and cystic bone lesions.

Signs and symptoms of the disorder are related to skeletal abnormalities, exposure of the kidney to high calcium levels, and elevated serum calcium levels (see hypercalcemia). At the present time, primary hyperparathyroidism usually manifests as an asymptomatic disorder that is discovered in the course of routine biochemical testing. Although thought to be asymptomatic, these patents may experience nonspecific constitutional symptoms such as fatigue, weakness, anorexia, and bone pain.

Secondary hyperparathyroidism involves hyperplasia of the parathyroid glands and occurs primarily in persons with chronic kidney disease. In the early stages of chronic kidney disease, an increase in PTH results from decreased serum calcium and activated vitamin D levels. As the disease progresses, there is a decrease in vitamin D and calcium receptors, making the parathyroid glands more resistant to feedback regulation by serum calcium and vitamin D levels. At this point, elevated phosphorus levels induce hyperplasia of the parathyroid glands independent of calcium and vitamin D levels. The bone disease seen in persons with secondary hyperparathyroidism due to chronic kidney disease is known as renal osteodystrophy (see Chapter 26).

**Treatment.** Treatment of hyperparathyroidism includes resolving the hypercalcemia with increased fluid intake. Whenever possible, the underlying cause of secondary hyperparathyroidism should be treated. Parathyroidectomy may be indicated in persons with symptomatic primary hyperparathyroidism. The goal of medical management is to normalize calcium levels. Calcitriol and other vitamin D analogs may be used to control parathyroid hyperplasia in chronic kidney disease. Persons with chronic kidney disease may also need phosphate binders to decrease intestinal absorption of phosphorus and prevent the skeletal disorders associated with the osteodystrophies (see Chapter 26). Calcimimetic agents, which act through the calcium-sensing receptor in the parathyroid gland, may be used to decrease PTH production in primary and secondary hyperparathyroidism.

**SUMMARY CONCEPTS**

- Calcium, phosphorus, and magnesium are the major divalent ions in the body. These ions are directly or indirectly regulated by a number of factors including vitamin D and PTH.

- Calcium is a major divalent cation with approximately 99% located in bone and less than 1% in the ECF compartment. Of the three forms of ECF calcium, only the ionized form can cross the cell membrane, contributing to neuromuscular function, blood clotting, and enzyme reactions. In hypocalcemia, decreased levels in ionized calcium produce an increase in neuromuscular excitability; and in hypercalcemia increased levels of ionized calcium produce a decrease in excitability.

- Phosphorus is largely an ICF anion, being incorporated into nucleic acids, adenosine triphosphate (ATP), and 2,3-diphosphoglycerate in the red blood cells. Hypophosphatemia, which is associated with decreased intestinal absorption, transcompartmental shifts, and disorders of renal elimination, causes signs and symptoms of neural dysfunction, disturbed musculoskeletal function, and hematologic disorders. Hyperphosphatemia, which occurs with renal failure and PTH deficiency, is associated with decreased plasma calcium levels.
Acid–Base Balance

Metabolic activities of the body require precise regulation of acid–base balance as reflected in the pH of the ECF, which is normally maintained within a very narrow range of 7.35 to 7.45. Membrane excitability, enzyme systems, and chemical reactions all depend on the pH being regulated within a narrow physiologic range to function in an optimal way.

Acid–Base Chemistry

Acids and bases have their own chemical properties and definitions. An acid is defined as a compound that can dissociate and release a hydrogen (H⁺) ion and a base as a compound that can accept or combine with H⁺. For example, hydrochloric acid (HCl) dissociates in water to form H⁺ and Cl⁻ ions. The bicarbonate ion (HCO₃⁻) is a base because it can combine with H⁺ to form carbonic acid (H₂CO₃). Most of the body’s acids and bases are weak; the most important are H₂CO₃, which is a weak acid derived from carbon dioxide (CO₂), and HCO₃⁻, which is a weak base.

The concentration of H⁺ in body fluids is low compared with other ions. For example, the Na⁺ is present at a concentration approximately 3.5 million times that of the H⁺. Because it is cumbersome to work with such a small number, the H⁺ concentration is commonly expressed in terms of the pH. Specifically, pH represents the negative logarithm (log₁₀) of the H⁺ concentration expressed in mEq/L. Since the pH is inversely related to the H⁺ concentration, a low pH indicates a high concentration of H⁺ and a high pH a low concentration of H⁺.

Acid and Base Production

Acids are continuously generated as by-products of metabolic processes (Fig. 8-16). Physiologically, these acids fall into two groups: volatile H₂CO₃ and all other nonvolatile or fixed acids (e.g., sulfuric, hydrochloric, and...
Body metabolism results in a continuous production of carbon dioxide (CO₂). As CO₂ is formed during the metabolic process, it diffuses out of body cells into the tissue spaces and then into the circulation. It is transported in the circulation in three forms: (1) dissolved in the plasma, (2) as bicarbonate, and (3) attached to hemoglobin.

1. **Plasma.** A small portion (about 10%) of the CO₂ that is produced by body cells is transported in the dissolved state to the lungs and then exhaled. The amount of dissolved CO₂ that can be carried in plasma is determined by the partial pressure of the gas (PCO₂) and its solubility coefficient (0.03 mL/100 mL plasma for each 1 mm Hg PCO₂). Thus, each 100 mL of arterial blood with a PCO₂ of 40 mm Hg would contain 1.2 mL of dissolved CO₂. It is the carbonic acid (H₂CO₃) formed from hydration of dissolved CO₂ that contributes to the pH of the blood.

2. **Bicarbonate.** Carbon dioxide in excess of that which can be carried in the plasma moves into the red blood cells, where the enzyme carbonic anhydrase (CA) catalyzes its conversion to carbonic acid (H₂CO₃). The H₂CO₃, in turn, dissociates into hydrogen (H⁺) and bicarbonate (HCO₃⁻) ions. The H⁺ combines with hemoglobin and the HCO₃⁻ diffuses into plasma, where it participates in acid-base regulation. The movement of HCO₃⁻ into the plasma is made possible by a special transport system on the red blood cell membrane in which HCO₃⁻ ions are exchanged for chloride ions (Cl⁻).
Transport

Hemoglobin. The remaining CO$_2$ in the red blood cells combines with hemoglobin to form carbaminohemoglobin (HbCO$_3$). The combination of CO$_2$ with hemoglobin is a reversible reaction characterized by a loose bond, so that CO$_2$ can be easily released in the alveolar capillaries and exhaled from the lung.

(text continued from page 191)

phosphoric acid). The difference between the two types of acids arises because H$_2$CO$_3$ is in equilibrium with dissolved CO$_2$, which is volatile and leaves the body in way of the lungs. The nonvolatile or fixed acids are not eliminated by the lungs. Instead, they are buffered by body proteins or extracellular buffers, such as HCO$_3^-$, and then eliminated by the kidney.

Carbon Dioxide and Bicarbonate Production. Carbon dioxide, which is the end product of aerobic metabolism, is transported in the circulation as a dissolved gas (i.e., PCO$_2$), as the HCO$_3^-$ ion, or as CO$_2$ bound to hemoglobin in carbaminohemoglobin (see understanding carbon dioxide transport). Collectively, dissolved CO$_2$ and HCO$_3^-$ account for approximately 77% of the CO$_2$ that is transported in the extracellular fluid; the remaining CO$_2$ travels as carbaminohemoglobin. Although CO$_2$ is a gas and not an acid, a small percentage of the gas combines with water to form the weak H$_2$CO$_3$ acid. The reaction that generates H$_2$CO$_3$ from CO$_2$ and water is catalyzed by an enzyme called carbonic anhydrase, which is present in large quantities in red blood cells, renal tubular cells, and other tissues in the body. (see Understanding: Carbon Dioxide Transport)

Because it is almost impossible to measure H$_2$CO$_3$, carbon dioxide measurements are commonly used when calculating pH. The H$_2$CO$_3$ content of the blood can be calculated by multiplying the partial pressure of CO$_2$ (PCO$_2$) by its solubility coefficient, which is 0.03. This means that the concentration of H$_2$CO$_3$ in the arterial blood, which normally has a PCO$_2$ of approximately 40 mm Hg, is 1.20 mEq/L (40 \times 0.03 = 1.20), and that for venous blood, which normally has a PCO$_2$ of approximately 45 mm Hg, is 1.35 mEq/L.

Production of Nonvolatile Acids and Bases. The metabolism of dietary proteins and other substances results in the generation of nonvolatile acids and bases. For example, the metabolism of sulfur-containing amino acids (e.g., methionine and cysteine) results in the production of sulfuric acid; of arginine and lysine, hydrochloric acid; and of nucleic acids, phosphoric acid. Incomplete oxidation of glucose results in the formation of lactic acid, and incomplete oxidation of fats, the production of ketoacids. The major source of bases is the metabolism of amino acids such as aspartate and glutamate and the metabolism of certain organic anions (e.g., citrate, lactate, acetate).

Calculation of pH

The serum pH can be calculated using an equation called the Henderson-Hasselbalch equation. This equation uses the dissociation constant for the bicarbonate buffer system (which is 6.1) plus the log of the HCO$_3^-$ to - PCO$_2$ (used as a measure of H$_2$CO$_3$) ratio (normally 20:1) to determine the pH (i.e., pH = 6.1 + log of 20 = 7.4). Because the ratio is used, a change in either HCO$_3^-$ or PCO$_2$ will have little or no effect on pH as long as there is an accompanying change in PCO$_2$ and HCO$_3^-$ (Fig. 8-17). The pH will decrease when the ratio decreases and increase when the ratio increases.

Regulation of pH

The pH of body fluids is regulated by three major mechanisms: (1) chemical buffer systems in body fluids, which immediately combine with excess acids or bases to prevent large changes in pH; (2) the lungs, which control
the elimination of CO₂; and (3) the kidneys, which eliminate H⁺ and both reabsorb and generate HCO₃⁻ (see Fig. 8-16).

**Chemical Buffer Systems**

The moment-by-moment regulation of pH depends on chemical buffer systems in the ICF and ECF. The three major buffer systems that protect the pH of body fluids are the bicarbonate buffer system, the transcellular hydrogen–potassium exchange system, and body proteins.⁵ Bone provides an additional buffering of body acids. These buffer systems are immediately available to combine with excess acids or bases and prevent large changes in pH from occurring during the time it takes for the respiratory and renal mechanisms to become effective.

The bicarbonate buffer system, which is the principal ECF buffer, uses H₂CO₃ as its weak acid and a bicarbonate salt such as sodium bicarbonate (NaHCO₃) as its weak base. It substitutes the weak H₂CO₃ for a strong acid such as hydrochloric acid or the weak bicarbonate base for a strong base such as sodium hydroxide. The bicarbonate buffer system is a particularly efficient system because its components can be readily added or removed from the body.⁶° Metabolism provides an ample supply of CO₂, which can replace any H₂CO₃ that is lost when excess base is added, and CO₂ can be readily eliminated when excess acid is added. Likewise, the kidney can conserve or form new HCO₃⁻ when excess acid is added, and it can excrete HCO₃⁻ when excess base is added.

The transcellular hydrogen/potassium exchange system provides another important system for regulation of acid–base balance. Both H⁺ and K⁺ are positively charged, and both ions move freely between the ICF and ECF compartments (see Fig. 8-10). When excess H⁺ is present in the ECF, it moves into the ICF in exchange for K⁺, and when excess K⁺ is present in the ECF, it moves into the ICF in exchange for H⁺. Thus, alterations in potassium levels can affect acid–base balance, and changes in acid–base balance can influence potassium levels. ¹

*Proteins* are the largest buffer system in the body. Proteins are *amphoteric*, meaning that they can function either as acids or bases. They contain many ionizable groups that can release or bind H⁺. The protein buffers are largely located within cells, and H⁺ ions and CO₂ diffuse across cell membranes for buffering by intracellular proteins. Albumin and plasma globulins are the major protein buffers in the vascular compartment.

*Bone* represents an additional source of acid–base buffering.⁶ Excess H⁺ ions can be exchanged for Na⁺ and K⁺ on the bone surface, and dissolution of bone minerals with release of compounds such as sodium bicarbonate (NaHCO₃) and calcium carbonate (CaCO₃) into the ECF can be used for buffering excess acids. It has been estimated that as much as 40% of buffering of an acute acid load takes place in bone. The role of bone buffers is even greater in the presence of chronic acidoses. The consequences of bone buffering include demineralization of bone and predisposition to development of kidney stones due to increased urinary excretion of calcium. Persons with chronic kidney disease are at particular risk for reduction in bone calcium due to acid retention.

**Respiratory Control Mechanisms**

The respiratory system provides for the elimination of CO₂ into the air and plays a major role in acid–base regulation. Increased pulmonary ventilation increases CO₂ elimination, producing a decrease in arterial PCO₂; whereas decreased ventilation decreases CO₂ elimination, producing an increase in arterial PCO₂. Chemoreceptors in the brain stem and the peripheral chemoreceptors in the carotid and aortic bodies sense changes in the PCO₂ and pH of the blood and alter the ventilatory rate. The respiratory control of pH is rapid, occurring within minutes, and is maximal within 12 to 24 hours.⁴ Although the respiratory response is rapid, it does not completely return the pH to normal and is only about 50% to 75% effective as a buffer system.⁶⁶

**Renal Control Mechanisms**

The kidneys play a critical role in maintaining acid–base balance.⁶⁷ They accomplish this through the reabsorption of HCO₃⁻, regulation of H⁺ secretion, and generation of new HCO₃⁻. The renal mechanisms for regulating acid–base balance cannot adjust the pH within minutes, as respiratory mechanisms can, but they continue to function for days until the pH has returned to normal or the near-normal range.

**Hydrogen/Bicarbonate Exchange.** The hydrogen/bicarbonate exchange system regulates pH through the secretion of excess H⁺ and reabsorption of HCO₃⁻ by the renal tubules. Bicarbonate is freely filtered in the glomerulus and reabsorbed or reclaimed in the tubules.² Each HCO₃⁻ that is reclaimed requires the secretion of a H⁺ ion, a process that is tightly coupled with Na⁺ reabsorption. Another mechanism that the kidney uses in

---

*FIGURE 8-17.* The pH represented as a balance scale. When the ratio of bicarbonate (HCO₃⁻) to carbonic acid (H₂CO₃, arterial PCO₂ × 0.30) = 20:1, the pH is 7.4.
controlling HCO₃⁻ loss is the chloride/bicarbonate anion exchange that occurs in association with Na⁺ reabsorption. Chloride is absorbed along with Na⁺ throughout the tubules. In situations of volume depletion due to vomiting and Cl⁻ depletion, the kidney is forced to substitute HCO₃⁻ for the Cl⁻ anion, thereby increasing its absorption of HCO₃⁻.

Both reabsorption of HCO₃⁻ and excretion of acid are accomplished through H⁺ secretion as the urine filtrate moves through the tubular structure of the kidney. The epithelial cells of the proximal tubule, the thick ascending limb of Henle, and distal tubule all secrete H⁺ into the tubular fluid by the Na⁺/H⁺ counter-transport mechanism (see Chapter 24). The potassium/hydrogen exchange system in the collecting tubules functions in H⁺ secretion by substituting the reabsorption of K⁺ for excretion of H⁺. Acidosis tends to increase H⁺ elimination and decrease K⁺ elimination, with a resultant increase in serum potassium levels, whereas alkalosis tends to decrease H⁺ elimination and increase K⁺ elimination, with a resultant decrease in serum potassium levels.⁶⁴–⁶⁶

**Generation of New Bicarbonate.** Another important but more complex buffer system that facilitates the excretion of H⁺ and generation of new HCO₃⁻ is the ammonia buffer system. Renal tubular cells are able to use the amino acid glutamine to synthesize ammonia (NH₃) and secrete it into the tubular fluid. Hydrogen ions then combine with the NH₃ to form ammonium ions (NH₄⁺). The NH₄⁺ ions, in turn, combine with Cl⁻ ions that are present in the tubular fluid to form ammonium chloride (NH₄Cl), which is then excreted in the urine. Under normal conditions, the amount of H⁺ ion eliminated by the ammonia buffer system is about 50% of the acid excreted and new HCO₃⁻ regenerated. However, with chronic acidosis, it can become the dominant mechanism for H⁺ excretion and new HCO₃⁻ generation.

**Phosphate Buffer System.** Because extremely acidic urine (pH 4.0 to 4.5) would be damaging to structures in the urinary tract, the elimination of H⁺ requires a buffer system. There are two important intratubular buffer systems: the phosphate buffer system and the previously described ammonia buffer system. The phosphate buffer system uses HPO₄²⁻ and H₂PO₄⁻ that are present in the tubular filtrate to buffer H⁺. Because HPO₄²⁻ and H₂PO₄⁻ are poorly absorbed, they become more concentrated as they move through the tubules.

**Laboratory Tests**

Laboratory tests that are used in assessing acid–base balance include arterial blood gases and serum electrolytes, base excess or deficit, and anion gap. Although useful in determining whether acidosis or alkalosis is present, the pH measurements of the blood provide little information about the cause of an acid–base disorder.

**Arterial blood gases** provide a means of assessing the respiratory component of acid–base balance. H₂CO₃ levels are determined from arterial PCO₂ levels and the solubility coefficient for CO₂ (normal arterial PCO₂ is 38 to 42 mm Hg). Arterial blood gases are used because venous blood gases are highly variable, depending on metabolic demands of the various tissues that empty into the vein from where the sample is being drawn. Laboratory tests are used to measure serum electrolytes, CO₂ content, and HCO₃⁻. These measurements are determined by adding a strong acid to a blood sample and measuring the amount of CO₂ that is produced. More than 70% of the CO₂ in the blood is in the form of bicarbonate. The serum bicarbonate is then determined from the total CO₂ content of the blood. Base excess or deficit is a measure of the HCO₃⁻ excess or deficit. It describes the amount of a fixed acid or base that must be added to a blood sample to achieve a pH of 7.4 (normal ± 2.0 mEq/L).⁶⁴ A base excess indicates metabolic alkalosis, and a base deficit indicates metabolic acidosis.

The **anion gap** describes the difference between the serum concentration of the major measured cation (Na⁺) and the sum of the measured anions (Cl⁻ and HCO₃⁻). This difference represents the concentration of unmeasured anions, such as phosphates, sulfates, organic acids, and proteins (Fig. 8-18). Normally, the anion gap ranges between 8 and 12 mEq/L (a value of 16 mEq/L is normal if both Na⁺ and K⁺ concentrations are used in the calculation). The anion gap is increased in conditions such as lactic acidosis and ketoacidosis that result in a decrease in HCO₃⁻, and it is normal in hyperchloremic acidosis, where Cl⁻ replaces the HCO₃⁻ anion.⁶⁴

**Disorders of Acid–Base Balance**

The terms acidosis and alkalosis describe the clinical conditions that arise as a result of changes in dissolved CO₂ and HCO₃⁻ concentrations.⁶⁴ There are two types...
of acid–base disorders: metabolic and respiratory (Table 8-9). Metabolic disorders produce an alteration in the serum HCO$_3^-$ concentration and results from the addition or loss of nonvolatile acid or alkali to or from the extracellular fluids. A reduction in pH due to a decrease in HCO$_3^-$ is called metabolic acidosis, and an elevation in pH due to increased HCO$_3^-$ levels is called metabolic alkalosis. Respiratory disorders involve an alteration in the arterial PCO$_2$, reflecting an increase or decrease in alveolar ventilation. Respiratory acidosis is characterized by a decrease in pH, reflecting a decrease in ventilation and an increase in PCO$_2$. Respiratory alkalosis involves an increase in pH, resulting from an increase in alveolar ventilation and a decrease in PCO$_2$.

Primary Versus Compensatory Changes in pH

Acidosis and alkalosis typically involve a primary or initiating event and a compensatory or adaptive state that results from homeostatic mechanisms that attempt to correct or prevent large changes in pH. For example, a person may have a primary metabolic acidosis as a result of overproduction of ketoacids and respiratory alkalosis because of a compensatory increase in ventilation (see Table 8-9).

Compensatory mechanisms provide a means to control pH when correction is impossible or cannot be immediately achieved. Often, they are interim measures that permit survival while the body attempts to correct the primary disorder. Compensation requires the use of mechanisms different from those that caused the primary disorder. For example, the lungs cannot compensate for respiratory acidosis that is caused by lung disease, nor can the kidneys compensate for metabolic acidosis that occurs because of chronic kidney disease. The body can, however, use renal mechanisms to compensate for respiratory-induced changes in pH, and it can use respiratory mechanisms to compensate for metabolically induced changes in acid–base balance. Because compensatory mechanisms become more effective with time, there are often differences between the level of pH change that is present in acute and chronic acid–base disorders.

### Single Versus Mixed Acid–Base Disorders

Thus far acid–base disorders have been discussed as if they existed as a single primary disorder such as metabolic acidosis, accompanied by a predicted compensatory response (i.e., hyperventilation and respiratory alkalosis). It is not uncommon, however, for persons to present with more than one primary disorder or a mixed disorder. For example, a person may present with a low serum HCO$_3^-$ concentration due to metabolic acidosis and a high PCO$_2$ due to chronic lung disease.

Values for the predicted renal or respiratory compensatory responses can be used in the diagnosis of these mixed acid–base disorders (see Table 8-9). If the values for the compensatory response fall outside the predicted values, it can then be concluded that more than one disorder (i.e., a mixed disorder) is present. Since the respiratory response to changes in HCO$_3^-$ occurs almost immediately, there is only one predicted compensatory response for primary metabolic acid–base disorders. This is in contrast to the primary respiratory disorders,

<table>

Note: Predicted compensatory responses are in italics.

*If blood values are the same as predicted compensatory values, a single acid–base disorder is present; if values are different, a mixed acid–base disorder is present.1-3

*Acute renal compensation ≤48 hours, chronic renal compensation >48 hours.12
which have two ranges of predicted values, one for the acute and one for the chronic response. Renal compensation takes several days to become fully effective. The acute compensatory response represents the HCO$_3^-$ levels before renal compensation has occurred and the chronic response after it has occurred. Thus, the values for the serum pH tend to become more normal in the chronic phase.

**Metabolic Acidosis**

Metabolic acidosis involves a decreased serum HCO$_3^-$ concentration along with a decrease in pH. In metabolic acidosis, the body compensates for the decrease in pH by increasing the respiratory rate in an effort to decrease PCO$_2$ and H$_2$CO$_3$ levels.$^{1-3}$

Metabolic acidosis can be caused by one or more of the following four mechanisms: (1) increased production of fixed metabolic acids or ingestion of fixed acids such as salicylic acid, (2) inability of the kidneys to excrete the fixed acids produced by normal metabolic processes, (3) excessive loss of bicarbonate by the kidneys or gastrointestinal tract, or (4) an increase in serum Cl$^-$ concentration.$^{64}$ The anion gap is often useful in determining the cause of the metabolic acidosis$^{66}$ (Chart 8-2). The presence of excess metabolic acids produces an increase in the anion gap as sodium bicarbonate is replaced by the sodium salt of the offending acid (e.g., sodium lactate).

**Increased Production of Metabolic Acids.** Among the causes of metabolic acidosis are an accumulation of lactic acid and excess production of ketoacids. *Acute lactic acidosis*, which is one of the most common types of metabolic acidosis, develops when there is excess production or diminished removal of lactic acid from the blood.$^{60}$ Lactic acid is produced by the anaerobic metabolism of glucose. Most cases of lactic acidosis are caused by inadequate oxygen delivery, as in shock or cardiac arrest.$^{63}$ Such conditions not only increase lactic acid production, but also tend to impair lactic acid clearance because of poor liver and kidney perfusion. Lactic acidosis can also occur during periods of intense exercise in which the metabolic needs of the exercising muscles outpace their aerobic capacity for production of ATP, causing them to revert to anaerobic metabolism and the production of lactic acid. Lactic acidosis is also associated with disorders in which tissue hypoxia does not appear to be present. It has been reported in persons with leukemia, lymphomas and other cancers, poorly controlled diabetes, or severe liver failure. Mechanisms causing lactic acidosis in these conditions are poorly understood. Some conditions such as neoplasms may produce local increases in tissue metabolism and lactate production or they may interfere with blood flow to noncancerous cells.

Ketoacids (i.e., acetoacetic and β-hydroxybutyric acid), which are produced in the liver from fatty acids, are the source of fuel for many body tissues.$^{64,67}$ An overproduction of ketoacids occurs when carbohydrate stores are inadequate or when the body cannot use available carbohydrates as a fuel. The most common cause of ketoacidosis is uncontrolled diabetes mellitus, in which an insulin deficiency leads to the release of fatty acids from adipose cells with subsequent production of excess ketoacids$^{67}$ (see Chapter 33). Ketoacidosis may also develop as the result of fasting or food deprivation, during which the lack of carbohydrates produces a self-limited state of ketoacidosis.$^{68}$

**Decreased Renal Function.** Chronic kidney disease is the most common cause of chronic metabolic acidosis. The kidneys normally conserve or generate HCO$_3^-$ and secrete H$^+$ ions into the urine as a means of regulating acid–base balance. In chronic kidney disease, there is loss of both glomerular and tubular function, with retention of nitrogenous wastes and metabolic acids. In a condition called *renal tubular acidosis*, glomerular function is normal, but the tubular secretion of H$^+$ or reabsorption of HCO$_3^-$ is abnormal (see Chapter 25).$^{75}$

**Increased Bicarbonate Losses.** Increased HCO$_3^-$ losses occur with the loss of bicarbonate-rich body fluids or with impaired conservation of HCO$_3^-$ by the kidney. Intestinal secretions have a high HCO$_3^-$ concentration.

Consequently, excessive loss of $\text{HCO}_3^-$ occurs with severe diarrhea; small-bowel, pancreatic, or biliary fistula drainage; ileostomy drainage; and intestinal suction. In diarrhea of microbial origin, $\text{HCO}_3^-$ is also secreted into the bowel as a means of neutralizing the metabolic acids produced by the microorganisms causing the diarrhea.

**Hyperchloremic Acidosis.** Hyperchloremic acidosis occurs when $\text{Cl}^-$ levels are increased. Because $\text{Cl}^-$ and $\text{HCO}_3^-$ are exchangeable anions, the serum $\text{HCO}_3^-$ decreases when there is an increase in $\text{Cl}^-$. Hyperchloremic acidosis can occur as the result of abnormal absorption of $\text{Cl}^-$ by the kidneys or as a result of treatment with chloride-containing medications (i.e., sodium chloride, amino acid–chloride hyperalimentation solutions, and ammonium chloride). With hyperchloremic acidosis, the anion gap remains within the normal range, while serum $\text{Cl}^-$ levels are increased and $\text{HCO}_3^-$ levels are decreased.

**Manifestations.** Metabolic acidosis is characterized by a decrease in serum pH (<7.35) and $\text{HCO}_3^-$ levels (<24 mEq/dL [24 mmol/L]) due to $\text{H}^+$ gain or $\text{HCO}_3^-$ loss. The manifestations of metabolic acidosis fall into three categories: signs and symptoms of the disorder causing the acidosis, changes in body function due to recruitment of compensatory mechanisms, and alterations in cardiovascular, neurologic, and musculoskeletal function resulting from the decreased pH. Metabolic acidosis is seldom a primary disorder; it usually develops during the course of another disease. The manifestations of metabolic acidosis frequently are superimposed on the symptoms of the contributing health problem. With diabetic ketoacidosis, which is a common cause of metabolic acidosis, there is an increase in blood and urine glucose and a characteristic smell of ketones to the breath. In metabolic acidosis that accompanies chronic kidney disease, blood urea nitrogen levels are elevated and other tests of renal function yield abnormal results.

Manifestations related to respiratory and renal compensatory mechanisms usually occur early in the course of metabolic acidosis. In situations of acute metabolic acidosis, the respiratory system compensates for a decrease in pH by increasing ventilation to reduce $\text{PCO}_2$; this is accomplished through deep and rapid respirations. There may be complaints of difficulty breathing or dyspnea with exertion; with severe acidosis, dyspnea may be present even at rest. Respiratory compensation for acute metabolic acidosis tends to be somewhat greater than for chronic acidosis. When kidney function is normal, $\text{H}^+$ excretion increases promptly in response to acidosis, and the urine becomes more acid.

</table>
Changes in pH have a direct effect on body function that can produce signs and symptoms common to most types of metabolic acidosis. A person with metabolic acidosis often complains of weakness, fatigue, general malaise, and a dull headache. They also may have anorexia, nausea, vomiting, and abdominal pain. Tissue turgor is decreased, and the skin is dry when fluid deficit accompanies acidosis. In persons with undiagnosed diabetes mellitus, the nausea, vomiting, and abdominal symptoms may be misinterpreted as being caused by gastrointestinal flu or another abdominal disease, such as appendicitis. Acidosis depresses neuronal excitability and as the condition progresses, the level of consciousness declines, and stupor and coma develop. The skin is often warm and flushed because blood vessels in the skin become less responsive to sympathetic nervous system stimulation and lose their tone.

When the pH falls to 7.0 to 7.1, cardiac contractility and cardiac output decrease, the heart becomes less responsive to catecholamines (i.e., epinephrine and norepinephrine), and arrhythmias, including fatal ventricular arrhythmias, can develop. A decrease in ventricular function may be particularly important in perpetuating shock-induced lactic acidosis, and partial correction of the acidemia may be necessary before tissue perfusion can be restored.¹

Chronic acidemia, as in chronic kidney disease, can lead to a variety of musculoskeletal problems, some of which result from the release of calcium and phosphate during bone buffering of excess H⁺ ions. Of particular importance is impaired growth in children. In infants and children, acidemia may be associated with a variety of nonspecific symptoms such as anorexia, weight loss, muscle weakness, and listlessness.¹ Muscle weakness and listlessness may result from alterations in muscle metabolism.

**Treatment.** The treatment of metabolic acidosis focuses on correcting the condition that is causing the disorder and restoring the fluids and electrolytes that have been lost from the body. For example, insulin administration and fluid replacement are frequently sufficient to correct a low pH in persons with diabetic ketosis (see Chapter 33).

The use of supplemental sodium bicarbonate (NaHCO₃) may be indicated in the treatment of some forms of normal anion gap acidosis. However, its use in treatment of metabolic acidosis with an increased anion gap is controversial, particularly in cases of impaired tissue perfusion.⁷⁰ In most patients with circulatory shock, cardiac arrest, or sepsis, impaired oxygen delivery is the primary cause of lactic acidosis. In these situations, the administration of large amounts of NaHCO₃ does not improve oxygen delivery and may produce hypernatremia, hyperosmolality, and decreased oxygen release by hemoglobin because of a shift in the oxygen dissociation curve.⁷⁰

**Metabolic Alkalosis**

Metabolic alkalosis is a systemic disorder caused by an increase in serum pH due to a primary excess in HCO₃⁻.⁷¹ It is reported to be the second most common acid–base disorder in hospitalized adults, accounting for about 32% of all acid–base disorders. The disorder can be caused by factors that generate a gain of bicarbonate, a loss of fixed acids, or those that maintain the alkalosis by interfering with excretion of the excess bicarbonate by the kidneys.

**Excess Bicarbonate Base.** Because the normal kidney is extremely efficient at excreting bicarbonate, excess base intake is rarely a cause of significant chronic metabolic alkalosis. Transient acute alkalosis, on the other hand, is a rather common occurrence during or immediately following excess oral ingestion of bicarbonate-containing antacids (e.g., Alka-Seltzer) or intravenous infusion of NaHCO₃ or base equivalent (e.g., acetate in hyperalimentation solutions, lactate in Ringer lactate, and citrate in blood transfusions). As noted earlier, the milk-alkali syndrome is a condition in which the chronic ingestion of milk and/or calcium carbonate antacids leads to hypercalcemia and metabolic alkalosis.⁵² In this case, the antacids raise the serum HCO₃⁻ concentration, while the hypercalcemia prevents the urinary excretion of HCO₃⁻. The most common cause at present is the administration of calcium carbonate as a phosphate binder to persons with chronic kidney disease.⁴

**Loss of Fixed Acids.** The loss of fixed acids occurs mainly through the loss of acid from the stomach and through the loss of chloride in the urine. Vomiting and removal of gastric secretions through the use of nasogastric suction are common causes of metabolic alkalosis in acutely ill or hospitalized patients. Bulimia nervosa with self-induced vomiting also is associated with metabolic alkalosis.⁷³ Gastric secretions contain high concentrations of HCl and lesser concentrations of potassium chloride. As Cl⁻ is taken from the blood and secreted into the stomach, it is replaced by HCO₃⁻. Under normal conditions, each mEq of H⁺ that is secreted into the stomach generates 1 mEq of serum HCO₃⁻.⁷² Thus, the loss of gastric secretions through vomiting or gastric suction is a common cause of metabolic alkalosis. The accompanying ECF volume depletion, hypochloremia, and hypokalemia serve to maintain the metabolic alkalosis by increasing HCO₃⁻ reabsorption by the kidneys (Fig. 8-19).

Other factors that predispose persons to the development of metabolic alkalosis include the loss of potassium, such as that caused by the loop and thiazide diuretics and the presence of excessive adrenal cortical hormones (as in hyperaldosteronism and Cushing disease). Hypokalemia contributes to metabolic alkalosis through renal mechanisms that conserve K⁺ while increasing H⁺ elimination and through a cellular shift of K⁺ into the ECF, while at the same time H⁺ moves back into the cell.

Metabolic alkalosis can also occur with abrupt correction of respiratory acidosis in persons with chronic respiratory acidosis. Chronic respiratory acidosis is associated with a compensatory loss of H⁺ and Cl⁻ in the urine along with HCO₃⁻ retention. When respiratory acidosis is corrected abruptly, as with mechanical
ventilation, metabolic alkalosis may develop due to a rapid drop in PCO₂, while serum HCO₃⁻, which must be eliminated through the kidney, remains elevated.

Maintenance of Metabolic Alkalosis. Maintenance of metabolic alkalosis resides within the kidney and its inability to rid the body of the excess HCO₃⁻. Many of the conditions that accompany the development of metabolic alkalosis, such as contraction of the ECF volume, hypochloremia, and hypokalemia, also increase reabsorption of HCO₃⁻ by the kidney, thereby contributing to its maintenance.

Manifestations. Metabolic alkalosis is characterized by a serum pH above 7.45, serum HCO₃⁻ above 29 mEq/L (29 mmol/L), and base excess above 3.0 mEq/L (3 mmol/L). Persons with metabolic alkalosis often are asymptomatic or have signs related to ECF volume depletion or hypokalemia. The manifestations of metabolic alkalosis are summarized in Table 8-10.

Neurologic signs and symptoms (e.g., hyperexcitability) occur less frequently with metabolic alkalosis than with other acid–base disorders because HCO₃⁻ enters the cerebrospinal fluid (CSF) more slowly than CO₂. When neurologic manifestations do occur, as in acute and severe metabolic alkalosis, they include mental confusion, hyperactive reflexes, tetany, and carpopedal spasm. Metabolic alkalosis also leads to a compensatory hypoventilation with development of various degrees of hypoxemia and respiratory acidosis. Significant morbidity occurs with severe metabolic alkalosis, including respiratory failure, arrhythmias, seizures, and coma.

Treatment. The treatment of metabolic alkalosis usually is directed toward correcting the cause of the condition. A chloride deficit requires correction. Potassium chloride usually is the treatment of choice when there is an accompanying potassium deficit. When potassium chloride is used as a therapy, the Cl⁻ anion replaces the HCO₃⁻ anion and the K⁺ corrects the potassium deficit, allowing the kidneys to retain H⁺ while eliminating K⁺. Fluid replacement is used in the treatment of volume contraction alkalosis.

Respiratory Acidosis

Respiratory acidosis represents a decrease in pH caused by an elevation in arterial PCO₂, usually due to conditions that impair alveolar ventilation. It can present as an acute or chronic condition, and can occur as the result of decreased ventilatory drive, lung disease, or disorders of the chest wall or respiratory muscles. Less commonly, it results from excess CO₂ production.

Acute Disorders of Ventilation. Acute respiratory failure is associated with a rapid rise in arterial PCO₂ along with a minimal increase in serum HCO₃⁻ and a large decrease in pH. It can be caused by impaired function of the respiratory center in the medulla (as in narcotic overdose), lung disease, chest injury, weakness of the respiratory muscles, or airway obstruction. Almost all persons with acute respiratory acidosis become hypoxic when breathing room air. In many cases, signs of hypoxemia develop prior to those of respiratory acidosis because CO₂ diffuses across the alveolar capillary membrane 20 times more rapidly than oxygen.

Chronic Disorders of Ventilation. Chronic respiratory acidosis is characterized by a sustained increase in arterial PCO₂, resulting in renal adaptation with a more marked increase in serum HCO₃⁻ and a lesser decrease in pH. It is a relatively common disturbance in persons with chronic obstructive pulmonary disease (COPD). In these persons, the persistent elevation of PCO₂ stimulates renal H⁺ secretion and HCO₃⁻ reabsorption. The effectiveness of these compensatory mechanisms can often return the pH to near-normal values as long as oxygen levels are maintained within a range that does not unduly suppress chemoreceptor control of respirations.

An acute episode of respiratory acidosis can develop in persons with chronic lung disease who receive oxygen therapy at a flow rate that raises their PO₂ to a level that produces a decrease in ventilation (see Chapter 23). In these persons, the medullary respiratory center has adapted to the elevated levels of CO₂ and no longer

![FIGURE 8-19. Renal mechanisms for bicarbonate (HCO₃⁻) reabsorption and maintenance of metabolic alkalosis following depletion of extracellular fluid volume, chloride (Cl⁻), and potassium (K⁺) due to vomiting. GFR, glomerular filtration rate.](image-url)
responds to increases in PCO₂. Instead, a decrease in the PO₂ becomes the major stimulus for respiration. If oxygen is administered at a flow rate that is sufficient to suppress this stimulus, the rate and depth of respiration decrease and PCO₂ increases. Thus, any person who is in need of additional oxygen should have it administered, but at a flow rate that does not depress the respiratory drive.

Increased Carbon Dioxide Production. Carbon dioxide is a product of the body’s metabolic processes, generating a substantial amount of acid that must be excreted by the lungs or kidney to prevent acidosis. An increase in CO₂ production can result from numerous processes, including exercise, fever, sepsis, and burns. For example, CO₂ production increases by approximately 13% for each 1°C rise in temperature above normal. Nutrition also affects the production of CO₂. A carbohydrate-rich diet produces larger amounts of CO₂ than one containing reasonable amounts of protein and fat. In healthy persons, the increase in CO₂ is usually matched by an increase in CO₂ elimination by the lungs, whereas persons with respiratory diseases may be unable to eliminate the excess CO₂.

Manifestations. Respiratory acidosis is associated with a serum pH below 7.35 and an arterial PCO₂ above 50 mm Hg. The signs and symptoms of respiratory acidosis depend on the rapidity of onset and whether the condition is acute or chronic (Table 8-11). Less severe forms of acidosis often are accompanied by warm and flushed skin, weakness, and tachycardia. Because respiratory acidosis often is accompanied by hypoxemia, the manifestations of respiratory acidosis often are intermixed with those of oxygen deficit. Carbon dioxide readily crosses the blood–brain barrier, exerting its effects by changing the pH of brain fluids. Elevated levels of CO₂ produce vasodilation of cerebral blood vessels, causing headache, blurred vision, irritability, muscle twitching, and psychological disturbances. If severe and prolonged, it can cause an increase in CSF pressure and papilledema. Impaired consciousness, ranging from lethargy to coma, develops as the PCO₂ rises to extreme levels. Paralysis of extremities may occur, and there may be respiratory depression.

Treatment. The treatment of acute and chronic respiratory acidosis is directed toward improving ventilation. In severe cases, mechanical ventilation may be necessary. The treatment of respiratory acidosis due to respiratory failure is discussed in Chapter 23.

Respiratory Alkalosis

Respiratory alkalosis is a systemic acid–base disorder characterized by a primary decrease in arterial PCO₂, which produces an elevation in pH and a subsequent decrease in HCO₃⁻. It is caused by hyperventilation or a respiratory rate in excess of that needed to maintain normal PCO₂ levels. It may occur as the result of central stimulation of the medullary respiratory center or stimulation of peripheral (e.g., carotid chemoreceptor) pathways to the medullary respiratory center. Because respiratory alkalosis can occur suddenly, a compensatory decrease in bicarbonate level may not occur before respiratory correction has already taken place.

Central stimulation of the medullary respiratory center occurs with anxiety, pain, pregnancy, febrile states, sepsis, encephalitis, and salicylate toxicity. One of the most common causes of respiratory alkalosis is

hyperventilation syndrome, which is characterized by recurring episodes of overbreathing often associated with anxiety. Persons experiencing panic attacks frequently present in the emergency room with manifestations of acute respiratory alkalosis. Progesterone increases ventilation in women; during the progesterone phase of the menstrual cycle, normal women decrease their PCO₂ values by 2 to 4 mm Hg and increase their pH by 0.01 to 0.02.74 Women can also develop substantial decrease in PCO₂ during pregnancy, most notably during the last trimester.72

Respiratory alkalosis has long been recognized as a common acid–base disorder in critically ill patients, and is a consistent finding in both septic shock and the systemic inflammatory response syndrome (see Chapter 20). Hypoxemia exerts its effect on pH through the peripheral chemoreceptors in the carotid bodies. Stimulation of peripheral chemoreceptors occurs in conditions that cause hypoxemia with relatively unimpaired CO₂ transport such as exposure to high altitudes.

Mechanical ventilation may produce respiratory alkalosis if the rate and tidal volume are set so that CO₂ elimination exceeds CO₂ production. Because carbon dioxide crosses the alveolar capillary membrane 20 times more rapidly than oxygen, the increased minute ventilation may be necessary to maintain adequate oxygen levels while producing a concomitant decrease in CO₂ levels. In some cases, respiratory alkalosis may be induced through mechanical ventilation as a means of controlling disorders such as severe intracranial hypertension.

**Manifestations.** Respiratory alkalosis manifests with a decrease in PCO₂ and a H₂CO₃ deficit. The pH is above 7.45, arterial PCO₂ is below 35 mm Hg, and serum HCO₃⁻ levels usually are below 24 mEq/L (24 mmol/L).

The signs and symptoms of respiratory alkalosis are associated with hypexcitability of the nervous system and a decrease in cerebral blood flow75 (see Table 8–1). A decrease in the CO₂ content of the blood causes constriction of cerebral blood vessels. CO₂ crosses the blood–brain barrier rather quickly; thus, the manifestations of acute respiratory alkalosis are usually of sudden onset. The person often experiences light-headedness, dizziness, tingling, and numbness of the fingers and toes. These manifestations may be accompanied by sweating, palpitations, panic, air hunger, and dyspnea. Chvostek and Trouseau signs may be positive, and tetany and convulsions may occur. Because CO₂ provides the stimulus for short-term regulation of respiration, short periods of apnea may occur in persons with acute episodes of hyperventilation.

**Treatment.** The treatment of respiratory alkalosis focuses on measures to correct the underlying cause. Hypoxia may be corrected by administration of supplemental oxygen. Changing ventilator settings may be used to prevent or treat respiratory alkalosis in persons who are being mechanically ventilated. Persons with hyperventilation syndrome may benefit from reassurance, rebreathing from a paper bag during symptomatic attacks, and attention to the psychological stress associated with the disorder.

### SUMMARY CONCEPTS

- **Normal body function depends on the precise regulation of acid–base balance.** Metabolic processes produce the volatile carbonic acid (H₂CO₃) in equilibrium with dissolved carbon dioxide (PCO₂), which is eliminated through the lungs, and nonvolatile acids, which are excreted by the kidneys.
- **Because of its low concentration in body fluids, the hydrogen (H⁺) concentration is expressed as pH, or the negative log of the H⁺ ion concentration.** It is the ratio of the bicarbonate (HCO₃⁻) concentration to H₂CO₃ (PCO₂), normally 20:1, that determines body pH.
- **The ability of the body to maintain pH within the normal range depends on intracellular and extracellular buffers, as well as respiratory and renal compensatory mechanisms.** The respiratory regulation of pH, which relies on pulmonary ventilation for release of CO₂ into the environment, is rapid but does not return the pH completely to normal. Renal mechanisms, which rely on the elimination of H⁺ ions and conservation of HCO₃⁻ ions, take longer but return pH to normal or near-normal levels.
- **Metabolic acid and base disorders reflect an increase or decrease in HCO₃⁻.** Metabolic acidosis, which reflects a decrease in pH due to a decrease in HCO₃⁻, is caused by conditions that prompt an excessive production and accumulation of metabolic acids or excessive loss of HCO₃⁻. Metabolic alkalosis, which reflects an increase in pH due to an increase in HCO₃⁻, is caused by conditions that produce a gain in HCO₃⁻ or a decrease in H⁺.
- **Respiratory acid–base disorders reflect an increase or decrease in PCO₂ levels due to altered pulmonary ventilation.** Respiratory acidosis, which reflects a decrease in pH due an increase in PCO₂ levels, is caused by conditions that produce hypoventilation. Respiratory alkalosis, which reflects an increase in pH due to a decrease in PCO₂ levels, is caused by conditions that produce hyperventilation.
A 34-year-old woman with diabetes is admitted to the emergency room in a stuporous state. Her skin is flushed and warm, her breath has a sweet odor, and her respirations are rapid and deep. Her initial laboratory tests indicate a blood sugar of 320 mg/dL, serum HCO$_3^-$ of 12 mEq/L (normal, 24 to 27 mEq/L), and a pH of 7.1 (normal, 7.35 to 7.45).

A. What is the most likely cause of her lowered pH and bicarbonate levels?
B. How would you account for her rapid and deep respirations?
C. How would you explain her warm, flushed skin and stuporous mental state?

3. A 50-year-old woman presents with symptomatic hypercalcemia. She has a recent history of breast cancer treatment.

A. How do you evaluate this person with increased serum calcium levels?
B. What is the significance of the recent history of malignancy?
C. What further tests may be indicated?

4. A 70-year-old woman who is taking furosemide (a loop diuretic) for congestive heart failure complains of weakness, fatigue, and cramping of the muscles in her legs. Her serum potassium is 2.0 mEq/L and her serum sodium is 140 mEq/L. She also complains that she notices a “strange heartbeat” at times.

A. What is the likely cause of this woman’s symptoms?
B. An ECG shows a depressed ST segment and low T-wave changes. Explain the physiologic mechanism underlying these changes.
C. What would be the treatment for this woman?

5. A 16-year-old girl is seen by her primary care provider because her parents are concerned about her binge eating and their recent discovery that she engages in self-induced vomiting. Initial laboratory tests reveal a serum K$^+$ of 3.0 mEq/L and Cl$^-$ of 93.

A. Explain her low K$^+$ and Cl$^-$.
B. What type of acid–base abnormality would you expect her to have?

6. A 65-year-old man with chronic obstructive lung disease has been using low-flow oxygen therapy. He has recently developed a severe respiratory tract infection and has trouble breathing. He is admitted to the emergency room because his wife is having trouble arousing him. She relates that he had “turned his oxygen way up” because of difficulty breathing. His respirations are 12 breaths/minute. Arterial blood gases, drawn on admission to the emergency room, indicated a PO$_2$ of 85 mm Hg (normal, 90 to 95 mmHg) and a PCO$_2$ of 90 mm Hg (normal, 40 mm Hg). His serum HCO$_3^-$ was 34 mEq/L (normal, 24 to 48 mEq/L). What is his pH?

A. What is the most likely cause of this man’s problem?
B. How would you explain the lethargy and difficulty in arousal?
C. What would be the main goal of treatment for this man in terms of acid–base balance?
D. Explain the concurrent respiratory and metabolic acidosis that often occurs in persons with chronic respiratory acidosis.

Stress and Adaptation

Stress, adaptation, and their relationship to health are a frequent topic of discussion. The human body and mind respond to stress by activating a complex repertoire of physiologic and behavioral adaptive responses which, if inadequate or excessive, may affect emotional behavior and have adverse effects on physiologic functioning. Stress may contribute directly to the production or exacerbation of a disease, or it may contribute to the development of behaviors such as smoking, overeating, and drug abuse that increase risk of disease.

The content in this chapter has been organized into two sections: the first focuses on stress and adaptation and the second on disorders of the stress response.

Stress and Adaptation

A variety of definitions have been ascribed to the phenomenon of stress. The concept of stress has been studied extensively by physiologists, psychologists, sociologists, and members of the health care professions. The nature of these disciplines and the individual work of their members have led to rather disparate bodies of knowledge about stress. Despite these disparities, the concept of stress is commonly viewed within the context of three major components: homeostasis, the stress response, and adaptation to stress.

Homeostasis

The concepts of stress and adaptation have their origin in the complexity of the human body and interactions between the body's cells and its many organ systems. These interactions require that a level of homeostasis or constancy be maintained during the many changes that occur in the internal and external environments. In effecting a state of constancy, homeostasis requires feedback control systems that regulate cellular function and integrate functions of the different body systems.

Constancy of the Internal Environment

The environment in which body cells live is not the external environment that surrounds the organism, but
rather the local fluid environment that surrounds each cell. Claude Bernard, a 19th-century physiologist, was the first to clearly describe the central importance of a stable internal environment, which he termed the \emph{milieu intérieur}. Bernard recognized that body fluids surrounding cells and various organ systems provide a means for exchange between the external and internal environments. It is from this internal environment that body cells receive their nourishment, and it is into this fluid that they secrete their wastes. Even contents of the gastrointestinal tract and lungs do not become part of the internal environment until they have been absorbed into the extracellular fluid. A multicellular organism is able to survive only as long as the composition of the internal environment is compatible with the survival needs of the individual cells. For example, even a small change in the pH of body fluids can disrupt metabolic processes of individual cells.

The concept of a stable internal environment was supported by Walter B. Cannon, who proposed that this kind of stability, which he called homeostasis, was achieved through a system of carefully coordinated physiologic processes that oppose change. Cannon proposed that these processes were largely automatic and emphasized that homeostasis involves resistance to both internal and external disturbances (Box 9-1).

In his book \textit{The Wisdom of the Body}, published in 1939, Cannon presented four tentative propositions to describe general features of homeostasis. Based upon this set of propositions, Cannon emphasized that when a factor is known to shift homeostasis in one direction, it is reasonable to expect mechanisms that have the opposite effect exist. For example, in the homeostatic regulation of blood sugar, mechanisms that both raise and lower blood glucose play significant roles. As long as the responding mechanism to the initiating disturbance can recover homeostasis, body integrity and normality are retained.

### Control Systems

The ability of the body to function and maintain homeostasis under conditions of change in the internal and external environment depends upon thousands of physiologic \textit{control systems} that regulate body function. A homeostatic control system consists of a collection of interconnected components that function to keep a physical or chemical parameter of the body relatively constant. The body's control systems regulate cellular function, control life processes, and integrate functions of different organ systems.

Neuroendocrine control systems that influence behavior have recently been studied extensively. Biochemical messengers in our brain control nerve activity, information flow, and, ultimately, behavior. These control systems mediate physical, emotional, and behavioral reactions to stressors. When taken together, these reactions are known as the \textit{stress response}.

Most control systems in the body operate by \textit{negative feedback mechanisms}, which function in a manner similar to the thermostat in a heating system. When the monitored function or value decreases below the set point of the system, feedback mechanisms cause the function or value to increase, and when the function or value is increased above the set point, the feedback mechanism causes it to decrease (Fig. 9-1). For example, in the negative feedback mechanism that controls blood glucose levels, an increase in blood glucose stimulates an increase in insulin, which enhances removal of glucose from the blood. When glucose has been taken up by cells and blood glucose levels fall, insulin secretion is inhibited and glucagon and other counter-regulatory mechanisms stimulate release of glucose from the liver, which causes blood glucose levels to return to normal.

Most physiologic control systems function under negative rather than \textit{positive feedback mechanisms} because

---

**BOX 9-1  Constancy of the Internal Environment**

1. Constancy in an open system, such as our bodies represent, requires mechanisms that act to maintain this constancy. Cannon based this proposition on insights into the ways by which steady states such as glucose concentrations, body temperature, and acid-base balance were regulated.

2. Steady-state conditions require that any tendency toward change automatically meets with factors that resist change. An increase in blood sugar results in thirst as the body attempts to dilute the concentration of sugar in the extracellular fluid.

3. The regulating system that determines the homeostatic state consists of a number of cooperating mechanisms acting simultaneously or successively. Blood sugar is regulated by insulin, glucagon, and other hormones that control its release from the liver or its uptake by the tissues.

4. Homeostasis does not occur by chance, but is the result of organized self-government.

---

**FIGURE 9-1. Illustration of negative feedback control mechanisms using blood glucose as an example.**
a positive feedback mechanism interjects instability into a system, not stability. It produces a cycle in which the initiating stimulus produces more of the same response. For example, in a positive feedback system, exposure to an increase in environmental temperature would invoke compensatory mechanisms designed to increase body temperature rather than to decrease it.

The Stress Response

In the early 1930s, world-renowned endocrinologist Hans Selye was the first to describe a group of specific anatomic changes that occurred in rats that were exposed to a variety of different experimental stimuli. He came to an understanding that these changes were manifestations of the body's attempt to adapt to stimuli. Selye described stress as "a state manifested by a specific syndrome of the body developed in response to any stimuli that made an intense systemic demand on it." As a young medical student, Selye noticed that patients with diverse disease conditions had many signs and symptoms in common. He observed that "whether a man suffers from a loss of blood, an infectious disease, or advanced cancer, he loses his appetite, his muscular strength, and his ambition to accomplish anything; usually the patient also loses weight and even his facial expression betrays that he is ill." Selye referred to this phenomenon as the "syndrome of just being sick."

In his early career as an experimental scientist, Selye noted that a triad of adrenal enlargement, thyrotic atrophy, and gastric ulcers appeared in rats he was using in his studies. These same three changes developed in response to many different or nonspecific experimental challenges. He assumed that the hypothalamic-pituitary-adrenal (HPA) axis played a pivotal role in development of this response. The primary effectors of the stress response are contained in the paraventricular nucleus of the hypothalamus, the anterior lobe of the pituitary gland, and the adrenal gland, making up the HPA axis. In addition to the HPA axis, the brain stem noradrenergic neurons, sympathetic adrenomedullary circuits, and parasympathetic systems also play important roles in the regulation of adaptive responses to stress.

Selye viewed the response to stressors as a process that enabled the rats to resist experimental challenges by activating the system best able to respond to it. He labeled the response the general adaptation syndrome (GAS): general because the effect was a general systemic reaction, adaptive because the response was in reaction to a stressor, and syndrome because the physical manifestations were coordinated and dependent upon each other. According to Selye, the GAS involves three stages: the alarm stage, the resistance stage, and the exhaustion stage. The alarm stage is characterized by a generalized stimulation of the sympathetic nervous system (SNS) and the HPA axis, resulting in release of catecholamines and cortisol. During the resistance stage, the body selects the most effective and economic channels of defense. During this stage, the increased cortisol levels present during the first-stage drop because they are no longer needed. If the stressor is prolonged or overwhelms the ability of the body to defend itself, the exhaustion stage ensues, resulting in depletion of resources and emergence of signs of "wear and tear" or systemic damage. Selye contended that many ailments, such as various emotional disturbances, mildly annoying headaches, insomnia, upset stomach, gastric and duodenal ulcers, certain types of rheumatic disorders, and cardiovascular and kidney diseases, appear to be initiated or encouraged by the "body itself because of its faulty adaptive reactions to potentially injurious agents." The events or environmental agents responsible for initiating the stress response were called stressors. According to Selye, stressors may be endogenous, arising from within the body, or exogenous, arising from outside the body. In explaining the stress response, Selye proposed that two factors determine the nature of the stress response: properties of the stressor and conditioning of the person being stressed. Selye indicated that not all stress is detrimental; hence, he coined the terms eustress and distress. He suggested that mild, brief, and controlled periods of stress may be perceived as positive stimuli to emotional and intellectual growth and development. Severe, protracted, and uncontrolled situations of psychological and physical distress are disruptive to health. For example, the joy of becoming a new parent and the sorrow of losing a parent are completely different experiences, yet the effect of these stressors, the nonspecific demand for adjustment to a new situation, may be similar.

The brain appears central to development of the stress response, as it determines what is threatening and therefore potentially stressful. Further, the brain elicits physiological and behavioral responses that can be either adaptive or harmful. It is becoming increasingly clear that the physiologic stress response is far more complicated than can be explained fully by classic stimulus–response mechanisms. These different responses occur in different persons, or in the same person at different times, indicating the influence of the adaptive capacity of the person, or what Selye called conditioning factors. These conditioning factors may be internal (e.g., genetic predisposition, age, gender) or external (e.g., exposure to environmental agents, life experiences, dietary factors, level of social support). The relative risk for development of a stress-related pathologic process seems, at least in part, to depend on these factors.

Richard Lazarus was a well-respected psychologist who devoted his career to the study of stress and emotions. He considered "meanings and values to be at the center of human life and to represent the essence of stress, emotion, and adaptation." Others described a "cognitive activation theory of stress" based on the belief that the stress response is dependent upon what a person expects to happen in a given situation based on previous learning experiences. In other words, stimuli are filtered or evaluated before they reach a response system. Furthermore, there is evidence that the HPA axis, the adrenomedullary hormonal system, and the SNS are differentially activated depending on the type and intensity of the stressor.
Neuroendocrine Responses

The stress response is mediated by anatomical structures found in both the central nervous system and peripheral tissues. Manifestations of the stress response are strongly influenced by both the nervous and endocrine systems. The neuroendocrine systems integrate signals received along sensory pathways and from circulating mediators that are carried in the bloodstream. In addition, the immune system both affects and is affected by the stress response. Table 9-1 summarizes the action of hormones involved in the neuroendocrine responses to stress. Results of the coordinated release of these neurohormones include mobilization of energy, a sharpened focus and awareness, increased cerebral blood flow and glucose utilization, enhanced cardiovascular and respiratory functioning, redistribution of blood flow to the brain and muscles, modulation of the immune response, inhibition of reproductive function, and a decrease in appetite.

The stress response is a normal, coordinated physiologic system intended to increase the probability of survival, but importantly, it also is designed to be an acute response. That is, optimally it is turned on when necessary to bring the body back to a stable state and turned off when the challenge to homeostasis abates. Therefore, under normal circumstances, the neural responses and hormones that are released during the response do not persist long enough to cause damage to vital tissues. Since the early 1980s, the term allostatic has been used by some investigators to describe the interactive physiologic changes in the neuroendocrine, autonomic, and immune systems that occur in response to either real or perceived challenges to homeostasis. More recently, others have proposed that allostatic is the body’s attempt to maintain stability through change, thereby adequately or inadequately adapting to threatening or unpredictable stimuli. The persistence or accumulation of these allostatic changes (e.g., immunosuppression, activation of the sympathetic nervous and renin-angiotensin-aldosterone systems) has been called an allostatic load, and this concept has been used to measure the cumulative effects of stress on humans. Allostatic load can result in weakening a person’s ability to respond to repeated stressors, and it may provide insight into how one might respond to future stressors. A number of indices have been suggested for measuring allostatic load, including blood pressure, cortisol, C-reactive protein, body mass index (BMI), and cholesterol. Integration of the components of the stress response, occurring at the level of the central nervous system (CNS), is complex and not completely understood. It relies on communication along neuronal pathways of the cerebral cortex, limbic system, thalamus, hypothalamus, pituitary gland, and reticular activating system (RAS). The cerebral cortex is involved in vigilance, cognition, and focused attention, while the limbic system is associated with emotional components (e.g., fear, excitement, rage, anger) of the stress response (Fig. 9-2). The thalamus functions as the relay center and is important in receiving, sorting out, and distributing sensory input. The hypothalamus coordinates responses of the endocrine system and autonomic nervous system (ANS). The RAS modulates mental alertness, ANS activity, and skeletal muscle tone using input from other neural structures. The musculoskeletal tension that occurs during the stress response reflects increased activity of the RAS and its influence on reflex circuits that control muscle tone. Adding to the complexity of this system is the fact that individual brain circuits that participate in mediation of the stress response interact and regulate each other’s activities. For example, reciprocal connections

209 C H A P T E R 9 Stress and Adaptation
exist between neurons in the hypothalamus that initiate release of corticotropin-releasing factor (CRF) and neurons in the locus ceruleus associated with release of norepinephrine. Thus, norepinephrine stimulates the secretion of CRF, and CRF stimulates the release of norepinephrine.\textsuperscript{16,17}

**Locus Ceruleus.** Central to the neural component of the neuroendocrine response to stress is an area of the brain stem called the *locus ceruleus* (LC).\textsuperscript{16,17} The LC is densely populated with neurons that produce norepinephrine (NE) and is thought to be the central integrating site for the ANS response to stressful stimuli (Fig. 9-3). The LC-NE system has afferent pathways to the hypothalamus, limbic system, hippocampus, and cerebral cortex.

The LC-NE system confers an adaptive advantage during a stressful situation. The SNS manifestation of the stress reaction has been called the *fight-or-flight response*.\textsuperscript{2} This reaction is the most rapid of the stress responses and represents the basic survival response of our primitive ancestors when confronted with perils of the wilderness and its inhabitants. The increase in SNS activity in the brain increases attention and arousal, and thus probably intensifies memory. Increased SNS arousal also results in heart and respiratory rate increases, moist hands and feet, dilated pupils, dry mouth, and reduced activity of the gastrointestinal tract.

**Corticotropin-Releasing Factor.** CRF is central to the endocrine component of the neuroendocrine response to stress, and it is the principal regulator of the HPA axis (see Fig. 9-3).\textsuperscript{3,16,17} Corticotropin-releasing factor, also known as *corticotropin-releasing hormone*, is a small peptide hormone found in both the hypothalamus and extrahypothalamic structures, such as the limbic system and brain stem. It is both an important endocrine regulator of pituitary and adrenal activity, as well as a neurotransmitter involved in ANS activity, metabolism, and behavior. In response to stressors, CRF is released into the hypophysial portal vessels that enter the anterior pituitary gland. Receptors for CRF are distributed throughout the brain as well as many peripheral sites. Corticotropin-releasing factor from the hypothalamus binds to corticotropes, inducing secretion...
of adrenocorticotropic hormone (ACTH) from the anterior pituitary gland into the systemic circulation. Adrenocorticotropic hormone, in turn, stimulates the adrenal gland to synthesize and secrete glucocorticoid hormones (e.g., cortisol). 25

Cortisol is the primary glucocorticoid in humans, representing a major subclass of steroid hormones that regulate metabolic, cardiovascular, immune, and behavioral responses. A glucocorticoid negative feedback system exists, whereby the HPA axis is subject to feedback inhibition from circulating glucocorticoids. These glucocorticoids have a number of direct or indirect physiologic effects that mediate the stress response, enhance the action of other stress hormones, or suppress other components of the stress system. In this regard, cortisol acts not only as a mediator of the stress response but also as an inhibitor so that overactivation of the stress response does not occur. 21, 23 Cortisol maintains blood glucose levels and enhances the effect of catecholamines on the cardiovascular system. Blood glucose levels are elevated rapidly, in part by mobilization of glucose stores and by inhibition of further storage through the antagonizing effects of insulin. 21 Cortisol also suppresses osteoblast activity, hematopoiesis, protein and collagen synthesis, and immune responses. All of these functions are meant to protect the organism against the effects of a stressor and to focus energy on regaining balance in the face of an acute challenge to homeostasis.

**Angiotensin II.** Stimulation of the SNS also activates the peripheral renin-angiotensin-aldosterone system (RAAS), which mediates a peripheral increase in vascular tone and renal retention of sodium and water (see Chapter 18). These changes contribute to the physiologic alterations that occur with the stress response; if prolonged, they may contribute to pathologic changes. Angiotensin II, peripherally delivered or locally produced, also has CNS effects; angiotensin II type 1 (AT₁) receptors are widely distributed in the hypothalamus and locus ceruleus. Through these receptors, angiotensin II enhances CRF formation and release, contributes to the release of ACTH from the pituitary, enhances stress-induced release of vasopressin from the posterior pituitary, and stimulates release of noradrenaline from the locus ceruleus. Results from animal studies on the effect of AT₁ receptor blockade suggest that receptor antagonists attenuate activation of the stress response and may be an effective treatment for chronic stimulation of the stress response. 26, 27

**Other Hormones.** A wide variety of other hormones, including growth hormone, thyroid hormone, and reproductive hormones, are responsive to stressful situations as well. 16, 17, 28 Systems responsible for reproduction, growth, and immunity are directly linked to the stress system, and hormonal effects of the stress response profoundly influence these systems.

Although growth hormone is initially elevated with the onset of stress, prolonged presence of cortisol leads to suppression of growth hormone, insulin-like growth factor 1 (IGF-1), and other growth factors, exerting a chronically inhibitory effect on growth. In addition, CRF directly increases somatostatin, which in turn inhibits growth hormone secretion. Although the connection is speculative, effects of stress on growth hormone may provide one of the vital links to understanding failure to thrive in children.

Stress-induced cortisol secretion also is associated with decreased levels of thyroid-stimulating hormone and inhibition of conversion of thyroxine (T₄) to the more biologically active triiodothyronine (T₃) in peripheral tissues (see Chapter 32). Both changes may serve as a means to conserve energy at times of stress.

**FIGURE 9-3.** Neuroendocrine-immune system regulation of the stress response. ACTH, adrenocorticotropic hormone; CRF, corticotropin-releasing factor.
Antidiuretic hormone (ADH) released from the posterior pituitary is also involved in the stress response, particularly in hypotensive stress or stress due to fluid volume loss. Antidiuretic hormone, also known as vasopressin, increases water retention by the kidneys and produces vasoconstriction of blood vessels. In addition, vasopressin, synthesized in paraventricular neurons of the hypothalamus and transported to the anterior pituitary, appears to synergize the capacity of the CRF to stimulate the release of ACTH.

The neurotransmitter serotonin or 5-hydroxytryptamine (5-HT) probably also plays a role in the stress response through neurons that innervate the hypothalamus, amygdala, and other limbic structures. Administration of 5-HT receptor agonists to laboratory animals was shown to increase the secretion of several stress hormones. In addition, it has been demonstrated that CRF inhibits the firing of serotonergic neurons.

Other hormones that have a presumed role in the stress response include vasoactive intestinal peptide, neuropeptide Y, cholecystokinin, and substance P. These hormones have well-characterized physiologic roles in the periphery but they are also found in the CNS, and several studies suggest that they are involved in the stress response. The reproductive hormones are inhibited by CRF at the hypophyseal level and by cortisol at the pituitary, gonadal, and target tissue levels. Sepsis and severe trauma can induce anovulation and amenorrhea in women and decreased spermatogenesis and decreased levels of testosterone in men.

**Immune Responses**

The hallmark of the stress response, as first described by Selye, is the endocrine–immune interactions (i.e., increased corticosteroid production and atrophy of the thymus) that are known to suppress the immune response. In concert, these two components of the stress system, through endocrine and neurotransmitter pathways, produce the physical and behavioral changes designed to adapt to acute stress. Much of the literature regarding stress and the immune response focuses on the causal role of stress in immune-related diseases. It also has been suggested that the reverse may occur; emotional and psychological manifestations of the stress response may be a reflection of alterations in the CNS resulting from the immune response (see Fig. 9-3). Immune cells such as monocytes and lymphocytes can penetrate the blood–brain barrier and take up residence in the brain, where they secrete chemical messengers called cytokines that influence the stress response.

The exact mechanism by which stress produces its effect on the immune response is unknown and probably varies from person to person, depending on genetic endowment and environmental factors. The most significant arguments for interaction between the neuroendocrine and immune systems derive from evidence that the immune and neuroendocrine systems share common signal pathways (i.e., messenger molecules and receptors), that hormones and neuromediators can alter the function of immune cells, and that the immune system and its mediators can modulate neuroendocrine function. Stress has the capacity to either enhance or suppress immune function. Receptors for a number of CNS-controlled hormones and neuromediators reportedly have been found on lymphocytes. Among these are receptors for glucocorticoids, insulin, testosterone, prolactin, catecholamines, estrogens, acetylcholine, and growth hormone, suggesting that these hormones and neuromediators influence lymphocyte function. For example, cortisol is known to suppress immune function, and pharmacologic doses of cortisol are used clinically to suppress the immune response. There is evidence that the immune system, in turn, influences neuroendocrine function. For example, it has been observed that the HPA axis is activated by cytokines such as interleukin-1, interleukin-6, and tumor necrosis factor that are released from immune cells (see Chapter 15).

A second possible route for neuroendocrine regulation of immune function is through the SNS and the release of catecholamines. The lymph nodes, thymus, and spleen are supplied with SNS nerve fibers. Centrally acting CRF activates the SNS through multisynaptic descending pathways, and circulating epinephrine acts synergistically with CRF and cortisol to inhibit the function of the immune system.

Not only is the quantity of immune expression changed because of stress, but the quality of the response is also changed. Stress hormones differentially stimulate proliferation of subtypes of T-lymphocyte helper cells. Because these T-helper cell subtypes secrete different cytokines, they stimulate different aspects of the immune response. One subtype tends to stimulate T lymphocytes and the cellular-mediated immune response, whereas a second type tends to activate B lymphocytes and humoral-mediated immune responses.

**Adaptation to Stress**

The ability to adapt to a wide range of environments and stressors is not peculiar to humans. According to René Dubos (a microbiologist noted for his study of human responses to the total environment), "adaptability is found throughout life and is perhaps the one attribute that distinguishes most clearly the world of life from the world of inanimate matter." Living organisms, no matter how primitive, do not submit passively to the impact of environmental forces. They attempt to respond adaptively, each in its own unique and most suitable manner. The higher the organism is on the evolutionary scale, the larger its repertoire of adaptive mechanisms and its ability to select and limit aspects of the environment to which it responds. The most fully evolved mechanisms are social responses through which individuals or groups modify their environments and/or habits in order to achieve a way of life that is best suited to their needs.

**Control Mechanisms**

Human beings, because of their highly developed nervous system and intellect, usually have alternative mechanisms for adapting and have the ability to control many aspects of their environment. Air conditioning and central heating limit the need to adapt to extreme changes
in environmental temperature. Availability of antiseptic agents, immunizations, and antibiotics eliminates the need to respond to common infectious agents. At the same time, modern technology creates new challenges for adaptation and provides new sources of stress, such as increased noise, air pollution, exposure to harmful chemicals, and changes in biologic rhythms imposed by shift work and transcontinental air travel.

Of particular interest are differences in the body’s response to events that threaten the integrity of the body’s physiologic environment, and those influences that threaten the integrity of the person’s psychosocial environment. Many of the body’s responses to physiologic disturbances are controlled on a moment-by-moment basis by feedback mechanisms that limit their application and duration of action. For example, the baroreflex-mediated rise in heart rate that occurs when a person moves from the recumbent to standing position is almost instantaneous and subsides within seconds. Furthermore, the response to physiologic disturbances that threaten the integrity of the internal environment is specific to the threat; the body usually does not raise the body temperature when an increase in heart rate is needed. In contrast, the response to psychological disturbances is not regulated with the same degree of specificity and feedback control; instead, the effect may be inappropriate and sustained.

**Adaptive Mechanisms**

Adaptation implies that an individual has successfully created a new balance between the stressor and the ability to deal with it. The means used to attain this balance are called coping strategies or coping mechanisms. Coping mechanisms are the emotional and behavioral responses used to manage threats to our physiologic and psychological homeostasis. According to Lazarus, the coping strategies used for stressful events depend on how the events are perceived and interpreted.

Is the event perceived as a threat of harm or loss? Is the event perceived as a challenge rather than a threat? Physiologic and anatomic reserve, time, genetic endowment, age, health status, nutrition, sleep–wake cycles, hardness, and psychosocial factors influence one’s appraisal of a stressor and the coping mechanisms employed to adapt to the new situation (Fig. 9-4).

**Physiologic and Anatomic Reserve.** Adaptation is greatly influenced by an individual’s physiologic and anatomic reserve. The safety margin for adaptation of most body systems is considerably greater than that needed for normal activities. Red blood cells carry more oxygen than tissues can use, the liver and fat cells store excess nutrients, and bone tissue stores calcium in excess of that needed for normal neuromuscular function. The ability of body systems to increase level of function, given the need to adapt, is known as the physiologic reserve. Many body organs, such as the lungs and kidney, are paired to provide anatomic reserve as well. Both organs are not needed to ensure the continued existence and maintenance of the internal environment. Many persons function normally with only one lung or one kidney.

**Nutrition**

**Hardiness**

**Genetic endowment and age**

**Adaptive capacity**

**Psychosocial factors**

**Physiologic reserve**

**Sleep–wake cycles**

**Rapidity with which need for adaptation occurs**

**FIGURE 9-4. Factors affecting adaptation.**

**Time.** Time is an essential element in adaptation. Adaptation is most efficient when changes occur gradually rather than suddenly. It is possible, for instance, to lose a liter or more of blood through chronic gastrointestinal bleeding over a week without manifesting signs of shock. However, a sudden hemorrhage that causes rapid loss of an equal amount of blood is likely to cause hypotension and shock.

**Genetic Endowment.** Genetic endowment is increasingly being viewed as a contributing factor in adaptation to stressful events, both physiologic and psychological. Recent advances in the field of genetic research suggest that different variants of certain genes determine how an individual responds to stressful life experiences. For example, an inherited variant of the serotonin transporter gene is associated with a number of conditions such as alcoholism, and individuals who have the variant are more vulnerable to respond to stressful experiences by developing depressive disorders.

There also is evidence linking variants in the glucocorticoid receptor gene, which controls the body’s response to cortisol during stressful situations, to the development of depressive disorders and posttraumatic stress disorder (PTSD). It seems likely that recent advances in genetic research methodology will allow investigators to identify additional patterns of response to stressful events and their link to psychological and physical health problems.

**Age.** The capacity to adapt to stress is also influenced by age. The ability to adapt is impaired by the immaturity of an infant, much as it is by the decline in functional reserve that occurs with aging. For example, the infant has difficulty concentrating urine because of immature renal structures, and therefore an infant is less able than an adult to cope with decreased water intake or exaggerated water losses. A similar situation exists in the elderly, owing to age-related changes in renal function. Likewise, there is a
reported decline in ANS and cardiovascular responsiveness to stress associated with advancing age. Aging is also associated with impaired activation and proliferation of T and B lymphocytes, as well as poorer natural killer cell response to stimulatory cytokines.

**Gender.** Within the last decade, primarily because females have been included in basic science and clinical investigations, differences between the sexes in cardiovascular, respiratory, endocrine, renal, and neurophysiologic function have been found, and it has been hypothesized that sex hormones are the basis of these biologic differences. Technological advances in cellular and molecular biology have made it clear, however, that there are fundamental differences in the locale and regulation of individual genes in the male and female genome that can account at a very basic level for differences in physiologic function and disease manifestation. These differences have general implications for the prevention, diagnosis, and treatment of disease and specific implications for our understanding of the sex-based differences in response to life’s stressors.

Given the nature of sex-based differences, it is not surprising that there are differences in the physiologic stress response in both the HPA axis and the ANS. For example, the male hypothalamus produces more CRF and more ACTH than the premenopausal female hypothalamus, in response to psychological stressors (e.g., public speaking). However, secretion of arginine vasopressin (AVP), a hormone that has cardiovascular and renal effects and potentiates the release of ACTH, is greater in the female. Premenopausal women also tend to have a lower activation of the SNS than men in response to stressors. The phase of menstruation (luteal vs. follicular), as well as menopausal status, can alter these responses and need to be considered when studying these responses. These sex-based differences in activation of the stress response may partially explain differences in susceptibility to diseases in which the stress response may play a causal role. These research results are not definitive, but they are intriguing and may serve as a foundation for further research.

**Health Status.** Physical and mental health status determine physiologic and psychological reserves, and they are strong determinants of one’s ability to adapt. For example, persons with heart disease are less able to adjust to stressors that require recruitment of cardiovascular responses. Severe emotional stress often produces disruption of physiologic function and limits the ability to make appropriate choices related to long-term adaptive needs. Professionals who have worked with acutely ill persons have witnessed that the will to live often has a profound influence on survival during life-threatening illnesses.

**Nutrition.** There are 50 to 60 essential nutrients, including minerals, lipids, certain fatty acids, vitamins, and specific amino acids. Deficiencies or excesses of any of these nutrients can alter a person’s health status and impair the ability to adapt. The importance of nutrition to enzyme function, immune response, and wound healing is well known. On a worldwide basis, malnutrition may be one of the most common causes of immunodeficiency.

Among problems associated with dietary excess are obesity and alcohol abuse. Obesity is a common problem. It predisposes an individual to a number of health problems, including atherosclerosis and hypertension. Alcohol is commonly used in excess. It acutely affects brain function, and with long-term use, can seriously impair function of the liver, brain, and other vital structures.

**Sleep–Wake Cycles.** Sleep is considered to be a restorative function, in which energy is restored and tissues are regenerated. Sleep occurs in a cyclical manner, alternating with periods of wakefulness and increased energy use. Biologic rhythms play an important role in adaptation to stress, development of illness, and response to medical treatment. Many rhythms such as rest and activity, work and leisure, and eating and drinking oscillate with a frequency similar to that of the 24-hour light–dark solar day. The term circadian, from the Latin circa (“about”) and dies (“day”), is used to describe these 24-hour diurnal rhythms.

Sleep disorders and alterations in the sleep–wake cycle have been shown to alter immune function, the normal circadian pattern of hormone secretion, and physical and psychological functioning. The two most common manifestations of an alteration in the sleep–wake cycle are insomnia and sleep deprivation or increased somnolence. In some persons, stress may produce sleep disorders; in others, sleep disorders may lead to stress. Acute stress and environmental disturbances, loss of a loved one, recovery from surgery, and pain are common causes of transient and short-term insomnia. Air travel and jet lag constitute additional causes of altered sleep–wake cycles, as does shift work.

**Hardiness.** Studies by social psychologists have focused on individuals’ emotional reactions to stressful situations and use of coping mechanisms in order to determine characteristics that help some people remain healthy despite being challenged by high levels of stressors. For example, the concept of hardiness describes a personality characteristic that includes a sense of having control over the environment, a sense of having a purpose in life, and an ability to conceptualize stressors as a challenge rather than a threat. Lower levels of hardiness have been linked with greater reaction to stress, including suppressed pro-inflammatory cytokines (IL-12), increased anti-inflammatory cytokines (IL-4, IL-10), and lower neuropeptide-Y levels. Individuals with higher levels of psychological hardiness demonstrated more moderate and healthy immune and neuroendocrine responses to stress.

**Psychosocial Factors.** Several studies have related social factors and life events to illness. Scientific interest in the social environment as a cause of stress has gradually broadened to include the social environment as a resource that modulates the relationship between stress and health. Presumably, persons who can mobilize strong supportive resources from within their social relationships are better able to withstand the negative effects of stress on their health. Studies suggest that social support has direct and indirect positive effects on
health status and serves as a buffer or modifier of the physical and psychosocial effects of stress. Social networks contribute in a number of ways to a person’s psychosocial and physical integrity. The configuration of significant others that constitutes this network functions to mobilize resources of the person; these friends, colleagues, and family members share the person’s tasks and provide monetary support, materials, and tools, as well as guidance in improving long-term problem-solving capabilities.

SUMMARY CONCEPTS

- Physiologic and psychological adaptation involves the ability to maintain constancy of the internal environment (homeostasis) and behavior in the face of a wide range of changes in the internal and external environments. It involves negative feedback control systems that regulate cellular function, control life’s processes, regulate behavior, and integrate functions of different body systems.
- The stress response involves activation of several physiologic systems: the sympathetic nervous system (SNS), hypothalamic pituitary adrenal (HPA) axis, and immune system that work in a coordinated fashion to protect the body against damage from intense demands made upon it.
- Selye, who referred to the stress response as the general adaptation syndrome, divided it into three stages: the alarm stage, with activation of the SNS and the HPA axis; the resistance stage, during which the body selects the most effective defenses; and the exhaustion stage, during which physiologic resources are depleted and signs of systemic damage appear.
- Activation and control of the stress response are mediated by combined efforts of the nervous and endocrine systems. The neuroendocrine systems integrate signals received from neurosensory pathways and circulating mediators that are carried in the bloodstream. In addition, the immune system both affects and is affected by the stress response.
- Adaptation implies that an individual has successfully created a new balance between the stressor and his or her ability to deal with it. Adaptation is affected by a number of factors, including experience and previous learning, the rapidity with which the need to adapt occurs, genetic endowment, age, health status, nutrition, sleep–wake cycles, hardiness, and psychosocial factors.

Disorders of the Stress Response

Stressors can assume a number of patterns in relation to time. They may be classified as acute time limited, chronic intermittent, or chronic sustained. An acute time-limited stressor is one that occurs over a short amount of time and does not recur; a chronic intermittent stressor is one to which a person is chronically exposed. The frequency or chronicity of circumstances to which the body is asked to respond often determines the availability and efficiency of the stress responses. The response of the immune system, for example, is more rapid and efficient on second exposure to a pathogen than it is on first exposure, but chronic exposure to a stressor can fatigue the system and impair its effectiveness.

Effects of Acute Stress

Generally, the stress response is meant to be acute and time limited. The time-limited nature of the process renders the accompanying catabolic and immunosuppressive effects advantageous. Reactions to acute stress are those associated with the ANS, the fight-or-flight response. Centrally, there is facilitation of neural pathways mediating arousal, alertness, vigilance, cognition, and focused attention, as well as appropriate aggression. For persons with limited coping abilities, either because of physical or mental illness, the acute stress response may be detrimental. For example, persons with preexisting heart disease who are faced with overwhelming sympathetic behaviors associated with the stress response may experience arrhythmias. In healthy individuals, the acute stress response may be detrimental as well, as it can redirect attention away from behaviors that promote health, such as attention to proper meals and getting adequate sleep. For persons with health problems, the stress response may result in interruption of compliance with medication regimens and exercise programs.

The acute physiologic stress associated with severe trauma, infection, and surgery can be extensive. Survival of such insults depends to a great extent upon the neuroendocrine component of the stress response, with activation of the HPA axis being one of the most important components of the response. Cortisol, the primary glucocorticoid secreted by the adrenal cortex in response to activation of the HPA, has an important role in many of the physiologic functions during trauma and critical illness. The actions of cortisol include anti-inflammatory effects, as well as effects on blood glucose, vascular tone, endothelial integrity, and modulation of angiotensinogen synthesis.

Of recent concern has been the dramatic increase in blood glucose levels that occur during the acute stress response to critical injury and illness. The causes of stress-induced hyperglycemia include enhanced release of glucose from glycogen stores, increased
production of glucose from non-carbohydrate sources such as amino acids, and an accompanying state of insulin resistance that impairs glucose uptake into skeletal muscle. Clinical data suggest that hyperglycemia results in worse outcomes and recovery from acute coronary syndromes\textsuperscript{11,51} (see Chapter 19), septic shock\textsuperscript{52,24} (see Chapter 20), hemorrhagic shock,\textsuperscript{49,53} and stroke\textsuperscript{66} (see Chapter 36). These findings have led to a goal for strict control of blood glucose in most critically ill patients. This control is often accomplished through the use of low-dose insulin infusions. Insulin itself has been shown to produce anti-inflammatory, antioxidative, antithrombotic, and profibrinolytic effects, separate from those involved in reducing blood glucose levels.\textsuperscript{31,53} The optimal level for regulation of blood glucose in the critical care setting, and the expediency of initiating insulin therapy, remain current areas of investigation.

**Effects of Chronic Stress**

The stress response is designed to be an acute self-limited response in which activation of the ANS and the HPA axis is controlled in a negative feedback manner. As with all negative feedback systems, pathophysiologic changes can occur in the stress response system. Function can be altered in several ways, including when a component of the system fails, when the neural and hormonal connections among components of the system are dysfunctional, and when the original stimulus for activation of the system is prolonged or of such magnitude that it overwhelms the ability of the system to respond appropriately. In these cases, the system may become overactive or underactive.

Chronicity and excessive activation of the stress response can result from chronic illnesses, and it can contribute to development of long-term health problems. It has been linked to a number of health disorders, including diseases of the cardiovascular, gastrointestinal, immune, and neurologic systems, as well as depression, chronic alcoholism and drug abuse, eating disorders, accidents, and suicide. Chronic activation of the stress response is also an important public health issue from both a health and an economic perspective. The National Institute for Occupational Safety and Health has declared stress as a hazard in the workplace.\textsuperscript{57}

Occurrence of acute necrotizing gingivitis, an oral disease in which normal bacterial flora of the mouth become invasive, is known by dentists to be associated with acute stress, such as final examinations.\textsuperscript{58} Similarly, herpes simplex virus type 1 infection (i.e., cold sores) often develops during periods of inadequate rest, fever, ultraviolet radiation, and emotional upset. The resident herpes virus is kept in check by body defenses, probably T lymphocytes, until a stressful event occurs that causes suppression of the immune system. Psychological stress is associated in a dose-response manner with an increased risk for development of the common cold, and this risk is attributable to increased rates of infection rather than frequency of symptoms after infection.\textsuperscript{59}

The inflammatory phase of wound repair appears to be disrupted in the presence of chronic stress.\textsuperscript{60} Skin blisters were induced on the forearms of 36 post-menopausal women. Women with greater stress produced significantly lower levels of IL-1α and IL-8, indicating a poorer response to the stressor. Lower cell-mediated immune response to influenza vaccination was observed in elderly participants experiencing chronic stress when compared with counterparts that were not experiencing chronic stress.\textsuperscript{61} Chronic stress also has been linked to specific signaling pathways that impact cancer growth and metastasis.\textsuperscript{62}

**Posttraumatic Stress Disorder**

Posttraumatic stress disorder (PTSD) is an example of chronic activation of the stress response to a traumatic event.\textsuperscript{63,64} It was formerly called battle fatigue or shell shock because it was first characterized in men and women returning from combat. Although war is still a significant cause of PTSD, other major catastrophic events, such as weather-related disasters (hurricanes and floods), airplane crashes, terrorist bombings, rape or child abuse, or intimate partner violence also may result in development of the disorder. People who are exposed to such events are also at risk for development of major depression, panic disorder, generalized anxiety disorder, and substance abuse.\textsuperscript{65} Frequently, bodily symptoms and physical illnesses such as hypertension, coronary heart disease, asthma, and chronic pain syndromes have been associated with PTSD.

**Definition.** The term posttraumatic stress disorder was originally defined in the third edition (1980) of the American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders (DSM-III) as a gross stress reaction that was considered a temporary condition; however it could be changed to a neurotic condition if it persisted.\textsuperscript{67} In the fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR) (1994), the diagnosis of acute stress disorder (ASD) was added to distinguish individuals with milder or more transient difficulties from those with PTSD.\textsuperscript{68} In the fifth edition (DSM-5-TR) (2013), the traumatic event has been defined as exposure to actual or threatened death, serious injury, or sexual experience by directly experiencing, witnessing, learning that it happened to a close family member or friend, or being repeatedly exposed to the aversive details of the event (e.g., first responders collecting human remains).\textsuperscript{69}

According to the DSM-5, the essential features of PTSD include exposure to actual or perceived threat.\textsuperscript{69,70} The exposure may not be as narrowly defined as previously thought, and it may include events such as rape, torture, combat, brutal assault, a difficult diagnosis, or sudden death of a loved one. A change in the DSM-5’s criteria for diagnosis of PTSD...
is the removal of the necessity for the individual to experience an intense emotional response at the time of the exposure. This change was made because many individuals, particularly professionals that witness horrific events, reported feeling nothing at the time of the event—instead their professional training “kicked in.” With PTSD, the threat results in a constellation of symptoms that are experienced as intrusion, avoidance, negative alterations in cognition and mood associated with the event, and marked alterations in arousal and reactivity associated with the event. Intrusion involves the recurrent involuntary distressing memories or “flashbacks” during waking hours or nightmares in which the past traumatic event is relived, often in vivid and frightening detail. In children, there may be frightening dreams without recognizable content. Avoidance refers to the attempt to avoid situations, including people, places, activities, and objects that arouse distressing memories. At least one avoidance symptom must be present for definitive diagnosis of PTSD. Negative alterations in cognition and mood involve an inability to remember an important aspect of the event (i.e., dissociative amnesia) that is not the result of a head injury, alcohol, or drugs. Marked alterations in arousal and reactivity replace the numbing symptom in DSM-IV, and it includes inability to experience positive emotions such as love, joy, pleasure, or satisfaction. In addition, distorted beliefs regarding blame of self or others about the causes or consequences of the traumatic event may occur. In addition, irritable and angry outbursts, reckless and destructive behavior, hypervigilance, problems with concentration, and sleep disturbances may occur. DSM-5 no longer includes immediate fear, helplessness, or horror following the event, as it did not improve diagnostic accuracy. Diagnosis of PTSD requires that the duration of disturbance persists for more than a month, causes clinically significant distress or impairment of social or other areas of functioning, and is not attributable to the effects of medication, alcohol, or other medical condition.

Pathophysiology. Although the pathophysiology of PTSD is not completely understood, there is increasing evidence that the disorder results from an exaggerated stress response and a failure of the stress response system to regain homeostasis. The SNS and the HPA axis are the major constituents of the body’s neuroendocrine response to physical and physiological threat and stress. Normally, the SNS response is brief, followed by an HPA axis response that serves to reinstate homeostasis and induces long-lasting adaptive changes that contribute to stress recovery and resilience. This is mediated by glucocorticoids (i.e., cortisol), the product of the HPA axis.

Initial research focused on an exaggerated and unrelenting extension of the normal sympathetic and HPA response to the stress associated with the traumatic event. More recent research has revealed that although persons with PTSD have been shown to have increased levels of the SNS activity, they have decreased cortisol levels and an enhanced negative feedback inhibition of cortisol release with the dexamethasone (a synthetic glucocorticoid) suppression test. Cortisol’s circadian rhythm, which is critically influenced by corticosteroid function, is altered with the progression of PTSD, suggesting an explanation for sleep disturbances that accompany the disorder.

Although neuroendocrine research suggests that lower cortisol levels are implicated in the pathophysiology of PTSD, emerging research findings suggest this may instead reflect pretraumatic stress vulnerability, explaining why some people develop the disorder and others do not. It has been suggested that genetic and previous environmental/experiential factors may predispose to subsequent development of PTSD.

In addition to the neuroendocrine changes that occur with PTSD, neuroanatomic studies have identified alterations in two brain structures (the amygdala and hippocampus) that occur in persons with PTSD. Positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) have shown increased reactivity of the amygdala and hippocampus and decreased reactivity of the anterior cingulate and orbitofrontal areas. These areas of the brain are involved in fear responses. The hippocampus also functions in memory processes. Differences in hippocampal function and memory processes suggest a neuroanatomic basis for the intrusive recollections and other cognitive problems that characterize PTSD.

Diagnosis and Treatment. Although originally conceptualized as a mental disorder, PTSD is becoming increasingly recognized as a highly comorbid condition, much like hypertension, cardiovascular disease, chronic fatigue syndrome, fibromyalgia, and other diseases. For a number of reasons, including the stigma attached to mental illness, limited availability and high cost of treatment, and socioeconomic issues associated with the disorder, people with PTSD frequently do not seek specialized mental health treatment until the disorder has been present for a considerable amount of time.

Initial treatment of PTSD focuses on reducing or eliminating the symptoms and signs of PTSD and any trauma-related comorbid conditions. Next, adaptive functioning must be improved, with an emphasis on returning the person to a psychological state of safety and trust. Finally, general treatment approaches focus on limiting any generalizations of the initial trauma and protecting the person with PTSD from subsequent relapse. Debriefing, or talking about the traumatic event at the time it happens, often is an effective therapeutic tool. Crisis teams are often among the first people to attend to the emotional needs of those caught in catastrophic events. Some people may need continued individual or group therapy. Selective serotonin reuptake inhibitors (SSRIs) are considered the first-line drug treatment for PTSD. Often concurrent pharmacotherapy with antidepressant, antianxiety,
antipsychotic, and/or psychotropic agents are useful and may help the individual participate more fully in therapy.\textsuperscript{80-82} In addition, exercise, participation in sports, and physical activity may be beneficial for persons with PTSD.\textsuperscript{83}

**Treatment of Stress Disorders**

The treatment of stress should be directed toward helping people avoid coping behaviors that impose a risk to their health and providing them with alternative stress-reducing strategies. Purposeful priority setting and problem solving can be used by persons who are overwhelmed by the number of life stressors to which they have been exposed. Some popular evidence-based nonpharmacologic methods of stress reduction are progressive muscle relaxation, guided imagery, music therapy, massage, and biofeedback.

**Progressive Muscle Relaxation Techniques**

Practices for evoking the relaxation response are numerous. They are found in virtually every culture and credited with producing a generalized decrease in SNS activity and musculoskeletal tension. According to Herbert Benson, a physician, who worked on developing various relaxation strategies, four elements are integral to the various strategies: a repetitive mental device, a passive attitude, decreased mental tonus, and a quiet environment.\textsuperscript{84} Benson incorporated these elements into a non-cultural method that is commonly used for achieving relaxation (Box 9-2). Progressive relaxation, also developed by Benson, is another method of relieving tension. This procedure, which has been modified by a number of therapists, consists of systematic contraction and relaxation of major muscle groups.\textsuperscript{85,86} This procedure involves deliberate contraction, followed by relaxation, of 16 isolated muscle groups. Individuals are instructed to focus all of their attention on their muscles, focusing first on the sensations of tension associated with the muscle contractions, and then focusing on the sensations of warmth, softening, and relaxation when the tension is released. The contraction is to be held for approximately 5 to 7 seconds, and the relaxation is intended to last for approximately 30 seconds. The ultimate goal is to reduce or eliminate the tension in the body, both physical and mental.

The relaxation response has been shown to be an effective tool for treating stress-related disease processes, particularly certain immunologic, cardiovascular, and neurodegenerative disorders. It has been suggested that common underlying molecular mechanisms may exist that represent a connection between the stress response, pathophysiology of the stress-related diseases, and physiologic changes associated with the relaxation response.\textsuperscript{87} Several molecular pathways have been suggested including those involving cortisol, norepinephrine/epinephrine, and nitric oxide signaling.

**Guided Imagery**

Guided imagery is another technique that can be used to achieve relaxation.\textsuperscript{88,89} It can be used to control pain and anxiety, as a sleep aid, and as a means of coping with a stressful diagnosis or treatment regimens. It also can be used as a method for relieving anxiety in children. It has been reported that children are quick and eager to use imagery as means of relieving pain or relieving the anxiety associated with surgery.

Guided imagery is a mind–body technique intended to relieve stress and promote a sense of peace and tranquility during periods of stress or difficulty.\textsuperscript{90} The individual is guided to focus on creating a specific mental image designed to bring about positive physical and/or emotional effects.\textsuperscript{91} Instructions are given to focus on the present; if possible, it is desirable to tune out all outside thoughts and ideas. Frequently instructions include going to a “special place” in their minds, such as a secluded beach or a babbling brook. Sometimes visualization is used, in which the person is asked to sit back, close their eyes, and concentrate on a scene narrated by the therapist. Whenever possible, all five senses are involved: the person attempts to see, feel, hear, smell, and taste aspects of the visual experience. Guided imagery may be practiced with a coach using a script, or it can be used independently, with or without a recorded message.

**Music Therapy**

Music therapy is used for both its physiologic and psychological effects. It involves listening to selected pieces of music as a means of ameliorating anxiety or stress, reducing pain, decreasing feelings of loneliness and isolation, buffering noise, and facilitating expression of emotion.\textsuperscript{92} Music is defined as having three components: rhythm, melody, and harmony. Rhythm is the order in the movement of the music. Rhythm is the most dynamic aspect of music, and particular pieces of music often are selected because they harmonize with body rhythms such as heart rhythm, respiratory rhythm, or gait. The melody is created by the musical pitch and the distance
(or interval) between the musical tones. The melody contributes to the listener’s emotional response to the music. Harmony results from the way pitches are blended together, with the combination of sounds described as consonant or dissonant by the listener. Music usually is selected based on a person’s musical preference and past experiences with music. Depending on the setting, headphones may be used to screen out other distracting noises. Radio and television music is inappropriate for music therapy because of the inability to control the selection of pieces that are played, the interruptions that occur (e.g., commercials and announcements), and the quality of the reception. Music therapy has been effective for reducing anxiety in many patient populations across the life span, including critical care, palliative care, and the perioperative arena.

**Massage Therapy**

Massage is the manipulation of the soft tissues of the body to promote relaxation and relief of muscle tension. The technique that is used may involve a gentle stroking along the length of a muscle (effleurage), application of pressure across the width of a muscle (petrisage), deep massage movements applied by a circular motion of the thumbs or fingertips (friction), squeezing across the width of a muscle (kneading), or use of light slaps or chopping actions (hacking). Massage may be administered by practitioners who have received special training in its use, and it can be delivered by less prepared persons such as parents of small children or caregivers of confused elders. It often is used as a means of physiologic relaxation and stress relief in critically ill patients, cancer patients, and persons with dementia.

**Biofeedback**

Biofeedback is a technique in which an individual learns to control physiologic functioning. It involves electronic monitoring of one or more physiologic responses to stress with immediate feedback of the specific response to the person undergoing treatment. Several types of responses are used: electromyographic (EMG), electrothermometer, and electrodermal. The EMG response involves the measurement of electrical potentials from muscles, usually the forearm extensor or frontalis. This technique is used to gain control over the contraction of skeletal muscles that occurs with anxiety and tension. The electrodermal sensors monitor skin temperature in the fingers or toes. The SNS exerts significant control over blood flow in the distal parts of the body such as the digits of the hands and feet. Consequently, anxiety often is manifested by a decrease in skin temperature in the fingers and toes. Electrodermal sensors measure conductivity of skin (usually the hands) in response to anxiety. Fearful and anxious people often have cold and clammy hands, which lead to a decrease in conductivity. Biofeedback has been used successfully to reduce anxiety in nursing students with test anxiety, patients with functional constipation, and those with cyclic vomiting syndrome.

**SUMMARY CONCEPTS**

- Stress, in and of itself, is neither negative nor deleterious to health. The stress response is designed to be time limited and protective. However, in situations of prolonged activation of the response because of overwhelming or chronic stressors, it can be damaging to health. The acute stress reaction and stress-induced hyperglycemia are of particular concern in persons with critical injuries or illness.
- Post-traumatic stress disorder (PTSD) is an example of chronic activation of the stress response as a result of experiencing a traumatic event that involved actual or threatened death or serious injury. Essential features of PTSD include a constellation of symptoms that are experienced as states of intrusion (flashbacks of the event), avoidance (emotional numbing), and hyperarousal (intense activation of the neuroendocrine system).
- Treatment of stress should be aimed at helping people avoid coping behaviors that can adversely affect their health and providing them with other ways to reduce stress. Some popular evidence-based non-pharmacologic methods used in the treatment of stress include progressive muscle relaxation techniques, guided imagery, music therapy, massage therapy, and biofeedback.

**REVIEW EXERCISES**

1. A 21-year-old college student notices that she frequently develops “cold sores” during the stressful final exam week.
   - What is the association between stress and the immune system?  
   - One of her classmates suggests that she listen to music or try relaxation exercises as a means of relieving stress. Explain how these interventions might work in relieving stress.

2. A 75-year-old woman with congestive heart failure complains that her condition gets worse when she worries and is under a lot of stress.
   - Relate the effects stress has on the neuroendocrine control of cardiovascular function and its possible relationship to a worsening of the woman’s congestive heart failure.
   - She tells you that she dealt with much worse stresses when she was younger and never had any problems. How would you explain this?
3. A 30-year-old woman who was rescued from a collapsed building has been having nightmares recalling the event, excessive anxiety, and loss of appetite, and is afraid to leave her home for fear something will happen.

A. Given her history and symptoms, what is the likely diagnosis?

CHAPTER 9 Stress and Adaptation

Nutritional status describes the condition of the body related to the availability and use of nutrients. Nutrients that are taken into the body can be used to provide the energy needed to perform various body functions or they can be stored for future use. The stability of body weight and composition of lean-to-fat tissue ratio over time requires that a person’s energy intake is balanced with energy expenditure. Also, because different foods contain different amounts of proteins, fats, carbohydrates, vitamins, and minerals, appropriate amounts of these nutrients must be maintained to ensure that the body’s metabolic systems are adequately supplied. This chapter discusses nutritional status, overnutrition and obesity, and undernutrition and eating disorders.

**Energetics and Nutritional Status**

Energy Metabolism

Nutritional Status

- Dietary Reference Intakes
  - Calories
  - Proteins, Fats, and Carbohydrates
  - Vitamins and Minerals
  - Fiber
  - Regulation of Food Intake
    - Hunger, Appetite, and Satiety
  - Regulatory Mechanisms
  - Assessment of Energy Stores and Nutritional Status
    - Anthropometric Measurements
    - Laboratory Studies

Overweight and Obesity

- Causes of Overweight and Obesity
  - Adipose Tissue
    - Adipose Tissue as an Endocrine Organ
    - Adipose Tissue and the Inflammatory Process
  - Types of Obesity
  - Prevention and Treatment of Obesity
  - Childhood Obesity

Undernutrition and Eating Disorders

- Malnutrition and Starvation
  - Protein-Energy Malnutrition
  - Malnutrition in Trauma and Illness
  - Diagnosis
  - Treatment

Eating Disorders

- Anorexia Nervosa
- Bulimia Nervosa
- Binge-Eating Disorder

The nutrients from the foods we eat are used by cells to provide the body with the energy needed to perform almost all cellular functions. Energy is measured in heat units called calories. A calorie, spelled with a small “c” and also called a gram calorie, is the amount of heat or energy required to raise the temperature of 1 g of water by 1°C. A kilocalorie (kcal), or large calorie (abbreviated as a capital C), is the amount of energy needed to raise the temperature of 1 kg of water by 1°C. Because a calorie is so small, kilocalories often are used in nutritional and physiologic studies.

**Energy Metabolism**

Metabolism is the organized process through which nutrients—carbohydrates, fats, and proteins—are broken down, transformed, or otherwise converted into cellular energy. The oxidation of carbohydrates and proteins provides 4 kcal/g, whereas fats yield 9 kcal/g. The process of metabolism is unique in that it enables the continual release of energy, and it couples this energy with physiologic functioning. For example, the energy
used for muscle contraction is derived largely from energy sources that are stored in muscle cells and then released as the muscle contracts. Because most of our energy sources come from the nutrients in food that is eaten, the ability to store energy and control its release is important. Normally, energy utilization is balanced with energy expenditure. When the intake of food consistently exceeds energy expenditure, the excess energy is stored as fat, and the person becomes overweight. Conversely, when food intake does not meet energy expenditure, fat stores and other body tissues are broken down and the person loses weight.

More than 90% of body energy is stored as triglycerides in the fat cells of the body. The body has a limited ability to store dietary carbohydrates and proteins as energy sources. Dietary carbohydrates are largely converted to glucose, which is stored as glycogen in liver and skeletal muscle cells. Liver glycogen stores reach a maximum of approximately 200 to 300 g after a high-carbohydrate meal, after which the liver begins to convert some of the excess glucose to triglycerides for storage in fat cells. The amino acids from protein in the diet are stored mainly in the form of structural proteins, enzymes, nucleoproteins, and other types of cellular proteins. After all the cells have reached their limits, the excess amino acids are converted to glucose and used for energy or stored in the liver as glycogen or in adipose tissue as triglycerides.

Triglycerides, which contain no water, have the highest caloric content of all nutrients and are an efficient form of energy storage. When calorie intake is restricted for any reason, the triglycerides in fat cells are broken down, and their fatty acids and glycerol released as energy sources. Fat cells synthesize triglycerides from glucose and fatty acids. Insulin is required for fat storage. It promotes glucose transport through the cell membrane of fat cells. Some of the glucose is used to synthesize fatty acids, but more importantly it forms large amounts of α-glycerol phosphate. This compound supplies the glycerol that combines with fatty acids to form triglycerides. Therefore, in the absence of insulin, the storage of triglycerides in adipose tissue is almost blocked.

Fat cells, or adipocytes, are modified fibroblasts that store almost pure triglycerides in quantities as great as 80% to 95% of their total cell volume. Adipocytes occur singly or in small groups in adipose connective tissue, entire regions of which are committed to triglyceride storage. Collectively, adipocytes constitute a large body organ that is metabolically active in the uptake, synthesis, storage, and mobilization of lipids. In addition, adipose tissue provides insulation for the body, fills body crevices, and protects body organs.

Early studies suggested that fully differentiated adipocytes do not undergo further cell division, and thus that the number of fat cells is fixed in early childhood. This theory proposed that subsequent gains in adipose tissue represented increases in fat cell size. This is no longer considered to be true, since adipose tissue in adults is now known to contain preadipocytes, capable of forming new fat cells, and fat deposition can result from proliferation of these immature adipocytes. Some medications can also increase fat cell numbers. For example, the thiazolidinedione (TZD) class of antidiabetic drugs can stimulate the formation of new fat cells from the preadipocytes, allowing increased uptake of glucose into these cells (and storage as fat), resulting in the desired reduction in serum glucose levels but with unwanted weight gain. In contrast, some drugs can cause loss of fat cells. This occurs in persons who are HIV-positive and are treated with highly active antiretroviral therapy (see Chapter 16). The mechanism of fat loss is not known; however, it may be due to increased apoptosis (programmed cell death) of the adipocytes.

There are two types of adipose tissue: white (unilocular) and brown (multilocular). White fat, which despite its name is cream colored or yellow, is the predominant form of adipose tissue in adults. The adipocytes of white fat are large spherical cells that become polyhedral or oval when crowded in adipose tissue. The functions of white fat include energy storage, endocrine and adipocytokine secretion, insulation, and cushioning of vital organs. In the connective tissue under the skin, the white fat layer has significant insulating functions. Concentrations are found under the skin of the abdomen, buttocks, axilla, and thigh. Sex differences in the thickness of this fatty layer in different parts of the body account, in part, for the differences in body composition between males and females. Internally, white adipose tissue is preferentially located in the greater omentum, mesentery, and retroperitoneal space and is usually abundant around the kidneys. It is also found in the orbits around the eyeballs, in the bone marrow, and between other tissues, where it fills spaces. It retains this structural function even during reduced caloric intake, when the lipid content of adipose tissue elsewhere has been depleted.

Brown fat differs from white fat in terms of its thermogenic capacity (its ability to produce heat). The color of brown fat reflects the presence of iron in its abundant mitochondria. Brown fat mitochondria produce a specific protein called uncoupling protein-1 (UCP-1) that releases the energy generated from metabolism as heat. It is found abundantly in newborns, in whom thermogenesis is critical because of their proportionally greater heat loss as compared to adults and their reduced ability to shiver. Historically, adults were thought to have only a small amount of brown fat; however, recent studies have confirmed that moderate deposits of brown fat are commonly present in adults and can be stimulated by several factors including cold and the sympathetic nervous system.

**Nutritional Status**

The body obtains the energy needed to perform its various functions and maintain the integrity and health of its cells from the various foods that are consumed in the diet. Because different foods contain different proportions of proteins, carbohydrates, fats, minerals, and vitamins, appropriate balances must be maintained among these constituents so that all segments of the body’s metabolic systems can be supplied with the prerequisite materials.
Dietary Reference Intakes

The Dietary Reference Intakes (DRIs) are a set of reference values that identify the level of nutrient intake an individual needs to maintain health and decrease the risk for disease. They are published by the National Academy of Sciences and are periodically reviewed and updated by the Institute of Medicine’s Food and Nutrition Board. A complete database of the DRIs is available online through the United States Department of Agriculture Food and Nutrition Information Center.

The DRIs are a set of reference values that identify the recommended estimated average requirement, dietary allowance, adequate intake, tolerable upper intake level, and acceptable macronutrient distribution range, each of which has specific uses. An Estimated Average Requirement (EAR) is the intake that meets the estimated nutrient need of half of the persons in a specific group. This figure is used as the basis for developing the Recommended Dietary Allowance (RDA), which defines the nutrient intakes that meet the needs of almost all healthy persons in a specific age and sex group. The Adequate Intake (AI) is set when there is not enough scientific evidence to derive an EAR and therefore the RDA. The AI is derived from experimental or observational data that show a mean intake that appears to sustain a desired indicator of health. The Tolerable Upper Intake Level (UL) is the maximum intake that is judged unlikely to pose a health risk in almost all healthy persons in a specified group. It refers to the total intake from food, fortified food, and nutrient supplements. This value is not intended to be a recommended level of intake, and there is no established benefit for persons who consume nutrients above the RDA or AI levels. The Acceptable Macronutrient Distribution Range (AMDR) is a percentage of energy intake for carbohydrates, proteins, and fats, including the linoleic and α-linolenic essential fatty acids, that is associated with good health. For example, the AMDR for protein is 10% to 35%; that is, no less than 10% and no more than 35% of the total energy (calorie) intake should come from proteins. Finally, the DRI for total energy is the estimated energy requirement (EER).

Food and supplement labels use the percent Daily Value (%DV), which is set by the Food and Drug Administration (FDA). The %DV tells the consumer what percent of an individual’s daily need for a given nutrient one serving of a food or supplement supplies.

Because individuals of different age and sex have different nutrient needs, the percent of DV is intended to be used as an example. It is based on a 2,000-calorie diet.

Calories

Energy requirements are greater during growth periods. Infants require approximately 115 kcal/kg of body weight at birth, 105 kcal/kg at 1 year of age, and 80 kcal/kg between 1 and 10 years of age. During adolescence, boys require 45 kcal/kg of body weight and girls require 38 kcal/kg. During pregnancy, a woman needs an extra 300 kcal/day above her usual requirement, and during the first 3 months of breast-feeding, she requires an additional 500 kcal. Table 10-1 identifies the EER for healthy adults.

Proteins, Fats, and Carbohydrates

Proteins, fats, and carbohydrates yield energy. They are referred to as macronutrients because the body requires them in relatively large amounts.

Proteins. Proteins are required for growth and maintenance of body tissues, enzymes and antibody formation, fluid and electrolyte balance, and nutrient transport. Proteins are composed of amino acids, nine of which

*Activity level definitions:
  Sedentary = rarely exercises
  Low active = less 1 hour/day
  Active = about 1 hour/day
  Very active = more than 1 hour/day

are essential to the body. These are leucine, isoleucine, methionine, phenylalanine, threonine, tryptophan, valine, lysine, and histidine. The foods that provide these essential amino acids in adequate amounts are milk, eggs, meat, fish, and poultry. Dried peas and beans, nuts, seeds, and grains contain all the essential amino acids but in less than adequate proportions. These proteins need to be combined with each other or with complete proteins to meet the amino acid requirements for protein synthesis.

Unlike carbohydrates and fats, which are composed of hydrogen, carbon, and oxygen, proteins contain nitrogen; therefore, nitrogen excretion is an indicator of protein intake. The average protein contains about 16% nitrogen. About 90% of this is excreted in the urine as urea, uric acid, creatinine, and other less important nitrogen breakdown products, with the rest being excreted in the feces. Therefore, the rate of protein breakdown can be estimated by measuring the amount of nitrogen in the urine. If the amount of nitrogen taken in by way of protein is equivalent to the nitrogen excreted, the person is said to be in nitrogen balance. A person is in positive nitrogen balance when the nitrogen consumed by way of protein is greater than the amount excreted. This occurs during growth, pregnancy, or healing after surgery or injury. A negative nitrogen balance often occurs with fever, illness, infection, trauma, or burns, when more nitrogen is excreted than is consumed. It represents a state of tissue breakdown.

Fats. Dietary fats are composed primarily of triglycerides (i.e., a compound consisting of three fatty acid chains attached to a glycerol backbone). Saturated fatty acids have no double bonds between carbon atoms in the chains, whereas monounsaturated fatty acids have one double bond in the chain, and polyunsaturated fatty acids have two or more double bonds. The saturated fatty acids elevate blood cholesterol, whereas the mono-unsaturated and polyunsaturated fats lower blood cholesterol. Saturated fats are usually derived from animal sources and remain solid at room temperature. With the exception of coconut and palm oils (which are saturated), unsaturated fats are found in plant oils and usually are liquid at room temperature. Trans fatty acids are produced when unsaturated oils are partially hydrogenated and are called artificial trans fats. They are found primarily in vegetable shortenings and some margarines and foods. Small amounts of natural trans fatty acids are found in dairy products, some meats, and other animal-based foods. Although trans fatty acids tend to increase low-density lipoprotein (LDL) cholesterol and decrease high-density lipoprotein (HDL) cholesterol, the naturally occurring trans fats may have a beneficial effect.

Dietary fats provide energy, function as carriers for the fat-soluble vitamins, serve as precursors of prostaglandins, and are a source of the essential fatty acids, linoleic and alpha-linolenic acids. Because vegetable oils are rich sources of linoleic acid, this level can be met by including two teaspoons per day of vegetable oil in the diet. Alpha-linolenic acid is found primarily in dark green, leafy vegetables, certain plant oils, soybeans, and walnuts. The AMDR for fat is 20% to 35% to prevent the fall of HDL cholesterol associated with very–low-fat diets. Guidelines from the National Cholesterol Education Program recommend that 25% to 35% of the calories in the diet should come from fats. The daily dietary recommendation for cholesterol is less than 300 mg. The American Heart Association recommends limiting saturated fat to less than 7% and trans fatty acids to less than 1% of calories daily.

Carbohydrates. Dietary carbohydrates include simple sugars, such as glucose, sucrose, and fructose, as well as complex carbohydrates, which are commonly called starches. Fiber is an indigestible form of complex carbohydrate. It is recommended that the majority of carbohydrates consumed in the diet be complex carbohydrates, which are rich in fiber and a variety of vitamins and minerals. In contrast, simple sugars do not provide fiber and, unless fortified, usually contain few vitamins and minerals. Moreover, sucrose (i.e., table sugar) is implicated in the development of dental caries, and excessive dietary fructose (e.g., from high-fructose corn syrup in soft drinks and other sweetened foods and beverages) has been increasingly associated with childhood and adult obesity, diabetes, and cardiovascular disease.

The current RDA for adults is 130 g of carbohydrates per day. Some tissues, such as the nervous system, require glucose as an energy source. Although this need can be met by gluconeogenesis, in which amino acids are converted to glucose, a carbohydrate-deficient diet usually results in the loss of tissue proteins. The fatty acids from triglycerides can be converted to ketones and used for energy by other body tissues when glucose is inadequate; however, excessive ketone production can prompt the development of ketosis. Because protein and fat metabolism increases the production of osmotically active metabolic wastes that must be eliminated through the kidneys, there is also danger of dehydration and electrolyte imbalances. The minimum amount of carbohydrates needed to prevent tissue wasting and ketosis is 50 to 100 g/day. In practice, most of the daily energy requirement should be from dietary carbohydrate sources. This is because protein is an expensive source of calories, and it is recommended that dietary fat not exceed 35% of the calorie intake. The AMDR for carbohydrates intake is 45% to 65% of total calories to prevent a high intake of fat.

Vitamins and Minerals

Vitamins are a group of organic compounds essential for numerous body functions. A compound cannot be classified as a vitamin unless it is shown that a deficiency causes disease. Contrary to popular belief, vitamins do not provide energy directly. Instead, many act as coenzymes, components of the enzyme systems required for the release of energy from protein, fat, and carbohydrates. Vitamins also are necessary for the formation of red blood cells, hormones, genetic materials, and the nervous system. They are essential for normal growth and development.

There are two types of vitamins: fat soluble and water soluble. The four fat-soluble vitamins are A, D,
E, and K. They require dietary fat for absorption and transport. The nine water-soluble vitamins are vitamin C and the B vitamins, which are thiamine, riboflavin, niacin, vitamin B₆, pantothenic acid, vitamin B₁₂, folate, and biotin. Because excess amounts of the water-soluble vitamins are excreted in the urine, it is less likely that they may become toxic to the body, but the fat-soluble vitamins are stored in adipose tissue and may reach toxic levels.

Minerals are inorganic elements, not compounds; however, they often function as components of certain enzyme systems, vitamins, and hormones. They are involved in energy metabolism, acid-base balance, maintenance of normal hemoglobin levels, and play a role in nervous system function, are involved in muscle contraction and skeletal development and maintenance, and are major components of bone tissue. Minerals that are present in relatively large amounts in the body are called major minerals. These include calcium, phosphorus, sodium, chloride, potassium, magnesium, and sulfur. The remainder are classified as trace minerals; they include iron, manganese, copper, iodine, zinc, cobalt, fluorid e, chromium, molybdenum, and selenium.

**Fiber**

Fiber cannot be digested by the human gastrointestinal system and is not classified as a nutrient; however, it increases stool bulk and facilitates bowel movements. Soluble fiber, the type that produces a gel in the intestinal tract, binds with cholesterol and prevents it from being absorbed by the body. Soluble fiber also lowers blood glucose. More studies are needed to establish whether fiber prevents colon cancer and promotes weight loss. The adequate daily intake for fiber for adult men and women up to age 50 is 38 and 25 g, respectively. Adults over age 50 should consume 30 and 21 g, respectively, each day. The recommendation for children ranges from 19 to 31 g, and the recommendation for teenagers is similar to that for adults.⁷

**Regulation of Food Intake**

Stability of body weight and composition over time requires that energy intake matches energy utilization. Environmental, cultural, genetic, and psychological factors all influence food intake and energy expenditure. In addition, body weight is tightly controlled by various physiologic feedback control systems that contribute to the regulation of hunger and food intake.

**Hunger, Appetite, and Satiety**

Hunger and appetite are closely associated with food intake. The sensation of hunger is associated with several sensory perceptions, such as the rhythmic contractions of the stomach and that “empty feeling” in the stomach that stimulates a person to seek food. A person’s appetite is the desire for a particular type of food. It is useful in helping the person determine the type of food that is eaten. Satiety is the feeling of fullness or decreased desire for food.

The hypothalamus contains the feeding center for hunger and satiety⁴ (Fig. 10-1). It receives neural input from the gastrointestinal tract, which provides information about stomach distention, chemical signals from nutrients (glucose, amino acids, and fatty acids) in the blood, and input from the cerebral cortex regarding the smell, sight, and taste of the food. Centers in the hypothalamus also control the secretion of several hormones (e.g., thyroid and adrenocortical hormones) that regulate energy balance and metabolism.

**FIGURE 10-1.** Feedback mechanisms for control of food intake. Black lines leading to − indicate feedback signals that decrease appetite and feeding, and blue lines with + indicate feedback signals that increase appetite and feeding. Stretch receptors in the stomach activate sensory afferent vagal pathways that inhibit food intake. Glucagon-like peptide-1 (GLP-1), cholecystokinin (CCK), and insulin are gastrointestinal hormones that are released by the ingestion of food and suppress further feeding. Ghrelin, which is released by the stomach and small intestine, especially during fasting, stimulates appetite. Leptin is a hormone produced by increasing amounts of fat cells as they increase in size; it inhibits food intake. (Modified from Guyton AC, Hall JE. Textbook of Medical Physiology. 11th ed. Philadelphia, PA: Elsevier Saunders; 2006:868.)
Regulatory Mechanisms

The control of food intake can be divided into short-term regulation, which is concerned with the amount of food that is consumed at a meal or snack, and intermediate and long-term regulation, which is concerned with the maintenance of constant stores of nutrients in the tissues, preventing them from becoming too low or too high.

Short-Term Regulation. The short-term regulation of food intake provides a person with the feeling of satiety and turns off the desire for eating when adequate food has been consumed. It requires rapid feedback mechanisms that signal the adequacy of food intake before digestion has taken place and nutrients have been absorbed into the blood. These mechanisms include stretch receptors that monitor filling of the gastrointestinal tract, oral receptors that monitor food intake, and gastrointestinal tract hormones that suppress or increase food intake. Stretch receptors in the gastrointestinal tract monitor gastrointestinal filling and send inhibitory impulses by way of the vagus nerve to the feeding center to suppress the desire for food. Oral receptors monitor the amount of food that passes through the mouth and sends impulses to the feeding center to suppress food intake. This effect occurs despite the fact that the gastrointestinal tract has not become the least bit filled and is thought to result from various oral factors such as tasting, chewing, and swallowing that meter food intake. However, the inhibition caused by this mechanism is considerably less intense and of shorter duration than that caused by gastrointestinal filling.

The gastrointestinal tract hormones that contribute to the short-term regulation of food intake include cholecystokinin (CCK), glucagon-like peptide 1 (GLP-1), and ghrelin. Cholecystokinin, which is released in response to fat in the duodenum, and GLP-1, which is released from the lower small bowel in response to nutrients, especially carbohydrates, have a strong suppressant effect on the hypothalamic feeding center. Ghrelin is a hormone released mainly from the stomach and to a lesser extent by the hypothalamic feeding center. Ghrelin is a hormone released from the stomach and to a lesser extent by the hypothalamic feeding center. Its levels peak just before eating and then fall after a meal, suggesting that it may also stimulate appetite and eating. The presence of food in the stomach increases the release of insulin and glucagon, both of which suppress the neurogenic feeding signals from the brain.

Intermediate and Long-Term Regulation. The intermediate and long-term regulation of food intake is determined by the amount of nutrients that are in the blood and in storage sites. It has long been known that a decrease in blood glucose causes hunger. In contrast, an increase in breakdown products of lipids such as ketoads produces a decrease in appetite. A ketogenic weight loss diet (the Atkins diet) relies partly on the appetite suppressant effects of ketones in the blood.

Recent evidence suggests that the hypothalamus also senses the amount of energy through a hormone called leptin that is produced by fat cells. The stimulation of leptin receptors in the hypothalamus has been shown to produce a decrease in appetite and food intake as well as an increase in metabolic rate and energy consumption. It also produces a decrease in insulin release from the beta cells of the pancreas, which decreases energy storage in fat cells.

Assessment of Energy Stores and Nutritional Status

The nutritional status of an individual can be assessed in a number of ways including a history of weight gain or loss, dietary intake, gastrointestinal symptoms that affect food intake, functional capacity, and physical signs of fat loss and muscle wasting. This information is usually combined with other objective measures of fat stores and skeletal muscle mass.

Anthropometric Measurements

Anthropometric measurements provide a means for assessing body composition, particularly fat stores and skeletal muscle mass. This is done by measuring height, weight, body circumferences, and thickness of various skinfold areas. These measurements commonly are used to determine growth patterns in children and appropriateness of current weight in adults.

Body weight is the most frequently used method of assessing nutritional status; it should be used in combination with measurements of body height to establish whether a person is underweight or overweight. For weight measurement, subjects should ideally be in light clothing and bare feet, fasting, and with an empty bladder. Repeat measurements are best made at the same time of the day.

The body mass index (BMI) uses height and weight to determine healthy weight (Table 10-2). It is calculated by dividing the weight in kilograms by the height in meters squared (BMI = weight [kg]/height [m²]). A BMI less than 18.5 is classified as being underweight and one between 25 and 29.9 is considered overweight. A BMI at or greater than 30.0 is diagnosed as obesity and is furthered classified into classes I (BMI 30.0 to 34.9), II (BMI 35.0 to 39.9), and III or extreme obesity (BMI > 40). Body weight reflects both lean body mass and adipose tissue and cannot be used as a method for describing body composition or the percentage of fat tissue present. Statistically, the best percentage of body fat for men is between 12% and 20%, and for women, it is between 20% and 30%. During physical training, body fat usually decreases, and lean body mass increases.

Among the methods used to estimate body fat are body circumferences, skinfold thickness, bioelectrical impedance, computed tomography (CT), and magnetic resonance imaging (MRI). The measurement of body circumferences has received attention because excess visceral (or intra-abdominal) fat is closely associated with metabolic syndrome (i.e., a syndrome described by a collection of cardiovascular risk factors). Measurements of skinfold thickness can provide a reasonable assessment of body fat, particularly if taken at...
multiple sites. They can provide information about the location of the fat and can be used together with equations and tables to estimate the percentage of lean body mass and fat tissue. However, these measurements often are difficult to perform, are subject to considerable variation between clinicians, and do not provide information about abdominal and intramuscular fat.

Bioelectrical impedance involves the use of electrodes attached to the wrists and ankles to send a harmless current through the body. The flow of the current is affected by the amount of water in the body. Because fat-free tissue contains virtually all the water and current-conducting electrolytes, measurements of the resistance (i.e., impedance) can be used to estimate the percentage of body fat present.

Computed tomography and MRI can be used to provide quantitative pictures from which the thickness of fat can be determined. Computed tomography scans also can be used to provide quantitative estimates of regional fat and give a ratio of intra-abdominal to extra-abdominal fat. Another novel way of measuring body composition is the BOD POD. The subject sits inside the device, and air displacement is measured to determine body composition (i.e., fat vs. lean tissue). Because these methods are costly, they usually are reserved for research studies.

**Laboratory Studies**

Various laboratory tests can aid in evaluating nutritional status. Some of the most commonly performed tests are serum albumin and prealbumin to assess the protein status, total lymphocyte count and delayed hypersensitivity reaction to assess cellular immunity, and creatinine–height index to assess skeletal muscle protein. Vitamin and mineral deficiencies can be determined by measurements of their levels in blood, saliva, and other body tissues or by measuring nutrient-specific chemical reactions.

---

**SUMMARY CONCEPTS**

- Nutritional status describes the condition of the body related to the availability and use of nutrients, which provide the energy and materials necessary for performing the activities of daily living and for the growth and repair of body tissues.
- Metabolism is the organized process whereby nutrients such as carbohydrates, fats, and proteins are broken down, transformed, or otherwise converted to cellular energy, measured in kilocalories (kcal or C). Carbohydrates are the body’s primary source of immediate energy. They supply 4 kcal/g, are stored in limited quantities as glycogen and can be converted to fatty acids. Fats are a concentrated water-free energy source. They contain 9 kcal/g and are stored in fat cells as triglycerides. Proteins, which are broken down into amino acids, generate 4 kcal/g. However, their main role is in building functional and structural body proteins. Excesses of any of the macronutrients will be stored as triglycerides in adipose tissue. Water, vitamins, and minerals are other essential nutrients.
- Nutritional status can be assessed by evaluation of dietary intake; anthropometric measurements such as measurements of height and weight, body circumference, and skinfold thickness; and laboratory tests.
Overweight and Obesity

Overweight and obesity have become global health problems, increasing the risk of hypertension, hyperlipidemia, type 2 diabetes, coronary heart disease, and other health problems. According to recent worldwide estimates, 1.7 billion people are classified as overweight, more than 1 billion have hypertension, and more than 500 million have either diabetes or impaired glucose tolerance.

Obesity is defined as having excess body fat, enlarged fat cells, and an increased number of fat cells. Clinically, obesity and overweight have been defined in terms of the BMI. Historically, various world bodies have used different BMI cutoff points to define obesity. In 1997, the World Health Organization (WHO) defined the various classifications of overweight (BMI ≥ 25) and obesity (BMI ≥ 30). This classification was subsequently adopted by the National Institutes of Health (NIH). The use of a BMI cutoff of 25 as a measure of overweight raised some concern in that the BMI of some men might be increased due to muscle rather than fat weight. However, it has been shown that a BMI cutoff of 25 can sensitively detect most overweight people and does not erroneously detect overly lean people. An important caveat is that certain ethnicities (e.g., Asians), can develop complications from lower levels of BMI and waist circumference than Caucasians. This has resulted in ethnicity-specific definitions being adopted (e.g., overweight in Asians is defined as >23) by the WHO.

Obesity is associated with increased risk for developing many medical, psychosocial, and behavioral problems. In terms of health problems, many disorders occur more frequently in obese people (Fig. 10-2). The most important and common of these are hyperlipidemia, hypertension, coronary artery disease, stroke, and type 2 diabetes mellitus. The increased weight associated with obesity stresses the bones and joints, increasing the likelihood of osteoarthritis. Certain cancers (endometrial, prostate, colon, uterine, ovarian), thromboembolic disorders, and gastrointestinal tract disease (gastroesophageal reflux and gallbladder disease) are also more prevalent in the obese. Other conditions associated with obesity include sleep apnea and pulmonary dysfunction, menstrual irregularities and complications of pregnancy, psychological distress, and nonalcoholic fatty liver disease (discussed in Chapter 30). Because some drugs are lipophilic and exhibit increased distribution in fat tissue, the administration of these drugs, including some anesthetic agents, can be more dangerous in obese persons. If surgery is required, obese persons heal slower and are at increased risk from anesthesia. Massive obesity, because of its close association with so many health problems, can be regarded as a disease in its own right. It is the second leading cause of preventable death.

Causes of Overweight and Obesity

Factors that are thought to lead to the development of overweight and obesity include the interaction of genotype and environmental factors, including diet and environmental factors, including diet and physical activity. Obesity is known to run in families, suggesting a hereditary component. The question that surrounds this observation is whether the disorder arises because of genetic endowment or environmental influences. Studies of twin and adopted children have provided evidence that heredity contributes to the disorder. The most recent update of the human obesity gene map suggests that there are about 30 obesity candidate genes that might contribute to the risk of obesity in humans. It is unknown what combinations of genes and mutations are involved in these risk factors and how environmental factors interact with them.

Although genetic factors may explain some of the individual variations in terms of excess weight, environmental influences are major contributors. These influences include family eating patterns, inactivity because of labor-saving devices and time spent on the computer and watching television, reliance on the automobile for transportation, easy access to food, energy density of food, increased consumption of sugar-sweetened beverages (especially fructose), and increasing portion sizes. The obese may be greatly influenced by the availability of food, the flavor of food, time of day, and other cues. The composition of the diet also may be a causal
factor, and the percentage of dietary fat independent of total caloric intake may play a part in the development of obesity. Psychological factors include using food as a reward, comfort, or means of getting attention. Eating may be a way to cope with tension, anxiety, and mental fatigue.

**Adipose Tissue**

Adipose tissue is no longer simply viewed as a reservoir for energy storage. Adipose tissue is now known to express and secrete a variety of bioactive peptides, known as adipocytokines (e.g., leptin, tumor necrosis factor-α [TNF-α], interleukin-6 [IL-6]) that have autocrine, paracrine, and endocrine effects on the brain, liver, skeletal muscle, and other tissues of the body. In addition, adipose tissue expresses numerous receptors that allow it to respond to afferent signals from traditional hormone systems as well as the central nervous system. Through this interactive network adipose tissue is integrally involved in coordinating a variety of physiologic processes including energy metabolism, neuroendocrine function, and immune function. It is the dysfunctional aspects of these processes that are implicated in the pathogenesis and adverse effects of adipose tissue excess or obesity.

**Adipose Tissue as an Endocrine Organ**

Adipose tissue is now recognized as an endocrine organ that produces several hormones, including leptin, an important mediator of body weight, and adiponectin, which regulates sensitivity to insulin and may be involved in the pathogenesis of type 2 diabetes. Leptin (from the Greek meaning “thin”), a peptide released from adipocytes, has led to renewed interest in the function of adipose tissue and its role in energy homeostasis. Leptin acts through binding to and activation of specific leptin receptors found in several peripheral tissues and in many areas of the brain, including specific regions of the hypothalamus. Receptors in these hypothalamic regions are known to be involved in appetite, food intake, sympathetic nervous system activity, temperature regulation, and insulin release by the pancreatic beta cells. Leptin levels rise following food intake, signaling the sensation of satiety, and fall during fasting, stimulating the sensation of appetite. Congenital leptin deficiency has been associated with hyperphagia (excessive eating) and obesity, impaired thermogenesis, insulin resistance, and hyperlipidemia, all reversed by leptin treatment. The biology of leptin in normal individuals and its involvement in obesity and obesity-related diseases is uncertain.

Adipose tissue also secretes adiponectin, which regulates sensitivity to insulin and may be involved in the pathogenesis of type 2 diabetes. Whereas dysfunctional adipose tissue increases the levels of certain other hormones and adipocytokines, the levels of adiponectin are decreased, leading to decreased insulin sensitivity, proatherosclerosis, and a proinflammatory milieu that can predispose the individual to metabolic syndrome (see Chapter 33) and its associated complications (including type 2 diabetes and cardiovascular disease).

**Adipose Tissue and the Inflammatory Process**

Recent evidence suggests that excess adipose tissue is also associated with a chronic inflammatory response, which is characterized by abnormal cytokine production; increased synthesis of acute-phase reactants, such as C-reactive protein; and activation of proinflammatory signaling pathways. Systemic chronic inflammation has been proposed to have an important role in the pathogenesis of obesity-related insulin resistance and development of type 2 diabetes. It might also contribute to a state of endothelial dysfunction, an abnormal lipid profile, hypertension, and vascular inflammation, all of which promote the development of atherosclerotic cardiovascular disease. Although there is evidence that the proinflammatory pathways are activated in adipose tissue in obesity, the source of the inflammatory mediators remains unclear. Besides adipocytes, adipose tissue contains a connective tissue matrix and macrophages, which may contribute to the production of inflammatory mediators.

**Types of Obesity**

Two types of obesity based on distribution of fat have been described: upper body and lower body obesity. Upper body obesity is also referred to as central, abdominal, or visceral obesity. Lower body obesity is also known as peripheral or gluteal-femoral obesity. Persons with upper body obesity are often referred to as being shaped like an “apple,” compared with those with lower body obesity, who are more “pear” shaped (Fig. 10-3). The obesity type is determined by dividing the waist by the hip circumference. A waist-to-hip ratio greater than 1.0 in men and 0.8 in women indicates upper body obesity. Research suggests that fat distribution may be a more important factor for morbidity and mortality than overweight or obesity.

**FIGURE 10-3. Distribution of adipose tissue in (A) upper body or central (visceral) obesity and (B) lower body or peripheral (subcutaneous) obesity. People with upper body obesity are often described as having an “apple-shaped” body and those with lower body obesity as having a “pear-shaped” body.**
The presence of excess fat in the abdomen out of proportion to total body fat is an independent predictor of risk factors and mortality. Both BMI and waist circumference are positively correlated with total body adipose tissue, but waist circumference is a better predictor of abdominal or visceral fat content than BMI. A waist circumference of 88 cm (35 inches) or greater in women and 102 cm (40 inches) or greater in men has been associated with increased health risk (see Table 10-2). In general, men have more intra-abdominal fat and women more subcutaneous fat. As men age, the proportion of intra-abdominal fat to subcutaneous fat increases. After menopause, women tend to acquire more intra-abdominal fat. Increasing weight gain, alcohol, and low levels of activity are associated with central obesity.

Although central obesity is usually considered to be synonymous with visceral fat, CT or MRI scans can differentiate central obesity into visceral fat and subcutaneous fat. Visceral fat stores are believed to be more lipolytically active than subcutaneous fat and have a greater potential to affect liver metabolism, given the fact that the fatty acids in their venous drainage flow directly to the liver. In addition to their lipolytic effects, visceral adipocytes produce greater amounts of adipocytokines (e.g., TNF-α, IL-6), except adiponectin whose levels are decreased, resulting in a more insulin resistant, proinflammatory, and proatherosclerotic environment. These changes contribute to the development of systemic insulin resistance, hypertension, hyperlipidemia, and other features of the metabolic syndrome, and are thought to be associated with greater cardiometabolic risk.

Cardiometabolic risk represents the overall risk of developing diabetes and/or atherosclerotic cardiovascular disease (e.g., myocardial infarction, stroke) due to a cluster of modifiable risk factors. These include abdominal obesity, dyslipidemia (elevated levels of triglycerides and low-density lipoproteins and decreased levels of high-density lipoproteins), hypertension, insulin resistance, and elevated blood glucose levels, the presence of inflammatory cytokines, and smoking. Emerging risk factors include endothelial dysfunction and a prothrombotic state. Many of these risk factors are also key components of what is termed the metabolic syndrome (see Chapter 33).

Visceral obesity is also associated with many other conditions including cancer (e.g., breast and endometrial cancer), gallbladder disease, osteoarthritis, menstrual irregularities, and infertility (especially as part of the polycystic ovarian syndrome) (see Fig. 10-2).

Weight loss causes a preferential loss of visceral fat (due to higher turnover of visceral fat cells than subcutaneous) and can result in improvements in metabolic and hormonal abnormalities. Although peripheral obesity is associated with varicose veins in the legs and mechanical problems, it is not as strongly associated with cardiometabolic risk.

Prevention and Treatment of Obesity

Emphasis is being placed on the prevention of obesity. It has been theorized that obesity is preventable because the effect of hereditary factors is no more than moderate. A more active lifestyle together with a low-fat diet (<30% of calories) is seen as the strategy for prevention. The target audience should be children, adolescents, and young adults. Tools needed to achieve this goal include promotion of regular meals, increased intake of fruits and vegetables, substituting water for calorie-containing beverages, decreased television viewing time, a low-fat diet, and increased activity. Other experts target the high-risk period from 25 to 35 years, menopause, and the year after successful weight loss.

The current recommendation is that treatment is indicated in all individuals who have a BMI of 30 or higher or who have a BMI of 25 to 29.9 or a high waist circumference plus two or more risk factors. Treatment should focus on individualized lifestyle modification through a combination of a reduced-calorie diet, increased physical activity, and behavior therapy. Before treatment begins, an assessment should be made of the degree of overweight, the person’s eating habits, the person’s physical activity level, and the presence of obesity-associated risk factors and complications. It also is advisable to determine the person’s barriers and readiness to lose weight.

Dietary therapy should be individually prescribed based on the person’s overweight status and risk profile. The diet should be a personalized plan with realistic goals that are 500 to 1000 kcal/day less than the current intake. The aim should be for weight loss initially, followed by a strategy for weight maintenance. Many popular diets exist such as Atkins, Ornish, Weight Watchers, and South Beach. A recent study comparing several of these diets suggested that adherence to the diet, not the diet itself, is most closely associated with weight loss (i.e., the best diet is the one the person likes best).

There is convincing evidence that increased physical activity decreases the risk of overweight and obesity. In addition, it reduces cardiovascular and diabetes risk beyond that achieved by weight loss alone. Although physical activity is an important part of weight loss therapy and helps with maintaining weight loss, it does not independently lead to a significant weight loss. It may, however, help reduce abdominal fat, increase cardiorespiratory fitness, and prevent the decrease in muscle mass that often occurs with weight loss. Exercise should be started slowly with the duration and intensity increased independent of each other.

Techniques for changing behavior include self-monitoring of eating habits and physical activity, stress management, stimulus control, problem solving, contingency management, cognitive restructuring, social support, and relapse prevention. Pharmacotherapy and surgery are available as adjuncts to lifestyle changes in individuals who meet specific criteria. Pharmacotherapy is usually considered only after combined diet, exercise, and behavioral therapy have been in effect for a reasonable period of time. Weight loss surgery is usually limited to persons with a BMI greater than 40, those with a BMI greater than 35 who have comorbid conditions and in whom efforts at medical therapy have failed, and those who have complications of extreme obesity. However, more recent studies have shown the potential
benefit of offering surgery to patients with even lower levels of obesity (e.g., BMI >30 with comorbid conditions such as diabetes).34

Childhood Obesity

Obesity is the most prevalent nutritional disorder affecting the pediatric population in industrialized countries in the world.35,36 The definition for obesity in children is a BMI at or above the sex- and age-specific 95th percentile, while a BMI between the 85th and 95th percentile is defined as being overweight.34 These criteria have been selected because they correspond to adult BMIs of 30 and 25, respectively.37 The findings from the National Health and Nutrition Examination Survey (NHANES), conducted between 2008 and 2010, indicated that 16.9% of children and adolescents were obese.35

The major concern of childhood obesity is that obese children will grow up to become obese adults. Health care providers are now beginning to see hypertension, dyslipidemia, type 2 diabetes, and psychosocial stigma in obese children and adolescents. In North America, type 2 diabetes now accounts for half of all new diagnoses of diabetes (type 1 and type 2) in some populations of adolescents.38 In addition, there is a growing concern that childhood and adolescent obesity may be associated with negative psychosocial consequences such as low self-esteem and discrimination by adults and peers.34

Childhood obesity is determined by a combination of hereditary and environmental factors. It is associated with obese parents, gestational diabetes and excessive weight gain during pregnancy, formula feeding, parenting style, parental eating habits, energy-dense food choices, erratic eating patterns, ethnicity, and sedentary lifestyle.34,36,38,39 Children with overweight parents are at highest risk. One of the factors leading to childhood obesity is the increase in inactivity. Increasing perceptions that neighborhoods are unsafe has resulted in less time spent outside playing and walking and more time spent indoors engaging in sedentary activities such as television viewing and computer usage. Television viewing is associated with consumption of calorie-dense snacks and decreased indoor activity. Studies have shown a 10% decrease in obesity risk for each hour per day of moderate to vigorous physical activity, while the risk increased by 12% for each hour per day of television viewing.38 Obese children may have a deficit in recognizing hunger sensations, stemming perhaps from parents who use food as gratification. The impact of fast food, increased portion size, calorie density, sugar-sweetened soft drinks and foods (especially fructose),32 and high-glycemic-index foods are likely contributing to the increased weights in children and adolescents.

Diagnosis and Treatment. Given the enormity of the problem of overweight and obesity in children, the American Medical Association (AMA), the Department of Health and Human Services’ Health Resources and Services Administration (HRSA), and the Centers for Disease Control and Prevention (CDC) assembled an expert committee to develop recommendations for the assessment, prevention, and treatment of this public health problem.37 Their recommendations include a yearly assessment of weight status in all children by measurement of height and weight to determine BMI for age and comparing it to standard growth charts. Children who are 2 to 18 years of age with a BMI greater than or equal to the 95th percentile for age and sex or a BMI greater than 30 (whichever is smaller) should be classified as obese. Those children with a BMI greater than or equal to the 85th percentile but less than the 95th percentile for age and sex should be placed in the overweight category.

Because adolescent obesity is predictive of adult obesity, treatment of childhood obesity is desirable.36 The goals of therapy in uncomplicated obesity are directed toward healthy eating and activity, not achievement of ideal body weight. Families should be taught awareness of current eating habits, activity, and parenting behavior and how to modify them. In children with complications secondary to the obesity, the medical goal should be to improve that problem. The weight loss interventions should include all family members and caregivers; begin early at a point when the family is ready for change; and assist the family to learn to monitor eating and activity patterns and to make small and acceptable changes in these patterns.

Overweight and obese children should be treated using a staged method based on their age, BMI, and related comorbidities. Dietary goals should focus on well-balanced meals with a healthy approach to eating. Specific strategies can include reduction of specific high-calorie foods or an appropriate balance of foods that are low, medium, and high calorie. Commercial diets should be used with caution. Pharmacologic therapy and bariatric surgery should be reserved for children with complications and for severe obesity, respectively.

SUMMARY CONCEPTS

- Obesity, which refers to excess body fat resulting from consumption of calories in excess of those expended for exercise and activities, reflects the influences of heredity; socioeconomic, cultural, and environmental factors; psychological influences; and activity levels.
- Overweight and obesity are determined by measurements of body mass index (BMI) and waist circumference, which is used to determine the distribution of body fat in terms of upper or lower body obesity. In upper body or central (visceral) obesity, the adipocytes release free fatty acids and adipokines that increase cardiometabolic risk and produce many of the adverse effects of obesity.
SUMMARY CONCEPTS (continued)

- The risks associated with obesity include hyperlipidemia, insulin resistance, and hypertension, which together predispose to the development of type 2 diabetes mellitus and atherosclerotic cardiovascular disease (e.g., coronary artery disease, stroke). Obesity is also associated with gallbladder disease, infertility, osteoarthritis, sleep apnea, complications of pregnancy, menstrual irregularities, nonalcoholic fatty liver disease, thromboembolic disorders, and poor wound healing.

- Childhood obesity is becoming an increasingly prevalent nutritional disorder that predisposes children and adolescents to hypertension, dyslipidemia, type 2 diabetes mellitus, and psychosocial stigma.

**Undernutrition and Eating Disorders**

Undernutrition continues to be a major health problem throughout the world. Protein-energy malnutrition is most obvious in developing countries of the world, where it is indirectly responsible for half of all deaths of young children. Even in developed nations, malnutrition remains a problem.

**Malnutrition and Starvation**

Malnutrition and starvation are conditions in which a person does not receive or is unable to use an adequate amount of nutrients for body function. An adequate diet should provide sufficient energy in the form of carbohydrates, fats, and proteins; essential amino acids and fatty acids for use as building blocks for synthesis of structural and functional proteins and lipids; and the necessary vitamins and minerals to function as coenzymes or hormones in vital metabolic processes or, as in the case of calcium and phosphate, as important structural components of bone.

Among the many causes of malnutrition are poverty and lack of knowledge about nutritional needs, acute and chronic illness, and self-imposed dietary restrictions. Homeless people, the elderly, and the children of the poor often demonstrate the effects of protein and energy malnutrition, as well as vitamin and mineral deficiencies. Even the affluent may fail to recognize that infants, adolescents, and pregnant women have increased nutritional needs. Some types of malnutrition are caused by acute and chronic illnesses, such as malabsorption disorders. In contrast, clinical eating disorders are caused by psychiatric illness.

**Protein-Energy Malnutrition**

Protein-energy malnutrition represents a depletion of the body’s lean tissues caused by starvation or a combination of starvation and catabolic stress. The lean tissues are the fat-free, metabolically active tissues of the body, namely the skeletal muscles, viscera, and cells of the blood and immune system. Because lean tissues are the largest body compartment, their rate of loss is the main determinant of total body weight in most cases of protein energy malnutrition.

Much of the literature on malnutrition and starvation has dealt with infants and children in underdeveloped countries in which food deprivation results in an inadequate intake of protein and calories to meet the body’s energy needs. Protein-energy malnutrition in this population commonly is divided into two distinct conditions: marasmus (protein and calorie deficiency) and kwashiorkor (protein deficiency). The pathologic changes for both types of malnutrition include humoral and cellular immunodeficiencies resulting from protein deficiency and lack of immune mediators. There is impaired synthesis of pigments of the hair and skin (e.g., hair color may change and the skin may become hyperpigmented) due to a lack of substrate (tyrosine) and coenzymes.

There are two functional compartments involved in the distribution of proteins within the body: the somatic compartment, represented by the skeletal muscles, and the visceral compartment, represented by protein stores in body organs, principally the liver. These two compartments are regulated differently, with the somatic compartment being affected more severely in marasmus and the visceral compartment affected more severely in kwashiorkor.

*Marasmus* represents a progressive loss of muscle mass and fat stores due to inadequate food intake that is equally deficient in calories and protein. It results in a reduction in body weight adjusted for age and size. The child with marasmus has a wasted appearance, with loss of muscle mass, stunted growth, and loss of subcutaneous fat; a protuberant abdomen (from muscular hypotonia); wrinkled skin; sparse, dry, and dull hair; and depressed heart rate, blood pressure, and body temperature. Diarrhea is common. Since immune function is impaired, concurrent infections occur and place additional stress on an already weakened body. An important characteristic of marasmus is growth failure; if sufficient food is not provided, these children will not reach their full potential stature.

*Kwashiorkor* results from a deficiency in protein in diets that are relatively high in carbohydrates. The term *kwashiorkor* comes from an African word meaning “the disease suffered by the displaced child,” because the condition develops soon after a child is displaced from the breast after the arrival of a new infant and placed on
a starchy gruel feeding. Kwashiorkor is a more severe form of malnutrition than marasmus. Unlike marasmus, severe protein deficiency is associated with severe loss of the visceral protein compartment with a resultant hypoalbuminemia that gives rise to generalized or dependent edema. The child with kwashiorkor usually presents with edema, desquamating skin, discolored hair, anorexia, and extreme apathy (Fig. 10-4). There are “flaky paint” lesions of the skin on the face (Fig. 10-5), extremities, and perineum and the hair becomes a sandy or reddish color, with linear depigmentation (flag sign). There is generalized growth failure and muscle wasting as in marasmus, but subcutaneous fat is normal, since calorie intake is adequate. Other manifestations include skin lesions, hepatomegaly and distended abdomen, cold extremities, and decreased cardiac output and tachycardia.

*Marasmus-kwashiorkor* is an advanced protein-calorie deficit together with increased protein requirement or loss. This results in a rapid decrease in anthropometric measurements with obvious edema and wasting and loss of organ mass. One essential aspect of severe protein-energy malnutrition is fatty degeneration of such diverse organs as the heart and liver. This degeneration causes subclinical and overt cardiac dysfunction, especially when malnutrition is accompanied by edema. A second injurious aspect is the loss of subcutaneous fat, which markedly reduces the body’s capacity for temperature regulation and water storage. As a consequence, malnourished children become dehydrated and hypothermic more quickly and more severely than normally nourished children. Most children with severe protein-energy malnutrition have asymptomatic infections because their immune systems fail to respond appropriately.

**Malnutrition in Trauma and Illness**

In industrialized societies, protein-energy malnutrition most often occurs secondary to trauma or illness. Kwashiorkor-like secondary protein-energy malnutrition occurs most commonly in association with hypermetabolic acute illnesses, such as trauma, burns, and sepsis. Marasmus-like secondary protein-energy malnutrition typically results from chronic illnesses such as chronic obstructive pulmonary disease (COPD), congestive heart failure, cancer, and HIV infection. Approximately half of all persons with cancer experience
tissue wasting, in which the tumor induces metabolic changes leading to a loss of adipose tissue and muscle mass.\textsuperscript{45}

In healthy adults, body protein homeostasis is maintained by a cycle in which the net loss of protein in the postabsorptive state is matched by a net postprandial gain of protein.\textsuperscript{46} In persons with severe injury or illness, net protein breakdown is accelerated and protein rebuilding disrupted. Protein mass is lost from the liver, gastrointestinal tract, kidneys, and heart. As protein is lost from the liver, hepatic synthesis of proteins declines, and plasma protein levels decrease. There also is a decrease in immune cells. Wound healing is poor, and the body is unable to fight off infection because of multiple immunologic malfunctions throughout the body. The gastrointestinal tract undergoes mucosal atrophy with loss of villi in the small intestine, resulting in malabsorption. The loss of protein from cardiac muscle leads to a decrease in myocardial contractility and cardiac output. The muscles used for breathing become weakened, and respiratory function becomes compromised as muscle proteins are used as a fuel source. A reduction in respiratory function has many implications, especially for persons with burns, trauma, infection, or chronic respiratory disease and for persons who are being mechanically ventilated because of respiratory failure.

In hospitalized patients, malnutrition increases morbidity and mortality rates, incidence of complications, and length of stay. Malnutrition may present at the time of admission or develop during hospitalization. The hospitalized patient often finds eating a healthy diet difficult and commonly has restrictions on food and water intake in preparation for tests and surgery. Pain, medications, special diets, and stress can decrease appetite. Even when the patient is well enough to eat, being alone in a room where unpleasant treatments may be given is not conducive to eating. Although hospitalized patients may appear to need fewer calories because they are on bed rest, their actual need for caloric intake may be higher because of other energy expenditures. For example, more calories are expended during fever, when the metabolic rate is increased. There also may be an increased need for protein to support tissue repair after trauma or surgery.

Diagnosis

No single diagnostic measure is sufficiently accurate to serve as a reliable test for malnutrition. Techniques of nutritional assessment include evaluation of dietary intake, anthropometric measurements, clinical examination, and laboratory tests.\textsuperscript{44} Evaluation of weight is particularly important. Body weight can be assessed in relation to height using the BMI. Evaluation of body composition can be performed by inspection or using anthropometric measurements such as skinfold thickness. Serum albumin and prealbumin are used in the diagnosis of protein-calorie malnutrition. Albumin, which has historically been used as a determinant of nutrition status, has a relatively large body pool and a half-life of 20 days and is less sensitive to changes in nutrition than prealbumin, which has a shorter half-life and a relatively small body pool.\textsuperscript{44}

Treatment

The treatment of severe protein-calorie malnutrition involves the use of measures to correct fluid and electrolyte abnormalities and replenish proteins, calories, and micronutrients.\textsuperscript{44} Treatment is started with modest quantities of proteins and calories based on the person’s actual weight. Concurrent administration of vitamins and minerals is needed. Either the enteral or parenteral route can be used. The treatment should be undertaken slowly to avoid complications. The administration of water and sodium with carbohydrates can overload a heart that has been weakened by malnutrition and result in congestive failure. Enteral feedings can result in malabsorptive symptoms due to abnormalities in the gastrointestinal tract. Refeeding edema is a benign dependent edema that results from renal sodium reabsorption and poor skin and blood vessel integrity. It is treated by elevation of the dependent area and modest sodium restrictions. Diuretics are ineffective and may aggravate electrolyte deficiencies.

Eating Disorders

Eating disorders, which include anorexia nervosa, bulimia nervosa, and binge-eating disorder and their variants to result from serious disturbances in eating, such as restriction of intake and binging, with an excessive concern over body shape or body weight.\textsuperscript{47–50} Eating disorders typically occur in adolescent girls and young women, although 10% of cases of anorexia nervosa and bulimia nervosa occur in boys and men.\textsuperscript{51} Binge-eating disorder is more prevalent in men than anorexia nervosa and bulimia combined. Compared with women, men tend to experience less pressure to engage in behaviors such as self-induced vomiting or laxative use when overeating, less of a sense of loss of control when binge eating, and a greater tendency to use compulsive exercise rather than purging for weight control.\textsuperscript{51}

Eating disorders are more prevalent in industrialized societies and occur in all socioeconomic and major ethnic groups. A combination of genetic, neurochemical, developmental, and sociocultural factors is thought to contribute to the development of the disorders.\textsuperscript{47,48} The American Psychiatric Association’s Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) has established criteria for the diagnosis of anorexia nervosa, bulimia nervosa, and binge-eating disorder.\textsuperscript{52} Although these criteria allow clinicians to make a diagnosis in persons with a specific eating disorder, the symptoms often occur along a continuum between those of anorexia nervosa and bulimia nervosa. Preoccupation with weight and excessive self-evaluation of weight and shape are common to both disorders, and persons with eating disorders may demonstrate a mixture of both disorders.\textsuperscript{48} The female athlete triad, which includes low energy availability, menstrual dysfunction,
such as amenorrhea, and low bone density,\textsuperscript{53} does not meet the strict DSM-5 criteria for anorexia nervosa or bulimia nervosa, but shares many of the characteristics and therapeutic concerns (see Chapter 44). Persons with eating disorders may require concomitant evaluation for psychiatric illness because eating disorders often are accompanied by mood, anxiety, and personality disorders.

**Anorexia Nervosa**

Anorexia nervosa is an eating disorder that usually begins in adolescence and is characterized by determined dieting, often accompanied by compulsive exercise and, in a subgroup of persons, purging behavior with or without binging, resulting in sustained low weight.\textsuperscript{54} Other features include a disturbed body image, a pervasive fear of becoming obese, and obsession with severely restricted caloric intake.

The causes of anorexia appear to be multifactorial, with determinants that include genetic influence, personality traits of perfectionism and compulsiveness, anxiety disorders, family history of depression and obesity, and peer, familial, and cultural pressures with respect to appearance.\textsuperscript{54} Other psychiatric disorders often coexist with anorexia nervosa, including major depression or dysthymia and obsessive–compulsive disorder.

Many organ systems are affected by the maldistribution that occurs in persons with anorexia nervosa. The severity of the abnormalities tends to be related to the degree of malnutrition and is reversed by refeeding. The most frequent complication of anorexia is amenorrhea and loss of secondary sex characteristics with decreased levels of estrogen, which can eventually lead to osteoporosis. Bone loss can occur in young women after as short a period of illness as 6 months.\textsuperscript{48} Symptomatic compression fractures and kyphosis have been reported. Constipation, cold intolerance and failure to shiver in cold, bradycardia, hypotension, decreased heart size, electrocardiographic changes, blood and electrolyte abnormalities, and skin with lanugo (i.e., increased amounts of fine hair) are common. Abnormalities in cognitive function may also occur. The brain loses both white and gray matter during severe weight loss; weight restoration results in return of white matter, but some loss of gray matter may persist.\textsuperscript{54} Unexpected sudden deaths have been reported; the risk appears to increase as weight drops to less than 35\% to 40\% of ideal weight. It is believed that these deaths are caused by myocardial degeneration and heart failure rather than arrhythmias.

The most exasperating aspect of the treatment of anorexia is the inability of the person with anorexia to recognize there is a problem. Because anorexia is a form of starvation, it can lead to death if left untreated. A multidisciplinary approach appears to be the most effective method of treating persons with the disorder. The goals of treatment are eating and weight gain, and efforts to work on psychological, relationship, and emotional issues. Adults whose weight is more than 25\% below the expected weight (or with less weight loss if there are coexisting medical or psychiatric conditions, or both) and children or adolescents who are losing weight rapidly generally require hospitalization to ensure an adequate food intake and to limit physical activity.\textsuperscript{54}

**Bulimia Nervosa**

Bulimia nervosa is defined by recurrent binge eating and activities including vomiting, fasting, excessive exercise, and use of diuretics, laxatives, or enemas to compensate for that behavior. Bulimia nervosa usually begins during adolescence, with a peak period of onset around 18 years of age.\textsuperscript{55} In contrast to anorexia nervosa, which is characterized by a weight that is less than 85\% of normal, most persons with bulimia nervosa are of normal weight. The disorder may be associated with other psychiatric disorders such as anxiety disorder or depression. There is also an association with substance abuse and risky and self-destructive behaviors.\textsuperscript{55}

The complications of bulimia nervosa include those resulting from overeating, self-induced vomiting, and cathartic and diuretic abuse.\textsuperscript{55}–\textsuperscript{57} Among the complications of self-induced vomiting are dental disorders, parotitis, and fluid and electrolyte disorders. Dental abnormalities, such as sensitive teeth, increased dental caries, and periodontal disease, occur with frequent vomiting because the high acid content of the vomitus causes tooth enamel to dissolve. Esophagitis, dysphagia, and esophageal stricture are common. With frequent vomiting, there often is reflux of gastric contents into the lower esophagus because of relaxation of the lower esophageal sphincter. Vomiting may lead to aspiration pneumonia, especially in intoxicated or debilitated persons. Potassium, chloride, and hydrogen are lost in the vomitus, and frequent vomiting predisposes to metabolic acidosis with hypokalemia (see Chapter 8). An unexplained physical response to vomiting is the development of benign, painless parotid gland enlargement.

The weights of persons with bulimia nervosa may fluctuate, although not to the dangerously low levels seen in anorexia nervosa. Their thoughts and feelings range from fear of not being able to stop eating to a concern about gaining too much weight. They also experience feelings of sadness, anger, guilt, shame, and low self-esteem.

Treatment strategies include psychological and pharmacologic treatments. Cognitive-behavioral therapy is the psychosocial therapy predominately used.\textsuperscript{56} This therapy is designed to help individuals become aware of other ways to cope with the feelings that precipitate the desire to purge and to try and correct maladaptive beliefs regarding their self-image. Unlike persons with anorexia nervosa, persons with bulimia nervosa are upset by the behaviors practiced and the thoughts and feelings experienced, and they are more willing to accept help. Pharmacotherapeutic agents include the tricyclic antidepressants, the selective serotonin reuptake inhibitors, and other antidepressant medications.\textsuperscript{55}
Binge-Eating Disorder

Binge-eating disorder is characterized by eating too much in a short period of time, eating too fast, eating alone, eating when not hungry, and feeling uncomfortably full. Unlike bulimia nervosa, persons with binge eating do not engage in compensatory behaviors such as vomiting and laxative abuse. The great majority of persons with binge-eating disorder are overweight, and in turn, obese persons have a higher prevalence of binge-eating disorder than the nonobese populations.56-59 The physical complications associated with binge-eating disorders are usually secondary to attendant obesity.

The primary goal of therapy for binge-eating disorders is to establish a regular, healthy eating pattern. Persons with binge-eating disorders who have been successfully treated for their eating disorder have reported that making meal plans, eating a balanced diet at three regular meals a day, avoiding high-sugar foods and other binge foods, recording food intake and binge-eating episodes, exercising regularly, finding alternative activities, and avoiding alcohol and drugs are helpful in maintaining their more healthful eating behaviors after treatment.

SUMMARY CONCEPTS

- Undernutrition, which can range from a selective deficiency of a single nutrient to starvation, is among the most widespread causes of morbidity and mortality in the world. Protein-energy malnutrition in this population is commonly divided into two distinct conditions: marasmus, (protein and calorie deficiency) in which there is a great loss of protein from the skeletal muscle compartment; and kwashiorkor (protein deficiency), in which there is a greater loss of visceral proteins, particularly those of the liver.

- Malnutrition is also common during illness, recovery from trauma, and hospitalization. The effects of malnutrition and starvation on body function are widespread, including loss of muscle mass, impaired immunologic function and wound healing, decreased appetite, loss of calcium and phosphate from bone, anovulation and amenorrhea in women, and decreased testicular function in men.

- Eating disorders, which include anorexia nervosa, bulimia, and binge-eating disorder, are psychiatric disorders characterized by severe disturbances in eating, such as willful restriction of intake and binge eating, as well as excessive concern over body weight and shape. Anorexia nervosa is characterized by a refusal to maintain a minimally normal body weight; bulimia nervosa is characterized by secretive episodes of binging followed by compensatory behaviors such as self-induced vomiting; and binge eating disorder is characterized by the consumption of unusually large quantities of food in a short period of time that is not followed by compensatory behaviors.

REVIEW EXERCISES

1. Stability of body weight and composition over time requires that energy (food) intake match energy utilization.
   A. Define the terms hunger and appetite and describe their role in regulating food intake.
   B. Differentiate between short- and long-term control of food intake and the neural and hormonal mechanisms involved in their regulation.

2. A 25-year-old woman is 65 inches (165 cm) tall and weighs 300 pounds (136 kg). She works as a receptionist in an office, brings her lunch to work with her, spends her evenings watching television, and gets very little exercise. She reports that she has been fat ever since she was a little girl, she has tried “every diet under the sun,” and when she diets she loses some weight but gains it all back again.
   A. Calculate her BMI using the website referred to in Table 10-1.
   B. How would you classify her obesity?
   C. What are her risk factors for obesity?
   D. What would be one of the first steps in helping her develop a plan to lose weight?

3. A 16-year-old high school student is brought into the physician’s office by her mother, who is worried because her daughter insists on dieting because she thinks she is too fat. The daughter is 67 inches tall and weighs 96 pounds. She is a straight A student, plays in the orchestra, and gets very little exercise. She reports that she has been fat ever since she was a little girl, she has tried “every diet under the sun,” and when she diets she loses some weight but gains it all back again.
   A. What are the characteristic behaviors associated with anorexia nervosa?
   B. What are some of the physiologic manifestations of the malnutrition and severe weight loss associated with this disorder?

Chapter 11

Disorders of White Blood Cells and Lymphoid Tissues

The hematopoietic system and lymphoid tissues are responsible for the generation and regulation of the blood cells that function in the transport of oxygen, defense against microorganisms, and preservation of the integrity of the vascular system. This chapter is divided into two parts: the first provides an introduction to the hematopoietic system, lymphoid tissues, and the white blood cells; and the second focuses on disorders of the white blood cells, including those of nonneoplastic (neutropenia and infectious mononucleosis) and neoplastic (lymphomas, leukemias, and multiple myeloma) origin. The megakaryocytes and platelets are discussed in Chapter 12, the red blood cells in Chapter 13, and the immune system (lymphocytes and monocytes) in Chapter 15.

Hematopoietic and Lymphoid Tissues

Blood consists of blood cells (i.e., leukocytes or white blood cells, thrombocytes or platelets, and erythrocytes or red blood cells) and the plasma in which the cells are suspended. These cells all derive from a single pool of pluripotent stem cells in the bone marrow, which give rise
to two types of multipotent stem cells: the hematopoietic stem cells, which remain in the bone marrow, and the lymphopoietic stem cells, which migrate to the thymus, lymph nodes, spleen, and mucosa-associated lymphoid tissues.

**The Bone Marrow and Hematopoiesis**

The bone marrow consists of hematopoietic or blood-forming cells and stromal tissue that provides support for the blood-forming cells. The blood-forming population of bone marrow is made up of three types of cells: pluripotent stem cells, multipotent stem cells, and committed progenitor cells that develop into the various types of blood cells\(^1\)–\(^4\) (Fig. 11-1). The pluripotent stem cells give rise to two types of multipotential stem cells, the common lymphoid and the common myeloid stem cells. The common lymphoid stem cells, in turn, differentiate into lineage-specific precursor cells that develop into T lymphocytes (T cells), B lymphocytes (B cells), and natural killer (NK) cells. From the common myeloid stem cells arise precursor cells capable of differentiating along the erythrocyte/megakaryocytic and granulocyte-monocyte pathways.

Several levels of differentiation lead to the development of committed unipotential cells, which are the progenitors for each of the blood cell types. These cells are referred to as colony-forming units (CFUs)\(^5\). These progenitor cells only have a limited capacity for self-renewal but retain the potential to differentiate into lineage-specific precursor cells. These precursor cells have morphologic characteristics that permit them to be recognized as the first cell of a particular cell line. They have lost their ability for self-renewal but undergo cell division and differentiation, eventually giving rise to mature lymphocytes, monocytes, granulocytes, megakaryocytes, or erythrocytes.

**Hematopoietic Growth Factors**

Under normal conditions, the numbers and total mass for each type of circulating blood cell remain relatively constant. This regulation of blood cells is thought to be at least partially controlled by hormone-like growth factors called cytokines. The cytokines are a family of short-lived mediators that stimulate the proliferation, differentiation, and functional activation of the various blood cells.

---

---

**FIGURE 11-1.** Major developmental stages of blood cells. NK, natural killer cell.
Many cytokines derived from lymphocytes or bone marrow stromal cells stimulate the growth and production of new blood cells. Several members of this family are called colony-stimulating factors (CSFs) because of their ability to promote the growth of hematopoietic cell colonies in the laboratory. The CSFs that act on committed progenitor cells include erythropoietin (EPO); thrombopoietin (TPO); granulocyte-monocyte colony-stimulating factor (GM-CSF), which stimulates progenitors for granulocytes, monocytes, erythrocytes, and megakaryocytes; granulocyte colony-stimulating factor (G-CSF), which promotes the proliferation of neutrophils; and macrophage colony-stimulating factor (M-CSF), which induces macrophage colonies. Other cytokines, such as the interleukins, interferons, and tumor necrosis factor, support the proliferation of stem cells and the development of lymphocytes and act synergistically to aid the multiple functions of the CSFs.

The genes for most hematopoietic growth factors have been cloned and their recombinant proteins have been generated for use in a wide range of clinical conditions. The clinically useful factors include EPO, G-CSF, and GM-CSF. They are used for treatment of bone marrow failure caused by chemotherapy or aplastic anemia, the anemia of kidney failure and cancer, hematopoietic neoplasms, infectious diseases such as acquired immunodeficiency syndrome (AIDS), and congenital and myeloproliferative disorders. Growth factors are used to increase peripheral stem cells for transplantation and to accelerate cell proliferation after bone marrow engraftment.

**Leukocytes (White Blood Cells)**

The leukocytes or white blood cells, which are the focus of this chapter, originate in the bone marrow and circulate throughout the lymphoid tissues of the body. Leukocytes are commonly classified into two groups based on the presence or absence of specific prominent granules in their cytoplasm. Those containing specific granules (neutrophils, eosinophils, basophils) are classified as granulocytes, and those that lack granules (lymphocytes and monocytes) as agranulocytes (Fig. 11-2). The granulocytes and the agranular monocytes/macrophages are derived from the myeloid stem cells in the bone marrow and circulate in the blood (see Fig. 11-1). The lymphocytes originate from lymphoid stem cells in the bone marrow and migrate between the blood and the lymphatic system.

**Granulocytes**

Granulocytes are spherical and have distinctive multilobar nuclei. They are all phagocytic cells that are identifiable because of their cytoplasmic granules. They have two types of granules: specific granules that bind neutral, basic, or acidic dye components, and azurophilic

---

**FIGURE 11-2.** White blood cells. Granulocytes (A–C) and agranulocytes (D, E). (A) The neutrophil has a large, segmented nucleus. (B) The eosinophil has many bright red-staining granules. (C) The basophil has large dark blue-staining granules. (D) The lymphocyte has a large undivided nucleus. (E) The monocyte is the largest of the leukocytes. (From Cohen BJ. Memmler’s The Human Body in Health and Disease. 11th ed. Baltimore, MD: Wolters Kluwer Health | Lippincott Williams & Wilkins; 2009:284.)
granules. The azurophilic granules stain purple and are lysosomes. The granulocytes are divided into three types—neutrophils, eosinophils, and basophils—according to the staining properties of their specific granules.

Neutrophils. The neutrophils, which constitute 60% to 65% of the total white blood cells, have specific granules that are neutral and do not stain with an acidic or a basic dye. Because these white cells have nuclei that are divided into three to five lobes, they are often called polymorphonuclear leukocytes (PMNs).

The neutrophils are primarily responsible for maintaining normal host defenses against invading bacteria and fungi, cell debris, and a variety of foreign substances. After release from the marrow, the neutrophils spend only approximately 4 to 8 hours in the circulation before moving into the tissues. They survive in the tissues for approximately 4 to 5 days. They die in the tissues by discharging their phagocytic function or from senescence. The pool of circulating neutrophils (i.e., those that appear in the blood count) is in a closely maintained equilibrium with a similar-sized pool of cells marginating along the walls of small blood vessels. These are the neutrophils that respond to chemotactic factors and migrate into the tissues toward the offending agent during an inflammatory reaction.

Eosinophils. The specific cytoplasmic granules of the eosinophils stain red with the acidic dye eosin. These leukocytes constitute 1% to 3% of the total white blood cells and increase in number during allergic reactions and parasitic infections. During allergic reactions, they are thought to release enzymes or chemical mediators that detoxify agents associated with the reaction. In parasitic infections, the eosinophils use surface markers to attach themselves to the parasite and then release hydrolytic enzymes that kill it.

Basophils. The basophils are the least numerous of the white blood cells, accounting for only 0.3% to 0.5% of the total leukocytes. The specific granules of the basophils stain blue with a basic dye. These granules contain heparin, an anticoagulant; histamine, a vasodilator; and other mediators of inflammation. The basophil, which is a blood cell, is related to the connective tissue mast cell that contains similar granules. Both the basophils and mast cells are thought to be involved in allergic and hypersensitivity reactions.

Agranulocytes

Agranulocytes are leukocytes that lack cytoplasmic granules. They include both the lymphocytes and monocytes/macrophages.

Lymphocytes. Lymphocytes are the most common of the agranulocytes, accounting for approximately 30% of the total blood leukocytes. They originate in the bone marrow from lymphoid stem cells and migrate through the peripheral lymphoid organs, where they recognize antigens and participate in immune responses.

There are three types of lymphocytes: B lymphocytes, T lymphocytes, and natural killer cells. The B lymphocytes are so named because they were first recognized as a separate population in the bursa of Fabricius in birds and bursa-equivalent organs (e.g., bone marrow) in mammals. They differentiate to form antibody-producing plasma cells and are involved in humoral-mediated immunity. The T lymphocytes differentiate in the thymus. They activate other cells of the immune system (helper T cells) and are involved in cell-mediated immunity (cytotoxic T cells). Natural killer cells participate in innate or natural immunity and their function is to destroy foreign cells. The lymphocytes of the three different subsets have unique surface markers that can be identified and used to define their function and diagnose disease (discussed in Chapter 15).

Although all lymphocytes are morphologically similar, they comprise elements that vary in terms of lineage, cell membrane molecules and receptors, function, and response to antigen. These cells are often distinguished by surface proteins that can be identified using panels of monoclonal antibodies. These identified proteins are then correlated with cell functions. The standard nomenclature for these proteins is the “CD” (clusters of differentiation) numeric designation (CD4, CD8), which is used to delineate surface proteins that define a particular cell type or stage of cell differentiation and are recognized by a cluster or group of antibodies. Although this nomenclature was originally developed for lymphocytes, it is now common practice to apply it to blood cells other than lymphocytes.

Monocytes/Macrophages. Monocytes are the largest of the white blood cells and constitute approximately 3% to 8% of the total leukocyte count. They are distinguished by a large amount of cytoplasm and a darkly stained kidney-shaped nucleus. Although these cells are considered agranular, they contain small, dense, azurophilic granules that contain lysosomal enzymes similar to those found in the azurophilic granules of neutrophils. Monocytes travel from the bone marrow to the body tissues, where they differentiate into various tissue phagocytes including the histiocytes of loose connective tissue, microglial cells of the brain, Kupffer cells of the liver, and tissue macrophages. During inflammation, monocytes leave the blood vessel at the site of inflammation and transform into tissue macrophages that phagocyte bacteria and tissue debris. Macrophages also play an important role in immune responses by activating lymphocytes and by presenting antigen to T cells (see Chapter 15).

Leukocyte Developmental Stages

Leukocyte development begins with the myeloid and lymphoid stem cells in the bone marrow (Fig. 11-3). The immature precursor cells for each of the cell lines are called blast cells. The names of the various leukocyte developmental stages are often used in describing blood cell changes that occur in hematopoietic disorders (e.g., acute lymphoblastic leukemia, chronic myelogenous leukemia).
The granulocytic precursor cells, which are called myeloblasts, have round to oval nuclei, with delicate chromatin and a blue to gray cytoplasm. During their next stage of development, the myeloblasts are transformed into promyelocytes with similar nuclei, but with a cytoplasm containing many primary granules. In the subsequent metamyelocyte stage, the nuclei distort and become arclike, producing the band developmental stage. Maturation from metamyelocyte to mature neutrophil involves progressive condensation of nuclear chromatin, increasing nuclear lobulation, and the appearance of secondary (specific) granules. Eosinophils and basophils undergo similar developmental stages but develop different secondary granules. Like granulocytes, monocytes develop from the granulocyte-monocyte progenitor cell and progress through monoblast and promonocyte stages.

Lymphocytes derive from lymphoid stem cells and progress through the lymphoblast and prolymphocyte stages. The prolymphocytes leave the bone marrow and travel to the lymphoid tissues, where further differentiation into T and B lymphocytes occurs.

**Lymphoid Tissues**

The body’s lymphatic system consists of the lymphatic vessels, lymphoid tissue and lymph nodes, thymus, and spleen (see Chapter 15). Although both precursor B and T lymphocytes begin their development in the bone marrow, they migrate to peripheral lymphoid structures to complete the differentiation process. B lymphocytes mature in the bone marrow, differentiate into plasma cells, and then move to the lymph nodes, where they continue to proliferate and produce antibodies. T lymphocytes leave the bone marrow as precursor T lymphocytes travel to the thymus, where they differentiate into CD4⁺ helper T cells and CD8⁺ cytotoxic T cells, after which many of them move to lymph nodes, where they undergo further proliferation.

Lymph nodes consist of organized collections of lymphoid tissue located along the lymphatic vessels. Typically grayish white and ovoid or bean shaped, they range in diameter from 1 mm to 1 to 2 cm. A fibrous capsule and radiating trabeculae provide a supporting structure, and a delicate reticular network contributes to internal support. The parenchyma of the lymph node is divided into an outer cortex and an inner medulla. The cortex contains well-defined B-cell and T-cell domains. The superficial outer cortex contains aggregates of cells called follicles. Follicles are the B-cell zones of the lymph nodes. There are two types of follicles: immunologically inactive follicles, called primary follicles, and active follicles that contain germinal centers, called secondary follicles. Germinal centers contain large lymphocytes (centroblasts) and small lymphocytes with cleaved nuclei (centrocytes). The mantle zone is the small layer of B cells surrounding the germinal centers. The cortex around the follicles is called the paracortex. This region contains most of the T cells in the lymph nodes. Like normal lymphocytes, malignant B and T cells tend to home to particular nodal sites, leading to characteristic patterns of involvement. For example, follicular lymphomas develop in the B-cell areas of the lymph node, whereas T-cell lymphomas typically grow in the paracortical T-cell zones.
The alimentary canal, respiratory passages, and genitourinary systems are guarded by accumulations of lymphoid tissue that are not enclosed in a capsule. This form of lymphoid tissue is called diffuse lymphoid tissue or mucosa-associated lymphoid tissue (MALT) because of its association with mucous membranes. Lymphocytes are found in the subepithelium of these tissues. Lymphomas can arise from either MALT or lymph node tissue.

Nonneoplastic Disorders of White Blood Cells

The number of leukocytes, or white blood cells, in the peripheral circulation normally ranges from 4500 to 10,500 cells/µL (4.5 to 10.5 × 10⁹/L). The nonneoplastic disorders of white blood cells include a deficiency of leukocytes (i.e., leukopenia) or proliferation of excess white blood cells (i.e., leukocytosis).

Neutropenia (Agranulocytosis)

The term leukopenia describes a decrease in the absolute number of leukocytes in the blood. The disorder may affect any of the specific types of white blood cells, but most often affects the neutrophils, which are the predominant type of granulocyte. Agranulocytosis denotes a virtual absence of neutrophils. In aplastic anemia, all of the myeloid stem cells are affected, resulting in anemia, thrombocytopenia, and agranulocytosis.

Neutropenia refers specifically to an abnormally low number of neutrophils and is commonly defined as a circulating neutrophil count of less than 1500/µL. It can be further graded as mild (1000 to 1500/µL), moderate (500 to 1000/µL), or severe (<500/µL) based on an absolute number of neutrophils circulating in the blood. Since the neutrophil protects against bacterial infections, persons with neutropenia are prone to recurrent and sometimes severe bacterial infections.

Individuals of African descent and some ethnic groups from the Middle East have lower neutrophil counts without predisposition to bacterial infection, a condition referred to as benign ethnic neutropenia.
Recent genetic studies in people of African descent have highlighted the role of the gene encoding the Duffy antigen receptor for chemokines (DARC). This genetic trait is strongly associated with protection against malaria.11

**Pathogenesis**

The reduction in the number of granulocytes in the blood (neutropenia) can be seen in a wide variety of conditions, including neoplasms, autoimmune disorders, and drug effect (Chart 11-1). Neutropenia is also a feature of a group of rare inherited disorders, such as Kostmann syndrome.8

**Congenital Neutropenia.** A decreased production of granulocytes is a feature of a group of hereditary hematologic disorders, including cyclic neutropenia and Kostmann syndrome.9–11 Periodic or cyclic neutropenia is an autosomal dominant disorder with variable expression that begins in infancy and persists for decades. It is characterized by periodic neutropenia that develops approximately every 21 days and lasts approximately 2 or 3 days.8 Although the cause is undetermined, it is thought to result from impaired feedback regulation of granulocyte production and release. Severe congenital neutropenia, also known as Kostmann syndrome, is a rare inherited form of neutropenia.9–11 The condition occurs sporadically or as an autosomal recessive disorder, causing severe neutropenia while preserving the erythroid and megakaryocyte cell lineages that result in red blood cell and platelet production. The syndrome is usually recognized at birth or shortly thereafter. Infants with the syndrome have almost no neutrophils that develop beyond the promyelocyte stage (see Fig. 11-3). Treatment includes the administration of G-CSF. Before the advent of effective therapy, almost all patients died in early childhood.

**Acquired Neutropenia.** A number of conditions, including aplastic anemia and treatment with cancer chemotherapeutic drugs and irradiation, may cause suppression of bone marrow stem cells, with decreased production of all blood cell types.8–10 Overgrowth of neoplastic cells in cases of nonmyelogenous leukemia and lymphoma also may suppress the function of neutrophil precursors. In splenomegaly, neutrophils may be trapped in the spleen along with other blood cells. Autoimmune disorders or idiosyncratic drug reactions may cause increased and premature destruction of neutrophils. In Felty syndrome, a variant of rheumatoid arthritis, there is increased destruction of neutrophils in the spleen. Infections by viruses or bacteria may drain neutrophils from the blood faster than they can be replaced, thereby depleting the neutrophil storage pool in the bone marrow.8

Many cases of neutropenia are drug related. Chemotherapeutic agents used in the treatment of cancer (e.g., alkylating agents, antimetabolites) cause predictable dose-dependent suppression of bone marrow function. The term idiosyncratic is used to describe drug reactions that are different from the effects observed in most persons and that cannot be explained in terms of allergy. A number of drugs, such as chloramphenicol (an antibiotic), phenothiazines (antipsychotic agents), propylthiouracil (used in the treatment of hyperthyroidism), and phenylbutazone (used in the treatment of arthritis), may cause idiosyncratic depression of bone marrow function.7,8,10 Many idiosyncratic cases of drug-induced neutropenia are thought to be caused by immunologic mechanisms, with the drug or its metabolites acting as antigens (i.e., haptons) to incite the production of antibodies reactive against the neutrophils.

**Clinical Course**

The clinical features of neutropenia usually depend on the cause and severity of the disorder. Neutropenia from any cause places persons at risk for infection by gram-positive and gram-negative bacteria and by fungi. The risk of infection is related to the severity of the neutropenia. Persons with chronic benign neutropenia are often free of infection despite low neutrophil counts.

Neutrophils provide the first line of defense against organisms that inhabit the skin and gastrointestinal tract. Thus, skin infections and ulcerative necrotizing lesions of the mouth are common types of infection in neutropenia. The most frequent site of serious infection

---

**CHART 11-1**  
**Principal Causes of Neutropenia**

**Congenital**
- Alloimmune neonatal neutropenia (transfer of maternal antibodies)
- Cyclic neutropenia
- Kostmann syndrome (severe congenital neutropenia)

**Acquired**
- Autoimmune
  - Primary (rare, usually occurs in children and runs a benign course)
  - Secondary
    - Systemic lupus erythematosus
    - Felty syndrome in persons with rheumatoid arthritis
- Infection related
  - Various infectious agents (most commonly viruses)
  - Mechanisms include increased consumption of neutrophils, production of autoantibodies, direct infiltration of hematopoietic cells, bone marrow suppression
- Drug related
  - Immune-mediated reactions in which drugs act as haptenes (e.g., penicillin, propylthiouracil, aminopyrine)
  - Accelerated apoptosis (clozapine [antipsychotic agent])
  - Bone marrow depression (i.e., vinblastine and other cancer chemotherapeutic agents)
  - Radiation therapy to bone marrow
- Hematologic malignancies
Infectious Mononucleosis

Infectious mononucleosis is a self-limiting lymphoproliferative disorder caused by the Epstein-Barr virus (EBV), a member of the herpesvirus family. The term EBV-associated infectious mononucleosis is often used to designate infectious mononucleosis caused by EBV as opposed to non–EBV-associated clinical syndromes of infectious mononucleosis caused by other agents. Infectious mononucleosis may occur at any age, but occurs principally in adolescents and young adults in developed countries. Epstein-Barr virus is one of the viruses that is most successful in evading the immune system, infecting about 90% of humans and persisting for the lifetime of the person. Epstein-Barr virus spreads from person to person primarily through contact with infected oral secretions. Transmission requires close contact with infected persons. Thus, the virus spreads readily among young children in crowded conditions, where there is considerable sharing of oral secretions. Kissing is also an effective mode of transmission.

Pathogenesis

Infectious mononucleosis is largely transmitted through oral contact with EBV-contaminated saliva. The virus initially penetrates the nasopharyngeal, oropharyngeal, and salivary epithelial cells. It then spreads to the underlying oropharyngeal lymphoid tissue and, more specifically, to B lymphocytes, all of which have receptors for EBV. Infection of the B cells may take one of two forms—it may kill the infected B cell, or the virus may incorporate itself into the cell’s genome. The B cells that harbor the EBV genome proliferate in the circulation and produce the well-known heterophil antibodies that are used for the diagnosis of infectious mononucleosis. A heterophil antibody is an immunoglobulin that reacts with antigens from another species—in this case, sheep red blood cells.

The normal immune response is important in controlling the proliferation of the EBV-infected B cells with the CD8+ cytotoxic T cells and NK cells playing the pivotal role. These virus-specific T cells appear as large, atypical lymphocytes that are characteristic of the infection (Fig. 11-5). In otherwise healthy persons, the humoral and cellular immune responses serve to control viral shedding by limiting the number of infected B cells rather than eliminating them.

Although infected B cells and free virions disappear from the blood after recovery from the disease, the virus remains in a few transformed B cells in the oropharyngeal region and is shed in the saliva. Once infected with the virus, persons remain asymptotically infected for life, and a few such persons intermittently shed EBV. Immunosuppressed persons shed the virus more frequently. Asymptomatic shedding of EBV by healthy persons is thought to account for most of the spread of infectious mononucleosis, despite the fact that it is not a highly contagious disease.

Clinical Course

The onset of infectious mononucleosis usually is insidious. The incubation period from time of initial exposure to onset of symptoms is estimated at 4 to 8 weeks. A prodromal period, which lasts for several days, follows and is characterized by malaise, anorexia, and chills. The prodromal period precedes the onset of fever, pharyngitis, and lymphadenopathy. Occasionally, the disorder comes on abruptly with a high fever. Most persons seek medical attention for severe pharyngitis, which usually is most severe on days 5 to 7 and persists for 7 to 14 days. The lymph nodes are typically enlarged throughout the body, particularly in the cervical, axillary, and groin areas. Hepatitis and splenomegaly are common manifestations of the disease and are thought to be immune mediated. Hepatitis is characterized by nausea, anorexia, hepatomegaly, and jaundice. Although discomforting, it usually is a benign condition that resolves without causing permanent liver damage. The spleen may be enlarged two to three times its normal size.

Although infected B cells and free virions disappear from the blood after recovery from the disease, the virus remains in a few transformed B cells in the oropharyngeal region and is shed in the saliva. Once infected with the virus, persons remain asymptotically infected for life, and a few such persons intermittently shed EBV. Immunosuppressed persons shed the virus more frequently. Asymptomatic shedding of EBV by healthy persons is thought to account for most of the spread of infectious mononucleosis, despite the fact that it is not a highly contagious disease.

Clinical Course

The onset of infectious mononucleosis usually is insidious. The incubation period from time of initial exposure to onset of symptoms is estimated at 4 to 8 weeks. A prodromal period, which lasts for several days, follows and is characterized by malaise, anorexia, and chills. The prodromal period precedes the onset of fever, pharyngitis, and lymphadenopathy. Occasionally, the disorder comes on abruptly with a high fever. Most persons seek medical attention for severe pharyngitis, which usually is most severe on days 5 to 7 and persists for 7 to 14 days. The lymph nodes are typically enlarged throughout the body, particularly in the cervical, axillary, and groin areas. Hepatitis and splenomegaly are common manifestations of the disease and are thought to be immune mediated. Hepatitis is characterized by nausea, anorexia, hepatomegaly, and jaundice. Although discomforting, it usually is a benign condition that resolves without causing permanent liver damage. The spleen may be enlarged two to three times its normal size.

normal size, and rupture of the spleen is an infrequent complication. In less than 1% of cases, mostly in the adult age group, complications of the central nervous system (CNS) develop. These complications include cranial nerve palsy, encephalitis, meningitis, transverse myelitis, and Guillain-Barré syndrome.

The peripheral blood usually shows an increase in the number of leukocytes, with a white blood cell count between 12,000 and 18,000 cells/μL, 60% of which are lymphocytes. The rise in white blood cells begins during the first week, continues during the second week of the infection, and then returns to normal around the fourth week. Although leukocytosis is common, leukopenia may be seen in some persons during the first 3 days of illness. Atypical lymphocytes are common, constituting more than 20% of the total lymphocyte count. Heterophil antibodies usually appear during the second or third week and decline after the acute illness has subsided. They may, however, be detectable for up to 9 months after onset of the disease.

Most persons with infectious mononucleosis recover without incident. The acute phase of the illness usually lasts for 2 to 3 weeks, after which recovery occurs rapidly. Some degree of debility and lethargy may persist for 2 to 3 months. Treatment is primarily symptomatic and supportive. It includes bed rest and analgesics such as acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs) to relieve the fever, headache, and sore throat. Although splenic rupture is rare, avoidance of contact sports for a minimum of 3 weeks after diagnosis is recommended.

In persons with immunodeficiency disorders that lead to defects in cellular immunity (e.g., human immunodeficiency virus [HIV] infection, immunosuppressant-treated recipients of organ or bone marrow transplants), EBV infection may contribute to the development of lymphoproliferative disorders (e.g., non-Hodgkin lymphoma). These persons have impaired T-cell immunity and are unable to control the proliferation of EBV-infected B cells.

Neoplastic Disorders of Hematopoietic and Lymphoid Origin

The neoplastic disorders of hematopoietic and lymphoid origin represent the most important of the white blood cell disorders. They can be divided into two broad categories based on the origin of the tumor cells: lymphoid neoplasms and myeloid neoplasms. The clinical features of these neoplasms are largely determined by their site of origin, the progenitor cell from which they originated, and the molecular events involved in their transformation into a malignant neoplasm.

Myeloid neoplasms arise from hematopoietic stem cells and normally give rise to monoclonal proliferations that replace normal bone marrow cells. They include the acute and chronic myelogenous leukemias. The lymphoid neoplasms encompass a group of entities that vary widely in their clinical presentation and behaviors. They include the B- and T-cell leukemias and lymphomas (non-Hodgkin and Hodgkin lymphomas) that originate in peripheral lymphoid structures such as the lymph nodes, where B and T lymphocytes undergo differentiation and proliferation. The plasma cell dyscrasias originate in the lymph nodes, where B cells differentiate into plasma cells.

Leukemias

The leukemias are malignant neoplasms of cells originally derived from precursor myeloid or lymphoid tissue cells. The term leukemia (i.e., “white blood”) was first used by Rudolf Virchow to describe a reversal of the usual ratio of red blood cells to white blood cells.
Because blood cells circulate throughout the body, these neoplasms are often disseminated from the onset. The leukemic cells may also infiltrate the liver, spleen, lymph nodes, and other tissues throughout the body, causing enlargement of these organs.

**Classification**

The leukemias commonly are classified according to their predominant cell type (i.e., lymphocytic or myelocytic) and whether the condition is acute or chronic. Biphenotypic leukemias demonstrate characteristics of both lymphoid and myeloid lineages. The lymphocytic leukemias involve immature lymphocytes and their progenitors that originate in the bone marrow but infiltrate the spleen, lymph nodes, CNS, and other tissues. The myelogenous leukemias, which involve the pluripotent myeloid stem cells in bone marrow, interfere with the maturation of all blood cells, including the granulocytes, erythrocytes, and thrombocytes.

A rudimentary classification system divides leukemia into four types: acute lymphocytic leukemia (ALL), chronic lymphocytic leukemia (CLL), acute myelocytic leukemia (AML), and chronic myelocytic leukemia (CML). Among children and adolescents, ALL is the most common type, accounting for 75% of leukemia cases. In adults 20 years of age and older, the most common types are CLL (38%) and AML (30%).

**Etiology and Molecular Biology**

The causes of leukemia are largely unknown and likely differ among the different types of leukemia. The incidence of acute leukemia among persons who have been exposed to high levels of radiation is unusually high. Exposure to ionizing radiation, including medical radiation used in cancer treatment, increases the risk of leukemia. Leukemia may occur as a second cancer after aggressive chemotherapy for other cancers, such as Hodgkin lymphoma. Some factors are associated with increased risk of certain types of leukemias. Exposure to certain chemicals such as formaldehyde and benzene (a compound in cigarette smoke and gasoline) also increases the risk of AML. Family history is one of strongest risk factors for CLL. The existence of a genetic predisposition to development of acute leukemia is suggested by the increased leukemia incidence among a number of congenital disorders, including trisomy 21 (Down syndrome), neurofibromatosis, and Fanconi anemia. In individuals with Down syndrome, the incidence of acute leukemia is 10 to 20 times that of the general population.

The molecular biology of leukemia suggests that the event or events causing the disorders exert their effects through disruption or dysregulation of genes that normally regulate blood cell development, blood cell homeostasis, or both. Most commonly, these are structural changes classified as translocations, in which a part of one chromosome becomes located on another chromosome and vice versa; inversions, in which part of a chromosome turns upside down and now is in reverse order but still attached to the original chromosome; and deletions, in which part of a chromosome has been lost (see Chapter 6). It is the disruption or dysregulation of specific genes and gene products occurring at the site of these chromosome aberrations that contributes to the development of leukemia. In many instances, these genes and their products have been shown to be directly or indirectly involved in the normal development or maintenance of the hematopoietic system. Thus, it would appear that leukemia results, at least in part, from disruption in the activity of genes that normally regulate blood cell development. Advances in the understanding of the molecular biology of leukemia are beginning to provide a more complete understanding of the molecular complexity of this disorder for the purposes of diagnosis, classification, treatment, and monitoring of clinical outcomes.

One of the more studied translocations is the Philadelphia chromosome, which was the first chromosomal abnormality identified in cancer. The Philadelphia chromosome translocation represents a reciprocal translocation between the long arm of chromosome 22 and the long arm of chromosome 9. During the translocation, a large portion of 22q is translocated to 9q, and a smaller piece of 9q is moved to 22q (Fig. 11-6). The portion of 9q that is translocated contains ABL, a proto-oncogene located at 9q34.

![Figure 11-6](image-url)
a proto-oncogene that is the cellular homolog of the Abelson murine leukemic virus. The ABL gene is received at a specific site on 22q called the breakpoint cluster region (BCR). The resulting BCR–ABL fusion gene codes for a novel protein that allows affected cells to bypass the regulated signals controlling normal cell growth and differentiation, and instead undergo malignant transformation to become leukemic cells. The Philadelphia chromosome translocation is found in more than 90% of persons with chronic myelogenous leukemia and in some persons with acute leukemia.7 The recent development of tyrosine kinase inhibitors (e.g., imatinib mesylate) has contributed to the targeted approach for treatment of leukemias that display the Philadelphia chromosome translocation.19

**Acute Leukemias**

The acute leukemias are cancers of the hematopoietic progenitor cells. They usually have a sudden and stormy onset with signs and symptoms related to depressed bone marrow function.16–20 There are two main forms of acute leukemia: acute lymphocytic (lymphoblastic) leukemia (ALL) and acute myeloid (myelogenous) leukemia (AML). Acute lymphocytic (lymphoblastic) leukemia is the most common form of leukemia in children. It accounts for three of four cases of childhood cancer, with ALL accounting for most of the remaining cases.22,23 Acute myeloid (myelogenous) leukemia is mainly a disease of older adults, but it is also seen in children and young adults.24,29

Acute lymphocytic (lymphoblastic) leukemia encompasses a group of neoplasms composed of precursor B (pre-B) or T (pre-T) lymphocytes referred to as lymphoblasts (see Fig. 11-3). Most cases (about 85%) of ALL are of pre-B-cell origin.4,7 Approximately 90% of persons with ALL have numeric and structural changes in the chromosomes of their leukemic cells. They include hyperploidy (i.e., more than 50 chromosomes), polyploidy (i.e., three or more sets of chromosomes), and chromosomal translocations and deletions. Many of these chromosomal aberrations serve to dysregulate the expression and function of transcription factors required for normal hematopoietic cell development.

The AMLs are a diverse group of neoplasms affecting myeloid precursor cells in the bone marrow.4,7 Most are associated with acquired genetic alterations that inhibit terminal myeloid differentiation. As a result, normal marrow elements are replaced by an accumulation of relatively undifferentiated blast cells. The result is suppression of the remaining progenitor cells and subsequent anemia, neutropenia, and thrombocytopenia. Specific chromosomal abnormalities, including translocations, are seen in a large number of AMLs. One subtype of AML, acute promyelocytic leukemia, which represents 10% of adult cases of AML, is associated with a (15;17) chromosomal translocation.26 This translocation results in the fusion of the retinoic acid receptor α (RARA) gene on chromosome 17 with the promyelocytic leukemia (PML) gene on chromosome 15. This change in the retinoic acid receptor produces a block in myeloid differentiation at the promyelocytic stage (see Fig. 11-3), probably by inhibiting the action of normal RARA receptors. This block can be overcome by pharmacologic preparations of retinoic acid (a vitamin A analog), causing the neoplastic promyelocytes to differentiate into neutrophils and die.

**Manifestations.** Although ALL and AML are distinct disorders, they typically present with similar clinical features. Both are characterized by an abrupt onset of symptoms, including fatigue resulting from anemia; low-grade fever, night sweats, and weight loss due to rapid proliferation and hypermetabolism of the leukemic cells; bleeding due to a decreased platelet count; and bone pain and tenderness due to bone marrow expansion.20–26 Infection results from neutropenia, with the risk of infection rising steeply as the neutrophil count falls below 500 cells/µL. Generalized lymphadenopathy, splenomegaly, and hepatomegaly caused by infiltration of leukemic cells occur in all acute leukemias but are more common in ALL.

In addition to the common manifestations of acute leukemia (i.e., fever, fatigue, weight loss, easy bruising), infiltration of malignant cells in the skin, gums, and other soft tissues is particularly common in the monocytic form of AML. The leukemic cells may also cross the blood–brain barrier and establish sanctuary in the CNS. Central nervous system involvement is more common in ALL than AML, and is more common in children than adults. Signs and symptoms of CNS involvement include cranial nerve palsies, headache, nausea, vomiting, papilledema, and occasionally seizures and coma.

**Leukostasis** is a condition in which the circulating blast count is markedly elevated (usually 100,000 cells/µL). The high number of circulating leukemic blasts increases blood viscosity and predisposes to the development of leukostatic emboli with obstruction of small blood vessels in the pulmonary and cerebral circulations. Occlusion of the pulmonary vessels leads to vessel rupture and infiltration of lung tissue, resulting in sudden shortness of breath and progressive dyspnea. Cerebral leukostasis leads to diffuse headache and lethargy, which can progress to confusion and coma. Once identified, leukostasis requires immediate and effective treatment to lower the blast count rapidly. Initial treatment uses apheresis to remove excess blast cells, followed by chemotherapy to stop leukemic cell production in the bone marrow.22

**Hyperuricemia** occurs as the result of increased proliferation or increased breakdown of purine nucleotides (i.e., one of the components of nucleic acids) secondary to leukemic cell death that results from chemotherapy. It may increase before and during treatment. Prophylactic therapy with allopurinol, a drug that inhibits uric acid synthesis, is routinely administered to prevent renal complications secondary to uric acid crystallization in the urine filtrate.

**Diagnosis and Treatment.** A definitive diagnosis of acute leukemia is based on blood and bone marrow studies; it requires the demonstration of leukemic cells in the peripheral blood, bone marrow, or extramedullary
tissue. Bone marrow biopsy may be used to determine the molecular characteristics of the leukemia, the degree of bone marrow involvement, and the morphology and histology of the disease. Cytogenetic studies, which are used to determine chromosomal abnormalities, are one of the most powerful prognostic indicators in acute leukemia. In ALL, the staging includes a lumbar puncture to assess CNS involvement. Imaging studies that include computed tomography (CT) of the chest, abdomen, and pelvis may also be obtained to identify additional sites of disease.

Several types of treatment may be used for the management of ALL and AML with the primary treatment being chemotherapy. Treatment of ALL in childhood represents one of the great success stories in oncology. During the past decade, advances in ALL therapy have led to 5-year survival rates of greater than 80% in children.29 Other age groups tend to do less well, with only about 30% to 40% of adults achieving long-term survival. Chemotherapy leads to remission in over 50% of patients with AML, but the overall survival rate is less than 30%.4 Bone marrow or stem cell transplantation is considered for persons with ALL and AML who have failed to respond to other forms of therapy.17 Because of the risk of complications, bone marrow transplantation is not usually recommended for patients older than 50 to 55 years of age.

Chronic Leukemias

In contrast to acute leukemias, chronic leukemias are malignancies involving proliferation of more fully differentiated myeloid and lymphoid cells.4,17 As with acute leukemia, there are two major types of chronic leukemia: chronic lymphocytic leukemia (CLL) and chronic myeloid (myelogenous) leukemia (CML). Chronic lymphocytic leukemia accounts for about one third of all leukemias and is mainly a disorder of older persons. The average age at time of diagnosis is approximately 72 years. It is rarely seen in people younger than 40 years of age, and is extremely rare in children.30 Chronic myeloid (myelogenous) leukemia accounts for 10% to 15% of all leukemias. As with CLL, it is predominantly a disorder of older adults, with an average age of approximately 67 years at the time of diagnosis.

Chronic Lymphocytic Leukemia. Chronic lymphocytic leukemia, a clonal malignancy of B lymphocytes, is the most common form of leukemia in adults in the Western world. In the past, CLL was viewed as a homogeneous disease of immature, immune-incompetent, minimally self-renewing B cells, which accumulated because of faulty apoptotic mechanisms. Chronic lymphocytic leukemia is now becoming viewed as two related entities based on aggressiveness of the disease. Some persons with CLL survive for many years without therapy and eventually succumb to unrelated diseases, whereas others have a rapidly fatal disease despite aggressive therapy. The two entities are thought to reflect differences in the expression of cell surface CD markers (e.g., CD38) in immunoglobulin variable (V) gene mutations.10–32

This difference is rarely present in normal B cells but is found in persons with CLL. Persons whose CLL cells have mutated forms of the immunoglobulin gene generally have a more indolent form of the disease; these cells express low levels of the surface antigen.

The clinical signs and symptoms of CLL are largely related to the progressive infiltration of the bone marrow and lymphoid tissues by neoplastic lymphocytes and to secondary immunologic defects. Persons with the indolent form of CLL are often asymptomatic at the time of diagnosis, and the increase in lymphocytes is noted on a complete blood count obtained for another, unrelated disorder. As the disease progresses, lymph nodes gradually increase in size and new nodes are involved, sometimes in unusual areas such as the scalp, orbit, pharynx, pleura, gastrointestinal tract, liver, prostate, and gonads. Persons with the aggressive form of CLL experience a more rapid sequence of clinical deterioration characterized by increasing lymphadenopathy, hepatosplenomegaly, fever, abdominal pain, weight loss, progressive anemia, and thrombocytopenia, with a rapid rise in lymphocyte count.

Hypogammaglobulinemia is common in CLL, especially in persons with advanced disease. An increased susceptibility to infection reflects an inability to produce specific antibodies and abnormal activation of complement. The most common infectious organisms are those that require opsonization for bacterial killing, such as Streptococcus pneumoniae, Staphylococcus aureus, and Haemophilus influenzae.

The diagnostic hallmark of CLL is isolated increase in lymphocytes. The white blood cell count is usually greater than 20,000/µL and may be elevated to several hundred thousand. Usually, 75% to 98% are lymphocytes. Tests to determine the presence of mutated forms of the immunoglobulin gene (which currently can be detected only in research laboratories) and expression of the CD38 surface antigen may be used to determine whether the leukemia is the indolent or aggressive type.31 Treatment of CLL usually depends on the presence of prognostic indicators.31 Persons with the low-risk or indolent form of CLL usually do not require specific treatment for many years after diagnosis and eventually die of apparently unrelated causes. Many persons with intermediate-risk disease may remain stable for many years as well, whereas others may develop complications and need treatment within a few months. Most persons with high-risk CLL require combination chemotherapy at the time of diagnosis. In younger patients with aggressive disease, an allogeneic ablative (destruction of bone marrow cells by irradiation or chemotherapy) or nonmyeloablative stem cell transplant is a treatment option.

Chronic Myelogenous Leukemia. Chronic myeloid (myelogenous) leukemia is a disorder of the pluripotent hematopoietic progenitor cell. It is characterized by excessive proliferation of marrow granulocytes, erythroid precursors, and megakaryocytes.4,7,33–38 The CML cells harbor a distinctive cytogenetic abnormality, the previously described Philadelphia chromosome. It is generally believed that CML develops when a single, pluripotent hematopoietic stem cell acquires a Philadelphia
chromosome. Although CML originates in the pluripotent stem cells, granulocyte precursors remain the dominant leukemic cell type.

The clinical course of CML is commonly divided into three phases: (1) a chronic phase of variable length, (2) a short accelerated phase, and (3) a terminal blast crisis phase. The onset of the chronic phase is usually slow, with nonspecific symptoms such as weakness and weight loss. The most characteristic laboratory finding at the time of presentation is leukocytosis with immature granulocyte cell types in the peripheral blood. Anemia and, eventually, thrombocytopenia develop. Anemia causes weakness, easy fatigability, and exertional dyspnea. Splenomegaly is often present at the time of diagnosis; hepatomegaly is less common; and lymphadenopathy is relatively uncommon. Persons in the early chronic phase of CML generally are asymptomatic, but without effective treatment most will enter the accelerated phase within 4 years.

The accelerated phase of CML is characterized by enlargement of the spleen and progressive symptoms. Splenomegaly often causes a feeling of abdominal fullness and discomfort. An increase in basophil count and more immature cells in the blood or bone marrow confirm transformation to the accelerated phase. During this phase, constitutional symptoms such as low-grade fever, night sweats, bone pain, and weight loss develop because of rapid proliferation and hypermetabolism of the leukemic cells. Bleeding and easy bruising may arise from dysfunctional platelets. Generally, the accelerated phase is short (6 to 12 months).

The terminal blast crisis phase of CML represents evolution to acute leukemia and is characterized by an increasing number of myeloid precursors, especially blast cells, in the blood (Fig. 11-7). Constitutional symptoms become more pronounced during this period, and splenomegaly may increase significantly. Isolated infiltrates of leukemic cells can involve the skin, lymph nodes, bones, and CNS. With very high blast counts (>100,000 cells/µL), symptoms of leukostasis may occur. The prognosis for patients who are in the blast crisis phase is poor, with a median survival of 3 months.

A diagnostic feature of CML is an elevated white blood count, with a median count of 150,000/µL at the time of diagnosis, although in some cases it is only modestly increased. The hallmark of the disease is the presence of the BCR–ABL gene product, which can be detected in the peripheral blood. The treatment of CML is evolving rapidly. An inhibitor of the BCR–ABL tyrosine kinase, imatinib mesylate, induces complete remission in a high fraction of persons with stable-phase CML. The only available curative treatment for CML is allogeneic bone marrow or stem cell transplantation.

Malignant Lymphomas

The lymphomas are a diverse group of solid tumors composed of neoplastic lymphoid cells that vary with respect to molecular features, genetics, clinical presentation, and treatment. Two groups of lymphomas are recognized: non-Hodgkin lymphomas (NHLs) and Hodgkin lymphoma (HL).

Non-Hodgkin Lymphomas

The NHLs are one of the most common cancers in the United States, accounting for about 4% of all cancers. The average American has a risk of developing NHL during his or her lifetime of about 1 in 50. Personal risk factors that may affect the incidence level include gender, ethnicity, chemical or radiation exposure, and immune dysfunction. Although some NHLs are common in children, more than 95% of cases occur in adults. More than half of the people who develop NHLs are over age 65.

As with most other malignancies, the cause of NHLs is largely unknown. However, impairment of the immune system and infectious agents may play a role. There is evidence of EBV infection in essentially all people with Burkitt lymphoma, which is endemic to some parts of Africa. A second virus, the human T-cell lymphotropic virus (HTLV-1), which is endemic in the southwestern islands of Japan, has been associated with adult T-cell leukemia/lymphoma. The NHLs are also seen with increased frequency in persons infected with HIV, in those who have received chronic immunosuppressive therapy after organ transplantation, and in individuals with acquired or congenital immunodeficiencies.

There is also a reported association between chronic Helicobacter pylori infection and low-grade MALT lymphoma of the stomach.

Non-Hodgkin lymphomas can originate from malignant transformation of either the T or B cells during their differentiation in the peripheral lymphoid tissues. Although the NHLs can originate in any of the lymphoid tissues, they most commonly originate in the lymph nodes. Like normal lymphocytes, transformed B and T cells tend to home into particular lymph node sites, leading to characteristic patterns of involvement. For example, B-cell lymphomas tend to proliferate in the B-cell areas of the lymph node, whereas T-cell lymphomas typically grow in the paracortical T-cell areas (see Fig. 11-4). All have the potential to spread.

FIGURE 11-7. Peripheral blood showing blast crisis in chronic myelogenous leukemia. (From the Centers for Disease Control and Prevention Public Health Image Library. No. 6. Courtesy of Stacy Howard.)
to various lymphoid tissues throughout the body, especially the liver, spleen, and bone marrow.

The classification of NHLs remains controversial and is still evolving. A commonly used classification is the World Health Organization (WHO) system (Chart 11-2). The WHO system classifies lymphomas in terms of cell type (B or T cell), level of maturation (e.g., immature or mature), and anatomic sites (e.g., MALT lymphoma of the stomach). The NHLs are actually a complex group of almost 40 distinct entities, based on the appearance of the lymphoma cells, the presence of surface markers (e.g., antigens, CD markers), and genetic features. In addition, the specific types of lymphomas are sometimes grouped into low-grade, aggressive, and very aggressive categories.

**Mature B-Cell Lymphomas.** Mature (peripheral) B-cell lymphomas are the most common type of lymphoma in the Western world. The most common of the mature B-cell lymphomas are the follicular lymphomas (22%) and diffuse large B-cell lymphomas (31%). Small lymphocytic lymphoma, mantle cell lymphoma, peripheral T-cell lymphoma, and MALT lymphoma together account for 28% of NHLs.

**Follicular lymphomas** are derived from germinal center B cells and consist of a mixture of centroblasts and centrocytes. Follicular lymphomas are a particularly common neoplasm in the United States, where they constitute about one third of all adult NHLs, with a peak incidence at 60 years of age. The lymphoma predominantly affects lymph nodes. Other sites of involvement include the spleen, bone marrow, peripheral blood, head and neck region, gastrointestinal tract, and skin. Most persons have advanced disease at presentation and an indolent clinical course, with a median survival of 6 to 10 years. Over time, approximately one of three follicular lymphomas transforms into a fast-growing diffuse large B-cell lymphoma.

**Diffuse large B-cell lymphomas** are a heterogeneous group of aggressive germinal or postgerminal center neoplasms. The disease occurs in all age groups but is most prevalent between 60 and 70 years of age. The cause of diffuse large B-cell lymphoma is unknown, but may involve EBV or HIV infections. It is a rapidly evolving, multifocal, nodal and extranodal tumor. Manifestations are typically seen at the time of presentation. As a group, diffuse large B-cell lymphomas are rapidly fatal if untreated. However, with intensive combination chemotherapy, complete remission can be achieved in 60% to 80% of persons and approximately 40% to 50% remain disease free after several years and can be considered cured.

**Burkitt lymphoma,** one of the most rapidly growing tumors of the NHLs, is also a disorder of germinal center B cells. Endemic Burkitt lymphoma is the most common childhood cancer (peak age 3 to 7 years) in Central Africa, often beginning in the jaw. It occurs in regions of Africa where both EBV and malarial infections are common. Virtually 100% of patients with African Burkitt lymphoma have evidence of previous EBV infection, and their tumors carry the EBV genome and express EBV-encoded antigens. Malarial infections in this population have been shown to cause T-cell immunodeficiencies, and it is postulated that this association may be the link between EBV infection and the development of lymphoma. A sporadic or nonendemic form of Burkitt lymphoma occurs less frequently in other parts of the world. The classic presentation of endogenous Burkitt lymphoma is a destructive tumor in the jaw and other facial bones (Fig. 11-8), whereas the sporadic form typically presents with abdominal masses. Both forms of Burkitt lymphoma respond to aggressive chemotherapy, with a cure rate of up to 90%.

**Mantle cell lymphomas** constitute less than 10% of NHLs and have their origin in the naive B cell. After the precursor stage, B cells undergo immunoglobulin (Ig) gene rearrangements and develop into surface IgM- and IgD-positive naive B cells. These cells give rise to mantle cell lymphoma. Mantle cell lymphomas do not occur in children, but affect older persons (median age, 60 years). They have a rapid rate of progression, and only one in five persons survives at least 5 years.

**Marginal zone lymphomas** involve late-stage memory B cells that reside in the marginal zone or outermost compartment of the lymph node follicle. Variants of marginal node lymphoma include splenic marginal zone lymphoma and MALT lymphomas of the stomach and other mucosal surfaces. Mucosa-associated lymphoid tissue lymphomas constitute 5% to 10% of all B-cell NHLs. Most MALT lymphomas involve the stomach or other mucosal sites, including the respiratory system. Mucosa-associated lymphoid tissue lymphomas tend to

---

**CHART 11-2**

**WHO Classification of Selected Non-Hodgkin Lymphomas (most common)**

**B-Cell Lymphomas**
- Precursor B-cell lymphomas
  - B-cell lymphoblastic lymphoma
- Mature B-cell lymphomas
  - Diffuse large B-cell lymphoma
  - Mediastinal large B-cell lymphoma
  - Follicular lymphoma
  - Small lymphocytic lymphoma
  - Lymphoplasmacytic lymphoma
  - Mantle cell lymphoma
  - Mucosa-associated lymphoid tissue (MALT) lymphoma
  - Burkitt lymphoma

**T-Cell Lymphomas**
- Precursor T-cell lymphomas
  - T-cell lymphoblastic lymphoma
- Mature T- (and natural killer) cell lymphomas
  - Anaplastic large cell lymphoma
  - Peripheral T-cell lymphoma (unspecified)

remain localized for prolonged periods and to follow an indolent course. Extranodal marginal B-cell lymphomas of the MALT type are curable by radiation or surgery when localized. Mucosa-associated lymphoid tissue lymphomas that occur in the stomach secondary to H. pylori infection often respond to treatment with appropriate antimicrobial agents.

**Clinical Manifestations.** The manifestations of NHLs depend on lymphoma type (i.e., indolent or aggressive) and the stage of the disease. Persons with indolent or slow-growing lymphomas usually present with painless lymphadenopathy, which may be isolated or widespread. Involved lymph nodes may be present in the retroperitoneum, mesentery, and pelvis. The indolent lymphomas are usually disseminated at the time of diagnosis, and bone marrow involvement is frequent. With or without treatment, the natural course of the disease may fluctuate over 5 to 10 or more years. Many low-grade lymphomas eventually transform into more aggressive forms of lymphoma leukemia.

Persons with intermediate or more aggressive forms of lymphoma usually present with accompanying constitutional symptoms such as fever, drenching night sweats, or weight loss. Frequently, there is increased susceptibility to bacterial, viral, and fungal infections associated with hypogammaglobulinemia and a poor humoral antibody response, rather than the impaired cellular immunity seen with Hodgkin lymphoma. Because of their high growth fraction, these lymphomas tend to be sensitive to radiation and chemotherapy. Hence, with intensive combination chemotherapy, complete remission can be achieved in 60% to 80% of cases.

**Diagnosis and Treatment.** A lymph node biopsy is used to confirm the diagnosis of NHLs and immunophenotyping to determine the lineage and clonality. Lymphomas can be grouped according to surface markers or phenotypic markers (e.g., CD20). Staging of the disease is important in selecting a treatment for persons with NHL. Bone marrow biopsy, blood studies, chest and abdominal CT scans, magnetic resonance imaging (MRI), positron emission tomography (PET), gallium scans, and bone scans may be used to determine the stage of the disease. Newer technologies, such as deoxyribonucleic acid (DNA) microarray analysis, which identifies genes that are either overexpressed or underexpressed by tumor cells, may be used to further classify patients into distinct risk groups.

Treatment of NHLs depends on the histologic type, stage of the disease, and clinical status of the person. For early-stage disease with single or limited node involvement, localized radiation may be used as a single treatment modality. However, because most people who present with indolent lymphomas have disseminated disease at the time of diagnosis, combination chemotherapy, combined adjuvant radiation therapy, or both are recommended. Persons with lymphomas that carry a risk of CNS involvement usually receive CNS prophylaxis with high doses of chemotherapeutic agents or cranial irradiation.

**Hodgkin Lymphoma**

Hodgkin lymphoma, previously known as Hodgkin disease, is a specialized form of lymphoma that features the presence of an abnormal cell called a Reed-Sternberg cell. Because of improved treatment methods, death rates have decreased by more than 60% since the early 1970s. Distribution of the disease is bimodal; it occurs more frequently in two separate groups, the first in early adulthood (15 to 40 years) and the second in older adulthood (55 years of age or older). About 10% to 15% of cases are diagnosed in children and teenagers.

Hodgkin lymphoma differs from NHLs in many aspects. First, HL usually arises in a single node or chain of nodes and spreads first to anatomically contiguous lymphoid tissues, while NHLs frequently originates at extranodal sites and spreads in an unpredictable fashion. Therefore, the staging of HL is much more important in guiding therapy than it is for NHLs. Second, HL also has distinctive morphological features. It is characterized by the presence of large, atypical, mononuclear tumor cells, called Reed-Sternberg cells (Fig. 11-9). These cells release factors that induce the accumulation of reactive lymphocytes, macrophages, and granulocytes, which typically make up greater than 90% of the tumor cells.

The origin of the neoplastic Reed-Sternberg cell of Hodgkin lymphoma has been difficult to study, in large part because these cells do not express many of the markers found on lymphocytes. It is only recently that methods have been developed that allow for the microanalysis of these cells and their variants. These studies have shown that the Reed-Sternberg cells of most individual cases harbor identical immunoglobulin genes that show evidence of mutation, establishing the cell of origin as a germinal center or postgerminal center B cell.
As with NHL, the cause of Hodgkin lymphoma is largely unknown. Although exposure to carcinogens and viruses as well as genetic and immune mechanisms have been proposed as causes, none has been proven to be involved in the pathogenesis of the disease. It appears that people with a history of infectious mononucleosis are at increased risk for the development of Hodgkin lymphoma.

**Classification.** The WHO classification proposed classifying Hodgkin lymphoma into two major categories: nodular lymphocyte-predominant Hodgkin lymphoma and classic Hodgkin lymphoma. Nodular lymphocyte-predominant Hodgkin lymphoma represents only a small portion of all cases of HL and is a unique form that generally exhibits a nodular growth pattern, with or without diffuse areas and with rare Reed-Sternberg cells called “popcorn” or “L&H” (lymphohistiocytic) cells. It is often localized rather than disseminated at the time of diagnosis, exhibits a slowly progressive course, and has an overall survival rate greater than 80%.

Classic Hodgkin lymphoma is characterized by clonal proliferation of typical mononuclear Hodgkin cells and multinucleated Reed-Sternberg cells with invariable expression of CD30. Four variants of classic Hodgkin lymphoma have been described: nodular sclerosing, mixed cellularity, lymphocyte rich, and lymphocyte-depleted. The nodular sclerosing type is the most common and is often found in adolescent and young adult women, 15 to 35 years of age. Lymphocyte-rich Hodgkin lymphoma is a newly defined entity, and lymphocyte-depleted Hodgkin lymphoma is rarely diagnosed. At present, all subtypes of classic Hodgkin lymphoma are treated in the same manner.

**Clinical Manifestations.** Most persons with Hodgkin lymphoma present with painless enlargement of a single node or group of nodes. The initial lymph node involvement typically is above the level of the diaphragm (i.e., in the neck, supraclavicular area, or axilla). Mediastinal masses are frequent and are sometimes discovered on routine chest radiography. There may be complaints of chest discomfort with cough or dyspnea. Involvement of subdiaphragmatic lymph nodes at the time of presentation is unusual and more common in elderly men. Additional symptoms that suggest Hodgkin lymphoma include fevers, chills, night sweats, and weight loss. Pruritus and intermittent fevers associated with night sweats are classic symptoms of Hodgkin lymphoma.

Other symptoms such as fatigue and anemia are indicative of disease spread. In the advanced stages of Hodgkin lymphoma, the liver, spleen, lungs, digestive tract, and, occasionally, CNS may be involved. As the disease progresses, the rapid proliferation of abnormal lymphocytes leads to an immunologic defect, particularly in cell-mediated responses, rendering the person more susceptible to viral, fungal, and protozoal infections. Anergy, or the failure to develop a positive response to skin tests such as the tuberculin test, is common early in the course of the disease.

**Diagnosis and Treatment.** A definitive diagnosis of Hodgkin lymphoma requires that the Reed-Sternberg cell be present in a biopsy specimen of lymph node tissue. Computed tomography scans of the chest and abdomen commonly are used to assess for involvement of mediastinal, abdominal, and pelvic lymph nodes. If with initial screening the extent of lymph node involvement cannot be determined, PET imaging may be helpful.

Persons with Hodgkin lymphoma are staged according to the number of lymph nodes involved, whether the lymph nodes are on one or both sides of the diaphragm, and whether there is disseminated disease involving the bone marrow, liver, lung, or skin. The staging of Hodgkin lymphoma is of great clinical importance because the choice of treatment and the prognosis ultimately are related to the distribution of the disease. In addition, patients are designated stage A if they lack constitutional symptoms and stage B if 10% weight loss (over 6 months) or night sweats are present.

Irradiation and chemotherapy are used in treating the disease. Most people with localized disease are treated with radiation therapy whereas a combined approach using radiation and chemotherapy is used in persons with advanced disease. As the accuracy of staging techniques, delivery of radiation, and curative efficacy of combination chemotherapy regimens have improved, the survival rate of people with Hodgkin lymphoma also has improved.

**Plasma Cell Dyscrasias**

Plasma cell dyscrasias are characterized by expansion of a single clone of immunoglobulin-producing plasma cells and a resultant increase in serum levels of a single monoclonal immunoglobulin or its fragments. The plasma cell dyscrasias include multiple myeloma, lymphoplasmacytic lymphoma, and monoclonal gammopathy of undetermined significance. *Monoclonal gammopathy of undetermined significance (MGUS)* is characterized by the presence of the monoclonal immunoglobulin in the serum without other findings of multiple myeloma. Monoclonal gammopathy of undetermined significance is considered a premalignant condition. Approximately 2% per year of persons...
with MGUS will go on to develop a plasma cell dyscrasia (multiple myeloma or lymphoplasmacytic lymphoma). The strong link between MGUS and multiple myeloma suggests that a first oncogenic event produces MGUS and a second event results in multiple myeloma.\(^4\)

**Multiple Myeloma**

Multiple myeloma is a B-cell malignancy of terminally differentiated plasma cells.\(^{48-52}\) It accounts for 1% of all cancers in Western countries. Its incidence is higher in men and people of African-American descent.\(^4\) It occurs most frequently in the elderly, with incidence peaking at the age of 63 to 70 years.

**Pathogenesis.** Multiple myeloma is characterized by proliferation of malignant plasma cells in the bone marrow and osteolytic bone lesions throughout the skeletal system. As with other hematopoietic malignancies, it is now recognized that multiple myeloma is associated with chromosomal abnormalities, including deletions of 13q and translocations involving the IgG locus on chromosome 14.\(^7\) Changes also occur in the bone marrow microenvironment, including the induction of angiogenesis, the suppression of cell-mediated immunity, and the development of paracrine signaling loops involving cytokines such as IL-6 and vascular endothelial growth factor (VEGF). Other growth factors that are implicated in multiple myeloma include granulocyte-CSF, interferon-\(\alpha\), and IL-10.

One of the characteristic features resulting from the proliferating neoplastic plasma cells in multiple myeloma is the unregulated production of an abnormal monoclonal paraprotein referred to as the \(M\) protein because it is detected as an M spike on protein electrophoresis. In most cases the M protein is either IgG or IgA. In some cases, the plasma cells produce only the light chains of the immunoglobulin molecule. Because of their low molecular weight, the light chains are readily excreted in the urine, where they are termed Bence Jones proteins. More commonly, however, malignant plasma cells produce both complete immunoglobulins and free light chains; therefore, both M proteins and Bence Jones proteins are present. The excess light chains are directly toxic to renal tubular structures and are an important aspect of the pathophysiology of multiple myeloma.

**Manifestations.** The main sites involved in multiple myeloma are the bones and bone marrow (Fig. 11-10). In addition to the abnormal proliferation of marrow plasma cells, there is proliferation and activation of osteoclasts, which leads to bone resorption and destruction. This increased bone resorption predisposes the individual to pathologic fractures and hypercalcemia. Very high concentrations of paraproteins may cause a hyperviscosity of body fluids. The light-chain component may break down into amyloid, a proteinaceous substance deposited between cells, causing heart failure and nephropathy. Renal involvement, generally called *myeloma nephrosis*, is a distinctive feature of multiple myeloma. Although multiple myeloma is characterized by excessive production of monoclonal immunoglobulin, levels of normal immunoglobulins are usually depressed. This contributes to a general susceptibility to recurrent bacterial infections.

The malignant plasma cells also can form plasmacytomas (plasma cell tumors) in bone and soft tissue sites. The most common site of soft tissue plasmacytomas is the gastrointestinal tract. The development of plasmacytomas in bone tissue is associated with bone destruction and localized pain. Osteolytic lesions and compression fractures may be seen in the axial skeleton and proximal long bones. Occasionally, the lesions may affect the spinal column, causing vertebral collapse and spinal cord compression.

Bone pain is one of the first symptoms to occur in approximately three fourths of all individuals diagnosed with multiple myeloma. Bone destruction also impairs the production of erythrocytes, leukocytes, and thrombocytes. This predisposes the patient to anemia, recurrent infections, and thrombocytopenic purpura. Many patients experience weight loss and weakness. Renal insufficiency occurs in 50% of patients. Neurologic manifestations caused by neuropathy or spinal cord compression also may be present.
Diagnosis and Treatment. Diagnosis of multiple myeloma is based on clinical manifestations, blood tests, and bone marrow examination. The classic triad of bone marrow plasmacytosis (>10% plasma cells), lytic bone lesions, and either the serum M-protein spike or the presence of Bence Jones proteins in the urine is definitive for a diagnosis of multiple myeloma. Bone radiographs are important in establishing the presence of bone lesions. Anemia is almost universal. Other laboratory features include hypercalcemia, an elevated erythrocyte sedimentation rate, and signs of kidney failure. The strongest predictors of outcome are low serum β₂-microglobulin (a small subunit of the major histocompatibility complex I molecule) and C-reactive protein levels.

The treatment of multiple myeloma is rapidly changing. Recently, thalidomide or lenalidomide (a second-generation thalidomide drug) combined with dexamethasone (a corticosteroid) have emerged as active agents for use in the initial treatment of multiple myeloma. Another agent, a reversible 26S proteasome inhibitor (bortezomib), was recently approved for treatment of multiple myeloma. High-dose chemotherapy with autologous stem cell transplantation is now considered appropriate frontline therapy for patients younger than 70 years of age newly diagnosed with multiple myeloma. Allogeneic transplantation offers prolonged disease-free outcomes and potential cure, but at a high cost of treatment-related mortality. Because of this, “mini-transplants” using non–marrow-ablative chemotherapy may be used to provide sufficient immune suppression to allow donor engraftment and subsequent graft-versus-tumor effect.

SUMMARY CONCEPTS

- The neoplastic disorders of hematopoietic and lymphoid origin include the leukemias, lymphomas, and multiple myeloma.
- The leukemias are malignant neoplasms arising from the transformation of a single blood cell line derived from hematopoietic stem cells in the bone marrow. Because leukemic cells are immature and poorly differentiated, they proliferate rapidly and have a long life span, they do not function normally, they interfere with the maturation of normal blood cells, and they circulate in the bloodstream, cross the blood–brain barrier, and infiltrate many body organs.
- Leukemias are classified according to cell type (i.e., lymphocytic or myelocytic) and whether the disease is acute or chronic. The lymphocytic leukemias involve immature lymphocytes and their progenitors that originate in the bone marrow but infiltrate the spleen, lymph nodes, CNS, and other tissues. The myelogenous leukemias involve the pluripotent myeloid stem cells in the bone marrow and interfere with the maturation of all blood cells, including the granulocytes, erythrocytes, and thrombocytes.
- The acute leukemias (i.e., ALL, which primarily affects children, and AML, which primarily affects adults) have a sudden and stormy onset with symptoms of depressed bone marrow function (anemia, fatigue, bleeding, and infections); bone pain; and generalized lymphadenopathy, splenomegaly, and hepatomegaly. The chronic leukemias, which largely affect adults, have a more insidious onset. Chronic lymphocytic leukemia often has the most favorable clinical course, with many persons living long enough to die of other, unrelated causes. The course of CML is slow and progressive, with transformation to a course resembling that of AML.
- The lymphomas (non-Hodgkin [NHL] and Hodgkin lymphoma) represent malignant neoplasms that arise in the peripheral lymphoid tissues. The NHLs, which usually originate in the lymph nodes, are multicentric in origin and spread early to various lymphoid tissues throughout the body, especially the liver, spleen, and bone marrow. Hodgkin lymphoma is a group of cancers characterized by Reed-Sternberg cells that begins as a malignancy in a single lymph node and then spreads to contiguous lymph nodes. Both types of lymphomas are characterized by manifestations related to uncontrolled lymph node and lymphoid tissue growth, bone marrow involvement, and constitutional symptoms (fever, fatigue, weight loss) related to the rapid growth of abnormal lymphoid cells and tissues.
- Multiple myeloma is a plasma cell dyscrasia characterized by expansion of a single clone of immunoglobulin-producing plasma cells and a resultant increase in serum levels of a single monoclonal immunoglobulin (paraprotein) or its fragments. The main sites involved in multiple myeloma are the bones and bone marrow. In addition to the abnormal proliferation of marrow plasma cells, there is proliferation and activation of osteoclasts, which leads to bone resorption and destruction and increased risk for pathologic fractures and development of hypercalcemia. Paraproteins secreted by the plasma cells may cause hyperviscosity of body fluids and may break down into amyloid, a proteinaceous substance deposited between cells that can cause heart failure and neuropathy.
1. Many of the primary immunodeficiency disorders, in which there is a defect in the development of immune cells of T- or B-lymphocyte origin, can be cured with allogeneic stem cell transplantation from an unaffected donor.

A. Explain why stem cells are used rather than mature lymphocytes. You might want to refer to Figure 11-5.

B. Describe how the stem cells would go about the process of repopulating the bone marrow.

2. A mother brings her 4-year-old son into the pediatric clinic because of irritability, loss of appetite, low-grade fever, pallor, and complaints that his legs hurt. Blood tests reveal anemia, thrombocytopenia, and an elevated leukocyte count with atypical lymphocytes. A diagnosis of acute lymphocytic leukemia (ALL) is confirmed with bone marrow studies.

A. What is the origin of the anemia, thrombocytopenia, elevated leukocyte count, and atypical lymphocytes seen in this child?

B. Explain the cause of the child’s fever, pallor, increased bleeding, and bone pain.

C. The parents are informed that the preferred treatment for ALL consists of aggressive chemotherapy with the purpose of achieving a remission. Explain the rationale for using chemotherapy to treat leukemia.

D. The parents are told that the child will need intrathecal chemotherapy administered by a lumbar puncture. Why is this treatment necessary?

3. A 36-year-old man presents to his health care clinic with fever, night sweats, weight loss, and a feeling of fullness in his abdomen. Subsequent lymph node biopsy reveals a diagnosis of non-Hodgkin lymphoma (NHL).

A. Although lymphomas can originate in any of the lymphoid tissues of the body, most originate in the lymph nodes, and most (80% to 85%) are of B-cell origin. Hypothesize as to why B cells are more commonly affected than T cells.

B. A newly developed monoclonal antibody, rituximab, is being used in the treatment of NHL. Explain how this agent exerts its effect and why it is specific for B-cell lymphomas.

Bleeding Associated with Vascular Disorders

Disseminated Intravascular Coagulation

Disorders of Hemostasis

Hemostasis is a multistep process that maintains the integrity of a closed high-pressure circulatory system after vessel injury. The normal process of hemostasis is regulated by a complex array of activators and inhibitors that maintain blood fluidity and prevent blood from leaving the vascular compartment. Hemostasis is normal when a blood vessel is sealed to prevent blood loss and hemorrhage. It is deemed abnormal when inappropriate blood clotting occurs or when clotting is insufficient to stop the flow of blood from the vascular compartment. Disorders of hemostasis fall into two main categories: the inappropriate formation of clots within the vascular system (thrombosis) and the failure of blood to clot in response to an appropriate stimulus (bleeding).

Hemostasis and Blood Coagulation

Hemostasis preserves vascular integrity by balancing the processes that maintain blood in a fluid state and prevent excessive bleeding following injury. The process involves the transformation of blood into a semisolid clot with erythrocytes trapped in its fibrin meshwork at the site of injury (Fig. 12-1).

Components of Hemostasis

Hemostasis is a multistep process that involves platelets, plasma clotting factors, naturally occurring anticoagulants, and the inherent properties of the endothelial lining of blood vessels.

Platelets

Platelets, also called thrombocytes, are large fragments from the cytoplasm of bone marrow cells called megakaryocytes. There are normally 150,000 to 400,000 platelets in each microliter (µL) of blood with an average platelet life span of 8 to 9 days. Platelets do not leave the blood as white blood cells do, but at any time about one third of them are stored in blood-filled spaces in the spleen and can be released into the circulation as needed. Platelet production is controlled by a protein...
called thrombopoietin that causes proliferation and maturation of megakaryocytes. Thrombopoietin is produced in the liver, kidney, smooth muscle, and bone marrow. Its production and release are regulated by the number of platelets in the circulation.

Although platelets lack a nucleus, they have many of the structural and functional characteristics of a whole cell. They contain an outer cell membrane, microtubular structures, and inner organelles (Fig. 12-2). The platelet cell membrane, which plays an important role in platelet adhesion and the coagulation process, is covered with a surface coat of glycocalyx, consisting of glycoproteins, glycosaminoglycans, and several coagulation factors adsorbed from the plasma. One of the important glycoproteins is glycoprotein IIb/IIIa (gpIIb/IIIa), which binds fibrinogen (factor I) and acts to connect platelets together to form large aggregates. Phospholipids, which are also present in the platelet membrane, provide critical binding sites for calcium and coagulation factors in the intrinsic coagulation pathway. The cell membrane is supported by a network of microtubules, actin filaments, myosin, and actin-binding proteins. They are arranged circumferentially and are responsible for maintaining the platelet’s disk shape.

The central part of the platelet contains mitochondria, enzymes needed for synthesis of adenosine triphosphate (ATP) and the prostaglandin thromboxane A2 (TXA2), glycogen, and two specific types of granules (α- and δ-granules) that release mediators for hemostasis. The α-granules contain fibrinogen, coagulation factors, plasminogen, plasminogen activator inhibitor, and platelet-derived growth factors. The contents of these granules play an important role in platelet aggregation, blood coagulation, and the initial phase of vessel repair. The release of growth factors causes vascular endothelial cells, smooth muscle cells, and fibroblasts to proliferate and grow. The δ-granules, or dense granules, mainly contain adenosine diphosphate (ADP), ATP, ionized calcium, serotonin, and histamine, which facilitate platelet adhesion and vasoconstriction at the site of vessel injury.

The Coagulation System

The coagulation system uses plasma proteins that are present as inactive procoagulation factors. Each of the procoagulation or coagulation factors, identified by Roman numerals, performs a specific step in the coagulation process. The activation of one procoagulant or proenzyme is designed to activate the next factor in the sequence (i.e., cascade effect). Because most of the inactive procoagulants are present in the blood at all times, the multistep process ensures that a massive episode of intravascular clotting does not occur by chance. It also means that abnormalities of the clotting process occur when one or more of the factors are deficient or when conditions lead to inappropriate activation of any of the steps.

Most of the coagulation factors are proteins synthesized in the liver. Vitamin K is necessary for the synthesis of factors VII, IX, and X; prothrombin (factor II); and proteins C and S. Calcium (factor IV) is required in all but the first two steps of the clotting process. The body usually has sufficient amounts of calcium for these reactions. Inactivation of the calcium ion prevents blood from clotting once removed from the body. The addition of citrate to blood stored for transfusion purposes prevents clotting by chelating ionized calcium.

A clot is not expected to be a permanent solution to vessel injury; thus, blood clotting is accompanied by processes designed to control the coagulation cascade and dissolve the clot once bleeding has been controlled.
Blood coagulation is regulated by several natural anticoagulants, such as antithrombin III and proteins C and S, which work by inactivating some of the clotting factors. The plasma also contains a plasma protein called plasminogen that gets activated and converted to plasmin, an enzyme capable of digesting the fibrin strands of the clot. In addition to removing clots that are no longer needed, plasmin scavenges continually to prevent clots from forming inappropriately.

**Endothelium**

The blood vessels themselves play an important role in preventing and controlling the formation of blood clots. Blood vessels are lined with endothelial cells that modulate several, frequently opposing stages of normal hemostasis. Under most circumstances endothelial cells maintain an environment that promotes blood flow by blocking platelet adhesion and activation, inhibiting the coagulation process, and lysing blood clots. It should be noted, however, that the endothelium can be activated by infectious agents, hemodynamic factors, plasma mediators, and cytokines that are liberated during an inflammatory reaction.

An intact endothelial surface prevents platelets and plasma coagulation factors from interacting with the underlying thrombogenic subendothelial extracellular matrix. Moreover, if platelets are activated, they are inhibited from adhering to the surrounding uninjured endothelium by endothelial prostacyclin (prostaglandin I\(^2\) [PGI\(_2\)] and nitric oxide (see Chapter 18). Both of these mediators are potent vasodilators and inhibitors of platelet aggregation. Endothelial cells also elaborate an enzyme called adenosine diphosphatase (ADP) that degrades and further inhibits platelet aggregation. The anticoagulant effects of endothelial cells are mediated by membrane-bound heparin and thrombomodulin, both of which inactivate thrombin (factor IIa). In addition, endothelial cells synthesize tissue plasminogen activator, promoting fibrinolytic activity that clears fibrin deposits from endothelial cell surfaces.

Although endothelial cells exhibit properties that inhibit blood clotting, they are also capable of exhibiting numerous procoagulant properties in response to injury and activation. An important function of activated endothelial cells is the synthesis of von Willebrand factor, which participates in platelet adhesion and blood clotting.

**Clot Formation and Dissolution**

Hemostasis is divided into five stages: (1) vessel spasm, (2) formation of the platelet plug, (3) blood coagulation or development of an insoluble fibrin clot, (4) clot retraction, and (5) clot dissolution. During the process of hemostasis, hairlike fibrin strands glue the aggregated platelets together and intertwine to form the structural basis of the blood clot. In the presence of fibrin, plasma becomes gel-like and traps red blood cells and other formed elements in the blood (see Fig. 12-1). Hemostasis is complete when fibrous tissue grows into the clot and seals the hole in the vessel.

**Vessel Spasm**

Vessel spasm is initiated by endothelial injury and caused by local and humoral mechanisms. It is a transient event, usually lasting less than one minute, that results from neural reflexes and humoral factors released from platelets and traumatized tissue. For smaller vessels, release of the vasoconstrictor TXA\(_2\) is responsible for much of the vessel spasm.

**Platelet Plug Formation**

The platelet plug, the second line of defense, is initiated as platelets come in contact with the vessel wall. Small breaks in the vessel wall are often sealed with the platelet plug rather than with a blood clot. Platelet plug formation involves adhesion, granule release, and aggregation of platelets. Platelets are attracted to a damaged vessel wall, become activated, and change from smooth disks to spiny spheres, exposing glycoprotein receptors on their surfaces. Platelet adhesion requires a protein molecule called von Willebrand factor (vWF). This factor is produced by both megakaryocytes and endothelial cells and circulates in the blood as a carrier protein for coagulation factor VIII. Adhesion to the vessel subendothelial layer occurs when the platelet membrane receptor binds to vWF at the injury site, linking the platelet to exposed collagen fibers.

Degranulation and release of the contents of both the α- and δ-granules occur soon after platelet adhesion. The δ-granule contents, including calcium, is required for the coagulation component of hemostasis. The binding of ADP to the platelet membrane induces a conformation change of the gpIIb/IIIa receptors, allowing them to bind fibrinogen and form aggregates. Besides ADP, platelets secrete the prostaglandin TXA\(_2\), which is an important stimulus for platelet aggregation. The combined actions of ADP and TXA\(_2\) lead to the expansion of the enlarging platelet aggregate, which is called the primary hemostatic platelet plug. Conversion of the primary platelet plug into a definitive clot (known as a secondary hemostatic plug) occurs as the coagulation pathway is activated on the surface of the aggregated platelets and fibrinogen is converted to fibrin (factor Iα), thereby creating a fibrin meshwork that cements the platelets and other blood components together.

Platelet aggregation inhibitors, including aspirin, clopidogrel (Plavix), and ticlopidine (Ticlid), can be used to prevent platelet aggregation and clot formation in persons who are at risk for myocardial infarction, stroke, or peripheral artery disease. Low-dose aspirin therapy inhibits prostaglandin synthesis, including TXA\(_2\). Clopidogrel and ticlopidine achieve their antiplatelet effects by inhibiting the ADP pathway in platelets. Unlike aspirin, these drugs have no effect on prostaglandin synthesis. Drugs that act as gpIIb/IIIa receptor inhibitors (abciximab, eptifibatide, tirofiban) have been developed for use in the treatment of persons with acute coronary syndromes (see Chapter 19).
Hemostasis, which refers to the stoppage of blood flow, is divided into five stages: (1) vessel spasm, (2) formation of the platelet plug, (3) development of a blood clot (coagulation cascade), (4) clot retraction, and (5) clot dissolution. This multistep process involves the interaction of substrates, enzymes, protein cofactors, and calcium ions that circulate in the blood or are released from platelets and cells in the vessel wall.

**1. Vessel Spasm.** Injury to a blood vessel causes vascular smooth muscle in the vessel wall to contract and thus instantaneously reduce blood flow. Both local neural reflexes and local humoral factors such as thromboxane A₂ (TXA₂), which is released from platelets, contribute to the vasoconstriction.

**2. Formation of the Platelet Plug.** Seconds after vessel injury, von Willebrand factor, released from the endothelium, binds to platelet receptors, causing adhesion of the platelets to the exposed collagen fibers (inset). As the platelets adhere to the collagen fibers on the damaged vessel wall, they become activated and release adenosine diphosphate (ADP) and TXA₂. The ADP and TXA₂ attract additional platelets, leading to platelet aggregation.
Blood Coagulation. Blood coagulation is a complex process involving the sequential activation of various factors in the blood. There are two coagulation pathways: (1) the intrinsic pathway which begins in the circulation and is initiated by activation of circulating factor XII, and (2) the extrinsic pathway which is activated by a cellular lipoprotein called tissue factor that becomes exposed when tissues are injured. Both pathways lead to the activation of factor X, conversion of prothrombin (II) to thrombin (IIa), and conversion of fibrinogen (I) to the insoluble fibrin (Ia) threads that hold the clot together.

Clot Retraction. Within a few minutes after a clot is formed, the actin and myosin in the platelets that are trapped in the clot begin to contract in a manner similar to that in muscles. As a result, the fibrin strands of the clot are pulled toward the platelets, thereby squeezing serum (plasma without fibrinogen) from the clot and causing it to shrink.

Clot Dissolution or Lysis. Clot dissolution begins shortly after a clot is formed. It begins with activation of plasminogen, an inactive precursor of the proteolytic enzyme, plasmin. When a clot is formed, large amounts of plasminogen are trapped in the clot. The slow release from injured tissues and vascular endothelium of a very powerful activator called tissue plasminogen activator (t-PA) converts plasminogen to plasmin, which digests the fibrin strands, causing the clot to dissolve.
The Coagulation Cascade

The coagulation cascade is the third component of the hemostasis. It is a stepwise process resulting in the conversion of the soluble plasma protein fibrinogen into insoluble fibrin strands. The fibrin strands create a meshwork that cements platelets and other blood components together to form the clot.

The coagulation process results from the activation of what have traditionally been designated the intrinsic and the extrinsic pathways (Fig. 12-3). The intrinsic pathway, which is a relatively slow process, begins in the circulation with the activation of factor XII (Hageman factor). The extrinsic pathway, which is a much faster process, begins with trauma to the blood vessel or surrounding tissues and the release of an adhesive lipoprotein called tissue factor (also known as thromboplastin or factor III) from the subendothelial cells. In the presence of calcium, factors V and VII form a complex that, in turn, activates factor X. The terminal steps in both pathways are the same: the activation of factor X and the conversion of prothrombin (II) to thrombin (IIa). Thrombin then acts as the enzyme to convert fibrinogen (I) to fibrin (Ia), the material that stabilizes a clot. The intrinsic system is activated as blood comes in contact with collagen in the injured vessel wall; the extrinsic system is activated when blood is exposed to tissue extracts. However, this classification is largely artificial since both systems are needed for normal hemostasis, and many interrelations exist between them. Moreover, each system is activated when blood leaks out of the vascular system.

Clinical laboratories assess the function of the two limbs of the coagulation pathway through two standard assays: the prothrombin time (PT) and the partial thromboplastin time (PTT). The PT assesses the function of the extrinsic pathway (factors VII, X, V, II, and fibrinogen), while the PTT assesses the function of the intrinsic pathway (factors XII, XI, IX, VII, X, V, II, and fibrinogen).

Once initiated, the coagulation cascade must be restricted to the local site of vascular injury to prevent clotting from occurring in the entire vascular system. Several natural anticoagulants function to control clotting—antithrombin III, proteins C and S, and tissue factor pathway inhibitor. Antithrombin III inhibits the activity of thrombin (IIa) and factors IXa, Xa, Xla, and XIIa (see Fig. 12-3). It is activated by binding to heparin-like molecules on endothelial cells. Proteins C and S are two vitamin K–dependent plasma proteins that inactivate the cofactors Va and VIIIa. Tissue factor pathway inhibitor is a protein secreted by the endothelium that inactivates factor Xa and tissue factor VIIa complexes.

The anticoagulant drugs warfarin and heparin are used to prevent thromboembolic disorders, such as deep vein thrombosis and pulmonary embolism. Warfarin acts by decreasing prothrombin and other procoagulation factors. It alters vitamin K in a manner that reduces its ability to participate in the synthesis of the vitamin K–dependent coagulation factors in the liver. Warfarin is readily absorbed after oral administration. Its maximum effect takes 36 to 72 hours because of the varying half-lives of different clotting factors that remain in the circulation. Heparin is naturally formed and released in small
amounts by mast cells in connective tissue surrounding capillaries. Heparin binds to antithrombin III, causing a conformational change that increases the ability of antithrombin III to inactivate thrombin (IIa), factor Xa, and other clotting factors. By promoting the inactivation of clotting factors, heparin ultimately suppresses the formation of fibrin and therefore inhibits coagulation. Pharmacologic preparations of heparin are extracted from animal tissues. Heparin is unable to cross the membranes of the gastrointestinal tract and must be given by injection, usually by intravenous infusion. Low–molecular-weight heparins have been developed that inhibit activation of factor X, but have little effect on thrombin and other coagulation factors. The low–molecular-weight heparins are given by subcutaneous injection and require less-frequent administration and monitoring compared with the standard (unfractionated) heparin.

**Clot Retraction**

Clot retraction normally occurs within 20 to 60 minutes after a clot has formed, contributing to hemostasis by squeezing serum from the clot and joining the edges of the broken vessel. Platelets, through the action of their actin and myosin filaments, also contribute to clot retraction. Clot retraction therefore requires large numbers of platelets, and failure of clot retraction is indicative of a low platelet count.

**Clot Dissolution**

The dissolution of a blood clot begins shortly after its formation; this allows blood flow to be reestablished and permanent tissue repair to take place. The process in which the strands of the clot are dissolved is called fibrinolysis. As with clot formation, clot dissolution requires a sequence of steps controlled by activators and inhibitors. Plasminogen, the proenzyme for the fibrinolytic process, normally is present in the blood in its inactive form. It is converted to its active form, plasmin, by plasminogen activators (PAs) formed in the vascular endothelium, liver, and kidneys. The plasmin formed from plasminogen digests the fibrin strands of the clot and certain clotting factors, such as fibrinogen (I), factor V, factor VIII, prothrombin (II), and factor XIII. The most important of the plasminogen activators is tissue-type plasminogen activator (tPA), which is synthesized principally by endothelial cells and is most active when attached to fibrin. The affinity of tPA for fibrin makes it a useful therapeutic agent, since it largely confines its activity to sites of recent thrombosis. Another plasminogen activator called urokinase-type plasminogen activator (uPA) is present in the tissues and can activate plasminogen in the fluid phase.

As with other potent physiologic systems, the activity of plasmin is tightly controlled. Excess circulating plasmin is rapidly inactivated by α2-antiplasmin, which limits the fibrinolytic process to the local clot rather than allowing it to spread throughout the entire circulation. Endothelial cells further modulate the coagulation/anti-coagulation process by releasing PA inhibitors, which block fibrinolysis and confer an overall procoagulation effect. The PA inhibitors are increased by certain cytokines and probably play a role in the intravascular thrombosis accompanying severe inflammation.

**SUMMARY CONCEPTS**

- Hemostasis is an orderly multistep physiological process that preserves vascular integrity by balancing the processes that maintain blood in a fluid state and prevent excessive bleeding following injury.
- Hemostasis involves platelets, plasma clotting factors, naturally occurring anticoagulants, and the endothelial cells that line blood vessels, in order to transform blood into a semisolid clot with erythrocytes trapped in its fibrin meshwork.
- The process of hemostasis begins when a loss of endothelial integrity causes platelet activation. Upon activation, platelets undergo adhesion, granule release, and aggregation to form a primary platelet plug.
- The formation of the secondary hemostatic plug cements the platelet plug, forming an insoluble hemostatic clot. To occur, the formation of the definitive clot requires activation of the coagulation cascade, which terminates with thrombin converting fibrinogen into insoluble fibrin.
- The final step of the process involves fibrinolysis or clot dissolution, which involves the action of plasmin to dissolve the clot and allow blood flow to be reestablished and tissue healing to take place.

**Hypercoagulability States**

Hypercoagulability represents an exaggerated form of hemostasis that predisposes to thrombosis and blood vessel occlusion. There are two general forms of hypercoagulability states: conditions that create increased platelet function and conditions that cause accelerated activity of the coagulation system. Chart 12-1 summarizes conditions commonly associated with hypercoagulability states. Arterial thrombi are usually due to turbulence and composed largely of platelet aggregates, whereas venous thrombi are usually due to stasis of flow and composed largely of platelet aggregates and fibrin complexes that result from activation of the coagulation cascade.

**Increased Platelet Function**

Increased platelet function predisposes to platelet adhesion, formation of platelet clots, and the disruption of blood flow. The causes of increased platelet function

**Accelerated Activity of the Clotting System**

**Inherited disorders (primary)**
- Mutation in the factor V gene (factor V Leiden)
- Mutation in the prothrombin gene

**Acquired (secondary)**
- Prolonged bed rest or immobility
- Oral contraceptive agents and pregnancy
- Myocardial infarction
- Heart failure
- Malignant diseases
- Antiphospholipid antibody syndrome

---

Inherited Disorders

Of the inherited causes of hypercoagulability, mutations in the factor V and prothrombin genes are the most common. In persons with inherited defects in factor V, the mutant factor Va cannot be inactivated by protein C; as a result, an important antithrombotic counterregulatory mechanism is lost. Approximately 2% to 5% of Caucasians carry a specific factor V mutation (referred to as the Leiden mutation, because of the Dutch city where it was first discovered). The defect predisposes to venous thrombosis, and among persons with recurrent deep vein thrombosis, the frequency of the mutation may be as high as 60%. It is one of the most common causes of primary and recurrent thromboembolism in pregnancy and is also associated with abruptio placentae (premature placental separation) and fetal growth disturbance.

A single nucleotide change in the prothrombin gene, which affects 1% to 2% of the population, is associated with elevated prothrombin levels and an almost threefold increase in venous thromboses. Another hereditary defect results in high circulating levels of homocysteine, which predisposes to venous and arterial thrombosis by activating platelets and altering antithrombotic mechanisms.

**Acquired Disorders**

Unlike the hereditary disorders, multiple conditions often predispose persons to acquired or secondary thrombotic disorders. Stasis of blood and accumulation of platelets and activated clotting factors are common in situations such as with prolonged bed rest and immobility. Hyperviscosity syndromes (e.g., polycythemia) and deformed red blood cells in sickle cell disease increase the resistance to flow and cause small vessel stasis. Hypercoagulability is associated with oral contraceptive use and the hyperestrogenic state of pregnancy, probably related to the increased synthesis of coagulation factors and reduced synthesis of antithrombin III. The incidence of stroke, thromboemboli, and myocardial infarction is greater in women who use oral contraceptives, particularly those older than 35 years of age and those who smoke tobacco. In disseminated cancer, release of procoagulant tumor products predisposes to thrombosis. Smoking and obesity promote hypercoagulability for unknown reasons.

**Antiphospholipid Syndrome**. Another cause of increased venous and arterial thrombosis is the antiphospholipid syndrome. This condition is associated with a family of autoantibodies directed against several negatively charged phospholipids, causing an increase in coagulation activity. It is unclear how antiphospholipid antibodies lead to hypercoagulability, but possible explanations include direct platelet activation, endothelial cell activation or injury, or interference with the phospholipid-binding proteins involved in the regulation of blood coagulation (e.g., tissue factor, prothrombin, antithrombin III, and protein C).

**Increased Clotting Activity**

Thrombus formation due to activation of the coagulation system can result from primary (genetic) or secondary (acquired) disorders affecting the coagulation components of the blood clotting process (i.e., an increase in procoagulation factors or a decrease in anticoagulation factors).
thrombosis, repeated fetal loss, and thrombocytopenia. The disorder can manifest either as a primary condition occurring in isolation with signs of hypercoagulability or as a secondary condition most often associated with connective tissue disorders, particularly systemic lupus erythematosus (SLE).

Persons with the disorder present with a variety of clinical manifestations, typically those characterized by recurrent venous and arterial thrombi. Cardiac valvular vegetations associated with thrombi adherence and thrombocytopenia due to excessive platelet consumption may also occur. Venous thrombosis, especially in the deep leg veins, occurs in up to 50% of persons with the syndrome, half of whom develop pulmonary emboli. Arterial thromboses are less common than venous thromboses and most frequently manifest with features of ischemia and infarction. The cerebral arteries are the most commonly affected. Other sites for arterial thrombosis are the coronary arteries of the heart and the retinal, renal, and peripheral arteries. Women with the disorder commonly have a history of recurrent pregnancy losses after the 10th week of gestation because of ischemia and thrombosis of the placental vessels. These women also have increased risk of giving birth to a premature infant owing to pregnancy-associated hypertension and uteroplacental insufficiency.

In most persons with antiphospholipid syndrome, the thrombotic events occur as a single episode at one anatomic site. In some persons recurrences may occur months or years later and mimic the initial event. Occasionally, someone may present with multiple vascular occlusions involving many organ systems. This rapid-onset condition is termed catastrophic antiphospholipid syndrome and is associated with a high mortality rate.

Treatment of the syndrome focuses on removal or reduction in factors that predispose to thrombosis, including tobacco cessation and avoidance of estrogen-containing oral contraceptives by women. The acute thrombotic event is treated with anticoagulants (heparin and warfarin) and immune suppression in refractory cases. Aspirin and anticoagulant drugs may be used to prevent future thrombosis.13

### Bleeding Disorders

Bleeding disorders or impairment of blood coagulation can result from defects in any of the factors that contribute to hemostasis. Bleeding can occur as a result of disorders associated with platelet count, platelet function, coagulation factors, or blood vessel integrity.

### Platelet Disorders

Bleeding due to platelet disorders reflects a failure of activated platelets to bring about hemostasis through the formation of a platelet plug at the site of injury to the blood vessel wall, an injury that causes physical and biochemical disruption of the endothelium.

### Thrombocytopenia

*Thrombocytopenia* refers to a decrease in the number of circulating platelets to a level less than 100,000/µL.15,16 The greater the decrease in the platelet count, the greater the risk of bleeding. However, spontaneous bleeding usually does not occur until the platelet count falls below 20,000/µL.

The anatomic sites of bleeding in persons with thrombocytopenia are the intercellular junctions in the postcapillary venules.16 Key molecules in the junctions include adhesive proteins and associated intracellular binding components (see Chapter 1). Different vascular beds with varying functions require different types of

---

**SUMMARY CONCEPTS**

- Increased platelet function usually results from disorders such as atherosclerosis that damage the vascular endothelium and disturb blood flow, or from conditions such as smoking that increase sensitivity of platelets to factors that promote adhesiveness and aggregation.
- Increased activity of the coagulation system results from hereditary (factor V Leiden mutation) or acquired disorders (immobility, hyperviscosity syndromes) causing alterations in the components of the coagulation system (i.e., an increase in procoagulation factors or a decrease in anticoagulation factors).
- Thrombocytosis refers to an increase in the platelet count that can occur as an essential (primary thrombocytosis) or a reactive process (secondary thrombocytosis). The antiphospholipid syndrome, another cause of venous and arterial clotting, manifests as a primary or a secondary disorder associated with systemic lupus erythematosus. It is associated with antiphospholipid antibodies, which promote thrombosis throughout the body.
junctures. For example, the regulatory control of capillary permeability in the skin and mucosal surfaces is far different from that in the brain. Common sites for spontaneous bleeding from platelet disorders are the skin and mucous membranes of the nose, mouth, gastrointestinal tract, and uterine cavity. Cutaneous bleeding is seen as purple areas of bruising (purpura) and pinpoint hemorrhages (petechiae) in dependent areas where the capillary pressure is higher. Petechiae are seen almost exclusively in conditions of platelet deficiency, not platelet dysfunction. They are also seen in conditions of poor collagen synthesis and impaired formation of capillary intercellular junctions (Fig. 12-4). Because tight regulation of capillary permeability in the brain is essential to prevent intercellular leakage, nontraumatic intracranial bleeding is relatively rare, even in persons with severe thrombocytopenia.

The major causes of thrombocytopenia are decreased platelet production, decreased platelet survival, splenic sequestration, and dilution. Decreased platelet production due to loss of bone marrow function may occur because of congenital anemia (e.g., Wiskott-Aldrich syndrome [see Chapter 16]), acquired anemia (e.g., aplastic anemia [see Chapter 13]), bone marrow infiltration by malignant cells (e.g., leukemia), or bone marrow depression (e.g., radiation therapy, chemotherapy). Infection with human immunodeficiency virus (HIV) or cytomegalovirus may suppress the production of megakaryocytes, the platelet precursors.

Reduced platelet survival is caused by a variety of immune and nonimmune mechanisms. Platelet destruction may be caused by antiplatelet antibodies. These antibodies may be directed against platelet self-antigens or against antigens formed on the platelets from prior blood transfusions or pregnancy. In acute disseminated intravascular clotting or thrombotic thrombocytopenic purpura (ITP), excessive platelet consumption leads to a deficiency.

Production of platelets may be normal, but excessive pooling of platelets in the spleen may occur (splenic sequestration). When necessary, hypersplenlic thrombocytopenia may be treated with splenectomy. Massive blood or plasma transfusions may cause a dilutional thrombocytopenia because blood stored for more than 24 hours has no viable platelets.

**Immune Thrombocytopenic Purpura.** Immune thrombocytopenic purpura (ITP) is an autoimmune disorder that results in platelet antibody formation and excess destruction of platelets. The thrombocytopenia that occurs in ITP is thought to result from multiple mechanisms, including antiplatelet antibodies against glycoproteins (IIb/IIIa and Ib/IX) in the platelet membrane. The platelets are made more susceptible to phagocytosis because of the antibodies and are subsequently destroyed in the spleen. The disorder can occur in the absence of any known risk factors (primary or idiopathic ITP) or as a secondary disorder due to an underlying condition; it can also be classified as acute (duration of 6 months or less) or chronic. Secondary forms of ITP may be associated with acquired immunodeficiency syndrome (AIDS), systemic lupus erythematosus, antiphospholipid syndrome, chronic lymphocytic leukemia, lymphoma, hepatitis C, and drugs such as heparin and quinidine.

About half of the cases of ITP occur as an acute primary disorder in children, affecting both boys and girls. The disorder occurs in young children (5 years of age), commonly following a viral infection. It is characterized by sudden onset of petechiae and purpura and is usually a self-limited disorder requiring no treatment. Most children recover in a few weeks. In contrast, primary ITP is often a chronic disorder in adults with an insidious onset that seldom follows an infection. Peak incidence is between the ages of 18 and 40 years, and is seen three times as often in women as in men.

Manifestations of ITP include a history of easy bruising, bleeding from gums, epistaxis, melena, and abnormal menstrual bleeding in those with moderately reduced platelet counts. Because the spleen is the site of platelet destruction, splenic enlargement may occur. The condition may be discovered incidentally or as a result of signs of bleeding, often into the skin (i.e., purpura and petechiae) or oral mucosa. About half of adults with primary ITP present with a platelet count of less than 10,000/µL and are at risk for internal hemorrhage.

Diagnosis of ITP usually is based on severe thrombocytopenia (platelet counts <20,000 to 30,000/µL) and exclusion of other causes. Tests for the platelet-bound antibodies are available but lack specificity (e.g., they react with platelet antibodies from other sources). The secondary form of ITP sometimes mimics the idiopathic form of the disorder; therefore, the diagnosis is made only after excluding other known causes of thrombocytopenia.

The decision to treat ITP is based on the platelet count and the degree of bleeding. Many persons with
ITP do well without treatment. Corticosteroids are used as initial therapy; other effective initial treatment includes intravenous immune globulin. However, this treatment is expensive and the beneficial effect may last only one to two weeks. Because the spleen is the major site of antibody formation and platelet destruction, splenectomy is the traditional second-line treatment for persons who relapse or do not respond to medications. Immunosuppressive therapy (i.e., azathioprine or cyclophosphamide) may be used in patients who are refractory to other forms of treatment.

**Drug-Induced Thrombocytopenia.** Some drugs, such as quinine, quinidine, and certain sulfa–containing antibiotics, may induce thrombocytopenia. These drugs act as hapten to induce an antigen–antibody response and formation of immune complexes that cause platelet destruction by complement-mediated lysis (see Chapter 15). In persons with drug-associated thrombocytopenia, there is a fall in platelet count 7 or more days after initiating therapy with a given drug for the first time (i.e., the needed to mount an immune response) or 2 to 3 days after resuming therapy with the same drug. The platelet count rises rapidly after the drug is discontinued. The anticoagulant drug heparin has been increasingly implicated in thrombocytopenia and, paradoxically, in thrombosis. The complications typically occur five days after the start of therapy and result from heparin-dependent antplatelet antibodies that cause aggregation of platelets and their removal from the circulation. The antibodies often bind to vessel walls, causing complications such as deep vein thrombosis, pulmonary embolism, myocardial infarction, and stroke. The treatment of heparin-induced thrombocytopenia (HIT) requires the immediate discontinuation of heparin therapy and the use of alternative anticoagulants (i.e., argatroban, fondaparinux) to prevent thrombosis recurrence. The use of low–molecular-weight heparin appears to have reduced the incidence of HIT, though there have only been a limited number of large, randomized, controlled studies.

**Thrombotic Microangiopathies.** The term thrombotic microangiopathies encompasses a spectrum of clinical syndromes that include thrombotic thrombocytopenic purpura (TTP) and hemolytic-uremic syndrome (HUS). As originally described, TTP is associated with a combination of manifestations that includes fever, thrombocytopenia, microangiopathic hemolytic anemia, renal failure, and transient neurologic abnormalities. Hemolytic-uremic syndrome is also associated with microangiopathic hemolytic anemia and thrombocytopenia, but it is distinguished from TTP by the dominance of acute renal failure and absence of neurologic manifestations. Fundamental to both conditions is the widespread formation of hyaline thrombi in the microcirculation that are composed primarily of dense aggregates of platelets surrounded by fibrin. The consumption of platelets leads to thrombocytopenia, and the narrowing of the blood vessels by the platelet-rich thrombi results in the microangiopathic hemolytic anemia.

The pathogenesis of TTP is elusive but likely results from introduction of platelet-aggregating substances into the circulation. The underlying cause of many cases is the deficiency of an enzyme (ADAMTS 13, formerly known as vWF-cleaving protease) that degrades very high–molecular–weight multimers of vWF, allowing them to accumulate and cause platelet aggregation and adhesion to the endothelium. The enzyme deficiency may be inherited or acquired as a result of antibody directed against the enzyme. Although TTP usually occurs in previously healthy persons, it may also complicate collagen vascular diseases (rheumatoid arthritis and systemic lupus erythematosus), drug-induced hypersensitivities, cancer chemotherapy, bone marrow transplantation, infections such as HIV, and pregnancy. Thrombotic thrombocytopenic purpura occurs at virtually every age, but is most common in women in their fourth or fifth decades. It can be chronic and recurrent, but more frequently the onset is abrupt and the outcome may be fatal. Widespread vascular occlusions result from thrombi in the arterioles and capillaries of many organs, including the heart, brain, and kidneys. The clinical manifestations include purpura, petechiae, vaginal bleeding, and neurologic symptoms ranging from headache to seizures and altered consciousness. Anemia is universal and may be marked. About half of patients have azotemia due to renal failure.

Emergency treatment for TTP includes plasmapheresis, a procedure that involves removal of plasma from withdrawn blood and replacement with fresh-frozen plasma. Plasma infusion provides the deficient enzyme. With plasmapheresis and plasma infusion treatment, there is a complete recovery in 80% of cases.

Although clinically similar to TTP, there is no underlying enzyme deficiency in HUS because ADAMTS 13 levels are normal. HUS in children and the elderly usually occurs following infectious gastroenteritis caused by *Escherichia coli* O157:H7 (see Chapter 29). The organism elaborates a toxin that damages endothelial cells, which initiates platelet activation and aggregation. Affected individuals often present with bloody diarrhea, which is followed a few days later by HUS. With supportive care and plasma exchange, recovery is possible, but irreversible renal damage and death can occur in severe cases.

**Impaired Platelet Function**

Impaired platelet function (also called thrombocytopenia) may result from inherited disorders of adhesion (e.g., von Willebrand disease) or acquired defects caused by drugs, disease, or surgery involving extracorporeal circulation (i.e., cardiopulmonary bypass). Defective platelet function is also common in uremia, presumably because of non-eliminated waste products.

The use of aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) is the most common cause of platelet dysfunction. Aspirin produces irreversible acetylation of platelet cyclooxygenase activity, and consequently the synthesis of TXA2, which is required for platelet aggregation. The effect of aspirin on platelet
aggregation lasts for the life of the platelet—approximately 8 or 9 days. In contrast to the effects of aspirin, the inhibition of cyclooxygenase by other NSAIDs is reversible and lasts only for the duration of drug action. Aspirin (81 mg daily) commonly is used to prevent formation of arterial thrombi and thus reduce the risk of cardiovascular (i.e., myocardial infarction) or cerebrovascular (i.e., stroke) accidents.

Coagulation Disorders

Blood coagulation defects can result from deficiencies or impaired function of one or more of the clotting factors, including vWF. Deficiencies can arise because of inherited disease or because of defective synthesis or increased consumption of the clotting factors. Bleeding resulting from clotting factor deficiencies typically occurs after injury or trauma. Large bruises (ecchymoses), hematomas, and prolonged bleeding into the gastrointestinal or urinary tracts or joints are common.

Inherited Disorders

Hemophilia A and von Willebrand disease are two of the most common inherited disorders of bleeding.\textsuperscript{[4]} Hemophilia A (factor VIII deficiency) affects 1 in 5000 male live births and von Willebrand disease about 1 in 1000 persons.\textsuperscript{[21]} Hemophilia B (Factor IX deficiency) is clinically similar to hemophilia A and affects approximately 1 in 20,000 persons, accounting for 15% of people with hemophilia.\textsuperscript{[4]}

Hemophilia A and von Willebrand disease are caused by defects involving the factor VIII–vWF complex. Von Willebrand factor, which is synthesized by the endothelium and megakaryocytes, is required for platelet adhesion to the subendothelial matrix of the blood vessel. It also serves as the carrier for factor VIII and it is important for the stability of factor VIII in the circulation by preventing its proteolysis. Factor VIII coagulant protein, the functional portion of factor VIII, is produced by the liver and endothelial cells. Thus, factor VIII and vWF, synthesized separately, come together and circulate in the plasma as a unit that serves to promote clotting and adhesion of platelets to the vessel wall.

Von Willebrand Disease. Von Willebrand disease is a relatively common hereditary bleeding disorder characterized by a deficiency or defect in vWF. It affects both men and women and is typically diagnosed in adulthood.\textsuperscript{[23,24]} In most cases, it is transmitted as an autosomal dominant disorder, but several rare autosomal recessive variants have been identified.

As many as 20 variants of von Willebrand disease have been described.\textsuperscript{[4]} These variants can be grouped into two categories: types 1 and 3, which are associated with reduced levels of vWF; and type 2, which is characterized by defects in vWF.\textsuperscript{[4]}

Type 1, an autosomal dominant disorder, accounts for approximately 75% of cases and is relatively mild. Type 2, also an autosomal dominant disorder, accounts for about 20% of cases and is associated with mild to moderate bleeding. Type 3, which is a relatively rare autosomal recessive disorder, is associated with extremely low levels of functional vWF and correspondingly severe clinical manifestations.

Persons with von Willebrand disease have a compound defect involving platelet function and the coagulation pathway. Clinical manifestations include spontaneous bleeding from the nose, mouth, and gastrointestinal tract; excessive menstrual flow; and a prolonged bleeding time in the presence of a normal platelet count. Most cases (i.e., types 1 and 2) are mild and the disorder is diagnosed when surgery or dental extraction results in prolonged bleeding. In severe cases (i.e., type 3), life-threatening gastrointestinal bleeding and joint hemorrhage may be similar to that seen in hemophilia.

The bleeding associated with von Willebrand disease is usually mild, and no treatment is routinely administered other than avoidance of aspirin. Desmopressin acetate (DDAVP), a synthetic analog of the hormone vasopressin, is used in the treatment of type 1 von Willebrand disease and for establishing hemostasis during surgical or dental procedures.\textsuperscript{[22,23]} DDAVP stimulates the endothelial cells to release stored vWF and plasminogen activator. The drug is available as an intranasal spray. A vWF-containing factor VIII concentrate may be used for treatment of persons with excessive bleeding.\textsuperscript{[21]}

Hemophilia A. Hemophilia A is an X-linked recessive disorder that primarily affects males.\textsuperscript{[3,4,22,24,25]} Although it is a hereditary disorder, there is no family history of the disorder in approximately 30% of newly diagnosed cases, suggesting that it has arisen as a new mutation in the factor VIII gene. Approximately 90% of persons with hemophilia produce insufficient quantities of the factor and 10% produce a defective form. The percentage of normal factor VIII activity in the circulation depends on the genetic defect and determines the severity of hemophilia (i.e., 6% to 30% in mild hemophilia, 2% to 5% in moderate hemophilia, and 1% or less in severe forms of hemophilia). In mild or moderate forms of the disease, bleeding usually does not occur unless there is a local lesion or trauma such as surgery or a dental procedure. The mild disorder may not be detected in childhood. In severe hemophilia, bleeding usually occurs in childhood (e.g., it may be noticed at the time of circumcision) and is spontaneous and severe, often occurring several times a month.

Characteristically, bleeding occurs in soft tissues, the gastrointestinal tract, and the hip, knee, elbow, and ankle joints. Spontaneous joint bleeding usually begins when a child begins to walk, with the target joint often prone to recurrent incidences. The bleeding causes inflammation of the synovium, with acute pain and swelling. Without proper treatment, chronic bleeding and inflammation cause joint fibrosis and contractures, resulting in major disability. Muscle hematomas may be present in 30% of episodes, and intracranial hemorrhage, although uncommon, is an important cause of death.\textsuperscript{[22,26]}

The prevention of trauma is important in persons with hemophilia. Aspirin and other NSAIDs that affect platelet function should be avoided. Factor VIII replacement therapy (either recombinant or heat-treated...
concentrates from human plasma) administered at home has reduced the typical musculoskeletal damage. It is initiated when bleeding occurs or as prophylaxis with repeated bleeding episodes. The newer recombinant products and continuous-infusion pumps may allow for prevention rather than therapy for hemorrhage. The development of inhibitory antibodies to recombinant factor VIII is still a major complication of treatment; 10% to 15% of treated persons produce high titers of antibodies that bind to and inhibit factor VIII. The rate of antibody production for plasma-derived products is approximately the same.

Current factor VIII products (both plasma derived and recombinant) are considered very safe as a result of technological advances over the last two decades. Until the mid-1980s when routine screening of blood for HIV antibodies was instituted, thousands of patients with hemophilia received plasma-derived factor VIII that was contaminated with HIV, and many developed AIDS. Effective donor screening and development of purification and viral inactivation procedures now provide a safer product. A number of recombinant factor VIII preparations are available. These products were made with the use of blood-derived additives of human or animal origin, such as albumin. These additives were needed to keep the cells viable so they could produce the factor VIII protein. With mild hemophilia A, the person’s endogenously produced factor VIII can be released by the administration of DDAVP. In persons with moderate to severe factor VIII deficiency, the stored levels of factor VIII are insufficient, and DDAVP treatment is ineffective.

The cloning of the factor VIII gene and progress in gene delivery systems have led to the hope that hemophilia A may be cured by gene replacement therapy. Carrier detection and prenatal diagnosis can now be done by analysis of direct gene mutation or DNA linkage studies.

**Acquired Disorders**

Coagulation factors II, V, VII, IX, X, XI, and XII; prothrombin (II); and fibrinogen (I) are synthesized in the liver. In liver disease, synthesis of these clotting factors is reduced, and bleeding may result. Of the coagulation factors synthesized in the liver, factors II, VII, IX, and X and prothrombin require the presence of vitamin K for normal activity. In vitamin K deficiency, the liver produces the clotting factor, but in an inactive form. Vitamin K is a fat-soluble vitamin that is continuously being synthesized by intestinal bacteria. This means that a deficiency in vitamin K is not likely to occur unless intestinal synthesis is interrupted or absorption of the vitamin is impaired. Vitamin K deficiency can occur in the newborn infant before the establishment of the intestinal flora; it can also occur as a result of treatment with broad-spectrum antibiotics that destroy intestinal flora. Because vitamin K is a fat-soluble vitamin, its absorption requires bile salts. Vitamin K deficiency may also result from impaired fat absorption caused by liver or gallbladder disease.

**Bleeding Associated with Vascular Disorders**

Bleeding resulting from vascular disorders, sometimes called *nonthrombocytopenic purpura*, is relatively common and results in mild bleeding disorders. These disorders may occur because of structurally weak vessel walls or because of damage to vessels by inflammation or immune responses. Most often they are characterized by easy bruising and the spontaneous appearance of petechiae and purpura of the skin and mucous membranes. In persons with bleeding disorders caused by vascular defects, the platelet count and results of other tests for coagulation factors are normal.

Among the vascular disorders that cause bleeding are hemorrhagic telangiectasia, vitamin C deficiency (scurvy), Cushing disease, and senile purpura. Hemorrhagic telangiectasia is an uncommon autosomal dominant disorder that is characterized by thin-walled, dilated capillaries and arterioles. Vitamin C is a reversible reducing agent that is an essential cofactor for the hydroxylation of proline in collagen synthesis. A severe vitamin C deficiency results in poor collagen synthesis and failure of capillary cells to be cemented together properly, which in turn causes a fragile vascular wall (see Fig. 12–4). Cushing disease causes protein wasting and loss of vessel tissue support because of excess cortisol (see Chapter 32). Senile purpura (i.e., bruising in elderly persons) is caused by impaired collagen synthesis due to the aging process.

**Disseminated Intravascular Coagulation**

Disseminated intravascular coagulation (DIC) is a paradox in the hemostatic sequence characterized by widespread coagulation and bleeding. It is not a primary disease but a complication of many different disorders. Disseminated intravascular coagulation begins with massive activation of the coagulation sequence, which leads to fibrin deposition and formation of thrombin in the microcirculation of the body (Fig. 12-5). The widespread deposition of fibrin leads to tissue ischemia and hemolytic anemia from fragmentation of red cells as they squeeze through the narrowed microvasculature. As a consequence of the thrombotic process, there is consumption of platelets and coagulation factors and the activation of plasminogen that leads to a hemorrhagic diathesis.

The disorder can be initiated by activation of the intrinsic or extrinsic pathway, or both. Activation through the extrinsic pathway occurs with liberation of tissue factors and is associated with obstetric complications, trauma, bacterial sepsis, and cancer. The intrinsic pathway may be activated through extensive endothelial damage, with activation of factor XII. Endothelial damage may be caused by viruses, infections, immune mechanisms, stasis of blood, or temperature extremes. Impaired anticoagulation pathways are also associated with reduced levels of antithrombin and the protein C anticoagulant system in DIC. There is increasing
evidence that the underlying cause of DIC is infection or inflammation, and the cytokines (tumor necrosis factor, interleukin-1, and others) liberated in the process are the pivotal mediators. These cytokines not only mediate inflammation, but can also increase the expression of tissue factor on endothelial cells and simultaneously decrease the expression of thrombomodulin. Thrombomodulin is a glycoprotein, present on the cell membrane of endothelial cells, that binds thrombin (IIa) and acts as an additional regulatory mechanism in coagulation. The net effect is a shift in balance toward a procoagulant state.

Common clinical conditions that may cause DIC include obstetric disorders, accounting for 50% of cases; massive trauma; shock; sepsis; and malignant disease. Chart 12-2 summarizes the conditions associated with DIC. The factors involved in the conditions that cause DIC are often interrelated. In obstetric complications, tissue factors released from necrotic placental or fetal tissue or amniotic fluid may enter the circulation, inciting DIC. The hypoxia, shock, and acidosis that may coexist also contribute by causing endothelial injury. Gram-negative bacterial infections result in the release of endotoxins, which activate both the extrinsic pathway by release of tissue factor and the intrinsic pathway through endothelial damage. Endotoxins also inhibit the activity of protein C. Antigen–antibody complexes associated with infection can activate platelets through complement fragments.

Although coagulation and formation of microemboli characterize DIC, its acute manifestations usually

---

**CHART 12-2  Conditions That Have Been Associated with Disseminated Intravascular Coagulation**

**Obstetric Conditions**
- Abruptio placentae
- Dead fetus syndrome
- Preeclampsia and eclampsia
- Amniotic fluid embolism

**Cancers**
- Metastatic cancer
- Acute promyelocytic leukemia

**Infections**
- Acute bacterial infections (e.g., meningococcal meningitis)
- Histoplasmosis, Aspergillosis
- Rickettsial infections (e.g., Rocky Mountain spotted fever)
- Parasitic infections (e.g., malaria)
- Sepsis/septic shock

**Trauma or Surgery**
- Burns
- Massive trauma
- Surgery involving extracorporeal circulation
- Snake bite
- Heatstroke

**Hematologic Conditions**
- Blood transfusion reactions
are more directly related to the bleeding problems that occur. The bleeding may be present as petechiae, purpura, oozing from puncture sites, or severe hemorrhage. Uncontrolled postpartum bleeding may indicate DIC. Microemboli may obstruct blood vessels and cause tissue hypoxia and necrotic damage to organ structures, such as the kidneys, heart, lungs, and brain. As a result, common clinical signs may be due to renal, circulatory, or respiratory failure; acute bleeding ulcers; or convulsions and coma. A form of hemolytic anemia may develop as red cells are damaged passing through vessels partially blocked by thrombus.

The treatment of DIC is directed toward managing the primary disease, replacing clotting components, and preventing further activation of clotting mechanisms. Transfusions of fresh-frozen plasma, platelets, or fibrinogen-containing cryoprecipitate may correct the clotting factor deficiency. Heparin may be given to decrease blood coagulation, thereby interrupting the clotting process. Heparin therapy is controversial, however, and the risk of hemorrhage may limit its use to severe cases. It typically is given as a continuous intravenous infusion that can be interrupted promptly if bleeding is accentuated. Tissue factor pathway inhibitors, antithrombin, protein C concentrates, and anti-inflammatory cytokines such as interleukin-10 are being evaluated in clinical trials as potential therapies.

**SUMMARY CONCEPTS**

- Bleeding disorders or impairment of blood coagulation can result from defects in any of the factors that contribute to hemostasis: platelets, coagulation factors, or vascular integrity.
- Disorders of platelet plug formation include a decrease in platelet numbers due to inadequate platelet production (bone marrow dysfunction), excess pooling of platelets in the spleen, excess platelet destruction (thrombocytopenia), abnormal platelet function (thrombocytopenia), or defects in von Willebrand factor.
- Impairment of blood coagulation can result from deficiencies of one or more of the known clotting factors. Deficiencies can arise because of acquired disorders (i.e., liver disease or vitamin K deficiency) or inherited disorders (i.e., hemophilia A or von Willebrand disease).
- Bleeding may also occur from structurally weak vessels that result from impaired synthesis of vessel wall components (i.e., vitamin C deficiency, excessive cortisol levels as in Cushing disease, or the aging process) or from damage by genetic mechanisms (i.e., hemorrhagic telangiectasia) or the presence of microthrombi.

**REVIEW EXERCISES**

1. A 55-year-old man has begun taking one 81-mg aspirin tablet daily on the recommendation of his physician. The physician had told him that this would help to prevent heart attack and stroke.
   
   A. What is the action of aspirin in terms of heart attack and stroke prevention?
   
   B. The drug clopidogrel (Plavix) is often prescribed along with aspirin to prevent thrombosis in persons with severe atherosclerotic disease who are at risk for myocardial infarction or stroke. Explain the rationale for using the two drugs.

2. The drug desmopressin acetate (DDAVP), which is a synthetic analog of arginine vasopressin, increases the half-life of factor VIII and is sometimes used to treat bleeding in males with mild hemophilia.
   
   A. Explain.

3. A 29-year-old new mother, who delivered her infant three days ago, is admitted to the hospital with chest pain and is diagnosed as having venous thrombosis with pulmonary emboli.
   
   A. What factors would contribute to this woman’s risk of developing thromboemboli?

4. The new mother is admitted to the intensive care unit and started on low–molecular-weight heparin and warfarin. She is told that she will be discharged in a day or two and will remain on the heparin for 5 days and the warfarin for at least 3 months.
   
   A. Use Figure 12-3 to explain the action of heparin and warfarin. Why is heparin administered for 5 days during the initiation of warfarin treatment?
   
   B. Anticoagulation with heparin and warfarin is not a definitive treatment for clot removal in pulmonary embolism, but a form of secondary prevention. Explain.
REFERENCES

Although the lungs provide the means for gas exchange between the external and internal environments, it is the hemoglobin in the red blood cells that transports oxygen to the tissues. The red blood cells also function as carriers of carbon dioxide and participate in acid–base balance. The function of the red blood cells, in terms of oxygen transport, is discussed in Chapter 21, and acid–base balance is discussed in Chapter 8. This chapter focuses on the red blood cell, anemia, polycythemia, and age-related changes in the red blood cells.

The Red Blood Cell

The erythrocytes or mature red blood cells are the most common type of blood cell, being 500 to 1000 times more numerous than other blood cells. The erythrocyte is a nonnucleated, thin, biconcave disk (Fig. 13-1). This unique shape contributes in two ways to the oxygen transport function of the erythrocyte. The biconcave shape provides a larger surface area for oxygen diffusion than would a spherical cell of the same volume, and the thinness of the cell membrane enables oxygen to diffuse rapidly between the exterior and the interior of the cell (Fig. 13-2A). Another structural feature that facilitates the transport function of the red blood cell is the flexibility of its membrane. The biconcave shape and flexibility of the red cell membrane are maintained by a complex network of fibrous proteins, especially one called spectrin (Fig. 13-3). Spectrin forms an attachment with another protein, called ankyrin, that resides on the inner surface of the membrane and is anchored to an integral protein that spans the membrane. This unique arrangement of proteins imparts elasticity and stability to the red blood cell membrane and allows it to deform easily as it moves through narrow spaces in the vascular network.

The function of the red blood cell, facilitated by the hemoglobin molecule, is to transport oxygen to the tissues. Because oxygen is poorly soluble in plasma, about 95% to 98% is carried bound to hemoglobin. The hemoglobin molecule is composed of two pairs of structurally different alpha (α) and beta (β) polypeptide chains (see Fig. 13-2B). Each of the four polypeptide chains consists
of a globin (protein) portion and a heme unit, which surrounds an atom of iron that binds oxygen. Thus, each molecule of hemoglobin can carry four molecules of oxygen. Hemoglobin is a natural pigment; because of its iron content, it appears reddish when oxygen is attached and has a bluish cast when deoxygenated. The production of each type of globin chain is controlled by individual structural genes with five different gene loci. Mutations, which can occur anywhere in these five loci, have resulted in over 550 types of abnormal hemoglobin molecules.

There are two major types of normal hemoglobin—adult hemoglobin (HbA) and fetal hemoglobin (HbF). Adult hemoglobin consists of a pair of α chains and a pair of β chains. Fetal hemoglobin is the predominant hemoglobin in the fetus from the third through the ninth months of gestation. It has a pair of gamma (γ) chains substituted for the α chains. Because of this chain substitution, HbF has a higher affinity for oxygen than adult hemoglobin. This affinity facilitates the transfer of oxygen across the placenta from the HbA in the mother’s blood to the HbF in the fetus’s blood. HbF is replaced within 6 months of birth with HbA.
Hemoglobin Synthesis

The rate at which hemoglobin is synthesized depends on the availability of iron for heme synthesis. A lack of iron results in relatively small amounts of hemoglobin in the red blood cells. Body iron is found in several compartments. About 65% of iron is in the form of hemoglobin, with small amounts found in the myoglobin of muscle, the cytochromes, and iron-containing enzymes. The remaining 15% to 30% is stored for later use, mainly in the liver but also in the reticuloendothelial cells of the bone marrow. Iron in the hemoglobin compartment is recycled. When red blood cells age and are destroyed in the spleen, the iron from their hemoglobin is released into the circulation and returned to the bone marrow for incorporation into new red blood cells or to the liver and other tissues for storage.

Dietary sources help to maintain iron stores. Iron, principally derived from meat, is absorbed in the small intestine, especially the duodenum (Fig. 13-4). When body iron stores are diminished or erythropoiesis is stimulated, absorption is increased. In iron overload, excretion of iron is accelerated. Normally, some iron is sequestered in the intestinal epithelial cells and is lost in the feces as these cells slough off. The iron that is absorbed enters the circulation, where it immediately combines with a β-globulin, apotransferrin, to form transferrin, which is then transported in the plasma. From the plasma, iron can be deposited in tissue cells such as the liver, where it is stored as ferritin, a protein–iron complex that is easily transferable back to the circulation. Serum ferritin levels can be measured in the laboratory to provide an index of body iron stores. Smaller quantities of iron are stored in cells in an extremely insoluble form called hemosiderin. This occurs when the total quantity of iron in the body is more than the ferritin storage pool can accommodate.

Red Cell Production

Erythropoiesis refers to the production of red blood cells. After birth, red cells are produced in the red bone marrow. Until 5 years of age, almost all bones produce red cells to meet the growth needs of a child, after which bone marrow activity gradually declines. After 20 years of age, red cell production takes place mainly in the membranous bones of the vertebrae, sternum, ribs, and pelvis. With this reduction in activity, the red bone marrow is replaced with fatty yellow bone marrow.

The red blood cells are derived from precursor cells called proerythroblasts, which are formed continuously from pluripotent stem cells in the bone marrow (Fig. 13-5). The red cell precursors move through a series of divisions, each producing a smaller cell as they continue to develop into mature red blood cells. Hemoglobin synthesis begins at the early erythroblast stage and continues until the cell becomes a mature erythrocyte. During its transformation from normoblast to reticulocyte, the red blood cell accumulates hemoglobin as the nucleus condenses and is finally lost. The period from stem cell to emergence of the reticulocyte in the circulation normally takes approximately one week and maturation of reticulocyte to erythrocyte takes about 24 to 48 hours. During this process, the red cell loses its mitochondria and ribosomes, along with its ability to produce hemoglobin and engage in oxidative metabolism. Most maturing red cells enter the blood as reticulocytes.

Erythropoiesis is governed for the most part by tissue oxygen needs. Any condition that causes a decrease in the amount of oxygen that is transported in the blood ordinarily produces an increase in the rate of red cell production. The oxygen content of the blood does not act directly on the bone marrow to stimulate red blood cell production. Instead, the decreased oxygen content is sensed by the kidneys, which then produce a hormone called erythropoietin. Normally, about 90% of all erythropoietin is produced by the kidneys, with the remaining 10% formed in the liver. Erythropoietin acts primarily in later stages of erythropoiesis to stimulate the production of proerythroblasts from stem cells in the bone marrow. In the absence of erythropoietin, as in kidney failure, hypoxia has little or no effect on red blood cell production. Human erythropoietin can be produced by recombinant deoxyribonucleic acid (DNA) technology. It is used for the management of anemia in cases of chronic kidney disease, for anemias induced by

![Diagram of iron cycle](image-url)

Chemotherapy in persons with malignancies, and in the treatment of anemia in human immunodeficiency virus (HIV)-infected persons treated with zidovudine.

Because red blood cells are released into the blood as reticulocytes, the percentage of these cells is higher when there is a marked increase in red blood cell production. In some severe forms of anemia, the reticulocytes (normally about 1%) may account for as much as 30% of the total red cell count. In some situations, red cell production is so accelerated that numerous erythroblasts appear in the blood.

Red Cell Life Span and Destruction

Mature red blood cells have a life span of approximately 4 months, or 120 days. Even though mature red cells do not have a nucleus, mitochondria, or endoplasmic reticulum, they have cytoplasmic enzymes that are capable of metabolizing glucose and forming small amounts of adenosine triphosphate (ATP). These enzymes also help to preserve the pliability of the cell membrane, maintain transmembrane transport of ions, keep the iron of the cell’s hemoglobin in the reduced ferrous form that binds oxygen, and prevent oxidation of the proteins. Even so, the metabolic activity in the cell decreases as the red cell ages, and the cell membrane becomes more and more fragile, causing it to rupture as it passes through tight places in the circulation. Many of the aged red cells self-destruct in the spleen as they squeeze through spaces between the trabeculae of the red pulp, which are only about 3 mm wide, in comparison with the 8-mm width of the red cell. The rate of red cell destruction (1% per day) normally is equal to the rate of red cell production, but in conditions such as hemolytic anemia, the cell’s life span may be shorter.

The destruction of red blood cells is facilitated by a group of large phagocytic macrophages found in the spleen, liver, bone marrow, and lymph nodes. These phagocytic cells recognize old and defective red cells and then ingest and destroy them in a series of enzymatic reactions. During these reactions, the amino acids from the globulin chains and iron from the heme units are salvaged and reused (Fig. 13-6). The bulk of the heme unit is converted to bilirubin, the pigment of bile, which is insoluble in plasma and attaches to plasma proteins for transport. Bilirubin is removed from the blood by the liver and conjugated with glucuronide to render it water soluble so that it can be excreted in the bile. The plasma-insoluble form of bilirubin is referred to as unconjugated bilirubin and the water-soluble form as conjugated bilirubin. Serum levels of conjugated and unconjugated bilirubin can be measured in the laboratory and are reported as direct and indirect, respectively. If the rate of red cell destruction and consequent bilirubin production exceed the liver’s ability to remove it from the blood, unconjugated bilirubin accumulates in the blood. This results in yellow discoloration of the skin, called jaundice.

When red blood cell destruction takes place in the circulation, as in hemolytic anemia, the hemoglobin remains in the plasma where it binds to a hemoglobin-binding protein called haptoglobin. Other plasma proteins, such as albumin, can also bind hemoglobin. With extensive intravascular destruction of red blood cells, hemoglobin levels may exceed the hemoglobin-binding capacity of haptoglobin and other plasma proteins. When this occurs, free hemoglobin appears in the blood (i.e., hemoglobinemia) and is excreted in the urine (i.e., hemoglobinuria).
Because excessive red blood cell destruction can occur in hemolytic transfusion reactions, urine samples are tested for free hemoglobin after a transfusion reaction.

**Laboratory Tests**

Red blood cells can be studied by means of a sample of blood (Table 13-1). In modern clinical laboratories, specialized blood cell counters rapidly provide accurate measurements of red cell content and cell indices. The **red blood cell count** measures the total number of red blood cells in a microliter (µL) of blood. The **percentage of reticulocytes** (normally approximately 1%) provides an index of the rate of red cell production. The **hemoglobin** (grams per deciliter [dL] or 100 milliliters [mL] of blood) measures the hemoglobin content of the blood. The major components of blood are the red cell mass and plasma volume. The **hematocrit** measures the red cell mass in a 100-mL plasma volume. To determine the hematocrit, a sample of blood is placed in a glass tube, which is then centrifuged to separate the cells and the plasma. The hematocrit may be deceptive because it varies with the quantity of extracellular fluid, rising with dehydration and falling with overexpansion of extracellular fluid volume (Fig. 13-7).

Red cell indices are used to differentiate types of anemias by size or color of red cells. The **mean corpuscular volume** (MCV) reflects the volume or size of the red cells. The MCV falls in microcytic (small cell) anemia and rises in macrocytic (large cell) anemia. Some anemias are normocytic (i.e., cells are of normal size or MCV). The **mean corpuscular hemoglobin concentration** (MCHC) is the concentration of hemoglobin in each cell. Hemoglobin accounts for the color of red blood cells. Anemias are described as normochromic (normal color or MCHC) or hypochromic (decreased color or MCHC). **Mean cell hemoglobin** (MCH) refers to the mass of the red cell and is less useful in classifying anemias.

A stained blood smear provides information about the size, color, and shape of red cells and the presence of immature or abnormal cells. If blood smear results are abnormal, examination of the bone marrow may be indicated. Bone marrow commonly is aspirated with a special needle from the posterior iliac crest or the sternum. The aspirate is stained and observed for number and maturity of cells and abnormal types.

**SUMMARY CONCEPTS**

- The function of red blood cells (RBC), facilitated by the iron-containing hemoglobin molecule, is to transport oxygen from the lungs to the tissues. The biconcave shape of the red cell increases the surface area for diffusion of oxygen across the thin cell membrane. Each red cell has four hemoglobin moieties, each composed of two polypeptide chains consisting of a globin portion and a heme unit that surround an iron atom that reversibly combines with oxygen.

- Erythropoiesis, or production of RBC, occurs in the bone marrow and requires iron, vitamin B<sub>12</sub>, and folate. RBC production is governed by tissue oxygen needs. The decrease in oxygen content in blood is sensed by the kidneys, which then produce a hormone called erythropoietin. Erythropoietin, in turn, stimulates the bone marrow to increase RBC production.

- The red blood cell has a life span of approximately 120 days and is broken down in the spleen, liver, or bone marrow. In the process of destruction, the heme portion of the hemoglobin molecule is converted to bilirubin. Bilirubin, which is insoluble in plasma, attaches to plasma proteins for transport in the blood. It is removed from the blood by the liver and conjugated to a water-soluble form so that it can be excreted in the bile.

- In the laboratory, automated blood cell counters rapidly provide accurate measurements of red blood cell count and cell indices. A stained blood smear provides information about the size, color, and shape of red cells and the presence of immature or abnormal cells. If blood smear results are abnormal, examination of the bone marrow may be indicated.
Anemia

Anemia is defined as an abnormally low number of circulating red blood cells or level of hemoglobin, or both, resulting in diminished oxygen-carrying capacity. Anemia usually results from excessive loss (bleeding) or destruction (hemolysis) of red blood cells or deficient red blood cell production because of a lack of nutritional elements or bone marrow failure. These mechanisms serve as the basis for classifying anemia.

The effects of anemia can be grouped into three categories: (1) manifestations of impaired oxygen transport and the resulting compensatory mechanisms, (2) reduction in red cell indices and hemoglobin levels, and (3) signs and symptoms associated with the pathologic process that is causing the anemia. The manifestations of anemia depend on its severity, the rapidity of its development, underlying pathologic mechanisms, and the person’s age and health status. If the onset is slow, the body compensates for the decrease in oxygen-carrying capacity of the blood with increases in plasma volume, cardiac output, and respiratory rate. These changes can largely compensate for the effects of mild to moderate anemia in otherwise healthy individuals but are less effective in those with compromised respiratory or cardiac function.

The redistribution of the blood from cutaneous tissues or the lack of hemoglobin causes pallor of the skin, mucous membranes, conjunctivae, and nail beds. Tachycardia and palpitations may occur as the body tries to compensate with an increase in cardiac output. Anemias caused by premature destruction of red cells (hemolytic anemias) are associated with hyperbilirubinemia, jaundice, and pigment gallstones. Anemias that result from ineffective hematopoiesis (premature death of red blood cells in the bone marrow) are associated with inappropriately high levels of iron absorption from the gut, which can lead to iron overload and eventual damage to endocrine organs and the heart.

Laboratory tests are useful in determining the severity and cause of the anemia. The red cell count and hemoglobin levels provide information about the severity of the anemia, whereas red cell characteristics such as size (normocytic, microcytic, macrocytic), color (normochromic, hypochromic), and shape often provide information about the cause of anemia (Fig. 13-8).

Blood Loss Anemia

The clinical manifestations and red cell changes associated with blood loss anemia depend on the rate of hemorrhage and whether the bleeding loss is internal or external. With rapid blood loss, circulatory collapse may occur. With more slowly developing blood loss, the amount of red cell mass lost may reach 50% without the occurrence of signs and symptoms.
The effects of acute blood loss are mainly due to loss of intravascular volume, which can lead to cardiovascular collapse and shock (see Chapter 20). A fall in the red blood cell count, and thus hemoglobin, is caused by hemo- dilution resulting from movement of fluid into the vascular compartment. Initially, the red cells are normal in size and color (normocytic, normochromic). The hypoxia that results from blood loss stimulates proliferation of committed erythroid stem cells in the bone marrow. It takes about 5 days for the progeny of hematopoietic stem cells to differentiate fully, an event that is marked by increased reticulocytes in the blood. If the bleeding is controlled and sufficient iron stores are available, the red cell concentration returns to normal within 3 to 4 weeks. External bleeding leads to iron loss and possible iron deficiency, which can hamper restoration of the red cell count.

Chronic blood loss does not affect blood volume but instead leads to iron-deficiency anemia with depleted iron stores. It is commonly caused by gastrointestinal bleeding and menstrual disorders. Because of compensatory mechanisms, persons are commonly asymptomatic until the hemoglobin level is less than 8 g/dL. The red cells that are produced have too little hemoglobin, giving rise to microcytic hypochromic anemia (see Fig. 13-8A).

Hemolytic Anemias

Hemolytic anemia is characterized by the premature destruction of red cells, the retention of iron and the other products of hemoglobin destruction, and a compensatory increase in erythropoiesis. Almost all types of hemolytic anemia are distinguished by normocytic and normochromic red cells. Because of the red blood cell’s shortened life span, the bone marrow usually is hyperactive, resulting in an increased number of reticulocytes in the circulating blood. As with other types of anemia, the person experiences easy fatigability, dyspnea, and other signs and symptoms of impaired oxygen transport.

Hemolytic anemias are commonly classified according to the red cell defect: intrinsic to the cell or due to some external factor. Intrinsic factors have been described for all components of the red cell, including the cell membrane, enzyme systems, and hemoglobin, most of which are hereditary. Extrinsic or acquired factors include immune mechanisms, mechanical trauma, and infections.

 Destruction of red cells can occur within the vascular compartment (intravascular) or within the phagocytic cells of the reticuloendothelial system (extravascular). Intravascular hemolysis is less common and occurs as a result of mechanical injury caused by defective cardiac valves, complement fixation in transfusion reactions, or exogenous toxic factors. Regardless of cause, intravascular hemolysis leads to hemoglobinemia, hemoglobinuria, and hemosiderinuria. The conversion of the heme pigment to bilirubin can result in unconjugated hyperbilirubinemia and jaundice. Massive intravascular hemolysis can lead to acute tubular necrosis (Chapter 25).

Extravascular hemolysis, the most common type of red cell destruction, takes place largely within the phagocytic cells of the spleen and liver. Because extreme changes in the red cell are necessary for red cells to navigate the splenic sinuses successfully, reduced deformability makes the passage difficult and leads to splenic sequestration, followed by phagocytosis. Extravascular hemolysis is not associated with hemoglobinemia or hemoglobinuria, but it often produces jaundice. It can also lead to the formation of bilirubin-rich gallstones, also called pigment stones.

Inherited Disorders of the Red Cell Membrane

Hereditary spherocytosis, in which the loss of membrane surface area relative to cytoplasmic contents causes the cell to become a tight sphere instead of a concave disk, is the most common inherited disorders of the red cell. The disorder, which transmitted as an autosomal dominant trait in about 75% of cases, is caused by disorders of the spectrin and ankyrin membrane proteins that lead to a loss of membrane surface. Although the spherical cell retains its ability to transport oxygen, it is poorly deformable and susceptible to destruction as it passes through the venous sinuses of the splenic circulation. Clinical signs are variable but typically include mild hemolytic anemia, jaundice, splenomegaly, and bilirubin gallstones. A life-threatening aplastic crisis may occur when a sudden disruption of red cell production (often from a viral infection) causes a rapid drop in the hemoglobin level. The disorder usually is treated with splenectomy to reduce red cell destruction, and with blood transfusions to support the circulation during a crisis.

Sickle Cell Disease

Sickle cell disease is an inherited disorder in which abnormal hemoglobin (hemoglobin S [HbS]) leads to chronic hemolytic anemia, pain, and organ failure. The HbS gene is transmitted by recessive inheritance and can manifest as sickle cell trait (i.e., heterozygote with one HbS gene) or sickle cell disease (i.e., homozygote...
with two HbS genes). Approximately 8% of African Americans are heterozygous for HbS and 0.1% to 0.2% are homozygous. In parts of Africa, where malaria is endemic, the gene frequency approaches 30%, attributed to the slight protective effect it confers against Plasmodium falciparum malaria.

The abnormal structure of HbS results from a point mutation in the β chain of the hemoglobin molecule, with an abnormal substitution of a single amino acid, valine, for glutamic acid (Fig. 13-9). In the heterozygote, only approximately 40% of the hemoglobin is HbS, but in the homozygote, 80% to 95% of the hemoglobin is HbS. Variations in proportions exist, and the concentration of HbS correlates with the risk of sickling. HbS polymerizes when deoxygenated, creating a semisolid gel that makes the erythrocyte rigid, distorts its shape, and causes structural damage to the red cell membrane (see Figure 13-8C). The sickled cell may return to its normal shape with oxygenation in the lungs. However, after repeated episodes of deoxygenation, the cells remain permanently sickled. The person with sickle cell trait who has less HbS has little tendency to sickle and is virtually asymptomatic. Fetal hemoglobin (HbF) inhibits the polymerization of HbS; therefore, most infants with sickle cell disease do not begin to experience the effects of the sickling until after 8 to 10 weeks of age, when the HbF has been replaced by HbS.

There are two major consequences of red blood cell sickling—chronic hemolytic anemia and blood vessel occlusion. Premature destruction of the cells due to the rigid, nondeformable membrane occurs in the spleen, causing hemolysis and anemia from a decrease in red cell numbers. Overall, the mean life span of red cells in persons with sickle cell disease averages only 20 days (one sixth of normal). Vessel occlusion disrupts blood flow, causing tissue ischemia and a pain crisis. Recent evidence suggests that vessel occlusion is a complex process involving an interaction among the sickled cells, vessel endothelial cells, platelets, and other blood components. The process is initiated by the adherence of sickled cells to the vessel endothelium, causing endothelial cell activation with liberation of inflammatory mediators and substances that increase platelet activation and promote blood coagulation.

Factors associated with sickling and vessel occlusion include cold, stress, physical exertion, infection, and illnesses that cause hypoxia, dehydration, or acidosis. The rate of HbS polymerization is affected by the concentration of hemoglobin in the cell. Dehydration increases the hemoglobin concentration and contributes to the polymerization and resultant sickling. Acidosis reduces the affinity of hemoglobin for oxygen, resulting in more deoxygenated hemoglobin and increased sickling. Even such trivial incidents as reduced oxygen tension induced by sleep may contribute to the sickling process.

**Clinical Course.** Persons who are homozygous for the HbS gene experience severe hemolytic anemia, chronic hyperbilirubinemia, and vaso-occlusive crises. The hyperbilirubinemia that results from the breakdown products of hemoglobin often leads to jaundice and the formation of pigment gallstones.

The complications of sickle cell disease are numerous, with two of the most common being vaso-occlusive pain crisis and acute chest syndrome. An acute pain episode results from tissue hypoxia due to vessel occlusion and can occur suddenly in almost any part of the body. Common sites obstructed by sickled cells include the abdomen, chest, bones, and joints. Many areas may be affected simultaneously. Infarctions caused by sluggish blood flow may cause chronic damage to the liver, spleen, heart, kidneys, retinas, and other organs (Fig. 13-10). **Acute chest syndrome** is an atypical pneumonia resulting from pulmonary infarction. It is the second leading cause of hospitalization in persons with sickle cell disease and is characterized by pulmonary infiltrates, shortness of breath, fever, chest pain, and cough. The syndrome can cause chronic respiratory insufficiency and is a leading cause of death in sickle cell disease. Children may experience growth retardation and susceptibility to osteomyelitis. Painful bone crises may be caused by marrow infarcts of the bones of the hands and feet, resulting in swelling of those extremities. Another major complication is stroke. Approximately 25% of persons with sickle cell disease have neurologic complications, including stroke, related to vessel occlusion.

![FIGURE 13-9. Mechanism of sickling and its consequences in sickle cell disease.](image)
In addition to these crises, persons with sickle cell disease are prone to infections. Because of the spleen’s sluggish blood flow and low oxygen tension, hemoglobin in red cells traversing the spleen becomes deoxygenated, causing ischemia. Splenic injury begins in early childhood, is characterized by intense congestion, and is usually asymptomatic. The congestion causes functional asplenia and predisposes the person to life-threatening infections by encapsulated organisms such as *Streptococcus pneumoniae*, *Haemophilus influenzae* type b, and *Klebsiella* species. Neonates and small children have not had time to create antibodies to these organisms and rely on the spleen for their removal. In the absence of specific antibody to the polysaccharide capsular antigens of these organisms, splenic activity is essential for removing these organisms when they enter the blood.

**Diagnosis and Treatment.** The signs and symptoms of sickle cell disease make their appearance during infancy. Neonatal diagnosis of sickle cell disease is made on the basis of clinical findings and hemoglobin solubility results, which are confirmed by hemoglobin electrophoresis. Prenatal diagnosis is done by the analysis of fetal DNA obtained by amniocentesis.

In the United States, screening programs have been implemented to detect newborns with sickle cell disease and other hemoglobinopathies. Cord blood or heel-stick samples are subjected to electrophoresis to separate the HbF from the small amount of HbA and HbS. Other hemoglobins may also be detected and quantified by further laboratory evaluation. According to the National Newborn Screening and Genetics Resource Center (NNSGRC), all 50 states require screening of all newborns regardless of ethnic origin.

The clinical course of persons with sickle cell disease is highly variable. As a result of improvements in supportive care, an increasing number of persons are surviving into adulthood and producing offspring. Of particular importance is the early prophylactic treatment with penicillin to prevent pneumococcal infection. Treatment should begin as early as 2 months of age and continued until at least 5 years of age. Maintaining full immunization, including the *H. influenzae* and hepatitis B vaccines, is recommended. The National Institutes of Health Committee on Management of Sickle Cell Disease also recommends administration of the 7-valent pneumococcal vaccine beginning at 2 to 6 months of age (see Chapter 25). The 7-valent vaccine should be followed by immunization with the 23-valent pneumococcal vaccine at 24 months of age or later. Most recent recommendations (Advisory Committee on Immunization Practices 2013) have also included the use of the 13-valent pneumococcal conjugate vaccine in children ages 6 to 18 years old with immunocompromising conditions such as functional asplenia.

Hydroxyurea, an inhibitor of DNA synthesis, has been shown to reduce pain crises and prevent the complications of sickle cell disease. The drug produces an increase of HbF in red cells by decreasing the terminal differentiation of erythroid stem cells into HbS; acts as an anti-inflammatory agent by inhibiting the production of white blood cells; and is oxidized by heme groups to produce nitric oxide, a potent vasodilator and inhibitor of platelet aggregation. Although the drug halves pain episodes and pulmonary complications, approximately 40% of persons do not respond. Other therapies under investigation include drugs that affect globin gene expression; prevent hemoglobin polymerization, membrane damage, and cell dehydration; or inhibit sickle cell adhesion to endothelial cells. Bone marrow or stem cell transplantation has the potential for cure in symptomatic children but carries the risk of graft-versus-host disease. Progress in gene therapy to treat sickle cell disease has been slow but promising, and may be a future option.
Thalassemias

The thalassemias are a heterogeneous group of inherited disorders caused by mutations that decrease the rate of synthesis of α- or β-globin chains. B-thalassemias are caused by deficient synthesis of the β chain and α-thalassemias by deficient synthesis of the α chain. The defect is inherited as a Mendelian trait, and a person may be heterozygous (mild disease) or homozygous (severe disease) for the trait. Like sickle cell disease, the thalassemias occur with a high degree of frequency in certain populations. B-thalassemia, sometimes called Cooley anemia or Mediterranean anemia, is most common in the Mediterranean populations of southern Italy and Greece, whereas the α-thalassemias are more common among Asians. Both α- and β-thalassemias are more common in Africans and African Americans. Two factors contribute to the anemia that occurs in thalassemia: a deficiency in hemoglobin due to the decreased synthesis of the affected chain, coupled with excess production of the unaffected chain. The reduced hemoglobin synthesis results in a hypochromic, microcytic anemia, whereas the accumulation of the unaffected chain interferes with normal red cell maturation and contributes to membrane changes that lead to hemolysis and anemia.

β-Thalassemias. The β-thalassemias result from a point mutation in the β-globin gene that directs β-chain synthesis. Sequencing of the β-thalassemia genes has revealed more than 100 different mutations, the majority of which consist of single-base changes. The presence of one normal gene in heterozygous persons (thalassemia minor) usually results in sufficient normal hemoglobin synthesis to prevent severe anemia. Persons who are homozygous for the trait (thalassemia major) have severe, transfusion-dependent anemia that is evident at about 6 months of age when the hemoglobin switches from HbF to HbA. If transfusion therapy is not started early in life, severe growth retardation occurs in children with the disorder.

Two conditions contribute to the pathogenesis of the anemia in β-thalassemias: inadequate HbA formation due to reduced β-globin chain synthesis, and red cell hemolysis resulting from an unbalanced rate of β-globin and α-globin synthesis. The excess α-globin chains form insoluble aggregates (Heinz bodies) that precipitate within red cells and produce severe membrane damage that causes extravascular hemolysis. Erythroblasts in the bone marrow undergo a similar fate, which in severe β-thalassemia results in destruction of the majority of erythroid precursors before their maturation into red cells. In addition to anemia, persons with moderate to severe forms of the disease suffer from coagulation abnormalities. Thrombotic events (stroke and pulmonary embolism) appear to be related to altered platelet function, endothelial activation, and an imbalance of procoagulant and anticoagulant factors.

In severe β-thalassemia, marked anemia produced by ineffective hematopoiesis and hemolysis leads to increased erythropoietin secretion and hyperplasia in the bone marrow and sites of extramedullary hematopoiesis. The expanding mass of erythropoietic marrow invades the bony cortex, impairs bone growth, and produces other bone abnormalities. There is thinning of the cortical bone, with new bone formation evident on the maxilla and frontal bones of the face (i.e., chipmunk facies). The long bones, ribs, and vertebrae may become vulnerable to fracture because of osteoporosis or osteopenia, which contributes to increased morbidity in older persons. Enlargement of the spleen (splenomegaly) and liver (hepatomegaly) result from extramedullary hematopoiesis and increased red cell destruction. Ineffective hematopoiesis also stimulates an inappropriate increase in absorption of dietary iron. Excess iron stores, which accumulate from increased dietary absorption and repeated transfusions, are deposited in the myocardium, liver, and endocrine organs and induce organ damage. Cardiac, hepatic, and endocrine diseases are common causes of morbidity and mortality from iron overload. Disorders of the pituitary, thyroid, and adrenal glands and the pancreas result in significant morbidity and require hormone replacement therapy.

Regular blood transfusions improve growth and development and prevent most of the complications, and iron chelation therapy can reduce the iron overload and extend life expectancy. Stem cell transplantation is a potential cure for low-risk patients, particularly in younger persons with no complications of the disease or its treatment, and has excellent results. In the future, stem cell gene replacement may provide a cure for many with the disease.

α-Thalassemias. The α-thalassemias are caused by a gene deletion that results in defective α-chain synthesis. Sequencing of the α-globin chains of hemoglobin is controlled by four genes (two pairs); hence, α-thalassemia shows great variation in severity related to the number of gene deletions. Silent carriers who have a deletion of a single α-globin gene are asymptomatic, whereas those with deletion of two genes have the α-thalassemia trait and exhibit mild hemolytic anemia. Deletion of three of the four α-chain genes leads to unstable aggregates of α chains called hemoglobin H (HbH). This disorder is the most important clinical form and is more common in Asians. The β chains are more soluble than the α chains, and their accumulation is less toxic to the red cells, so that senescent rather than precursor red cells are affected. Most persons with HbH have moderately severe hemolytic anemia but do not usually require transfusions. The most severe form of α-thalassemia occurs in infants in whom all four α-globin genes are deleted. Such a defect results in a hemoglobin molecule (Hb Bart) that is formed exclusively from the chains of HbF. Hb Bart, which has an extremely high oxygen affinity, and cannot release oxygen in the tissues. This disorder usually results in death in utero or shortly after birth.

Inherited Enzyme Defects

The red cell is vulnerable to injury by endogenous and exogenous oxidants, which are normally inactivated by the glucose-containing tripeptide glutathione, one of the
body’s principal means of preventing oxidative damage. Abnormalities of glutathione metabolism resulting from impaired enzyme function reduce the ability of red cells to protect against oxidative stress. The most common inherited enzyme defect that results in hemolytic anemia is a deficiency of glucose-6-phosphate dehydrogenase (G6PD). The gene that determines this enzyme is located on the X chromosome, and the defect is expressed only in males and homozygous females. There are several hundred variants of this gene, but only the G6PD A-variant, found in 10% to 15% of African Americans, and the G6PD Mediterranean variant are known to cause clinically significant hemolytic anemia. The disorders are also associated with favism, a disorder of hemolysis due to consumption of fava beans.

Glucose-6-phosphate dehydrogenase deficiency makes red cells more vulnerable to oxidants. The disorder features direct oxidation of hemoglobin to methemoglobin, which cannot transport oxygen, and denaturing of the hemoglobin molecule to form Heinz bodies, which are precipitated in the red blood cells. Hemolysis usually occurs as the damaged red blood cells move through the narrow vessels of the spleen, causing hemoglobinemia, hemoglobinuria, and jaundice. The hemolysis is short-lived, occurring 2 to 3 days after the triggering event. In African Americans, the defect is mildly expressed and is not associated with chronic hemolytic anemia unless triggered by oxidant drugs, acidosis, or infection. In affected persons, the hemolysis can be triggered by exposure to oxidant drugs such as the antimalarial drug primaquine, quinine, the sulfa drugs, and nitrofurantoin. Severe G6PD deficiency (as in Mediterranean variants) may produce a chronic hemolytic anemia. The disorder can be diagnosed through the use of a G6PD assay and other screening blood tests (complete blood count, bilirubin, and reticulocyte count). No treatment is necessary except to avoid known oxidant drugs.

**Acquired Hemolytic Anemias**

Several acquired factors exogenous to the red blood cell produce hemolysis by direct membrane destruction or antibody-mediated lysis. Various drugs, chemicals, toxins, venoms, and infections such as malaria destroy red cell membranes. Hemolysis can also be caused by mechanical factors such as prosthetic heart valves, vasculitis, and severe burns. Obstructions in the microcirculation, as in disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, and renal disease, may traumatize the red cells by producing turbulence and changing pressure gradients.

Although commonly referred to as autoantibody anemia, the currently preferred designation is immunohemolytic anemia, since it may be initiated by an ingested drug. The antibodies that cause hemolysis are of two types: warm-reacting antibodies of the immunoglobulin G (IgG) class, which are maximally active at 37°C, and cold-reacting antibodies of the IgM type, which are optimally active at about 4°C.

In the warm-reacting antibody type, the most common form of immunohemolytic anemia, the antibodies react with antigens on the red cell membrane, causing destructive changes that lead to spherocytosis, with subsequent phagocytic destruction in the spleen or reticuloendothelial system. The antibodies lack specificity for the ABO antigens but may react with the Rh antigens. The hemolytic reactions usually have a rapid onset and may be severe and life-threatening. There are varied causes for this anemia: approximately 50% are idiopathic, and 50% are related to predisposing conditions such as lymphoid neoplasms, autoimmune disorders (particularly systemic lupus erythematosus), and exposure to drugs such as penicillin and the cephalosporins. Some drugs, of which the antihypertensive drug α-methyldopa is the prototype, induce the production of antibodies against red cell antigens, particularly Rh antigens. About 10% of persons taking α-methyldopa develop antibodies, and about 10% develop clinically significant hemolysis.

In the cold-reacting agglutinin type of hemolytic anemia, which is less common than the warm-reacting type, IgM antibodies bind red cells and cause agglutination and activate complement. Cold agglutinin antibodies sometimes appear transiently following certain infections (e.g., Epstein-Barr, influenza), in which case the condition is relatively benign. The condition may also develop as a chronic complication of B-cell neoplasms and as an idiopathic entity. Symptoms are variable and occur in parts of the body, such as the ears, fingers, and toes, where the temperature may fall below 30°C. They manifest due to vascular obstruction caused by agglutinated red cells resulting in pallor, cyanosis, and Raynaud phenomenon.

The diagnosis of immunohemolytic anemia requires use of the Coombs test to detect the presence of antibody or complement on the surface of red blood cells. The direct Coombs test uses antibodies specific for human immunoglobulins or complement to detect antibodies on red blood cells. It is positive in cases of autoimmune hemolytic anemia, Rh disease of the newborn, transfusion reactions, and drug-induced hemolysis. The indirect Coombs test uses commercially available red cells with known antigens to characterize the antigen target and temperature dependence of the responsible antigen.

**Anemias of Deficient Red Cell Production**

Anemia may result from the decreased production of erythrocytes by the bone marrow. This category includes anemias caused by a deficiency of substances that are needed for hematopoiesis, particularly iron, vitamin B₁₂, and folic acid. Other disorders that suppress erythropoiesis include those associated with bone marrow failure or replacement of the bone marrow by tumor or inflammatory cells.

**Iron-Deficiency Anemia**

Iron deficiency is a common worldwide cause of anemia affecting persons of all ages. The anemia results from dietary deficiency, loss of iron through bleeding,
or increased demands. Because iron is a component of heme, a deficiency leads to decreased hemoglobin synthesis and consequent impairment of oxygen delivery.

Body iron is used repeatedly. When red cells become senescent and are broken down, their iron is released and reused in the production of new red cells. Despite this efficient process, small amounts of iron are lost in the feces and need to be replaced by dietary uptake. Iron balance is maintained by the absorption of 0.5 to 1.5 mg daily to replace the 1 mg lost in the feces. The average Western diet supplies about 20 mg. The absorbed iron is more than sufficient to supply the needs of most individuals, but may be barely adequate in toddlers, adolescents, and women of child-bearing age.

The usual reason for iron deficiency in adults in the Western world is chronic blood loss because iron cannot be recycled to the pool. In men and postmenopausal women, blood loss may occur from gastrointestinal bleeding because of peptic ulcer, intestinal polyps, hemorroids, or cancer. Excessive aspirin intake may cause undetected gastrointestinal bleeding. In women, menstruation may account for an average of 1.5 mg of iron lost per day, causing a deficiency. Although cessation of menstruation removes a major source of iron loss in the pregnant woman, iron requirements increase during this time, and deficiency is common. The expansion of the mother’s blood volume in addition to the growing fetus increase the total iron needs to about 1000 mg (27 mg/day) during pregnancy. In the postnatal period, lactation requires approximately 1 mg of iron daily.

A child’s growth places extra demands on the body. Blood volume increases, with a greater need for iron. Iron requirements are proportionally higher in infancy (3 to 24 months) than at any other age, although they are also increased in childhood and adolescence. In infancy, the two main causes of iron-deficiency anemia are low iron levels at birth because of maternal deficiency and a diet consisting mainly of cow’s milk, which is low in absorbable iron. Adolescents are also susceptible to iron deficiency because of high requirements due to growth spurts, dietary deficiencies, and menstrual loss.

Iron-deficiency anemia is characterized by low hemoglobin and hematocrit, decreased iron stores, and low serum iron and ferritin levels. The red cells are decreased in number and are microcytic and hypochromic (see Fig. 13-8). Poikilocytosis (irregular shape) and anisocytosis (irregular size) are also present. Laboratory values show reduced MCHC and MCV. Membrane changes may predispose to hemolysis, causing further loss of red cells.

The manifestations of iron-deficiency anemia are related to impaired oxygen transport and lack of hemo
globin. Depending on the severity of the anemia, pallor, easy fatigability, dyspnea, and tachycardia may occur. Epithelial atrophy is common and results in waxy pallor, brittle hair and nails, sometimes a spoon-shaped deformity of the fingernails, smooth tongue, sores in the corners of the mouth, and sometimes dysphagia and decreased acid secretion. A poorly understood symptom occasionally seen is pica, the bizarre, compulsive eating of ice, dirt, or other abnormal substances. Iron deficiency in infants may also result in long-term manifestations such as poor cognitive, motor, and emotional function that may be related to effects on brain development and neurotransmitter function.

Prevention of iron deficiency is a primary concern in infants and children. Avoidance of cow’s milk, iron supplementation at 4 to 6 months of age in breast-fed infants, and use of iron-fortified formulas and cereals are recommended for infants younger than 1 year of age. In the 2nd year, a diet rich in iron-containing foods and use of iron-fortified vitamins will help prevent iron deficiency. The treatment of iron-deficiency anemia in children and adults is directed toward controlling chronic blood loss, increasing dietary intake of iron, and administering supplemental iron. Ferrous sulfate, which is the usual oral replacement therapy, replenishes iron stores in several months. Parenteral iron therapy may be used when oral forms are not tolerated or are ineffective. Caution is required because of the possibility of severe hypersensitivity reactions.

**Megaloblastic Anemias**

Megaloblastic anemias are caused by impaired DNA synthesis that results in enlarged red cells (MCV > 100 fL) due to impaired maturation and division. There are two principal causes of megaloblastic anemia: vitamin B12 and folic acid deficiencies. Because megaloblastic anemias develop slowly, there are often few symptoms until the anemia is far advanced.

**Vitamin B12–Deficiency Anemia.** Vitamin B12, also known as cobalamin, serves as a cofactor for two important reactions in humans. It is essential for DNA synthesis and nuclear maturation, which in turn leads to normal red cell maturation and division. Vitamin B12 is also involved in a reaction that prevents abnormal fatty acids from being incorporated into neuronal lipids. This abnormality may predispose to myelin breakdown and produce some of the neurologic complications of vitamin B12 deficiency.

Vitamin B12 is found in all foods of animal origin. Dietary deficiency is rare and usually found only in strict vegetarians who avoid all dairy products as well as meat and fish. Vitamin B12 is absorbed by a unique process. After release from the animal protein, it is bound to the intrinsic factor, a protein secreted by the gastric parietal cells (Fig. 13-11). The vitamin B12-intrinsic factor complex protects vitamin B12 from digestion by intestinal enzymes. The complex travels to the ileum, where it binds to membrane receptors on the epithelial cells. Vitamin B12 is then separated from intrinsic factor and transported across the membrane into the circulation. There it is bound to its carrier protein, transcobalamin II, which transports vitamin B12 to its storage and tissue sites.

An important cause of vitamin B12 deficiency is pernicious anemia, resulting from atrophic gastritis (see Chapter 29). Pernicious anemia is believed to result from immunologically mediated, possibly autoimmune, destruction of the gastric mucosa. The resultant chronic atrophic gastritis is marked by loss of parietal
cells and production of antibodies that interfere with binding of vitamin B₁₂ to intrinsic factor. Other causes of vitamin B₁₂ deficiency anemia include gastrectomy, ileal resection, inflammation or neoplasms in the terminal ileum, and malabsorption syndromes in which vitamin B₁₂ and other B-vitamin compounds are poorly absorbed.

The hallmark of vitamin B₁₂ deficiency is megaloblastic anemia. When vitamin B₁₂ is deficient, the red cells that are produced are abnormally large because of excess cytoplasmic growth and structural proteins (see Fig. 13-8B). The cells have immature nuclei with evidence of cellular destruction and delicate membranes that are oval rather than biconcave. These oddly shaped cells have a short life span that can be measured in weeks rather than months. The loss of red cells results in moderate to severe anemia and mild jaundice. The MCV is elevated, and the MCHC is normal. As with other anemias, there is pallor, easy fatigability, and in severe cases dyspnea. The megaloblastic state also produces changes in mucosal cells, leading to glossitis (sore tongue), as well as other vague gastrointestinal disturbances such as anorexia and diarrhea. Vitamin B₁₂ deficiency also leads to a complex neurologic syndrome caused by deranged methylation of myelin protein. Demyelination of the dorsal and lateral columns of the spinal cord causes symmetric paresthesias of the hands and feet, loss of vibratory and position sense, and eventual spastic ataxia. In more advanced cases, cerebral function may be altered with dementia and other neuropsychiatric changes preceding hematologic changes.

Diagnosis of vitamin B₁₂ deficiency is made by finding an abnormally low serum vitamin B₁₂ level. The diagnosis of pernicious anemia is usually made by the detection of parietal cell and intrinsic factor antibodies.²⁰ Lifelong treatment consisting of intramuscular injections or high oral doses of vitamin B₁₂ reverses the anemia and prevents the neurologic changes.

**Folic Acid–Deficiency Anemia.** Folic acid is also required for DNA synthesis and red cell maturation, and its deficiency produces the same type of megaloblastic red cell changes that occur in vitamin B₁₂ deficiency anemia (i.e., increased MCV and normal MCHC). Folic acid is readily absorbed from the intestine. It is found in vegetables (particularly the green leafy types), fruits, cereals, and meats. Much of the vitamin, however, is lost in cooking. The most common causes of folic acid deficiency are malnutrition or dietary lack, especially in the elderly or in association with alcoholism. Total body stores of folic acid amount to 2000 to 5000 µg with a 50 µg daily dietary requirement. A dietary deficiency may result in anemia in a few months. Malabsorption of folic acid may be due to syndromes such as celiac disease or other intestinal disorders. Anti-epileptic medications such as primidone, phenytoin, phenobarbital, and the diuretic triamterene predispose to a deficiency by interfering with folic acid absorption. In neoplastic disease, tumor cells compete for folate, and deficiency is common. Methotrexate, a folic acid analog used in the treatment of cancer, impairs the action of folic acid by blocking its conversion to the active form. Because pregnancy increases the need for folic acid 5- to 10-fold, a deficiency commonly occurs. Poor dietary habits, anorexia, and nausea are other reasons for folic acid deficiency during pregnancy. Studies have shown an association between folate deficiency and neural tube defects (see Chapter 6).²⁰

The features of folic acid deficiency are similar to those of vitamin B₁₂ deficiency, with megaloblastic anemia and symptoms referable to changes in the mucosal surface of the gastrointestinal tract. However, there are essentially none of the neurologic abnormalities associated with B₁₂ deficiency.

**Aplastic Anemia**

Aplastic anemia describes a disorder of pluripotential bone marrow stem cells that results in a reduction of all three hematopoietic cell lines—red blood cells, white blood cells, and platelets.²²,²³ Pure red cell aplasia, in which only the red cells are affected, rarely occurs. Anemia results from the failure of the marrow to replace senescent red cells that are destroyed and leave the circulation, although the cells that remain are of normal size and color. At the same time, because the leukocytes, particularly the neutrophils, and the thrombocytes have a short life span, a deficiency of these cells usually is apparent before the anemia becomes severe.

The onset of aplastic anemia may be insidious, or it may strike with suddenness and great severity. It can occur at any age. The initial presenting symptoms include weakness, fatigability, and pallor caused by anemia. Petechiae (i.e., small, punctate skin hemorrhages [see Chapter 12, Fig. 12-4]) and ecchymoses (i.e., bruises) often occur on the skin, and bleeding from the nose, gums, vagina, or gastrointestinal tract may occur because of decreased platelet levels. The decrease in the number of neutrophils increases susceptibility to infection.
Causes of aplastic anemia include exposure to high doses of radiation, chemicals, and toxins that suppress hematopoiesis directly or through immune mechanisms. Chemotherapy and irradiation commonly result in bone marrow depression, which causes anemia, thrombocytopenia, and neutropenia. Identified toxic agents include benzene, the antibiotic chloramphenicol, and the alkylating agents and antimetabolites used in the treatment of cancer (see Chapter 7). Aplastic anemia caused by exposure to chemical agents may be an idiosyncratic reaction because it affects only certain susceptible persons. It typically occurs weeks after a drug is initiated. Such reactions often are severe and sometimes irreversible and fatal. It can also develop in the course of many infections and has been reported most often as a complication of viral hepatitis, mononucleosis, and other viral illnesses, including acquired immunodeficiency syndrome (AIDS). In two thirds of cases, the cause is unknown, a condition referred to as idiopathic aplastic anemia. The mechanisms underlying the pathogenesis of aplastic anemia are unknown. It is suggested that exposure to the chemicals, infectious agents, and other insults generates a cellular immune response resulting in production of cytokines by activated T cells. These cytokines (e.g., interferon, tumor necrosis factor [TNF]) then suppress hematopoietic stem cell growth and development.5

Therapy for aplastic anemia in the young and severely affected includes stem cell replacement by bone marrow or peripheral blood transplantation. Histocompatible donors supply the stem cells to replace the patient’s destroyed marrow cells. Graft-versus-host disease, rejection, and infection are major risks of the procedure, yet 75% or more survive.22 For those who are not transplantation candidates, immunosuppressive therapy with lymphocytic immune globulin (i.e., antithymocyte globulin) prevents suppression of proliferating stem cells, producing remission in up to 50% of patients.22,23 Persons with aplastic anemia should avoid the offending agents and be treated with antibiotics for infection. Red cell transfusions to correct the anemia and platelets and corticosteroid therapy to minimize bleeding may also be required.

Anemia of Chronic Disease

Anemia often occurs as a complication of infections, inflammation, and cancer. The most common causes of chronic disease anemias are acute and chronic infections, including AIDS and osteomyelitis; cancers; autoimmune disorders such as rheumatoid arthritis, systemic lupus erythematosus, and inflammatory bowel disease; and chronic kidney disease.24 It is theorized that the short red cell life span, deficient red cell production, a blunted response to erythropoietin, and low serum iron are caused by actions of cytokines and cells of the reticuloendothelial system. Microorganisms, tumor cells, and autoimmune dysregulation lead to T-cell activation and production of cytokines (e.g., interleukin-1, interferon, and TNF) that suppress the erythropoietin response, inhibit erythroid precursors, and cause changes in iron homeostasis.24 The mild anemia is normocytic and normochromic with low reticulocyte counts.

Chronic renal failure almost always results in anemia, primarily because of erythropoietin deficiency. Unidentified uremic toxins and retained nitrogen also interfere with the actions of erythropoietin and with red cell production and survival. Hemolysis and blood loss associated with hemodialysis and bleeding tendencies associated with platelet dysfunction also contribute to the anemia of renal failure. Therapy for these anemias includes treatment of the underlying disease, short-term erythropoietin therapy, iron supplementation, and blood transfusions.24

SUMMARY CONCEPTS

- Anemia, which is a deficiency of red cells or hemoglobin, results from excessive loss (blood loss anemia), increased destruction (hemolytic anemia), or impaired production of red blood cells (iron-deficiency, megaloblastic due to a Vitamin B₁₂ deficiency, and aplastic anemias).
- Blood loss anemia can be acute or chronic. With bleeding, iron and other components of the erythrocyte are lost from the body.
- Hemolytic anemia is characterized by the premature destruction of red cells, with body retention of iron and the other products of red cell destruction. It can be caused by defects in the red cell membrane, hemoglobinopathies (sickle cell disease or thalassemia), or inherited enzyme defects (G6PD deficiency). Acquired forms of hemolytic anemia are caused by agents extrinsic to the red blood cell, such as medications, bacterial and other toxins, antibodies, and physical trauma.
- Aplastic anemia is caused by bone marrow suppression and usually results in a reduction of white blood cells and platelets, as well as red blood cells.
- Chronic diseases such as inflammatory disorders (rheumatoid arthritis), cancers, and renal failure cause anemia through the production of inflammatory cytokines that interfere with erythropoietin production or response.
- The manifestations of anemia are caused by the decreased hemoglobin in the blood (pallor), tissue hypoxia due to deficient oxygen transport (weakness and fatigue), and recruitment of compensatory mechanisms (tachycardia and palpitations) designed to increase oxygen delivery to the tissues.
Polycythemia

Polycythemia represents an abnormally high total red blood cell count with a hematocrit greater than 50%. It is categorized as relative or absolute. In relative polycythemia, the hematocrit rises because of a loss of plasma volume without a corresponding increase in red cells. This may occur with water deprivation, excess use of diuretics, or gastrointestinal losses. Relative polycythemia is corrected by increasing the vascular fluid volume. Absolute polycythemia is a rise in hematocrit due to an increase in total red cell mass and is classified as primary or secondary.

Primary Polycythemia

Primary polycythemia, or polycythemia vera, is a neoplastic disease of the pluripotent cells of the bone marrow characterized by an absolute increase in total red blood cell mass accompanied by elevated white cell and platelet counts. It most commonly is seen in men and may occur at any age with a median age of 62 years at the time of diagnosis. In polycythemia vera, the manifestations are variable and are related to an increase in the red cell count, hemoglobin level, and hematocrit with increased blood volume and viscosity. Additional early findings include splenomegaly and depletion of iron stores. Viscosity rises exponentially with the hematocrit and interferes with cardiac output and blood flow. Hypertension is common and there may be complaints of headache, dizziness, inability to concentrate, and some difficulty with hearing and vision because of decreased cerebral blood flow. Venous stasis gives rise to a dusky red or bluish skin color, particularly of the lips, fingernails, and mucous membranes. Because of the increased concentration of blood cells, the person may experience itching (abnormal histamine release) and pain in the fingers or toes, and the hypermetabolism may induce night sweats and weight loss. Thromboembolism and hemorrhage, due to hyperviscosity and platelet and neutrophil abnormal activation, are common complications that can be prevented by phlebotomy to reduce the hematocrit to less than 42% in women and less than 45% in men.

The goal of treatment in primary polycythemia is to reduce blood viscosity. This can be done by withdrawing blood by periodic phlebotomy to reduce red cell volume. Low-dose aspirin may control the high platelet counts, and suppression of bone marrow function with medication (hydroxyurea) controls the elevated white cell count.

Secondary Polycythemia

Secondary polycythemia results from a physiologic increase in the level of erythropoietin, commonly as a compensatory response to hypoxia. Conditions causing hypoxia include living at high altitudes, chronic heart and lung disease, and smoking. The resultant release of erythropoietin by the kidney causes the increased formation of red blood cells in the bone marrow. Neoplasms that secrete erythropoietin may also cause a secondary polycythemia. Kidney disease such as hydronephrosis or renal cysts may obstruct blood flow, cause hypoxia, and lead to an increase in erythropoietin as well. Treatment of secondary polycythemia focuses on relieving hypoxia. For example, continuous low-flow oxygen therapy can be used to correct the severe hypoxia that occurs in some persons with chronic obstructive pulmonary disease. This form of treatment is thought to relieve the pulmonary hypertension and polycythemia and to delay the onset of cor pulmonale (right heart failure due to lung disease).

SUMMARY CONCEPTS

- Polycythemia describes a condition of increased red blood cell (RBC) mass. It can present as a relative or absolute disorder, with the latter subcategorized as primary or secondary. Relative polycythemia results from a loss of vascular volume (i.e., diuretic use) and is corrected by fluid replacement.
- Primary polycythemia, or polycythemia vera, is a proliferative disease of the bone marrow with an absolute increase in total RBC mass accompanied by elevated white cell and platelet counts. Secondary polycythemia results from increased erythropoietin levels caused by hypoxic conditions such as chronic heart and lung disease.
- Many of the manifestations of polycythemia are related to increased blood volume and viscosity that lead to hypertension and stagnation of blood flow.

Age-Related Changes in Red Blood Cells

The red blood cell count and hemoglobin concentration are high at birth and decline with age. The process of aging and other health conditions often impair red cell development, with anemia being a common problem among the elderly.

Red Cell Changes in the Neonate

At birth, changes in the red blood cell indices reflect the transition to extrauterine life and the need to transport oxygen from the lungs (Table 13-2). Hemoglobin concentrations at birth are high, reflecting the high synthetic activity in utero to provide adequate oxygen delivery. Toward the end of the first postnatal week, hemoglobin concentration begins to decline, gradually falling to a minimum value at approximately age 2 months.
The red cell count, hematocrit, and MCV likewise fall. The factors responsible for the decline include reduced red cell production and plasma dilution caused by increased blood volume with growth. Neonatal red cells also have a shorter life span of 50 to 70 days, and are thought to be more fragile than those of older persons. In addition, during the early neonatal period, there is a switch from HbF to HbA. The amount of HbF in term infants averages about 70% of the total hemoglobin and declines to trace amounts by 6 to 12 months of age.27 The switch to HbA provides greater unloading of oxygen to the tissues because HbA has a lower affinity for oxygen compared with HbF. Infants who are small for gestational age, born to diabetic or smoking mothers, or who experienced hypoxia in utero have higher total hemoglobin levels, higher HbF levels, and a delayed switch to HbA.

Physiologic anemia of the newborn develops at approximately 2 months of age. It seldom produces symptoms and cannot be altered by nutritional supplements. Anemia of prematurity, an exaggerated physiologic response in infants with low birth weight, is thought to result from a poor erythropoietin response. A contributing factor is the frequent blood sampling often required in these infants. The hemoglobin level rapidly declines after birth to a low of 7 to 10 g/dL at approximately 6 weeks of age. Signs and symptoms include apnea, poor weight gain, pallor, decreased activity, and tachycardia. In infants born before 33 weeks gestation or those with hematocrits below 33%, the clinical features are more evident.

Anemia at birth, characterized by pallor, congestive heart failure, or shock, usually is caused by hemolytic disease of the newborn. Bleeding from the umbilical cord, internal hemorrhage, congenital hemolytic disease, or frequent blood sampling are other possible causes of anemia. The severity of symptoms and presence of coexisting disease may warrant red cell transfusion.

### Hyperbilirubinemia in the Neonate

Hyperbilirubinemia, an increased level of serum bilirubin, is a common cause of jaundice in the neonate. A benign, self-limited condition, it most often is related to the developmental state of the neonate. Rarely, cases of hyperbilirubinemia are pathologic and may lead to serious brain damage.

In the 1st week of life, approximately 60% of term and 80% of preterm neonates are jaundiced.28 This physiologic jaundice appears in term infants on the second or third day of life. Ordinarily, the indirect bilirubin in umbilical cord blood is 1 to 3 mg/dL and increases by no more than 5 mg/dL in 24 hours, giving rise to jaundice. The levels peak at 5 to 6 mg/dL between days 2 and 4 and decrease to less than 2 mg/dL by days 5 to 7.28 The increase in bilirubin is related to the increased red cell breakdown and the inability of the immature liver to conjugate bilirubin for excretion. Premature infants exhibit a slower rise and longer duration of serum bilirubin levels, perhaps because of poor hepatic uptake and reduced albumin binding of bilirubin. Peak bilirubin levels of 8 to 12 mg/dL appear on days 5 to 7. Most neonatal jaundice resolves within 1 week and is untreated.

Many factors can contribute to elevated bilirubin levels in the neonate, including breast-feeding, hemolytic disease of the newborn, hypoxia, infections, and acidosis. Bowel or biliary obstruction and liver disease are less common causes. Associated risk factors include prematurity, Asian ancestry, and maternal diabetes. Breast milk jaundice occurs in approximately 2% of breast-fed infants.28 These neonates accumulate significant levels of unconjugated bilirubin 7 days after birth, with maximum levels of 10 to 30 mg/dL reached in the 3rd week of life. It is thought that the breast milk contains fatty acids that inhibit bilirubin conjugation in the neonatal liver. A factor in breast milk is also thought to increase the absorption of bilirubin in the duodenum. This type of jaundice disappears if breast-feeding is discontinued. Nursing can be resumed in 3 to 4 days without any hyperbilirubinemia ensuing.

Hyperbilirubinemia places the neonate at risk for the development of a neurologic syndrome called kernicterus. This condition is caused by the accumulation of unconjugated bilirubin in brain cells. Unconjugated bilirubin is lipid soluble, crosses the permeable blood–brain barrier of the neonate, and is deposited in cells of the basal ganglia, causing brain damage. Asphyxia and

hyperosmolality may also contribute by damaging the blood–brain barrier and allowing bilirubin to cross and enter the cells. The level of unconjugated bilirubin and the duration of exposure that will be toxic to the infant are unknown. The less-mature infant, however, is at greater risk for kernicterus.24 The manifestations of kernicterus may appear 2 to 5 days after birth in term infants or by day 7 in premature infants. Lethargy, poor feeding, and short-term behavioral changes may be evident in mildly affected infants. Severe manifestations include rigidity, tremors, ataxia, and hearing loss. Extreme cases cause seizures and death. Most survivors are seriously damaged and by three years of age exhibit involuntary muscle spasms, seizures, mental retardation, and deafness.

Hyperbilirubinemia in the neonate is treated with phototherapy or exchange transfusion. Phototherapy is more commonly used to treat jaundiced infants and reduce the risk of kernicterus. Exposure to fluorescent light in the blue range of the visible spectrum (420- to 470-nm wavelength) reduces bilirubin levels. Bilirubin in the skin absorbs the light energy and is converted to a structural isomer that is more water soluble and can be excreted in the stool and urine. Effective treatment depends on the area of skin exposed and the infant’s ability to metabolize and excrete bilirubin. Frequent monitoring of bilirubin levels, body temperature, and hydration is critical to the infant’s care. Exchange transfusion is considered when signs of kernicterus are evident or hyperbilirubinemia is sustained or rising and unresponsive to phototherapy.

### Hemolytic Disease of the Newborn

*Erythroblastosis fetalis,* or hemolytic disease of the newborn, occurs in Rh-positive infants of Rh-negative mothers who have been sensitized. The mother can produce anti-Rh antibodies from pregnancies in which the fetus is Rh positive or from blood transfusions of Rh-positive blood. The Rh-negative mother usually becomes sensitized during the first few days after delivery, when fetal Rh-positive red cells from the placental site are released into the maternal circulation. Because the antibodies take several weeks to develop, the first Rh-positive infant of an Rh-negative mother usually is not affected. Infants with Rh-negative blood have no antigens on their red cells to react with the maternal antibodies and are not affected.

After an Rh-negative mother has been sensitized, the Rh antibodies from her blood are transferred to subsequent infants through the placental circulation. These antibodies react with the red cell antigens of the Rh-positive fetus, causing agglutination and hemolysis. This leads to severe anemia with compensatory hyperplasia and enlargement of the blood-forming organs, including the spleen and liver, in the fetus. Liver function may be impaired, with decreased production of albumin causing massive edema, called *hydrops fetalis.* If blood levels of unconjugated bilirubin are abnormally high because of red cell hemolysis, there is a danger of kernicterus developing in the infant, resulting in severe brain damage or death.

Several advances significantly decreased the threat to infants born to Rh-negative mothers: prevention of sensitization, antenatal identification of the at-risk fetus, and intrauterine transfusion to the affected fetus. The injection of Rh immune globulin (i.e., γ-globulin containing Rh antibody) prevents sensitization in Rh-negative mothers who have given birth to Rh-positive infants if administered at 28 weeks gestation and within 72 hours of delivery, abortion, genetic amniocentesis, or fetal-maternal bleeding. After sensitization has developed, the immune globulin is of no value. Fetal Rh phenotyping can now be performed to identify at-risk fetuses in the first trimester using fetal blood or amniotic cells.29 Hemolysis in these fetuses can be treated by intrauterine transfusions of red cells through the umbilical cord. Exchange transfusions are administered after birth by removing and replacing the infant’s blood volume with type O Rh-negative blood. The exchange transfusion removes most of the hemolyzed red cells and some of the total bilirubin, treating the anemia and hyperbilirubinemia.

### Red Cell Changes in the Elderly

Anemia is an increasingly common health problem in the elderly, affecting approximately one fourth of all 80-year-olds and half of the chronically ill elderly.30,31 Its prevalence is known to increase with age, with the highest incidence in men aged 85 years and older. Undiagnosed and untreated anemia can have severe consequences and is associated with increased risk of mortality, cardiovascular disease, lower functional ability, self-care deficits, cognitive disorders, and reduced bone density that increases the risk for fractures with falls.30

Hemoglobin levels decline after middle age. In studies of men older than 60 years of age, mean hemoglobin levels ranged from 15.3 to 12.4 g/dL, with the lowest levels found in the oldest persons. The decline is less in women, with mean levels ranging from 13.8 to 11.7 mg/dL.30 In most asymptomatic elderly persons, lower hemoglobin levels result from iron deficiency and anemia of chronic disease.

As with other body systems, the capacity for red cell production changes with aging. The location of bone cells involved in red cell production shifts toward the axial skeleton, and the number of progenitor cells declines from approximately 50% at age 65 to approximately 30% at age 75.32 Despite these changes, the elderly are usually able to maintain hemoglobin and hematocrit levels within a range similar to that of younger adults. However, during a stress situation such as bleeding, the red blood cells of the elderly are not replaced as promptly as those of their younger counterparts. This inability to replace red blood cells closely correlates with the increased prevalence of anemia in the elderly.

Although the age-associated decline in the hematopoietic reserve in the elderly is not completely understood, several factors seem to play a role, including a reduction...
in hematopoietic progenitors, reduced production of hematopoietic growth factors, and inhibition of erythropoietin or its interaction with its receptors. Inflammatory cytokines, which have been found to increase with age, may mediate this reduced sensitivity to erythropoietin.

The diagnosis of anemia in the elderly requires a complete physical examination, a complete blood count, and studies to rule out comorbid conditions such as malignancy, gastrointestinal conditions that cause bleeding, and pernicious anemia. The complete blood count should include a peripheral blood smear and a reticulocyte count and index. If the reticulocyte index is appropriately increased for the level of anemia, then decreased red cell production is presumed. If the reticulocyte index is inappropriately low, then blood loss or red cell destruction should be suspected. If the reticulocyte index is inappropriately low, then decreased red cell production is presumed.

The treatment of anemia in the elderly should focus on the underlying cause and correction of the red cell deficit. An important aspect of anemia of chronic disease is the inability to use and mobilize iron effectively. Orally administered iron is poorly used in older adults, despite normal iron absorption. Although erythropoietin remains the treatment of choice for anemias associated with cancer and renal disease, its potential use in treating anemias associated with aging remains to be established.

**SUMMARY CONCEPTS**

- The red blood count along with hemoglobin concentration changes from being high at birth, reflecting the in-utero need for oxygen, to declining in the elderly due to a decrease in the replacement ability of red cells.
- During the early neonatal period, there is a shift from fetal to adult hemoglobin. Many infants have physiologic jaundice because of hyperbilirubinemia during the 1st week of life, related to the increase in red blood cell breakdown and the inability of the infant’s liver to conjugate bilirubin.
- Hemolytic disease of the newborn occurs in Rh-positive infants of Rh-negative mothers who have been sensitized. It involves hemolysis of an infant’s red cells in response to maternal Rh antibodies that have crossed the placenta.
- Anemia is an increasingly common health problem in the elderly. Although most elderly persons are able to maintain their hemoglobin and hematocrit levels within a normal range, they are unable to replace their red cells as promptly as their younger counterparts during a stress situation such as bleeding.

**REVIEW EXERCISES**

1. A 29-year-old woman complains of generalized fatigue. Her physical examination reveals a heart rate of 115 beats/minute, blood pressure of 115/75 mmHg, and respiratory rate of 28 breaths/minute. Her skin and nail beds are pale. Her laboratory results include red blood cell count $3.0 \times 10^{12}/\mu L$, hemoglobin 9 g/dL, hematocrit 20%, and a decrease in serum ferritin levels.

   A. What disorder do you suspect this woman has?
   B. What additional data would be helpful in determining the etiology of her condition?
   C. Which of her signs reflect the body’s attempt to compensate for the disorder?
   D. What is the significance of the low ferritin level, and how could it be used to make decisions related to her treatment?

2. A 65-year-old woman is seen in the clinic because of numbness in her lower legs and feet and difficulty walking. She has no other complaints. She takes a blood pressure pill, two calcium pills, and a multivitamin pill daily. Her laboratory results include red blood cell count $3.0 \times 10^{12}/\mu L$, hemoglobin 9 g/dL, hematocrit 20%, and a markedly elevated MVC.

   A. What type of anemia does she have?
   B. What is the reason for her neurologic symptoms?
   C. What type of treatment would be appropriate?

3. A 12-year-old boy with sickle cell disease presents in the emergency department with severe chest pain. His mother reports that he was doing well until he came down with a respiratory tract infection. She also states he insisted on playing basketball with the other boys in the neighborhood even though he wasn’t feeling well.

   A. What is the most likely cause of pain in this boy?
   B. Infections and aerobic-type exercise produce sickling in persons who are homozygous for the sickle cell gene and have sickle cell disease, but not in persons who are heterozygous and have sickle cell trait. Explain.
   C. People with sickle disease experience anemia but not iron deficiency. Explain.

- Study Guide for Essentials of Pathophysiology
All living creatures share two basic objectives in life: survival and reproduction. This doctrine applies equally to bacteria, viruses, fungi, and protozoa. To satisfy these goals, organisms must extract from the environment essential nutrients for growth and proliferation; for countless microscopic organisms, that environment includes the human body.

The content in this chapter has been divided into four parts: (1) general concepts of infectious diseases, (2) epidemiology of infectious diseases, (3) general principles of diagnosis and treatment, and (4) new and emerging infectious diseases.

**General Concepts of Infectious Diseases**

Normally, the contact between humans and microorganisms is incidental and, in certain situations, may actually benefit both organisms. Under extraordinary circumstances, however, the invasion of the human body by microorganisms can produce harmful and potentially lethal consequences. The consequences of these invasions are collectively called *infectious diseases*.

**Terminology**

All scientific disciplines evolve with a distinct vocabulary, and the study of infectious diseases is no exception. The most appropriate way to approach this subject is...
with a brief discussion of the terminology used to characterize interactions between humans and microbes.

Any organism capable of supporting the nutritional and physical growth requirements of another is called a host. Throughout this chapter, the term host most often refers to humans supporting the growth of microorganisms. Occasionally, infection and colonization are used interchangeably. However, the term infection describes the presence and multiplicity within another living organism, with subsequent injury to the host, whereas colonization describes the act of establishing a presence, a step required in the multifaceted process of infection.

One common misconception should be dispelled from the start: not all interactions between microorganisms and humans are detrimental—in fact, most are beneficial. The internal and external exposed surfaces of the human body are normally and harmlessly inhabited by a multitude of bacteria, collectively referred to as the normal microflora. Although the colonizing bacteria acquire nutritional support from the host, the host is not adversely affected by the relationship. An interaction such as this is called mutualism, and the colonizing microorganisms are sometimes referred to as commensal flora. The term mutualism is applied to an interaction in which the microorganism and the host both derive benefits from the interaction. For example, certain inhabitants of the human intestinal tract extract nutrients from the host and secrete essential vitamin by-products of metabolism (e.g., vitamin K) that are absorbed and used by the host. A parasitic relationship is one in which only the infecting organism benefits from the relationship and the host either gains nothing from the relationship or sustains injury from the interaction. An infectious disease occurs if the host sustains injury in a parasitic relationship.

The severity of an infectious disease can range from mild to life-threatening depending on many variables, including the health of the host at the time of infection and the virulence (disease-producing potential) of the microorganism. A select group of microorganisms called pathogens are so virulent that they are rarely found in the absence of disease. Fortunately, there are few human pathogens in the microbial world. Most microorganisms are harmless saprophytes, free-living organisms obtaining their growth from dead or decaying organic material in the environment. However, all microorganisms, even saprophytes and members of the normal flora, can be opportunistic pathogens capable of producing an infectious disease when the health and immunity of the host have been severely weakened by illness, malnutrition, or medical therapy.

Agents of Infectious Disease

The agents of infectious disease include prions, viruses, bacteria, Rickettsiaceae and Chlamydiaceae, fungi, and parasites. A summary of the salient characteristics of these human microorganisms is provided in Table 14-1.

Prions

Can a protein alone cause a transmissible infectious disease? Prior to the discovery of prions, scientists assumed that all infectious agents must possess a genetic master plan (a genome of either ribonucleic acid [RNA] or deoxyribonucleic acid [DNA]) that codes for the production of the essential proteins and enzymes necessary for survival and reproduction. Prions, protein particles that lack any kind of a demonstrable genome, appear to be an exception to this rule. A number of prion-associated diseases have been identified, including Creutzfeldt-Jakob disease in humans, chronic wasting disease in deer and elk, scrapie in sheep, and bovine spongiform encephalopathy (BSE or mad cow disease) in cattle. The various prion-associated diseases produce very similar pathologic processes and symptoms in the hosts and are collectively called transmissible neurodegenerative diseases. All are characterized by a slowly progressive, noninflammatory neuronal degeneration, leading to loss of coordination (ataxia), dementia, and death over a period ranging from months to years.
The prion protein (PrP) is a human protein expressed on the cell surface. Its normal role is not well understood, but it is hypothesized to be involved in cell adhesion, cell binding, copper metabolism, or synaptic function.

Recent studies have shown that the prion proteins in disease (called PrP^{Sc}) are actually altered or mutated forms of a normal host protein called PrP^{C}. Differences in the posttranslational structure cause the two proteins to behave differently. The PrP^{Sc} is resistant to the action of proteases (enzymes that degrade excess or deformed proteins) and aggregates in the cytoplasm of affected neurons as amyloid fibrils. The normal PrP^{C} is protease sensitive and appears on the cell surface.

Prion diseases present significant problems to the medical community because their method of replication is not clearly understood. Based on current models, it is believed that PrP^{Sc} binds to the normal PrP^{C} on the cell surface, causing it to be processed into PrP^{Sc}, which is released from the cell and then aggregates into amyloid-like plaques in the brain. The cell then replenishes the PrP^{C} and the cycle continues. As PrP^{Sc} accumulates, it spreads within the axons of the nerve cells, causing progressively greater damage to host neurons and the eventual incapacitation of the host. In addition, because prions lack reproductive and metabolic functions, the currently available antimicrobial agents are useless against them.

**Viruses**

Viruses are the smallest obligate intracellular pathogens. They have no organized cellular structures but instead consist of a protein coat, or capsid, surrounding a nucleic acid core, or genome, of RNA or DNA—never both (Fig. 14-1). Some viruses are enclosed within a lipoprotein envelope derived from the cell membrane of the parasitized host cell. Enveloped viruses include members of the herpesvirus group and paramyxoviruses, such as influenza and poxviruses. Certain viruses, enveloped in buds pinched from the cell membrane, are continuously shed from the infected cell surface.

The viruses of humans and animals have been categorized somewhat arbitrarily according to various characteristics. These include the type of viral genome (single-stranded or double-stranded DNA or RNA), physical characteristics (e.g., size, presence or absence of a membrane envelope), the mechanism of replication (e.g., retroviruses), the mode of transmission (e.g., arthropod-borne viruses, enteroviruses), target tissue, and the type of disease produced (e.g., hepatitis A, B, C, D, and E viruses), to name just a few.

Viruses are incapable of replication outside of a living cell. They must penetrate a susceptible living cell and use the biosynthetic machinery of the cell to produce viral progeny. The process of viral replication is shown in Figure 14-2. Not every viral agent causes lysis and death of the host cell during the course of replication. Some viruses enter the host cell and insert their genome into the host cell chromosome, where it remains in a latent state for long periods without causing disease. Under the appropriate stimulation, the virus undergoes active replication and produces symptoms of disease months to years later. Members of the herpesvirus group and adenovirus are the best examples of latent viruses. Herpesviruses include the viral agents of chickenpox and zoster (varicella-zoster), cold sores (herpes simplex virus [HSV], usually type 1), genital herpes (HSV, usually type 2), infectious mononucleosis (cytomegalovirus or Epstein-Barr virus), and Kaposi sarcoma (human herpesvirus 8). The resumption of the latent viral replication may produce symptoms of primary disease (e.g., genital herpes) or cause an entirely different symptomatology (e.g., shingles instead of chickenpox).

Since the early 1980s, members of the retrovirus group have received considerable attention after identification of the human immunodeficiency viruses (HIV) as the causative agent of acquired immunodeficiency syndrome (AIDS). The retroviruses have a unique mechanism of replication. After entry into the host cell, the viral RNA genome is first translated into DNA by a viral enzyme called reverse transcriptase (see Chapter 16). The viral DNA copy is then integrated into the host chromosome where it exists in a latent state, similar to the herpesviruses. Reactivation and replication require a reversal of the entire process. Some retroviruses lyse the host cell during the process of replication. In the case of HIV, the infected cells regulate the immunologic defense system of the host and their lysis leads to a permanent suppression of the immune response.

In addition to causing infectious diseases, certain viruses also have the ability to transform normal host cells into malignant cells during the replication cycle. This group of viruses is referred to as oncogenic and includes certain retroviruses and DNA viruses, such as...
the Epstein-Barr virus, hepatitis B virus, and human papillomavirus (see Chapter 7).

**Bacteria**

Bacteria are autonomously replicating unicellular organisms known as *prokaryotes* because they lack an organized nucleus. Compared with nucleated eukaryotic cells (see Chapter 1), the bacterial cell is small and structurally primitive (Fig. 14-3). Similar to eukaryotic cells but unlike viruses, bacteria contain both DNA and RNA, although their genome is considerably smaller than eukaryotes and typically is encoded on a single chromosome. Many bacteria transiently harbor smaller extrachromosomal pieces of circular DNA called *plasmids*. Occasionally, plasmids contain genetic information that increases the virulence or antibiotic resistance of the organism.

The prokaryotic cell is organized into an internal compartment called the *cytoplasm*, which contains the reproductive and metabolic machinery of the cell. The cytoplasm is surrounded by a flexible lipid membrane, called the *cytoplasmic membrane*. This in turn is enclosed within a rigid cell wall. The structure and synthesis of the cell wall determine the microscopic shape of the bacterium (e.g., spherical [coccicci], helical [spirilla], or elongate [bacilli], Fig. 14-4). Most bacteria produce a cell wall composed of a distinctive polymer known as *peptidoglycan*. This polymer is produced only by prokaryotes and is therefore an attractive target for antibacterial therapy. For example, the penicillin antibiotics target the peptidoglycan cell wall. Several bacteria synthesize an extracellular capsule composed of protein or carbohydrate. The capsule protects the organism from environmental hazards such as the immunologic defenses of the host.

Certain bacteria are motile as the result of external whip-like appendages called *flagella*. The flagella rotate like a propeller, transporting the organism through a liquid environment. Bacteria can also produce hairlike structures projecting from the cell surface called *pili* or *fimbriae*, which enable the organism to adhere to surfaces such as mucous membranes or other bacteria.

**Reproduction.** Most prokaryotes reproduce asexually by simple cellular division. The manner in which an organism divides can influence the microscopic morphology. For instance, when the cocci divide in chains, they are called *streptococci*; in pairs, *diplococci*; and in clusters, *staphylococci* (Fig. 14-5). The growth rate of bacteria varies significantly among different species and depends greatly on physical growth conditions and the availability of nutrients. In the laboratory, a single bacterium placed in a suitable growth environment, such as an agar plate, reproduces to the extent that it forms a

visible colony composed of millions of bacteria within a few hours.

In nature, however, bacteria rarely exist as single cells floating in an aqueous environment. Rather, bacteria prefer to stick to and colonize environmental surfaces, producing structured communities called biofilms (Fig. 14-6). The organization and structure of biofilms permit access to available nutrients and elimination of metabolic waste. Within the biofilm, individual organisms use chemical signaling as a form of primitive intercellular communication to represent the state of the environment. These signals inform members of the community when sufficient nutrients are available for proliferation or when environmental conditions warrant dormancy or evacuation. Examples of biofilms abound in nature and are found on the surfaces of aquatic environments, in the human oral cavity, on indwelling medical devices, and on human cells. One has only to

Bacteria are extremely adaptable life forms. They are found not just in humans and other hosts, but in almost every environmental extreme on earth. However, each individual bacterial species has a well-defined set of growth parameters, including nutrition, temperature, light, humidity, and atmosphere. Bacteria with extremely strict growth conditions are called fastidious. For example, Neisseria gonorrhoeae, the bacterium that causes gonorrhea, cannot live for extended periods outside the human body. Aerobes are bacteria that require oxygen for growth and metabolism; anaerobes cannot survive in an oxygen-containing environment. An organism capable of adapting its metabolism to aerobic or anaerobic conditions is facultatively anaerobic. It is of interest to note that the vast majority of bacterial species found in humans and in the surrounding environment have not been cultivated on artificial media.

In the laboratory, bacteria are generally classified according to the microscopic appearance and staining properties of the cell. The Gram stain, originally developed in 1884 by Danish bacteriologist Christian Gram, is still the most widely used staining procedure. Bacteria are designated as gram-positive organisms if they are stained purple by a primary basic dye (usually crystal violet); those that are not stained by the crystal violet but are counterstained red by a second dye (safranin) are called gram-negative organisms. Staining characteristics and microscopic morphology are used in combination to describe bacteria. For example, Streptococcus pyogenes, the agent of pharyngitis and rheumatic fever, is a gram-positive streptococcal organism that is spherical, grows in chains, and stains purple by Gram stain. Legionella pneumophila, the bacterium responsible for Legionnaire’s disease, is a gram-negative rod.

Another means of classifying bacteria according to microscopic staining properties is the acid-fast stain. Because of the unique fatty acid content and composition of their cell membrane, certain bacteria are resistant to the decolorization of a primary stain (either carbol fuchsin or a combination of auramine and rhodamine) when treated with a solution of acid alcohol. These organisms are termed acid-fast and include a number of significant human pathogens, most notably Mycobacterium tuberculosis (the cause of tuberculosis) and other mycobacteria.

For purposes of taxonomy (i.e., identification and classification), each member of the bacterial kingdom is categorized into a small group of genetically related organisms called the genus, and further subdivided into distinct individuals within the genus called species. The genus and species assignment of the organism is reflected in its name (e.g., Staphylococcus [genus] aureus [species]).

Spirochetes. The spirochetes are an eccentric category of bacteria that are mentioned separately because of their unusual cellular morphology and distinctive mechanism of motility. Technically, the spirochetes are gram-negative rods but are unique in that the cell’s shape is helical and the length of the organism is many times its width (Fig. 14-7). A series of filaments are wound about the cell wall and extend the entire length of the cell. These filaments propel the organism through an aqueous environment in a corkscrew motion.

Spirochetes are composed of four genera: Leptospira, Borrelia, Treponema, and Brachyspira. Each genus has saprophytic and pathogenic strains. The pathogenic leptospiries infect a wide variety of wild and domestic animals. Infected animals shed the organisms into the environment through the urinary tract. Transmission to humans occurs by contact with infected animals or urine-contaminated surroundings. Leptospiries gain access to the host directly through mucous membranes or breaks in the skin and can produce a severe and potentially fatal illness called Weil syndrome. In contrast, the borreliae are transmitted from infected animals to humans through the bite of an arthropod vector such as lice or ticks. (A vector is any organism that carries a pathogen from a source to a host.) Included in the genus Borrelia are the agents of relapsing fever (Borrelia recurrentis) and Lyme disease (Borrelia burgdorferi). Included in the genus Borrelia are the agents of relapsing fever (Borrelia recurrentis) and Lyme disease (Borrelia burgdorferi) is the most common in North America.

**FIGURE 14-6.** Electron micrograph depicting large numbers of Staphylococcus aureus bacteria, which were found on the luminal surface of an indwelling catheter. Of importance are the sticky-looking substances woven between the round cocci bacteria, which were composed of polysaccharides and are known as biofilm. This biofilm has been found to protect the bacteria that secrete the substance from attacks by antimicrobial agents such as antibiotics (magnified × 2363). (From the Centers for Disease Control and Prevention Public Health Images Library. No. 7488. Courtesy of Rodney M. Donlan, Janice Carr.)
Pathogenic Treponema species require no intermediates and are spread from person to person by direct contact. The most important member of the genus is Treponema pallidum, the causative agent of syphilis.

Mycoplasmas. The mycoplasmas are unicellular prokaryotes capable of independent replication. These organisms are less than one-third the size of bacteria and contain a small DNA genome approximately one-half the size of the bacterial chromosome. The cell is composed of cytoplasm surrounded by a membrane, but, unlike bacteria, the mycoplasmas do not produce a rigid peptidoglycan cell wall. As a consequence, the microscopic appearance of the cell is highly variable, ranging from coccoid forms to filaments, and the mycoplasmas are resistant to cell wall–inhibiting antibiotics such as penicillins and cephalosporins. The mycoplasmas affecting humans are divided into three genera: Mycoplasma, Ureaplasma, and Acholeplasma. The first two require cholesterol from the environment to produce the cell membrane; the acholeplasmas do not. In the human host, mycoplasmas are commensals. However, a number of species are capable of producing serious diseases, including pneumonia (Mycoplasma pneumoniae), genital infections (Mycoplasma hominis and Ureaplasma urealyticum), and maternally transmitted respiratory infections to infants with low birth weight (U. urealyticum).

Rickettsiaceae, Anaplasmataceae, Chlamydiaceae, and Coxiella

This interesting group of organisms combines the characteristics of viral and bacterial agents to produce disease in humans. All are obligate intracellular pathogens, like the viruses, but produce a rigid peptidoglycan cell wall, reproduce asexually by cellular division, and contain RNA and DNA, similar to the bacteria. The Rickettsiaceae depend on the host cell for essential vitamins and nutrients, but the Chlamydiaceae appear to scavenge intermediates of energy metabolism such as adenosine triphosphate (ATP). The Rickettsiaceae infect but do not produce disease in the cells of certain arthropods such as fleas, ticks, and lice. The organisms are accidentally transmitted to humans through the bite of the arthropod (i.e., the vector) and produce a number of potentially lethal diseases, including Rocky Mountain spotted fever and epidemic typhus.

The Chlamydiaceae are slightly smaller than the Rickettsiaceae but are structurally similar and are transmitted directly between susceptible vertebrates without an intermediate arthropod host. Transmission and replication of Chlamydiaceae occur through a defined life cycle. The infectious form, called an elementary body, attaches to and enters the host cell, where it transforms into a larger reticulate body. This undergoes active replication into multiple elementary bodies, which are then shed into the extracellular environment to initiate another infectious cycle. Chlamydial diseases of humans include sexually transmitted genital infections (Chlamydia trachomatis; see Chapter 41); ocular infections and pneumonia of newborns (C. trachomatis); and respiratory disease acquired from infected birds (Chlamydia psittaci).

Organisms within the family Anaplasmataceae (including the reorganized genera Ehrlichia, Anaplasma, Neorickettsia, and Wolbachia) are also obligate intracellular organisms that resemble the Rickettsiaceae in structure and produce a variety of veterinary and human diseases, some of which have a tick vector. These organisms target host mononuclear and polymorphonuclear white blood cells for infection and, similar to the Chlamydiaceae, multiply in the cytoplasm of infected leukocytes within vacuoles called morulae. Unlike the Chlamydiaceae, however, the Anaplasmataceae do not have a defined life cycle and are independent of the host cell for energy production. The most common infections caused by Anaplasmataceae are human monocytic and granulocytic ehrlichiosis. Human monocytic ehrlichiosis is a disease caused by Ehrlichia chaffeensis that can easily be confused with Rocky Mountain spotted fever. Clinical disease severity ranges from mild to life-threatening. Manifestations include generalized malaise, anorexia and nausea, fever, and headache. Decreases in white blood cells (leukopenia) and platelets (thrombocytopenia) often occur. Severe sequelae include severe respiratory failure, encephalopathy, and acute renal failure. The disease is usually more severe in the elderly and persons with compromised immune function (e.g., those with HIV/AIDS). Human granulocytic ehrlichiosis is also transmitted by ticks, but is caused by Anaplasma phagocytophilum. The symptoms are similar to those seen with human monocytic ehrlichiosis.
The genus *Coxiella* contains only one species, *Coxiella burnetii*. Like its rickettsial counterparts, it is a gram-negative intracellular organism that infects a variety of animals, including cattle, sheep, and goats. In humans, *Coxiella* infection produces a disease called *Q* fever, characterized by a nonspecific febrile illness often accompanied by headache, chills, arthralgias, and mild pneumonia. The organism produces a highly resistant sporelike stage that is transmitted to humans when contaminated animal tissue is aerosolized (e.g., during meat processing) or by ingestion of contaminated milk.

**Fungi**

The fungi are free-living, eukaryotic saprophytes found in every habitat on earth. Some are members of the normal human microflora. Fortunately, few fungi are capable of causing diseases in humans, and most of these are incidental, self-limited infections of skin and subcutaneous tissue. Serious fungal infections are rare and usually initiated through puncture wounds or inhalation. Despite their normally harmless nature, fungi can cause life-threatening opportunistic diseases when host defense capabilities have been disabled.

The fungi can be separated into two groups, yeasts and molds, based on rudimentary differences in their morphology (Fig. 14-8). The yeasts are single-celled organisms, approximately the size of red blood cells that reproduce by a budding process. The buds separate from the parent cell and mature into identical daughter cells. Molds produce long, hollow, branching filaments called *hyphae*. Some molds produce cross-walls (called septations), which segregate the hyphae into compartments, and others do not. A limited number of fungi are capable of growing as yeasts at one temperature and as molds at another. These organisms are called *dimorphic fungi* and include a number of human pathogens such as the agents of blastomycosis (*Blastomyces dermatitidis*) and histoplasmosis (*Histoplasma capsulatum*).

The appearance of a fungal colony tends to reflect its cellular composition. Colonies of yeast are generally smooth with a waxy or creamy texture. Molds tend to produce cottony or powdery colonies composed of mats of hyphae collectively called a *mycelium*. The mycelium can penetrate the growth surface or project above the colony like the roots and branches of a tree. Yeasts and molds produce a rigid cell wall layer that is chemically unrelated to the peptidoglycan of bacteria and is therefore not susceptible to the effects of penicillin-like antibiotics.

Most fungi are capable of sexual or asexual reproduction. The former process involves the fusion of zygotes with the production of a recombinant zygospore. Asexual reproduction involves the formation of highly resistant spores called *conidia* or *sporangiospores*, which are borne by specialized structures that arise from the hyphae. Molds are identified in the laboratory by

![Figure 14-8](image-url)
the characteristic microscopic appearance of the asexual fruiting structures and spores.

Like the bacterial pathogens of humans, fungi can produce disease in the human host only if they can grow at the temperature of the infected body site. For example, a number of fungal pathogens called dermatophytes are incapable of growing at core body temperature (37°C), and the infection is limited to the cooler cutaneous surfaces. Diseases caused by these organisms, including ringworm, athlete’s foot, and jock itch, are collectively called superficial mycoses. Systemic mycoses are serious fungal infections of deep tissues and, by definition, are caused by organisms capable of growth at 37°C. Yeasts such as Candida albicans are commensal flora of the skin, mucous membranes, and gastrointestinal tract and are capable of growth at a wider range of temperatures. Intact immune mechanisms and competition for nutrients provided by the bacterial flora normally keep colonizing fungi in check. Alterations in either of these components by disease states or antibiotic therapy can upset the balance, permitting fungal overgrowth and setting the stage for opportunistic infections.

Parasites

In a strict sense, any organism that derives benefits from its biologic relationship with another organism is a parasite. In the study of clinical microbiology, however, the term parasite has evolved to designate members of the animal kingdom that infect and cause disease in other animals and includes protozoa, helminths, and arthropods.

The protozoa are unicellular animals with a complete complement of eukaryotic cellular machinery, including a well-defined nucleus and organelles. Reproduction may be sexual or asexual, and life cycles may be simple or complicated, with several maturation stages requiring more than one host for completion. Most are saprophytes, but a few have adapted to the accommodations of the human environment and produce a variety of diseases, including malaria, amebic dysentery, and giardiasis. Protozoan infections can be passed directly from host to host through sexual contact, indirectly through contaminated water or food, or by way of an arthropod vector. Direct or indirect transmission results from the ingestion of highly resistant cysts or spores that are shed in the feces of an infected host. When the cysts reach the intestine, they mature into vegetative forms called trophozoites, which are capable of asexual reproduction or cyst formation. Most trophozoites are motile by means of flagella, cilia, or ameboid motion.

The helminths are a collection of wormlike parasites that include the nematodes or roundworms, cestodes or tapeworms, and trematodes or flukes. The helminths reproduce sexually within the definitive host, and some require an intermediate host for the development and maturation of offspring. Humans can serve as the definitive or intermediate host or, in certain diseases such as trichinosis, as both. Transmission of helminth diseases occurs primarily through the ingestion of fertilized eggs (ova) or the penetration of infectious larval stages through the skin—directly or with the aid of an arthropod vector. Helminth infections can involve many organ systems and sites, including the liver and lung, urinary and intestinal tracts, circulatory and central nervous systems, and muscle. Although most helminth diseases have been eradicated from the United States, they are still a major health concern of developing nations.

The parasitic arthropods of humans and animals include the vectors of infectious diseases (e.g., ticks, mosquitoes, biting flies) and the ectoparasites. The ectoparasites infest external body surfaces and cause localized tissue damage or inflammation secondary to the bite or burrowing action of the arthropod. The most prominent human ectoparasites are mites (scabies), chiggers, lice (head, body, and pubic), and fleas. Transmission of ectoparasites occurs directly by contact with immature or mature forms of the arthropod or its eggs found on the infested host or the host’s clothing, bedding, or grooming articles such as combs and brushes. Many of the ectoparasites are vectors of other infectious diseases, including endemic typhus and bubonic plague.

**SUMMARY CONCEPTS**

- Throughout life, humans are continuously and harmlessly exposed to and colonized by a multitude of microscopic organisms. This relationship is kept in check by the intact defense mechanisms of the host (e.g., mucosal and cutaneous barriers, normal immune function) and the innocuous nature of most environmental microorganisms.

- The agents of infectious disease represent a diversity of microorganisms that are usually not visible to the human eye. The term infection describes the presence and injurious multiplication of an infectious agent within a human host, whereas colonization describes the act of establishing a presence, a step required in the multifaceted process of infection.

- Microorganisms can be separated into eukaryotes (fungi and parasites), organisms containing a membrane-bound nucleus; and prokaryotes (bacteria), organisms in which the nucleus is not separated. Both eukaryotes and prokaryotes are organisms because they contain all the biologic equipment necessary for replication and metabolism.

- Viruses, which are the smallest pathogens, have no organized cellular structure, but consist of a protein coat surrounding a nucleic acid core of DNA or RNA. Unlike eukaryotes and prokaryotes, viruses are incapable of replication outside of a living cell.

(continued)
SUMMARY CONCEPTS (continued)

- Bacteria are autonomously replicating unicellular organisms known as prokaryotes because they lack an organized nucleus. Most bacteria produce a cell wall that is produced only by prokaryotes and is therefore an attractive target for antibacterial therapy.

- The Rickettsiaceae, Anaplasmataceae, Chlamydiaceae, and Coxiella are obligate intracellular pathogens, like the viruses, but produce a rigid peptidoglycan cell wall, reproduce asexually by cellular division, and contain RNA and DNA, similar to the bacteria. Chlamydial diseases include sexually transmitted genital infections, neonatal and adult conjunctivitis, and infant pneumonia.

- Fungi are free-living, eukaryotic saprophytes, some of which are members of the normal human microflora. Fortunately, few fungi are capable of causing diseases in humans, and most of these are incidental, self-limited infections of skin and subcutaneous tissue. Despite their normally harmless nature, fungi can cause life-threatening opportunistic diseases when host defense capabilities have been disabled.

- Parasites (protozoa, helminths, and arthropods) are members of the animal kingdom that infect or colonize other animals, which then transmit them to humans. In some cases, they directly infect the human host.

Epidemiology of Infectious Diseases

Epidemiologists working in infectious disease study the factors, events, and circumstances that influence the transmission of infectious diseases among humans. The ultimate goal of epidemiologists is to devise strategies that interrupt or eliminate the spread of infectious agents. To accomplish this, they classify infectious diseases according to incidence, portal of entry and source, symptoms, disease course, site of infection, and virulence factors so that potential outbreaks may be predicted and averted or appropriately treated.

Mechanisms of Transmission

The outcomes of infections depend on the ability of microbes to breach host barriers and colonize and damage host tissues. Host barriers to infection prevent the microbes from entering the body and assist innate and adaptive immune defenses in eliminating the agent (see Chapter 15).

Portal of Entry

Microbes can enter the host by direct contact, ingestion, and inhalation. The portal of entry does not dictate the site of infection. Ingested pathogens may penetrate the intestinal mucosa, disseminate through the circulatory system, and cause diseases in other organs such as the lung or liver. Whatever the mechanisms of entry, the transmission of infectious agents is directly related to the number of infectious agents absorbed by the host.

Penetration. Any disruption in the integrity of the body’s surface barrier—skin or mucous membranes—is a potential site for invasion of microorganisms. The break may be the result of an accidental injury causing abrasions, burns, or penetrating wounds; medical procedures such as surgery or catheterization; or a primary infectious process such as chickenpox or impetigo that produces surface lesions. Direct inoculation from intravenous drug use or an animal or arthropod bite also can occur.

Direct Contact. Some pathogens are transmitted directly from infected tissue or secretions to exposed, intact mucous membranes. This is especially true of certain sexually transmitted infections (STIs) such as gonorrhea, syphilis, chlamydia, and genital herpes, for which exposure of uninfected membranes to pathogens occurs during intimate contact (see Chapter 41).

The transmission of STIs is not limited to sexual contact. Vertical transmission of these agents, from mother to child, can occur across the placenta or during birth when the mucous membranes of the child come in contact with infected vaginal secretions of the mother. When an infectious disease is transmitted from mother to child during gestation or birth, it is classified as a congenital infection. The most frequently observed congenital infections include toxoplasmosis (caused by the parasite Toxoplasma gondii), syphilis, rubella, cytomegalovirus infection, and herpes simplex virus infections (the so-called TORCH infections, discussed in Chapter 6); varicella-zoster (chickenpox); parvovirus B19; group B streptococci (Streptococcus agalactiae); and HIV. Of these, cytomegalovirus is by far the most common cause of congenital infection in the United States, affecting nearly 1% of all newborns. However, with more than 500,000 babies contracting HIV from their mother and with a 25% to 30% chance of vertical transmission without appropriate antiretroviral treatment, HIV is rapidly gaining in stature as a congenitally transmitted infection (see Chapter 16).

Ingestion. The entry of pathogenic microorganisms or their toxins through the oral cavity and gastrointestinal tract represents one of the more efficient means of disease transmission in humans. Many bacterial, viral, and parasitic infections, including cholera, typhoid fever, dysentery (amebic and bacillary), food poisoning, traveler’s diarrhea, cryptosporidiosis, and hepatitis A, are initiated through the ingestion of contaminated food and water. This mechanism of transmission necessitates
that an infectious agent survive the low pH and enzyme activity of gastric secretions and the peristaltic action of the intestines in numbers sufficient to establish infection, deemed an infectious dose. Ingested pathogens also must compete successfully with the normal bacterial flora of the bowel for nutritional needs. Persons with reduced gastric acidity because of disease or medication are more susceptible to infection by ingestion because the number of ingested microorganisms surviving the gastric environment is greater. Ingested pathogens also must compete successfully for nutrients with the normal bacterial flora of the colon. Ingestion has also been postulated as a means of transmission of HIV infection from mother to child through breast-feeding.

Inhalation. The respiratory tract of a healthy person is equipped with a multilayered defense system to prevent potential pathogens from entering the lungs. The surface of the respiratory tree is lined with a layer of mucus that is continuously swept up and away from the lungs and toward the mouth by the beating motion of ciliated epithelial cells. Humidification of inspired air increases the size of aerosolized particles, which are effectively filtered by the mucous membranes of the upper respiratory tract. Coughing also aids in the removal of particulate matter from the lower respiratory tract. Respiratory secretions contain antibodies and enzymes capable of inactivating infectious agents. Particulate matter and microorganisms that ultimately reach the lungs are cleared by phagocytic cells.

Despite this impressive array of protective mechanisms, a number of pathogens can invade the human body through the respiratory tract, including agents of bacterial pneumonia (Streptococcus pneumoniae, L. pneumophila), meningitis (Neisseria meningitidis, Haemophilus influenzae), and tuberculosis, as well as the viruses responsible for measles, mumps, chickenpox, influenza, and the common cold. Defective pulmonary function or mucociliary clearance caused by noninfectious processes such as cystic fibrosis, emphysema, or smoking can increase the risk of inhalation-acquired diseases.

Source

The source of an infectious disease refers to the location, host, object, or substance from which the infectious agent was acquired: essentially the “who, what, where, and when” of disease transmission. The source may be endogenous (acquired from the host’s own microbial flora, as would be the case in an opportunistic infection) or exogenous (acquired from sources in the external environment, such as the water, food, soil, or air). The source of the infectious agent can also be another human being, as from mother to child during gestation (congenital infections); an inanimate object; an animal; or a biting arthropod. Inanimate objects that carry an infectious agent are known as fomites. For example, rhinoviruses and many other nonenveloped viruses can be spread by contact with contaminated fomites such as handkerchiefs and toys. Zoonoses are a category of infectious diseases passed from other animal species to humans. Examples of zoonoses include cat-scratch disease, rabies, and Creutzfeldt-Jakob disease (vCJD). The spread of infectious diseases such as Lyme disease through biting arthropod vectors has already been mentioned.

Source can denote a place. For instance, infections that develop in patients while they are hospitalized are called nosocomial or hospital acquired, and those that are acquired outside of health care facilities are called community acquired. The source may also pertain to the body substance that is the most likely vehicle for transmission, such as feces, blood, body fluids, respiratory secretions, and urine. Infections can be transmitted from person to person through shared inanimate objects (fomites) contaminated with infected body fluids. An example of this mechanism of transmission would include the spread of the HIV and hepatitis B virus through the use of shared syringes by intravenous drug users. Infection can also be spread through a complex combination of source, portal of entry, and vector. Infection with hantavirus pulmonary syndrome is a prime example. This viral illness is transmitted from mice to humans by inhalation of dust contaminated with saliva, feces, and urine of infected rodents.

Mechanisms of Disease Production

Infectious agents establish infection and damage tissues by entering host cells and directly causing their death; by inducing host responses that, although directed against the invader, cause additional tissue damage; and by generating virulence factors, substances or products generated by infectious agents that enhance their ability to cause disease. Although a large number of microbial products fit this description, they can be grouped into four categories: toxins, adhesion factors, evasive factors, and invasive factors (Table 14-2).

Toxins

Toxins are substances that alter or destroy the normal function of the host or host’s cells. Toxin production is a trait chiefly monopolized by bacterial pathogens, although certain fungal and protozoan pathogens also produce substances toxic to humans. Bacterial toxins have a diverse spectrum of activity and exert their effects on a wide variety of host target cells. For classification purposes, however, the bacterial toxins can be divided into two main types: endotoxins and exotoxins.

Bacterial endotoxins are lipopolysaccharides (LPS) found in the cell wall of gram-negative bacteria. Free LPS attaches to a circulating LPS-binding protein, and the complex then binds to specific leukocyte receptors that participate in activation of the innate immune system (see Chapter 15). The host response to low levels of LPS induces many important cytokines, as well as expression of costimulatory molecules, resulting in leukocyte recruitment and enhancement of T-lymphocyte activation. However, at high levels, LPS can precipitate septic shock, disseminated intravascular coagulation, and acute respiratory distress syndrome.

**Exotoxins** are proteins released from the bacterial cell during growth. Bacterial exotoxins enzymatically inactivate or modify key aspects of host cell structure or function, leading to cell death or dysfunction. Diphtheria toxin, for example, inhibits protein synthesis; botulism toxin decreases the release of neurotransmitter from cholinergic neurons, causing flaccid paralysis; tetanus toxin decreases the release of neurotransmitter from inhibitory neurons, producing spastic paralysis; and cholera toxin induces fluid secretion into the lumen of the intestine, causing diarrhea. Bacterial exotoxins that produce vomiting and diarrhea are sometimes referred to as *enterotoxins*. There has been resurgent interest in streptococcal pyrogenic exotoxin A (SPEA), an exotoxin produced by certain strains of group A, β-hemolytic streptococci (*S. pyogenes*) that causes a life-threatening toxic shock-like syndrome. The syndrome, sometimes called *Henson disease* because this infection caused the death of famous puppeteer Jim Henson, is typified by invasion of the skin and soft tissues, acute respiratory distress syndrome, and renal failure. Other enterotoxins that have gained notoriety include the Shiga toxins produced by *Escherichia coli* O157:H7 (see Chapter 29). The ingestion of undercooked hamburger meat or unpasteurized fruit juices contaminated with this organism produces hemorrhagic colitis and a sometimes fatal illness called *hemolytic uremic syndrome* (HUS), characterized by vascular endothelial damage, acute renal failure, and thrombocytopenia. Hemolytic uremic syndrome occurs primarily in infants and young children who have not developed antibodies to the Shiga toxins.

**Adhesion Factors**

No interaction between microorganisms and humans can progress to infection or disease if the pathogen is unable to attach to and colonize the host. The process of microbial attachment may be site specific (e.g., mucous membranes, skin surfaces), cell specific (e.g., T lymphocytes, respiratory epithelium, intestinal epithelium), or nonspecific (e.g., moist areas, charged surfaces). In any of these cases, adhesion requires a positive interaction between the surfaces of host cells and the infectious agent.

After initial attachment, some bacterial agents become embedded in a gelatinous matrix of polysaccharides called a *slime (or mucous) layer*. The slime layer serves two purposes: it anchors the agent firmly to host tissue surfaces and it protects the agent from the immunologic defenses of the host.

Many viral agents, including influenza, mumps, measles, and adenovirus, produce hair-like appendages or spikes called *fimbriae*. Fimbriae are used by bacteria to attach to one another or attach to cell surfaces. On the distal tips of fimbriae, *hemagglutinins* recognize carbohydrate receptors on the surfaces of specific cells in the host, allowing the bacteria to attach to the host cell in a specific manner.

**Evasion Factors**

A number of factors produced by microorganisms enhance virulence by evading various components of the host’s immune system. Extracellular polysaccharides, including capsules, slime, and mucous layers, discourage engulfment and killing of pathogens by the host’s phagocytic white blood cells (i.e., neutrophils and macrophages). Encapsulated organisms such as *Cryptococcus neoformans*, *S. pneumoniae*, *N. meningitidis*, and *H. influenzae* type b (before the vaccine) are a cause of significant morbidity and mortality in neonates and children who lack protective anticapsular antibodies.

Some bacterial, fungal, and parasitic pathogens avoid phagocytosis by excreting leukocidin C toxins, which cause specific and lethal damage to the cell membrane of host neutrophils and macrophages. Other pathogens, such as the bacterial agents of salmonellosis,
listeriosis, and Legionnaires’ disease, are adapted to survive and reproduce within phagocytic white blood cells after ingestion, avoiding or neutralizing the usually lethal products contained within the lysosomes of the cell. *H. pylori*, the infectious cause of gastritis and gastric ulcers, produces a urease enzyme on its outer cell wall. The urease converts gastric urea into ammonia, thus neutralizing the acidic environment of the stomach and allowing the organism to survive in this hostile environment.

Other unique strategies used by pathogenic microbes to evade immunologic surveillance have evolved solely to avoid recognition by host antibodies. Strains of *S. aureus* produce a surface protein (protein A) that immobilizes immunoglobulin G (IgG), holding the antigen-binding region harmlessly away from the organisms. This pathogen also secretes a unique enzyme called coagulase. Coagulase converts soluble human coagulation factors into a solid clot, which envelops and protects the organism from phagocytosis by host cells and antibodies. *H. influenzae* and *N. gonorrhoeae* secrete enzymes that cleave and inactivate secretory IgA, neutralizing the primary defense of the respiratory and genital tracts at the site of infection. *Borrelia* species, including the agents of Lyme disease and relapsing fever, alter surface antigens during the disease course to avoid immunologic detection.

### Invasion Factors

Infectious agents also produce invasive factors that facilitate the penetration of anatomic barriers and host tissue. Most invasive factors are enzymes capable of destroying cell membranes (e.g., phospholipases), connective tissue (e.g., elastases, collagenases), intercellular matrices (e.g., hyaluronidase), and structural protein complexes (e.g., proteases). The effects of the pathogen’s invasive factors and toxins, combined with the antimicrobial and inflammatory substances released by host cells, mediate the tissue damage and pathophysiology of infectious diseases.

### Clinical Presentation

The term *symptomatology* refers to the collection of signs and symptoms expressed by the host during the disease course. This is also known as the *clinical presentation* and can be characteristic of any given infectious agent. In terms of pathophysiology, symptoms are the outward expression of the struggle between invading organisms and the retaliatory inflammatory and immune responses of the host. The symptoms of an infectious disease may be specific and reflect the site of infection (e.g., diarrhea, rash, convulsions, hemorrhage, and pneumonia). Conversely, symptoms such as fever, myalgia, headache, and lethargy are relatively nonspecific and can be shared by a number of etiologic agents. The symptoms of a diseased host can be obvious, as in the case of chickenpox or measles. Other, covert symptoms, such as an increased white blood cell count, may require laboratory testing to detect. Accurate recognition and documentation of symptomatology can aid in the diagnosis of an infectious disease.

### Site of Infection

Inflammation of an anatomic location is usually designated by adding the suffix *-itis* to the name of the involved tissue (e.g., bronchitis, inflammation of the bronchi and bronchioles; encephalitis, brain inflammation; carditis, inflammation of the heart). These are general terms, however, and they apply equally to inflammation from infectious and noninfectious causes. The suffix *-emia* is used to designate the presence of a substance in the blood (e.g., bacteremia, viremia, and fungemia describe the presence of these infectious agents in the bloodstream). The term *sepsis,* or *septicemia,* refers to the presence of a proven bloodstream infection combined with a systemic immune response.

The site of an infectious disease is ultimately determined by the type of pathogen, the portal of entry, and the competence of the host’s immunologic defense system. Many pathogenic microorganisms are restricted in their capacity to invade the human body. *M. pneumoniae,* influenza viruses, and respiratory syncytial virus rarely cause disease outside the respiratory tract; infections caused by *N. gonorrhoeae* are generally confined to the genitourinary tract; and *Clostridium difficile,* shigellosis, and giardiasis seldom extend beyond the gastrointestinal tract. These are considered localized infectious diseases. The bacterium *Helicobacter pylori* is an extreme example of a site-specific pathogen. *H. pylori* is a significant cause of gastric ulcers but has not been implicated in disease processes elsewhere in the human body. Bacteria such as *N. meningitidis,* a prominent pathogen of children and young adults; *Salmonella typhi,* the cause of typhoid fever, and *B. burgdorferi,* the agent of Lyme disease, tend to disseminate from the primary site of infection to involve other locations and organ systems. These are examples of systemic pathogens disseminated throughout the body by the circulatory system.

An *abscess* is a localized pocket of infection composed of devitalized tissue, microorganisms, and the host’s phagocytic white blood cells: in essence, a stalemate in the infectious process. In this case, the dissemination of the pathogen has been contained by the host, but white cell function within the toxic environment of the abscess is hampered, and the elimination of microorganisms is inhibited. Abscesses usually must be surgically drained to affect a complete cure. Similarly, infections of biomedical implants such as catheters, artificial heart valves, and prosthetic bone implants are seldom cured by the host’s immune response and antimicrobial therapy. The infecting organism colonizes the surface of the implant, producing a dense matrix of cells, host proteins, and capsular material—a *biofilm*—necessitating the removal of the device.
Disease Course

The course of any infectious disease can be divided into several distinguishable stages after the point when the potential pathogen enters the host. These stages are the incubation period, the prodromal stage, the acute stage, the convalescent stage, and the resolution stage (Fig. 14-9). The stages are based on the progression and intensity of the host’s symptoms over time. The duration of each phase and the pattern of the overall illness can be specific for different pathogens, thereby aiding in the diagnosis of an infectious disease.

The incubation period is the phase during which the pathogen begins active replication without producing recognizable symptoms in the host. The incubation period may be short, as in the case of salmonellosis (6 to 24 hours), or prolonged, such as that of hepatitis B (50 to 180 days) or HIV (months to years). The duration of the incubation period can be influenced by additional factors, including the general health of the host, the portal of entry, and the infectious dose of the pathogen.

The hallmark of the prodromal stage is the initial appearance of symptoms in the host, although the clinical presentation during this time may be only a vague sense of malaise. The host may experience mild fever, myalgia, headache, and fatigue. These are constitutional changes shared by a great number of disease processes. The duration of the prodromal stage can vary considerably from host to host.

The acute stage is the period during which the host experiences the maximum impact of the infectious process corresponding to rapid proliferation and dissemination of the pathogen. During this phase, toxic by-products of microbial metabolism, cell lysis, and the immune response mounted by the host combine to produce tissue damage and inflammation. The symptoms of the host are pronounced and more specific than in the prodromal stage, usually typifying the pathogen and sites of involvement.

The convalescent period is characterized by the containment of infection, progressive elimination of the pathogen, repair of damaged tissue, and resolution of associated symptoms. Similar to the incubation period, the time required for complete convalescence may be days, weeks, or months, depending on the type of pathogen and the voracity of the host’s immune response. The resolution is the total elimination of a pathogen from the body without residual signs or symptoms of disease.

Several notable exceptions to the classic presentation of an infectious process have been recognized. Chronic infectious diseases have a markedly protracted and sometimes irregular course. The host may experience symptoms of the infectious process continuously or sporadically for months or years without a convalescent phase. In contrast, subclinical or subacute illness progresses from infection to resolution without clinically apparent symptoms. A disease is called insidious if the prodromal phase is protracted; a fulminant illness is characterized by abrupt onset of symptoms with little or no prodrome. Fatal infections are variants of the typical disease course.

SUMMARY CONCEPTS

- Epidemiology is the study of factors, events, and circumstances that influence the transmission of disease.
- The outcomes of infections depend on the ability of microbes to breach host barriers and colonize and damage host tissues. Microbes can enter the host by direct contact, ingestion, and inhalation. The source of infection may be endogenous (acquired from the host’s own microbial flora, as would be the case in an opportunistic infection) or exogenous (acquired from sources in the external environment, such as the water, food, soil, or air). It can also be another human being, as from mother to child during gestation (congenital infections); an inanimate object; an animal; or a biting arthropod.
- The site of an infectious disease is determined ultimately by the type of pathogen, the portal of entry, and the competence of the host’s immunologic defense system. It may be localized to the site of entry, disseminate from the primary site of infection to involve other locations and organ systems, or travel through the circulatory system to produce disseminated infection.
Diagnosis of Infectious Diseases

The diagnosis of an infectious disease requires two criteria: the recovery of a probable pathogen or evidence of its presence from the infected sites of a diseased host and accurate documentation of clinical signs and symptoms (symptomatology) compatible with an infectious process. In the laboratory, the diagnosis of an infectious agent is accomplished using three basic techniques: culture, serology, or the detection of characteristic antigens, genomic sequences, or metabolites produced by the pathogen.

Culture

Culture refers to the propagation of a microorganism outside of the body, usually on or in artificial growth media such as agar plates or broth (Fig. 14-10). The specimen from the host is inoculated into broth or onto the surface of an agar plate, and the culture is placed in a controlled environment such as an incubator until the growth of microorganisms becomes detectable. In the case of a bacterial pathogen, identification is based on microscopic appearance and Gram stain reaction, shape, texture, and color (i.e., morphology) of the colonies, by a panel of biochemical reactions that fingerprint salient biochemical characteristics of the organism, and by the organism’s protein profile. Certain bacteria such as *Mycobacterium leprae*, the agent of leprosy, and *T. pallidum*, the syphilis spirochete, do not grow on artificial media and require additional methods of identification. Fungi and mycoplasmas are cultured in much the same way as bacteria, but with more reliance on microscopic and colonial morphology for identification.

*Chlamydiaceae*, *Rickettsiaceae*, and all human viruses are obligate intracellular pathogens. As a result, the propagation of these agents in the laboratory requires the inoculation of eukaryotic cells grown in culture (cell cultures). Cell culture is becoming more infrequent in modern clinical laboratories due to the extended time required for growth of viruses and reported poor sensitivity of culture. Diagnosis of viruses, *Chlamydiaceae*, and *Rickettsiaceae* now relies primarily on serology and nucleic acid detection, which will be discussed later in this chapter.

Although culture media have been developed for the growth of certain human-infecting protozoa and helminths in the laboratory, the diagnosis of parasitic infectious diseases has traditionally relied on microscopic or, in the case of worms, visible identification of organisms, cysts, or ova directly from infected patient specimens.

![FIGURE 14-10. Use of agar culture for propagation and identification of microorganisms. (A) Photograph showing numerous Legionella species colonies that have been cultivated on an agar culture plate and illuminated using ultraviolet light. (B) Quantitative differences in hemolytic reactivity seen in trypticase soy agar culture plate containing 5% sheep’s blood growing group D Streptococci (left wedge), group B Streptococci (middle wedge), and group A Streptococci (right wedge) bacteria. The plate was grown under normal atmospheric conditions, at 35°C, for a period of 18 hours. It is important to note that the group B Streptococci (GBS) in the center wedge produced a hemolytic reaction that is less than the reaction produced by group A Streptococci (GAS) in the right wedge of bacterial growth. Hemolysis, which results from destruction of red blood cells, is one of the traits used to help identify the bacteria. organism may appear bright green or orange against

Depending on the type of fluorescent dye used, the
Fluorescent antibodies allow visualization of an infec-
tious process. IgM-specific antibodies generally rise and
fall during the acute phase of the disease, whereas the
synthesis of the IgG class of antibodies increases during
the acute phase and remains elevated until or beyond
resolution.

Measurements of class-specific antibodies are also
useful in the diagnosis of congenital infections. IgM
antibodies do not cross the placenta, but cer-
tain IgG antibodies are transferred passively from
mother to child during the final trimester of gestation.
Consequently, an elevated level of pathogen-specific
IgM antibodies in the serum of a neonate must have
originated from the child and therefore indicates con-
genital infection. A similarly increased IgG titer in
the neonate does not differentiate congenital from
maternal infection.

The technology of direct antigen detection incorpo-
rates features of culture and serology but reduces to a
fraction the time required for diagnosis. In principle,
this method relies on purified antibodies to detect anti-
gens of infectious agents in specimens obtained from
the diseased host. Common sources of these antibod-
ies are hybridomas, cell lines created by fusing normal
antibody-producing spleen cells from an immunized ani-
mal with malignant myeloma cells. The resulting hybrid
synthesizes large quantities of so-called monoclonal
antibodies that are highly specific for a single antigen
and a single pathogen.

The antibodies are labeled with a substance that
allows microscopic or overt detection when bound
to the pathogen or its products. In general, the three
types of labels used for this purpose are fluorescent
dyes, enzymes, and particles such as latex beads.
Fluorescent antibodies allow visualization of an infec-
tious agent with the aid of fluorescence microscopy.
Depending on the type of fluorescent dye used, the
organism may appear bright green or orange against
a black background, making detection extremely easy.
Enzyme-labeled antibodies function in a similar man-
ner. The enzyme is capable of converting a colorless
compound into a colored substance, thereby permit-
ting detection of antibody bound to an infectious
agent without the use of a fluorescent microscope.
Particles coated with antibodies clump together, or
agglutinate, when the appropriate antigen is present in

Serology

Serology—literally, “the study of serum”—is an indi-
rect means of identifying infectious agents by measur-

ing serum antibodies in the diseased host. A tentative
diagnosis can be made if the antibody level, also called
antibody titer, against a specific pathogen rises during
the acute phase of the disease and falls during conva-
lescence. Serologic identification of an infectious agent
is not as accurate as culture, but it may be a useful
adjunct, especially for the diagnosis of diseases caused
by pathogens such as the hepatitis B virus that cannot
be cultured or diagnosis of past diseases. The measure-
ment of antibody titers has another advantage in that
specific antibody types such as IgM and IgG are pro-
duced by the host during different phases of an infec-
tious process. IgM-specific antibodies generally rise and
fall during the acute phase of the disease, whereas the
synthesis of the IgG class of antibodies increases during
the acute phase and remains elevated until or beyond
resolution.

measurements of class-specific antibodies are also
useful in the diagnosis of congenital infections. IgM
antibodies do not cross the placenta, but cer-
tain IgG antibodies are transferred passively from
mother to child during the final trimester of gestation.
Consequently, an elevated level of pathogen-specific
IgM antibodies in the serum of a neonate must have
originated from the child and therefore indicates con-
genital infection. A similarly increased IgG titer in
the neonate does not differentiate congenital from
maternal infection.

The technology of direct antigen detection incorpo-
rates features of culture and serology but reduces to a
fraction the time required for diagnosis. In principle,
this method relies on purified antibodies to detect anti-
gens of infectious agents in specimens obtained from
the diseased host. Common sources of these antibod-
ies are hybridomas, cell lines created by fusing normal
antibody-producing spleen cells from an immunized ani-
mal with malignant myeloma cells. The resulting hybrid
synthesizes large quantities of so-called monoclonal
antibodies that are highly specific for a single antigen
and a single pathogen.

The antibodies are labeled with a substance that
allows microscopic or overt detection when bound
to the pathogen or its products. In general, the three
types of labels used for this purpose are fluorescent
dyes, enzymes, and particles such as latex beads.
Fluorescent antibodies allow visualization of an infec-
tious agent with the aid of fluorescence microscopy.
Depending on the type of fluorescent dye used, the
organism may appear bright green or orange against
a black background, making detection extremely easy.
Enzyme-labeled antibodies function in a similar man-
ner. The enzyme is capable of converting a colorless
compound into a colored substance, thereby permit-
ting detection of antibody bound to an infectious
agent without the use of a fluorescent microscope.
Particles coated with antibodies clump together, or
agglutinate, when the appropriate antigen is present in

a specimen. Particle agglutination is especially useful
when examining infected body fluids such as urine,
serum, or spinal fluid.

Protein Detection

Mass spectrometry is a technique for determining the
composition of a sample. It generates a protein-based
profile or “fingerprint” from microbes that is unique
to a given species. By analyzing the proteins that make
up bacteria, yeast, or molds, clinical laboratories can
quickly fingerprint these organisms and identify them
based on the size and number of proteins detected.
For example, analysis of bacteria such as S. aureus
can often be accomplished by direct analysis of colony
growth by the mass spectrometer within minutes of
bacterial growth.

DNA and RNA Detection

Methods for identifying a pathogen by its unique DNA
or RNA sequence are increasingly being used. Several
techniques have been devised to accomplish this goal,
each having different degrees of sensitivity regarding the
number of organisms that need to be present in a speci-
men for detection. The first of these methods is called DNA probe
hybridization. Small fragments of DNA are cut from
the genome of a specific pathogen and labeled with
compounds (photo-emitting chemicals or antigens)
that allow detection. The labeled DNA probes are
added to specimens from an infected host. If the patho-
gen is present, the probe attaches to the complementary
strand of DNA on the genome of the infectious agent,
permitting rapid diagnosis. The use of labeled probes
has allowed visualization of particular agents within
and around individual cells in histologic sections of
tissue.

A second and more sensitive method of DNA detection
is the polymerase chain reaction (PCR). This method allows
technicians to tag a segment of pathogen DNA—if present in the patient sample—and then multiply it to detectable levels. To perform the assay,
a specimen containing the suspect pathogen is heated
(Fig. 14-11). This causes the double-stranded DNA
in the specimen to separate into single strands. It is
then allowed to cool. Next, two short DNA sequences
(usually less than 25 nucleotides long) called prim-
ers are added to the specimen. These primers locate
and bind only to the complementary target DNA of
the pathogen in question. Then, a heat-stable DNA
polymerase—an enzyme that catalyzes the synthesis
of DNA—is added. It begins to replicate the DNA
from the point at which the primers attached, similar
to two trains approaching each other on separate but
converging tracks. After the initial cycle, DNA polymer-
erization ceases at the point where the primers were
located, producing two new strands of DNA.

The specimen is heated again, and the process starts anew.

After many cycles of heating, cooling, and polymerization, and only if the specific pathogen (or its DNA) is present in the specimen, millions of uniformly sized pathogen DNA fragments are produced. The polymerized DNA fragments are separated by electrophoresis and visualized with a dye or identified by hybridization with a specific probe.

A modification of PCR, known as real-time PCR, continues to revolutionize medical diagnostics. Real-time PCR uses the same principles as PCR, but includes a fluorescence-labeled probe that specifically binds a target DNA sequence between the oligonucleotide primers. As the DNA is replicated by the DNA polymerase, the level of fluorescence in the reaction is measured. If fluorescence increases beyond a minimum threshold, the PCR is considered positive and indicates the presence of the target DNA in a specimen.

Several variations of molecular gene detection techniques in addition to PCR have been developed and incorporated into diagnostic kits for use in the clinical laboratory, including, transcription-mediated amplification (TMA), strand displacement amplification, hybrid capture assays, and DNA sequencing.

Many of the newer gene detection technologies have been adapted for quantification of the target DNA or RNA in serum or plasma specimens of patients infected with viruses such as HIV and hepatitis C. If the therapy is effective, viral replication is suppressed and the viral load (level of viral genome) in the peripheral blood is reduced. Conversely, if mutations in the viral genome lead to resistant strains or if the antiviral therapy is ineffective, viral replication continues and the patient’s viral load rises, indicating a need to change the therapeutic approach.

Molecular biology has revolutionized medical diagnostics. Using techniques such as PCR, laboratories now can detect as little as one virus or bacterium in a single specimen, allowing for the diagnosis of infections caused by microorganisms that are impossible or difficult to grow in culture. These methods have increased sensitivity while decreasing the time required to identify the etiologic agent of infectious disease. For example, using standard viral culture, it can take days to weeks to grow a virus and correlate the CPE with the virus. Using molecular biologic techniques, laboratories are able to complete the same work in a few hours.

**DNA Sequencing**

Originally described in 1976, DNA sequencing has gone through many modifications and has become one of the most powerful tools for laboratory diagnostics. The most common sequencing method is known as Sanger sequencing. Sanger sequencing uses nucleotides (similar to PCR) to build a chain of DNA. Terminator dyes that have been fluorescently labeled are inserted into the elongating fragment, causing the PCR reaction to stop at random lengths. The newly labeled double-stranded DNA fragments are broken apart, and separated by size (with a resolution of just one nucleotide) by gel or capillary electrophoresis. The resulting chart indicates the terminator color and the length of the fragment at termination (Fig. 14-12).

Sanger sequencing has quickly become the “gold standard” for identification of microbes that cannot be identified by other routine methods. Sequencing has also become the most accurate method for classifying microbes into their taxonomic group (Genus and species).

While Sanger sequencing has improved diagnosis of infectious diseases, it is still limited to sequencing a very small section of the genome. Consider that Sanger sequencing was used in the first complete sequence of the human genome, which took more
than 10 years to complete at a cost of more than $3 billion. Today newer sequencing methods, collectively known as Next Generation Sequencing (NGS), have allowed laboratories to sequence whole genomes of bacteria, molds, mycobacteria, and even humans at a fraction of the cost and within days rather than decades. For infectious diseases, the applications of sequencing are exciting and impactful. In epidemiology, next-generation sequencing will likely replace our current laboratory methods. For example, in 2011 a new strain of E. coli was detected in an outbreak of serious foodborne illness beginning in northern Germany that ultimately affected nearly 4000 patients with 53 dead. Within 1 week of isolating the new strain of E. coli, clinical microbiologists had grown the organism, sequenced it, and identified the source of the outbreak. With powerful laboratory technologies like sequencing, epidemiologists will be better equipped to identify outbreaks early or even prevent them from occurring.

**Antibacterial Agents**

Antibacterial agents are generally called antibiotics. Most antibiotics are actually produced by other microorganisms, primarily bacteria and fungi, as by-products of metabolism, and usually are effective only against other prokaryotic organisms. An antibiotic is considered bactericidal if it causes irreversible and lethal damage to the bacterial pathogen and bacteriostatic if its inhibitory effects on bacterial growth are reversed when the agent is eliminated. Antibiotics can be classified into families of compounds with related chemical structure and activity.

Not all antibiotics are effective against all pathogenic bacteria. Some agents are effective only against gram-negative bacteria, and others only gram-positive bacteria. The so-called broad-spectrum antibiotics, such as the newer cephalosporins, are active against a wide variety of gram-positive and gram-negative bacteria. The four basic mechanisms of antibiotic action...
are interference with a specific step in bacterial cell wall synthesis (e.g., penicillins, cephalosporins); inhibition of bacterial protein synthesis (e.g., aminoglycosides, tetracyclines); interruption of nucleic acid synthesis (e.g., fluoroquinolones, nalidixic acid); and interference with normal metabolism (e.g., sulfonamides, trimethoprim).

Of great concern is the increasing prevalence of bacteria resistant to the effects of antibiotics. The mechanisms by which bacteria acquire resistance to antibiotics include the production of enzymes that inactivate antibiotics, such as β-lactamases; genetic mutations that alter antibiotic binding sites; alternative metabolic pathways that bypass antibiotic activity; and changes in the filtration qualities of the bacterial cell wall that prevent access of antibiotics to the target site in the organism. It is the continuous search for a “better mousetrap” that makes anti-infective therapy such a fascinating aspect of infectious diseases.

**Antiviral Agents**

Until recently, few effective antiviral agents were available for treating human infections. The reason for this is host toxicity; viral replication requires the use of eukaryotic host cell enzymes, and the drugs that effectively interrupt viral replication are likely to interfere with host cell reproduction as well.

Almost all antiviral compounds are synthetic and, with few exceptions, their primary target is viral RNA or DNA synthesis. Like antibiotics, antiviral agents may be active against RNA viruses only, DNA viruses only, or occasionally both. A common class of antiviral drugs is the nucleoside analogs, which include agents such as acyclovir. These mimic the nucleoside building blocks of RNA and DNA. During active viral replication, the nucleoside analogs inhibit the viral DNA polymerase, preventing duplication of the viral genome and thus limiting the spread of infectious viral progeny to other susceptible host cells.

In response to the AIDS epidemic, there has been massive, albeit delayed, development of antiretroviral agents capable of targeting the replication of HIV, a retrovirus (see Chapter 16). These include the nucleoside analogs such as zidovudine as well as nonnucleoside inhibitors, which impair the synthesis of the HIV-specific enzyme reverse transcriptase. This key enzyme is essential for viral replication and has no counterpart in the infected eukaryotic host cells. Another class of antiviral agents developed solely for the treatment of HIV infections are the protease inhibitors. These drugs inhibit an HIV-specific enzyme that is necessary for late maturation events in the virus life cycle.

**Antifungal Agents**

The target site of the two most important families of antifungal agents is the cytoplasmic membranes of yeasts or molds. Fungal membranes differ from human cell membranes in that they contain the sterol ergosterol instead of cholesterol. The polyene family of antifungal compounds (e.g., amphotericin B, nystatin) preferentially binds to ergosterol and forms holes in the cell membrane, causing leakage of the fungal cell contents and, eventually, lysis of the cell. The imidazole class of drugs (e.g., fluconazole, itraconazole) inhibits the synthesis of ergosterol, thereby damaging the integrity of the fungal cytoplasmic membrane. Both types of drugs bind to a certain extent to the cholesterol component of host cell membranes and elicit a variety of toxic side effects in treated patients.

A new class of antifungal agents known as the echinocandins (e.g., caspofungin, micafungin, and anidulafugin) inhibit synthesis of the glucan in the cell wall, preventing the fungal cell wall from cross-linking. The lack of cross-linking causes the cell wall to become unstable and eventually lyse. The echinocandins are primarily active against *Candida* and *Aspergillus*.

**Surgical Interventions**

Before the discovery of antimicrobial agents, surgical removal of infected tissues, organs, or limbs was occasionally the only option available to prevent the demise of the infected host. Today, medicinal therapy with antibiotics and other anti-infective agents is an effective solution for most infectious diseases. However, surgical intervention is still an important option for cases in which the pathogen is resistant to available treatments. Surgical interventions may be used to hasten the recovery process by providing access to an infected site by antimicrobial agents (drainage of an abscess), cleaning the site (débridement), or removing infected organs or tissue (e.g., appendectomy). In some situations, surgery may be the only means to a complete cure, as in the case of endocarditis resulting in an infected heart valve, in which the diseased valve must be replaced with a mechanical or biologic valve to restore normal function. In other situations, surgical containment of a rapidly progressing infectious process such as gas gangrene may be the only means of saving a person’s life.
Global Infectious Diseases

Aided by a global market and the ease of international travel, the end of the 20th century and the first years of the 21st century have witnessed the importation of a host of novel infectious diseases. Unexpected pathogens in the 1990s, such as the outbreak of the West Nile virus (WNV) in the New York City area, have become important reminders of emerging infections. In fact, WNV has become almost synonymous with mosquito-borne illness. Because WNV is a mosquito-borne disease and is transmitted to a number of susceptible avian (e.g., blue jays, crows, and hawks) and equine hosts, the potential for rapid and sustained spread of the disease across the United States was appreciated early. The disease ranges in intensity from a nonspecific febrile illness to fulminant meningoencephalitis. Efforts to prevent further spread of the disease are currently centered on surveillance of WNV-associated illness in birds, humans, and other mammals, as well as mosquito control.

In 2011, one of the largest foodborne outbreaks of E. coli emerged as a global threat. Beginning in May 2011, German public health authorities reported an outbreak of hemolytic-uremic syndrome. Within 3 weeks German authorities announced the source of the outbreak was cucumbers from Spain, a report later proven incorrect. As the investigation into the source of the outbreak continued, patients in surrounding countries also began to report illness. As the outbreak continued, epidemiologists focused their investigation on bean sprouts from a farm in Lower Saxony, Germany. They found that people who had eaten bean sprouts were 9 times more likely to develop bloody diarrhea versus those who had not consumed bean sprouts. Finally, more than one month following initiation of the outbreak, scientists at the Robert Koch Care Institute isolated a novel strain of E. coli, known as O104:H4, from bean sprouts that had been contaminated with human feces. Interestingly, further study has demonstrated the O104:H4 strain of E. coli likely circulated in humans for 10 years prior to the outbreak.

As a result of the outbreak, Germany has implemented a policy to reduce the reporting time for potential outbreaks from 18 to 3 days. However, there are many obstacles to improving surveillance from reimbursement for medical tests, to communication between clinicians and public health authorities, to technologies for identification of relatedness among outbreak-causing diseases.

New and Emerging Infectious Diseases

In recent years, the terms emerging (i.e., newly recognized) and reemerging (i.e., previously recognized) infectious diseases have entered the vocabulary of medical science. These infections also include deliberately emerging infections that are the result of bioterrorism.

The worldwide movement of animals for commercial trade represents a substantial risk for translocation of zoonotic infections. In 2003, monkeypox, one of the orthopoxvirus family viruses, was introduced into the United States when a shipment of African Gambian giant rats was sold to dealers, one of whom housed the rats with prairie dogs intended for the pet market. The prairie dogs subsequently became ill and transmitted the infection to 71 humans, including prairie dog owners and veterinary staff caring for the animals. These three scenarios highlight the rapidity with which novel or exotic diseases can be introduced into nonindigenous regions of the world and to a susceptible population. Although great strides in molecular microbiology have allowed for the rapid identification of new or rare microorganisms, the potential devastation in terms of human life and economic loss is great, underscoring the need to maintain resources for public health surveillance and intervention.

SUMMARY CONCEPTS

- The challenges associated with maintaining health throughout a global community are becoming increasingly apparent.
- Aided by a global market and the ease of international travel, the past decade has witnessed the importation and emergence of a host of novel infectious diseases. There is also the potential threat of the deliberate use of microorganisms as weapons of bioterrorism.

REVIEW EXERCISES

1. Newborn infants who have not yet developed intestinal flora are routinely given an intramuscular injection of vitamin K to prevent bleeding due to a deficiency in vitamin K–dependent coagulation factors.
   A. Use the concept of mutualism to explain why this is done.

2. Persons with human granulocytic ehrlichiosis may be coinfected with Lyme disease.
   A. Explain.

3. Persons with chronic lung disease are often taught to contact their health care provider when they notice a change in the color of their sputum (i.e., from white or clear to yellow or green tinged) because it might be a sign of a bacterial infection.
   A. Explain.
4. Microorganisms are capable of causing infection only if they can grow at the temperature of the infected body site.

A. Using this concept, explain the different sites of fungal infections due to the dermatophyte fungal species that cause tinea pedis (athlete’s foot) and Candida albicans, which causes infections of the mouth (thrush) and female genitalia (vulvovaginitis).

BIBLIOGRAPHY

The immune system has evolved to defend against bacteria, viruses, and other foreign substances. Through recognition of molecular patterns, the immune system can distinguish itself from foreign substances and can discriminate potentially harmful from non-harmful agents. It also defends against abnormal cells and molecules that periodically develop. Although the immune response normally is protective, it also can produce undesirable effects such as when the response is excessive, as in allergies, or when it recognizes self-tissue as foreign, as in autoimmune disease. This chapter is divided into three parts: (1) introduction to the immune system, (2) innate immunity, (3) adaptive immunity, and (4) developmental aspects of the immune system.

### Introduction to the Immune System

The term *immunity* has come to mean protection from disease and, more specifically, infectious disease. The collective, coordinated response of the cells and molecules of the immune system is called the *immune response*. Although the relationship between microbes and infectious diseases dates far back in history, it has only been within the last 30 to 40 years that an understanding of the cellular and biochemical mechanisms involved in the immune response has begun to emerge. Advances in cell culture techniques, immunohemistry, recombinant deoxyribonucleic acid (DNA) technology, and the creation of genetically altered animals, such as “transgenic” and “knockout” mice, have transformed immunology from a largely descriptive science to one of immune phenomena that can be explained in structural and biochemical terms.

### Innate and Adaptive Immunity

There are two host defenses that cooperate to protect the body—the early, rapid responses of innate immunity, and the very effective but later responses of adaptive immunity. As the first line of defense, *innate* (also called *natural*
or *native* immunity consists of the physical, chemical, molecular, and cellular defenses that are in place before infection and can function immediately as an effective barrier to microbes. *Adaptive* (also called *specific* or *acquired*) immunity is the second major immune defense, responding less rapidly than innate immunity but more effectively. Adaptive immunity uses focused recognition of each unique type of foreign agent followed, in days, by an amplified and effective response.

The major components of innate immunity are the skin and mucous membranes, phagocytic leukocytes (mainly neutrophils and macrophages), specialized lymphocytes (the natural killer cells), and several plasma proteins, including the proteins of the complement system (Fig. 15-1). The innate immune system is able to distinguish self from nonself and is able to recognize and react against various classes of microbial agents. The response of the innate immune system is rapid, usually within minutes to hours, and prevents the establishment of infection and deeper tissue penetration of microorganisms. The effector responses used by the innate immune system to eliminate the microbes are very similar for different classes of microorganisms. Although most innate responses are very effective in controlling and destroying the invading agent, pathogenic microbes have evolved several approaches to evade innate defenses. The microorganisms not controlled by innate immunity are usually controlled by the more specific approaches of adaptive immunity.

The adaptive immune system consists of two groups of lymphocytes and their products, including antibodies (see Fig. 15-1). Whereas the cells of the innate immune system recognize structures shared by classes of microorganisms, the cells of the adaptive immune system are capable of recognizing numerous microbial and non-infectious substances and developing a unique specific immune response for each substance. Substances that elicit adaptive immune responses are called *antigens.* A memory of the substance is also developed so that a repeat exposure to the same microbe or agent produces a quicker and more vigorous response.

There are two types of adaptive immune responses: humoral and cell-mediated immunity. *Humoral immunity* is mediated by molecules called *antibodies* that are produced by cells called *B lymphocytes.* Antibodies are secreted into the circulation and mucosal fluid, where they neutralize or eliminate extracellular microbes and microbial toxins. One of the important functions of

---

**Figure 15-1.** Mechanisms of innate and adaptive immunity. (A) The major effectors of the innate immune system include the immediately available epithelial barriers, phagocytic leukocytes, natural killer (NK) cells, and complement system. These effectors are in place before an encounter with an infectious agent and provide rapid protection against infection. (B) Adaptive immunity develops later than innate immunity, is acquired through previous experience with a foreign agent, and is mediated by T and B lymphocytes and their products. Humoral immunity is provided by B lymphocytes that differentiate into antibody-producing plasma cells that interact with and protect against microbes that are present in the blood or on mucosal surfaces. Cell-mediated immunity is provided by cytotoxic T cells that destroy cells infected with intracellular pathogens. MHC-1, major histocompatibility complex-1; TCR, T-cell receptor.
humoral immunity is to stop microbes that are present on mucosal surfaces and in the blood from gaining access to and colonizing body tissues. Cell-mediated immunity, which defends against intracellular microbes such as viruses, is provided by cells called T lymphocytes. Some T lymphocytes activate phagocytes to destroy microbes that have been engulfed, whereas others kill any type of host cell that is harboring microbes.

Recent studies have shown that essential, cooperative interactions exist between innate and adaptive immunity. Innate immunity communicates to lymphocytes involved in adaptive immunity the characteristics of the pathogen and information about its intracellular or extracellular location. The innate immune response also stimulates and influences the nature of adaptive immune responses. At the effector stage of immunity, the adaptive immune response amplifies and increases its efficiency by recruitment and activation of additional phagocytes and molecules of the innate immune system. Both innate and adaptive immunity destroy the invading agent by using the effector responses of phagocytosis and the complement system. Thus, immunity is truly an interactive, cooperative effort.

**Cells of the Immune System**

All of the cellular elements of the blood, including the red blood cells, platelets, and white blood cells, derive from the hematopoietic stem cells in the bone marrow (see Chapter 11). As these stem cells differentiate, they give rise to cells with more limited developmental potential, including the immediate progenitors of the two main categories of white blood cells, the myeloid and lymphoid lineages. The common myeloid progenitor is the precursor of most of the phagocytic cells of the innate immune system, and the lymphoid lineage consists of the lymphocytes of the adaptive immune system and natural killer cells of innate immunity. The general properties of these cells are presented in this section, whereas their specific functions in relation to innate or adaptive immunity are discussed in those sections of the chapter.

**Myeloid Lineage Phagocytic Cells**

The common myeloid progenitor is the precursor of the monocytes/macrophages, granulocytes, and dendritic cells of the innate immune system. These three cell types make up the phagocytic cells of the immune system.

**Monocytes/Macrophages.** Macrophages are part of the monocytic phagocyte system, a family of phagocytic cells. They are resident in almost all tissues and are the mature form of monocytes, which circulate in the blood and continually migrate into tissues, where they differentiate into macrophages. Macrophages are relatively long-lived cells and perform several different functions during the innate and adaptive immune responses. One function is to engulf and kill invading microorganisms. In this phagocytic role they are an important first-line defense in innate immunity, and they dispose of pathogens and infected cells targeted for disposal by an adaptive immune response.

Although their primary role is in phagocytosis, macrophages also function as antigen-presenting cells of the adaptive immune response. That is, they process and present molecules of foreign antigens to the lymphocytes involved in adaptive immunity. Macrophages also help induce inflammation, and they secrete signaling proteins that activate other immune cells and recruit them into an immune response. In addition to these immune-system roles, macrophages act as general scavenger cells in the body, clearing dead cells and cell debris.

**Granulocytes.** The granulocytes are so called because they have densely staining granules in the cytoplasm. There are three types of granulocytes—neutrophils, eosinophils, and basophils—which are distinguished by the staining properties of their granules. Compared to the macrophages, they are relatively short-lived, surviving only a few days, and are produced in increased numbers during an immune response. Neutrophils, which are named for their neutral-staining granules, are the most numerous of the granulocytes and the most important cell in innate immunity. They take up a variety of microorganisms by phagocytosis and efficiently destroy them using degradative enzymes and other antimicrobial substances stored in their cytoplasmic granules. The protective functions of the basophils, which stain blue, and eosinophils, which stain red, are less well understood. They are thought to be an important defense against parasites, which are too large to be ingested by macrophages and neutrophils. They are also involved in allergic reactions, in which their effects are damaging and not protective (see Chapter 16).

**Dendritic Cells.** The dendritic cells are the third class of phagocytic cells of the immune system. They have long fingerlike processes, which give them their name. Most dendritic cells are found as immature cells under epithelial tissue and in most organs, where they are poised to capture foreign agents and transport them to peripheral lymphoid organs. Once activated, they undergo a complex maturation process as they migrate to the regional lymph nodes.

Like macrophages, dendritic cells function as key antigen-presenting cells that initiate adaptive immune responses by processing and presenting molecules of foreign antigens to B and T lymphocytes. Both macrophages and dendritic cells also release several communication molecules that direct the nature of adaptive immune responses. Thus, they serve as important intermediaries between innate and adaptive immunity.

**Lymphocytes and Natural Killer Cells**

The common lymphoid progenitor in the bone marrow gives rise to two types of antigen-specific lymphocytes—the B and T lymphocytes of the adaptive immune system—and a third type of lymphocyte, the natural killer cell, that does not respond to specific antigens but is considered part of the innate immune system. The B and T lymphocytes are the only cells that produce specific receptors for antigen and thus are the key mediators of adaptive immunity. A naive lymphocyte is a mature
B or T lymphocyte that has not previously encountered antigen or is not the progeny of an antigen-stimulated mature lymphocyte.

B lymphocytes (B cells) are the only cells capable of producing antibodies; therefore, they are the cells that mediate humoral immunity. B cells use membrane-bound antibodies to recognize a wide variety of proteins, polysaccharides, lipids, and small chemicals. These antigens may be expressed on microbial surfaces or they may be in soluble forms (toxins). In response to antigen and other signals, B cells differentiate into plasma cells which produce antibody. The secreted antibodies enter the circulation and mucosal fluids and bind to microbes before they have a chance to colonize body tissues.

T lymphocytes (T cells) are responsible for cell-mediated immunity. The antigen receptors of most T lymphocytes only recognize peptide fragments of protein antigens that are bound to specialized peptide display molecules called major histocompatibility complex (MHC) molecules on the surface of antigen-presenting cells. Among T lymphocytes is a subset of T cells called helper T cells that help B lymphocytes produce antibodies and help phagocytic cells destroy ingested pathogens, and another subset called cytotoxic T cells that kill or lyse intracellular microbes.

Although all lymphocytes are morphologically similar, they vary in terms of lineage, cell membrane molecules and receptors, function, and response to antigen. These cells are often distinguished by surface proteins. The standard nomenclature for these proteins is the CD (clusters of differentiation) numeric designation (CD4+, CD8+), which is used to delineate surface proteins that define a particular cell type or stage of cell differentiation and are recognized by a “cluster” of antibodies.

The CD classification is now widely used in clinical medicine and experimental immunology. In human immunodeficiency virus (HIV) infection, for example, a decline or rise in the CD4+ helper T-cell count is used to follow the progression of the disease and response to treatment. Further investigation of the CD molecules has shown that they are not merely phenotypic markers of cell type but are themselves involved in a variety of lymphocyte functions, including promotion of cell-to-cell adhesion and transduction of signals that lead to lymphocyte activation.

The third type of lymphocyte, the natural killer (NK) cell is part of the innate immune system and may be the first line of defense against viral infections. The NK cell also has the ability to recognize and kill tumor cells, abnormal body cells, and cells infected with intracellular pathogens, such as viruses and intracellular bacteria.

**Organs and Tissues of the Immune System**

The cells of the immune system are present in large numbers in the central and peripheral lymphoid organs. These organs and tissues are widely distributed in the body and provide different, but often overlapping, functions (Fig. 15-2). The lymphoid organs are connected by networks of lymph channels, blood vessels, and capillaries. The immune cells continuously circulate through the various tissues and organs to seek out and destroy foreign material.

**Central Lymphoid Tissues**

The central lymphoid tissues, the bone marrow and thymus gland, provide the environment for immune cell production and maturation (see Chapter 11). The specialized microenvironment of the bone marrow provides signals both for the development of lymphocyte progenitors from the hematopoietic stem cells and for the subsequent differentiation of B cells.

T-cell progenitors migrate from the bone marrow to the thymus where the process of maturation occurs. The thymus is an elongated, bilobed structure located in the neck region of the chest above the heart. The function of the thymus is central to the development of the immune system because it generates mature, immunocompetent T lymphocytes expressing appropriate receptors. The thymus is fully formed and functional at birth. It persists...
as a large organ until about the time of puberty, when T-cell development and proliferation are reduced and the thymus begins slowly regressing and is replaced by adipose tissue. Nevertheless, some thymus tissue persists and can be restimulated under conditions that demand rapid T-cell proliferation.

Precursor T (pre-T) cells enter the thymus as functionally and phenotypically immature T cells. They undergo cycles of proliferation and selection as they move from the cortical to medullary compartments of the thymus. Rapid cell multiplication, maturation, and selection occur in the cortex under the influence of the microenvironment, thymic hormones, and cytokines. As the T cells multiply and mature, they acquire T-cell receptors, surface markers that distinguish among the different types of T cells, and antigens that distinguish them from nonself. Only those T cells able to recognize foreign antigens and distinguish self from nonself are allowed to mature and leave the thymus. This process is called thymic selection. The thymus must be extremely thorough in eliminating self-reactive cells to ensure that autoimmune reactivity and disease do not result. Mature, immunocompetent T-helper and T-cytotoxic cells leave the thymus in 2 to 3 days and enter the peripheral lymphoid tissues through the bloodstream.

The process of B-cell maturation, which is similar to that of T-cell maturation, occurs in the bone marrow. Here, the B cells multiply and acquire immunoglobulin (Ig) signaling molecules and cell markers that distinguish them from nonself. As with T cells, only those B cells that are able to distinguish self from nonself are allowed to mature and leave the bone marrow.

Peripheral Lymphoid Tissues

The peripheral lymphoid structures, which consist of the lymph nodes, the spleen, and other secondary lymphoid tissues, function to concentrate antigen, aid in processing of antigen, and promote the cellular interactions necessary for development of adaptive immune responses.

Lymph Nodes. The vessels of the lymphatic system remove protein-rich fluid, called lymph, from the intercellular spaces and return it to the circulation (see the lymphatic system, Chapter 17). Before lymph is returned to the blood, it passes through lymph nodes, which are highly organized lymphoid organs with two distinct functions. First, they filter foreign material from lymph before it enters the bloodstream. Lymph nodes are located at points of convergence of lymphatic vessels, with aggregates of lymph nodes processing lymph from discrete anatomic sites, including the axillae and groin, and along the great vessels of the neck, thorax, and abdomen (see Fig. 15-2). Second, they serve as centers for proliferation and response of immune cells.

Each lymph node is a small, bean-shaped, encapsulated organ (Fig. 15-3). Lymph enters the node through afferent vessels that penetrate the capsule, and leaves through efferent vessels located in the deep indentation of the hilus. Lymphocytes and macrophages flow slowly through the node, which allows trapping and interaction of antigen and immune cells. As lymph passes through the lymph nodes, antigen-presenting cells in the nodes are able to sample the antigens that enter through the epithelia. In addition, microbes that bypass the epithelial barriers of the innate immune system are captured by resident dendritic cells and transported to draining lymph nodes.

A lymph node is divided into several specialized areas: an outer cortex, a paracortex, and an inner medulla. B lymphocytes are more abundant in the follicles located in the outer cortex. The T lymphocytes proliferate on antigenic stimulation and migrate to the follicles, where they interact with B lymphocytes. These activated follicles become germinal centers, containing macrophages, follicular dendritic cells, and maturing T and B cells. Activated B cells then migrate to the medulla, where they complete their maturation into plasma cells. These cells stay localized in the lymph node but release large quantities of antibodies into the circulation.

Spleen. The spleen is a large, ovoid secondary lymphoid organ located high in the left abdominal cavity. The spleen filters antigens from the blood and is important in the response to systemic infections. The spleen is composed of red and white pulp. The red pulp is well supplied with arteries and is the area where senescent and injured red blood cells are removed. The white pulp contains concentrated areas of B and T lymphocytes permeated by macrophages and dendritic cells. A sequence of activation events similar to that seen in the lymph nodes occurs in the spleen.

Other Secondary Lymphoid Tissues. Other secondary lymphoid tissues include the mucosa-associated lymphoid tissues (MALT). These nonencapsulated clusters of lymphoid tissues are located around
membranes lining the respiratory, digestive, and urogenital tracts. These gateways into the body must harbor the immune cells needed to respond to a large and diverse population of microorganisms. In some tissues, the lymphocytes congregate in loose clusters, but in other tissues such as the tonsils, Peyer patches in the intestine, and the appendix, organized structures are evident (see Fig. 15-2). These tissues contain all the necessary cell components (i.e., T cells, B cells, macrophages, and dendritic cells) for an immune response. Because of the continuous stimulation of the lymphocytes in these tissues by microorganisms constantly entering the body, large numbers of plasma cells are evident. Immunity at the mucosal layers helps to exclude many pathogens and thus protects the vulnerable internal organs.

Cytokines That Mediate and Regulate Immunity

Although cells of both the innate and adaptive immune systems communicate critical information by cell-to-cell contact, many interactions and effector responses depend on the secretion of short-acting soluble molecules called cytokines. The sources and properties of the main cytokines that participate in innate and adaptive immunity are summarized in Table 15-1.

General Properties of Cytokines

Cytokines are low–molecular-weight regulatory proteins that are produced by cells of the innate and adaptive immune systems and that mediate many of the actions of these cells. The names of specific types of cytokines were derived from the biologic properties first ascribed to them. For example, interleukins (ILs) were found to be made by leukocytes and to act on leukocytes, and interferons (IFNs) were found to interfere with virus multiplication.

Although cytokines have many diverse actions, all share several important properties. Most cytokines are released at cell-to-cell interfaces, where they bind to specific receptors on the membrane surface of their target cells. All cytokines are secreted in a brief, self-limited manner. They are not usually stored as preformed molecules and their synthesis is limited to new gene transcription resulting from cellular activation. The short half-life of cytokines ensures that excessive immune responses and systemic activation do not occur.

The actions of cytokines are often pleiotropic and redundant. Pleiotropism refers to the ability of a cytokine to act on different cell types. For example, IL-2, initially discovered as a T-cell growth factor, is also known to affect the growth of B cells and NK cells. Interferon-γ is the key macrophage-activating cytokine that functions in both innate and adaptive immune responses. Although pleiotropism allows cytokines to mediate diverse effects, it greatly limits their use for therapeutic purposes because of numerous unwanted side effects. Redundancy refers to the ability of different cytokines to stimulate the same or overlapping biologic functions. Because of this redundancy, antagonists against a single cytokine may not have functional consequences because other cytokines may compensate.

Not only are the actions of cytokines pleiotropic and redundant, but the same cytokines may be produced by several different cell types. For example, IL-1 can be produced by virtually all leukocytes, endothelial cells, and fibroblasts. Cytokines often influence the synthesis and actions of other cytokines. The ability of one cytokine to stimulate the production of others often leads to cascades in which the second and third cytokines may mediate the biologic effects of the first. Cytokines may also serve as antagonists to inhibit the action of another cytokine, or in some cases they may produce additive or greater than anticipated effects.

Cytokine actions may be local or systemic. Most cytokines act close to where they are produced, acting on the same cell that secreted the cytokine (autocrine mechanism), or they may influence the activity of nearby cells (paracrine mechanism). When produced in large amounts, cytokines may enter the bloodstream and exert their action on distant cells in an endocrine manner; the best examples are IL-1 and tumor necrosis factor-α (TNF-α), which produce the systemic acute-phase response during inflammation.

Chemokines

Chemokines are cytokines that stimulate the migration and activation of immune and inflammatory cells. There are two major subclasses, termed CC chemokines and CXC chemokines, which are distinguished by their amino acid sequence. The largest family, the CC chemokines, attracts mononuclear leukocytes to sites of chronic inflammation. The CXC chemokines attract neutrophils to sites of acute inflammation.

Chemokines are implicated in a number of acute and chronic diseases, including atherosclerosis, rheumatoid arthritis, inflammatory bowel disease (Crohn disease and ulcerative colitis), allergic asthma and chronic bronchitis, multiple sclerosis, systemic lupus erythematosus, and HIV infection. To enter target cells, HIV type 1 requires two distinct elements: the CD4 recognition molecule of the helper T cell and either the CXCR4 or CCR5 chemokine. The targeting of T cells and monocytes allows HIV-1 access to sanctuary sites throughout the body and also cripples the CD4+ T-helper cell that orchestrates antiviral immunity (discussed in Chapter 16).

Colony-Stimulating Factors

Colony-stimulating factors (CSFs) are cytokines that stimulate bone marrow pluripotent stem and progenitor or precursor cells to produce large numbers of platelets, erythrocytes, lymphocytes, neutrophils, monocytes, eosinophils, basophils, and dendritic cells. The CSFs were named according to the type of target cell on which they act (see Table 15-1). Granulocyte-monocyte colony-stimulating factor (GM-CSF) acts on
the granulocyte-monocyte progenitor cells to produce monocytes, neutrophils, and dendritic cells; granulocyte colony-stimulating factor (G-CSF) specifically induces neutrophil proliferation; and macrophage colony-stimulating factor (M-CSF) directs the mononuclear phagocyte progenitor. Other cytokines, including IL-3, IL-7, and IL-11, also influence hematopoiesis. Recombinant CSF molecules are currently being used to increase the success rates of bone marrow transplantations. The availability of recombinant CSFs and cytokines offers the possibility of several clinical therapies where stimulation or inhibition of the immune response or cell production is desirable.

**SUMMARY CONCEPTS**

- Immunity is the resistance to a disease that is provided by the immune system. Innate immunity, which is the first line of defense against microbial agents, can distinguish between self and nonself but not among specific pathogens. Adaptive immunity, which involves humoral and cell-mediated immune responses...
that react to a unique antigen, can distinguish self from nonself, and develop immunologic memory, allowing a prompt and heightened response on subsequent encounters with the same antigen.

The cellular components of innate and adaptive immunity include the phagocytic cells that are of myeloid lineage and the lymphocytes that are of lymphoid lineage. The phagocytic granulocytes, macrophages, and dendritic cells, along with the natural killer (NK) cells, participate in innate immune responses, and the B and T lymphocytes participate in adaptive immune responses.

The tissues of the immune system consist of the generative or central lymphoid organs in which B and T lymphocytes originate and mature and the peripheral lymphoid organs in which adaptive immune responses to microbes is initiated.

Cytokines are soluble proteins secreted by cells of both the innate and adaptive immune systems that mediate many of the functions of these cells. Some cytokines mediate inflammation or interfere with viral replication. Chemokines are cytokines that stimulate the migration and activation of immune and inflammatory cells. Colony-stimulating factors are cytokines that stimulate the growth and differentiation of bone marrow progenitors of immune cells.

### Innate Immunity

The innate immune system consists of the epithelial barriers; phagocytic neutrophils, macrophages, dendritic cells, NK cells; and several plasma proteins, including those of the complement system. These mechanisms are present in the body before an encounter with an infectious agent and are rapidly activated by microbes before the development of adaptive immunity. The innate immune system also interacts with and directs adaptive immune responses.

With the ever-expanding wealth of information on immune system function, it is becoming clear that the innate immune system not only protects against microbial agents, but may also play a role in the pathogenesis of disease. Among the functions of the innate immune system is induction of a complex cascade of events known as the inflammatory response (discussed in Chapter 3). Recent evidence suggests that low-grade inflammation and activation of the innate immune system play a key role in the pathogenesis of a number of disorders, such as atherosclerosis and coronary artery disease, bronchial asthma, type 2 diabetes mellitus, rheumatoid arthritis, multiple sclerosis, and systemic lupus erythematosus.

### Epithelial Barriers

Our outer body surfaces are protected by epithelia, which provide physical and chemical barriers between the internal environment and the pathogens of the external world. Epithelia include the epidermis of the skin and linings of the respiratory, gastrointestinal, and urogenital tracts. The intact skin is a formidable physical barrier because of its closely packed cells, multiple layers, continuous shedding of cells, and presence of the protective protein keratin. In addition to its barrier function, the skin has chemicals that create a salty and acidic environment, and antibacterial proteins, such as the enzyme lysozyme, that inhibit the colonization of microorganisms and aid in their destruction.

The mucous membrane linings of the gastrointestinal, respiratory, and urogenital tracts are protected by sheets of tightly packed epithelial cells that block the entry of microbes and destroy them by secreting antimicrobial enzymes, proteins, and peptides. Specialized cells in these linings secrete a viscous material called mucus. Mucus traps and washes away microorganisms, especially with the help of additional secretions such as saliva. Also in the lower respiratory tract, hairlike structures called cilia protrude through the epithelial cells. The synchronous action of the cilia moves many microbes trapped in the mucus toward the throat. The physiologic responses of coughing and sneezing further aid in their removal from the body.

Once microbes are trapped, various chemical defenses come into play. These include lysozyme, a hydrolytic enzyme capable of cleaving the walls of bacterial cells; complement, which binds and aggregates bacteria to increase their susceptibility to phagocytosis or disrupt their lipid membrane; and members of the collectin family of surfactant proteins (e.g., surfactants [SP]-A and SP-D) in the respiratory tract (see Chapter 21). The best-defined function of the surfactants is their ability to opsonize pathogens, including bacteria and viruses, and to facilitate phagocytosis by innate immune cells such as macrophages. In the stomach and intestines, death of microbes results from the action of digestive enzymes, acidic conditions, and secretions of defensins, small cationic peptides that rapidly kill many types of bacteria by disrupting their membrane.

### Cells of Innate Immunity

Some pathogens can penetrate the epithelial barriers of the host and cause infection, particularly when the barrier has been breached as in wounds, burns, or loss of the body’s internal epithelia. The subsequent innate immune response to the penetration of these invaders is initiated by several types of immune cells with receptors for recognition of general groups of microbes. The key cells of innate immunity include phagocytic leukocytes and NK cells.

Several types of phagocytic leukocytes recognize and kill infectious agents during an innate immune response. The early-responding phagocytic cell is the neutrophil, followed shortly by the more efficient,
multifunctional macrophage. Phagocytes are activated to engulf and digest microbes that attach to their cell membrane. Once the cell is activated and the microbe ingested, the cell generates digestive enzymes and toxic oxygen and nitrogen intermediates (e.g., hydrogen peroxide or nitric oxide) that kill the pathogen. The phagocytic killing of microorganisms helps prevent the spread of infectious agents until adaptive immunity can be marshaled.

Dendritic cells, which are derived from bone marrow cells and related in lineage to the macrophage, also play important roles in the innate immune response to infections and in linking innate and adaptive immune responses (to be discussed in section on antigen-presenting cells). One subpopulation of dendritic cells governs the early response to viral infections. They recognize phagocytosed viruses and produce type 1 interferons that have potent antiviral actions.

NK cells are a class of lymphocytes that recognize infected and stressed cells and respond by killing these cells. Activation of NK cells triggers the release of cytoplasmic granules toward the infected cells. These NK granules contain molecules that form pores in the cell membrane and other molecules that induce apoptosis (programmed cell death). NK cells control their responses by using both activating and inhibitory receptors (Fig. 15-4). Their activating receptors (i.e., killer cell receptors) recognize altered host molecules expressed on stressed tissue cells that may be infected with intracellular microbes. The inhibitory receptors on NK cells recognize molecules on normal host cells and function to stop the killing response. This control ensures that normal body cells are not inappropriately destroyed. In contrast to the cytotoxic T lymphocytes of the adaptive immune system, which need to undergo amplification and maturation to become cytotoxic, the NK cell is directly programmed to kill foreign cells.

**Pathogen Recognition**

The ability of leukocytes and epithelial cells to participate in innate immunity depends on their first recognizing molecules that are a normal component of microbes but not host cells. These components are often essential for infectivity and cannot be mutated to allow the microbe to evade destruction. The receptors that the innate immune system uses to recognize and react against microbes are expressed on phagocytic leukocytes, NK cells, and other cells that participate in defense against various classes of microbes. These receptors are molecules that first tag the microbe and then bind it to the effector cell of the innate immune system. Microbial binding results in effector cell activation, phagocytosis, and subsequent killing of the microbe. Several classes of receptors have been identified that are specific for different types of microbial products including pattern receptors, Toll-like receptors, and serum proteins (e.g., complement proteins) that promote phagocytosis.

**Pattern Recognition**

Microbes typically bear repeating patterns of molecular structure on their surface. The cell walls of Gram-negative and Gram-positive bacteria are composed of a matrix of sugars, lipid molecules, proteins, or patterns of modified nucleic acids. The lipopolysaccharides of the outer wall of Gram-negative bacteria, for example, are important recognition sites for the innate immune system. Other microbial components also have repetitive structures. Bacterial DNA contains unmethylated cysteine-guanine (CpG) sequences and viruses invariably express double-stranded RNA as part of their life cycle. These repetitive
structures are generally known as pathogen-associated molecular patterns (PAMPs), and the receptors that recognize them as pattern recognition receptors (PRRs).

The recognized structures of PAMPs are essential to the functioning and infectivity of the microbe. The microbe cannot, therefore, evade innate immune recognition through mutation or a lack of production of the molecules because they would not survive. Humans inherit a limited number of germline genes for PRRs that effectively recognize major groups of microbes. One such receptor is the mannose-binding lectin (MBL), which is present as a free protein in the blood plasma. Pathogen recognition and discrimination of self from nonself by the MBL is due to the particular orientation and spacing of particular sugar residues, which are found only on microbes and not on host cells.

The phagocytic cells of the innate immune system are also equipped with several cell surface receptors that recognize pathogen surfaces directly. Among these is the macrophage-mannose receptor. This receptor binds certain sugars found on the surface of many bacteria and viruses, including HIV. A second set of phagocytic receptors, called the scavenger receptors, were originally defined as molecules that bind and mediate endocytosis of oxidized or acetylated low-density lipoproteins (LDLs) that do not interact with the conventional LDL receptor (see Chapter 18). Macrophage scavenger receptors bind a variety of microbes in addition to LDL particles.

Not all receptors that recognize pathogen-specific molecules are phagocytic receptors. The binding of pathogens to some receptors on leukocytes initiates a series of signaling events that lead to the tissue changes associated with acute inflammation. Stimulation of other pattern receptors leads macrophages and dendritic cells to display co-stimulatory molecules that enable them to act as antigen-presenting cells to lymphocytes and initiate an adaptive immune response.

**Toll-Like Receptors**

The best-defined activation pathway for the pathogen sensors of innate immunity is a family of transmembrane receptors called Toll-like receptors (TLRs). Interestingly, the first protein to be identified in this family was the Drosophila Toll protein, which was found in the fruit fly Drosophila, where it functions in embryonic development as well as in protecting the fly from lethal fungal infections.

Eleven different TLRs have thus far been identified, each specific for different components of microbes (Table 15-2). Although most TLRs are found on the surface of the leukocytes, a few are intracellular, where they recognize viruses and intracellular pathogens such as Mycobacterium. Because there are only 11 recognized TLR genes, the Toll-like receptors have limited specificity compared with the antigen receptors of the adaptive immune system. Despite this limited diversity, they can recognize elements of most microorganisms.

Ligand binding to the TLR at the cell surface leads to an intracellular cascade of events which ultimately regulates the production of several proteins that are important components of innate immunity. Alterations in the structure of TLRs or mutations in the signaling system associated with TLRs have been suggested to play a pathologic role in disorders such as atherosclerosis, allergies, and certain autoimmune diseases.

**Soluble Mediators of Innate Immunity**

Although cells of the innate immune system can communicate critical information about microbial agents and self–nonself recognition through cell-to-cell contact, soluble mediators are essential for many other aspects of the response. Development of innate immunity and regulation of the behavior of effector cells both depend on the secretion of soluble mediators such as opsonins, cytokines, and proteins of the complement system.

**Opsonins**

Various soluble molecules can tag microorganisms for more efficient recognition by phagocytes. The coating of particles, such as microbes, is called opsonization, (text continues on page 330)
The complement system provides one of the major effector mechanisms of both humoral and innate immunity. The system consists of a group of proteins (complement proteins C1 through C9) that are normally present in the plasma in an inactive form. Activation of the complement system is a highly regulated process, involving the sequential breakdown of the complement proteins to generate a cascade of cleavage products capable of proteolytic enzyme activity. This allows for tremendous amplification because each enzyme molecule activated by one step can generate multiple activated enzyme molecules at the next step. Complement activation is inhibited by proteins that are present on normal host cells; thus, its actions are limited to microbes and other antigens that lack these inhibitory proteins. The reactions of the complement system can be divided into three phases: (1) the initial activation phase, (2) the early-step inflammatory responses, and (3) the late-step membrane attack responses.

**Initial Activation Phase.** There are three pathways for recognizing microbes and activating the complement system: (1) the alternative pathway, which is activated by microbial cell surfaces in the absence of antibody and is a component of innate immunity; (2) the classical pathway, which is activated by certain types of antibodies bound to antigen and is part of humoral immunity; and (3) the lectin pathway, which is activated by a plasma lectin that binds to mannose on microbes and activates the classical system pathway in the absence of antibody.
**Chapter 15**

**Innate and Adaptive Immunity**

---

**2 Early-Step Inflammatory Responses.** The central component of complement for all three pathways is the activation of the complement protein C3 and its enzymatic cleavage into larger C3b fragments and smaller C3a fragments. The smaller C3a fragments stimulate inflammation by acting as a chemoattractant for neutrophils. The larger C3b fragment becomes attached to the microbe and acts as an opsonin for phagocytosis. They also act as an enzyme to cleave C5 (see next step).

---

**C3**

**C5**

**3b bound to microbe**

**C5a**

**Vascular dilation and permeability**

**Chemotaxis**

**Phagocytosis**

---

**3 Late-Step Membrane Attack.** In the late-step responses, C3b binds to other complement proteins to form an enzyme that cleaves C5, generating C5a and C5b fragments. C5a stimulates the influx of neutrophils and the vascular phase of acute inflammation. The C5b fragment, which remains attached to the microbe, initiates the formation of a complex of complement proteins C6, C7, C8, and C9 into a membrane attack complex protein, or pore, which allows fluids and ions to enter and cause cell lysis.

and the coating materials are called opsonins. Once the opsonin-coated microbe attaches to a complementary receptor on a phagocytic cell, phagocytosis is activated. Opsonins important in innate immunity and acute inflammation include acute-phase proteins, lectins (carbohydrate-binding proteins such as MBL), and complement. With the activation of adaptive humoral immunity, IgG and IgM antibodies can coat microbes and act as opsonins by binding to receptors on neutrophils and macrophages. The adaptive immune response can thus enhance the phagocytic function of innate cells.

**Inflammatory Cytokines**

The cytokines involved in innate immunity include TNF-α, the interleukins IL-1, IL-6, and IL-12; interferons (IFN-γ, IFN-α, IFN-β); and chemokines (see Table 15-1). These cytokines serve various functions. They influence the events of inflammation and innate immunity by producing chemotaxis of leukocytes, stimulating acute-phase protein production, inhibiting viral replication, and affecting the development of cells of the innate and adaptive immune systems. A leukocyte exposed to an external stimulus (e.g., bacteria) can be activated through appropriately triggered receptors (e.g., TLRs) and can respond by secreting small amounts of cytokines and other soluble mediators. If many cells are activated, the concentration of cytokines may be sufficient to influence the function of tissues distant from the site of infection, a true endocrine action. The short half-life of cytokines ensures that an excessive immune response and systemic activation do not usually occur.

Other cytokines important in innate immunity are the interferons, so named because of their ability to interfere with virus infections. Although macrophages and NK cells are the major producers of these cytokines, they can also be secreted by tissue cells. Interferon-α and interferon-β are classified as type I IFNs and are made by fibroblasts and macrophages. They function to inhibit the replication of viruses and improve the recognition of a virally infected cell by cells of the adaptive immune response. Type I IFNs interact with receptors on neighboring cells to stimulate the translation of an antiviral protein that affects viral synthesis and its spread to uninfected cells. The actions of type I IFNs are effective against different types of viruses and intracellular parasites and are thus considered part of innate immunity. Interferon-γ can activate macrophages in innate immunity and regulate lymphocytes in adaptive immunity. Interferon-γ is the most important cytokine produced by the T-helper 1 subclass of T lymphocytes. It is a potent activator of macrophages and enables them to destroy pathogens that proliferate in their vesicles. Interferon-γ also stimulates the production of antibodies that promote phagocytosis of microbes through the complement system.

In addition to their local effects, several of the inflammatory cytokines (e.g., TNF-α, IL-1, and IL-6) have important long-range effects that contribute to host defense. One of the most important of these is the initiation of the acute-phase response. This involves a shift in the proteins synthesized by the liver into the plasma. Two of these, MBL and C-reactive protein (CRP), are of particular interest because they mimic the action of antibodies of the adaptive immune response, but unlike antibodies, these proteins have broad specificity for PAMPs and depend only on the presence of cytokines for their production. Mannose-binding lectin and CRP function as opsonins as well as activators of the complement system.

**The Complement System**

The complement system is an important effector of both innate and humoral immunity that enables the body to localize and destroy infectious pathogens. The complement system, like the blood coagulation system, consists of a group of proteins that are present in the circulation as functionally inactive precursors. These proteins, mainly proteolytic enzymes, make up 10% to 15% of the plasma proteins. For a complement reaction to occur, the complement components must be activated in the proper sequence. Uncontrolled activation of the complement system is prevented by inhibitor proteins and the instability of the activated complement proteins at each step of the process.

There are three parallel but independent pathways for recognizing microorganisms that result in activation of the complement system: the classical, the lectin, and the alternative pathways. The classical pathway recognizes complement-fixing antibodies (IgG, IgM) of adaptive immunity bound to the surface of a microbe or other structure. The lectin pathway uses a plasma protein called the mannose-binding ligand (MBL) that binds to mannose residues on microbial glycoproteins or glycolipids. It is a component of innate immunity, as is the alternative pathway, which recognizes certain microbial molecules in the absence of antibody.

The reactions of the complement systems can be divided into three phases: (1) initial activation, (2) amplification of inflammation, and (3) membrane attack response (See Understanding the Complement System).

Although the classical, lectin, and alternative pathways differ slightly in the proteins they use in the initial activation phase, all converge in the process by acting on the key complement protein C3, essential for the amplification phase. All generate a series of enzymatic reactions that prompt enzymatic cleavage of C3 into two fragments. The larger C3b fragment is a key opsonin that coats microbes and allows them to be phagocytized after binding to the type 1 complement receptor on leukocytes. The smaller C3a fragment triggers an influx of neutrophils to enhance the inflammatory response. Production of C3a and C5a also leads to the activation of basophils and mast cells and the release of inflammatory mediators that produce smooth muscle contraction, increased vascular permeability, and changes in endothelial cells to enhance migration of phagocytes.

The late phase of the complement cascade triggers the assembly of a membrane attack complex (MAC) made up of complement proteins C5 to C9. As its name suggests, the membrane attack complex leads to the lytic destruction of many kinds of cells, including bacteria and altered blood cells. The multiple functions of the
Role of Innate Immunity in Stimulating Adaptive Immunity

In addition to its role as a first-line defense in recognizing microbes and preventing infections, the innate immune response generates molecules that function as “second signals” together with antigens to activate the adaptive immune response. Full activation of antigen-specific B and T lymphocytes requires two signals. Antigen provides the first signal. Microbes, the response of the innate immune system to microbes, and host cells damaged by microbes all may provide the second signal. This requirement for a second microbe-initiated signal ensures that lymphocytes respond to microbes (the natural inducers of innate immunity) and not to harmless noninfectious substances. For the purpose of inducing immunity through vaccination, adaptive immune responses may be induced by antigens without microbes. In such instances, the antigens have to be administered with substances called adjuvants that elicit the same adaptive immune reactions as microbes do.

The second signals that are necessary for activation of the adaptive immune system can be generated by antigen-presenting dendritic cells and macrophages or by activation of the complement system. Microbes that breach the epithelial barriers of the innate immune system stimulate dendritic cells and macrophages to produce two types of second signals that activate T lymphocytes. First, the dendritic cells and macrophages express surface molecules called co-stimulators, which bind to receptors on naïve T cells and function together with antigen recognition to activate T cells. Second, the dendritic cells and macrophages secrete cytokines that stimulate the differentiation of naïve T cells into effector cells of cell-mediated adaptive immunity. Blood-borne microbes activate the complement system by the alternative pathway. One of the proteins produced by the complement system becomes covalently attached to the microbe, producing a second signal for activation of B lymphocytes.

Adaptation

The adaptive immune system is able to distinguish among different, even closely related, microbes and molecules and to “remember” the pathogen by quickly producing a heightened immune response on subsequent encounters with the same agent. The components of the adaptive immune system are lymphocytes and their products. Foreign substances that elicit specific responses are called antigens.

There are two types of adaptive immune responses: humoral and cell-mediated immunity. Humoral immunity is mediated by secreted molecules and is the principal defense against extracellular microbes and toxins. Cell-mediated immunity, or cellular immunity, is mediated by specific T lymphocytes and defends against intracellular microbes such as viruses.

Antigens

Before discussing the cells and responses inherent to adaptive immunity, it is important to understand the substances that elicit a response from the host. Antigens, also called immunogens, are substances foreign to the
host that can stimulate an immune response. These foreign molecules are recognized by receptors on immune cells and by secreted proteins, called antibodies or immunoglobulins, made in response to the antigen. Antigens include bacteria, fungi, viruses, protozoa, and parasites. Nonmicrobial agents such as plant pollens, poison ivy resin, insect venom, and transplanted organs can also act as antigens. Although most antigens are macromolecules, such as proteins and polysaccharides, lipids and nucleic acids occasionally serve as antigens.

Antigens, which in general are large and chemically complex, are biologically degraded into smaller chemical units or peptides. These discrete, immunologically active sites on antigens are called antigenic determinants, or epitopes. It is the unique molecular shape of the epitope that is recognized by a specific immunoglobulin receptor found on the surface of a lymphocyte or by an antigen-binding site of a secreted antibody (Fig. 15-5). A single antigen may contain multiple antigenic determinants, each stimulating a distinct clone of T and B lymphocytes. For example, different proteins that comprise the influenza virus may function as unique antigens (A, B, C, H, and N antigens), each of which contains several antigenic determinants. Hundreds of antigenic determinants are found on structures such as the bacterial cell wall.

Smaller substances (molecular masses <10,000 daltons) usually are unable to stimulate an adequate immune response by themselves. When these low–molecular-weight compounds, known as haptens, combine with larger carrier molecules, they function as antigens. The hapten–carrier complex can stimulate the production of antibodies, some of which combine with the hapten portion of the complex. An allergic response to the antibiotic penicillin is an example of a medically important reaction due to hapten–carrier complexes. Penicillin (molecular mass of approximately 350 daltons) is normally a nonantigenic molecule. However, in some individuals, it can chemically combine with body proteins to form larger complexes that can then generate a potentially harmful immune allergic response.

Cells and Molecules of Adaptive Immunity

B and T lymphocytes are the effector cells of the adaptive immune system that specifically recognize and respond to foreign antigens. Accessory cells, such as macrophages and dendritic cells, function as antigen-presenting cells by first processing a complex antigen into epitopes and then displaying the foreign and self-peptides on their membranes so that appropriate activation of lymphocytes occurs. We will begin with a discussion of the antigen-presenting cells, move to the lymphocytes, and end with the MHC molecules that display antigens for recognition by T lymphocytes.

Antigen-Presenting Cells

Macrophages are key members of the mononuclear phagocytic system that engulf and digest microbes and other foreign substances. The monocytes migrate from the blood to various tissues, where they mature into the major tissue phagocytes, the macrophages. As the general scavenger cells of the body, the macrophages can be fixed in a tissue or free to migrate from an organ to lymphoid tissues. The tissue macrophages are scattered in connective tissue or may be clustered in the lung (alveolar macrophages), liver (Kupffer cells), spleen, lymph nodes, peritoneum, or central nervous system (microglial cells).

Dendritic cells are found in most tissues where antigen enters the body and in the peripheral lymphoid tissues, where they function as potent antigen-presenting cells. In these environments, dendritic cells can acquire specialized functions and appearances, as do macrophages. Langerhans cells are specialized dendritic cells in the skin, whereas follicular dendritic cells are found in the lymph nodes. Langerhans cells are constantly surveying the skin for antigen and can transport foreign material to a nearby lymph node. Skin dendritic cells and macrophages also are involved in cell-mediated immune reactions of the skin such as allergic contact dermatitis.

Lymphocytes

Like other blood cells, B and T lymphocytes are generated from stem cells in the bone marrow. Undifferentiated, immature lymphocytes move to the central lymphoid tissues, where they develop into distinct types of mature lymphocytes (Fig. 15-6). B lymphocytes mature in the bone marrow and then move to the peripheral lymphoid tissues where they are exposed to antigen and stimulated to differentiate into antibody-producing plasma cells. T lymphocytes complete their maturation in the thymus and then move to the peripheral lymphoid tissues, where they function to produce cell-mediated immunity,
as well as aiding in antibody production. High concentrations of mature T and B lymphocytes are found in the lymph nodes, spleen, skin, and mucosal tissues, where they can respond to antigen.

B and T lymphocytes possess all of the key properties associated with the adaptive immune response—specificity, diversity, memory, and self/nonself recognition. These cells can exactly recognize and target a specific antigen and differentiate it from other substances that may be similar. The approximately $10^{12}$ lymphocytes in the body have tremendous diversity. They can respond to the millions of different kinds of antigens encountered daily. This diversity occurs because an enormous variety of lymphocyte populations have been programmed and selected during development, each to respond to a different antigen. After responding, they can acquire immunologic memory. The memory B and T lymphocytes that are generated remain in the body for a longer time and can respond more rapidly on repeat exposure than naive cells. Because of this heightened state of immune reactivity, the immune system usually can respond to commonly encountered microorganisms so efficiently that we are unaware of the response.

Adaptive immune responses are initiated when the antigen receptors of lymphocytes recognize antigens. The key trigger for the activation of B and T cells is the recognition of the antigen by unique surface receptors. B-cell antigen receptors (membrane-bound antibodies) and the antibodies that B cells secrete are able to recognize a broad range of structurally different molecules of varied sizes. This enables antibodies to detect diverse microbes and toxins. In contrast, the T-cell receptor recognizes only peptides, and only when these peptides are displayed on antigen-presenting cells bound to membrane proteins encoded by the MHC gene. Thus, T cells are only able to detect cell-associated microbes and antigens.

Activation of the lymphocytes depends on appropriate processing and presentation of antigen to T lymphocytes by antigen-presenting cells such as macrophages and dendritic cells (Fig. 15-7). On recognition of antigen and after additional stimulation by cytokines, the B and T lymphocytes divide several times to form clonal cell populations that continue to differentiate into effector and memory cells. After antigen binds to a B-cell receptor, the cell proliferates and differentiates into plasma cells that secrete antibodies that are a form of the B-cell receptor and have identical antigen specificity. Thus, the antigen that activates a given B cell becomes the target of the antibody produced by the cell’s progeny. After a T cell is activated by its first encounter with an antigen, it proliferates and differentiates into helper or cytotoxic T cells. Helper T cells provide signals that activate antigen-stimulated B cells to differentiate and produce antibody. Some helper T cells also activate macrophages to become more efficient at killing engulfed pathogens. Cytotoxic T cells kill cells that are infected with viruses or other intracellular pathogens.

**Major Histocompatibility Complex Molecules**

Major histocompatibility complex molecules are membrane-bound proteins encoded by a MHC gene locus that display peptides for recognition by T lymphocytes. Although first identified as antigens that evoke rejection of transplanted organs, histocompatibility (i.e., tissue compatibility) molecules are now known to be extremely important for induction and regulation of immune responses. Recall that T cells (in contrast to B cells) can only recognize membrane-bound antigens, and hence histocompatibility molecules are critical to the induction of T-cell immunity. In humans, the genes encoding the most important MHC molecules are clustered on a small segment of chromosome 6.

The MHC molecules involved in self-recognition and cell-to-cell communication fall into two classes, class I and class II (Fig. 15-8). Class I MHC (MHC-I) molecules, which are expressed on all nucleated cells and platelets, are cell surface molecules that interact with the receptor–antigen peptide complex on CD8+ cytotoxic T cells. Class II MHC (MHC-II) molecules, which are expressed mainly on dendritic cells, macrophages, and B lymphocytes, communicate with the antigen receptor and the CD4 molecule on helper T cells.

Although the MHC-I and MHC-II proteins differ in subunit composition, they are similar in overall structure, and each contains a peptide-binding cleft on the extracellular portion of the molecule. The MHC-I molecule contains a cleft that accommodates a peptide fragment of antigen. Cytotoxic T cells can become activated only...
when they are presented with the foreign antigen peptide associated with the class I MHC molecule. During a typical viral infection of a cell, small peptides from degraded viral proteins associate with MHC-I molecules and are then transported to the infected cell membrane. This complex communicates to the cytotoxic T cell that the cell must be destroyed for the overall survival of the host. The MHC-II molecule’s binding cleft accommodates a fragment of antigen from pathogens that have been engulfed and digested by an antigen-presenting cell during the process of phagocytosis. The engulfed pathogen is degraded into peptides in cytoplasmic vesicles and then complexed with the MHC-II molecule. Helper T cells recognize these complexes on the surface of antigen-presenting cells and become activated. These triggered helper T cells multiply quickly and direct other immune cells to respond to the invading pathogen through the secretion of cytokines.

Each individual has a unique collection of MHC proteins, and a variety of MHC molecules can exist in a population. Thus, MHC molecules are both polygenic and polymorphic. The MHC genes are the most polymorphic genes known. Because of the number of MHC genes and the possibility of several alleles for each gene, it is almost
impossible for any two individuals to have an identical MHC profile, unless they are identical twins. Major histocompatibility complex alleles affect immune responses as well as susceptibility to a number of diseases.

Human MHC proteins are called human leukocyte antigens (HLAs) because they were first detected on white blood cells. Because these molecules play a role in transplant rejection and are detected by immunologic tests, they are commonly called antigens. The classic human MHC-I molecules are divided into types called HLA-A, HLA-B, and HLA-C, and the MHC-II molecules are identified as HLA-DR, HLA-DP, and HLA-DQ (Table 15-3). Each of the gene loci that describe HLA molecules can be occupied by multiple alleles or alternative genes. For example, there are more than 350 possible alleles for the A locus, 650 alleles for the B locus, and 180 alleles for the C locus. The genes and their expressed molecules are designated by a letter and numbers (e.g., HLA-B27).

Because the class I and II MHC genes are closely linked on one chromosome, the combination of HLA genes usually is inherited as a unit, called a haplotype. Each person inherits a chromosome from each parent and therefore has two HLA haplotypes. The identification or typing of HLA molecules is important in tissue or organ transplantation, forensics, and paternity evaluations. In organ or tissue transplantation, the closer the matching of HLA types, the greater the probability of identical antigens and the lower the chance of rejection.

**B Lymphocytes and Humoral Immunity**

Humoral immunity is mediated by antibodies, which are produced by B lymphocytes and their progeny. B lymphocytes can be identified by the presence of membrane immunoglobulin that functions as the antigen receptor, class II MHC proteins, complement receptors, and specific CD molecules. During the maturation process in the bone marrow, B-cell progenitors (pre-B cells) develop into mature or naive B cells. The mature B cell leaves the bone marrow, enters the circulation, and migrates to the various peripheral lymphoid tissues, where it is stimulated to respond to a specific antigen. Each of the stages of B-cell development are characterized by a specific pattern of immunoglobulin (Ig) gene expression and the expression of other cell surface proteins that serve as phenotypic markers of these maturational stages.

The commitment of a B-cell line to a specific antigen is evidenced by the expression of the membrane-bound Ig receptors that recognize antigen. B cells that encounter antigen complementary to their surface immunoglobulin receptor and receive T-cell help undergo a series of changes that transform them into antibody-secreting plasma cells or into memory B cells (Fig. 15-9). The antibodies produced by the plasma cells are released into the lymph and blood, where they bind and remove their unique antigen with the help of other immune effector cells and molecules. The longer-lived memory B cells are distributed to the peripheral tissues in preparation for subsequent antigen exposure.

Immunoglobulins

Immunoglobulins, or antibodies, function as antigen receptors for B cells or as effector molecules of the humoral immune response. The immunoglobulins have been divided into five classes—IgG, IgA, IgM, IgD, and IgE—each with a different role in the immune defense strategy (Table 15-4). Immunoglobulins have a characteristic four-polypeptide structure consisting of at least two identical antigen-binding sites (Fig. 15-10). Each Ig is composed of two identical light (L) chains and two identical heavy (H) chains to form a “Y”-shaped structure.

Immunoglobulin G is the only immunoglobulin that is present in body fluids and readily enters the tissues. It is abundant among the circulating immunoglobulins. It is produced by B cells and can switch from IgM to IgG, causing the B-cell clone to produce one of the different immunoglobulin types. During the course of the immune response, class switching (e.g., from IgM to IgG) can occur, causing the B-cell clone to produce one of the different immunoglobulin types.

**Immunoglobulin G** (gamma globulin) is the most abundant of the circulating immunoglobulins. It is present in body fluids and readily enters the tissues. Immunoglobulin G is the only immunoglobulin that crosses the placenta and can transfer immunity from the mother to the fetus. This class of immunoglobulin protects against bacteria, toxins, and viruses in body fluids and activates the complement system. This antibody can also bind to target cells and Fc receptors on NK cells and macrophages, leading to lysis of the target cell. There are four subclasses of IgG (i.e., IgG₁, IgG₂, IgG₃, and IgG₄), each of which has some restrictions in its response to certain types of antigens. For example, IgG₂ appears to be responsive to bacteria that are encapsulated with a polysaccharide layer, such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*.

**Immunoglobulin A** is a secretory immunoglobulin, is found in saliva, tears, breast milk, and bronchial, gastrointestinal, prostatic, and vaginal secretions. This dimeric secretory immunoglobulin is considered a primary defense against local infections in mucosal tissues. Immunoglobulin A prevents the attachment of viruses and bacteria to epithelial cells.

**Immunoglobulin M** is a macromolecule that forms a polymer of five basic immunoglobulin units. It cannot cross the placenta and thus does not transfer maternal immunity. It is the first circulating immunoglobulin to appear in response to an antigen and is the first antibody type made by a newborn. This is diagnostically useful because the presence of IgM suggests a current infection in the infant by a specific pathogen. The identification of newborn IgM rather than maternally transferred IgG to the specific pathogen is indicative of an in utero or newborn infection.

**Immunoglobulin D** is found primarily on the cell membranes of B lymphocytes. It serves as an antigen receptor for initiating the differentiation of B cells.

**Immunoglobulin E** is involved in inflammation, allergic responses, and combating parasitic infections. It binds to mast cells and basophils. The binding of antigen to mast cell– or basophil-bound IgE triggers these cells to release histamine and other mediators important in inflammation and allergies.

### Humoral Immunity

Humoral immunity functions to eliminate extracellular microbes and microbial toxins. The combination of antigen with antibody can result in several effector responses, such as precipitation of antigen–antibody complexes, agglutination or clumping of cells, neutralization of bacterial toxins and viruses, lysis and destruction of pathogens or cells, adherence of antigen to immune cells, facilitation of phagocytosis, and complement activation. For example, antibodies can neutralize a virus by blocking the sites on the virus where it binds to the host cell, thereby negating its ability to infect the cell.

Two types of responses occur in the development of humoral immunity: primary and secondary (Fig. 15-11). A primary immune response occurs when the antigen is first introduced into the body. During the primary response, there is a latent period or lag before the antibody can be detected in the serum. This latent period involves the processing of antigen by the antigen-presenting cells and its recognition by CD4⁺ helper T cells. After the antigen...
receptors on CD4+ helper T cells recognize the antigenic peptide–class II MHC molecules, the T cells become activated and produce cytokines to further stimulate and direct the immune system. In humoral immunity, activated CD4+ helper T cells trigger B cells to proliferate and differentiate into a clone of plasma cells that produce antibody. This activation process takes 1 to 2 weeks, but once generated, detectable antibody continues to rise for several weeks. Recovery from many infectious diseases occurs during the primary response when the antibody concentration is reaching its peak.

The secondary or memory response occurs on second or subsequent exposures to the antigen. During the primary response, a fraction of activated B cells does not differentiate into plasma cells but instead forms a pool of memory B cells. In a secondary response, the rise in antibody occurs sooner and reaches a higher level because of these available memory cells. The booster immunization given for some diseases, such as tetanus, makes use of the memory response. For a person who has been previously immunized, administration of a booster shot causes an almost immediate rise in antibody to a level sufficient to prevent development of the disease. Activated T cells can also generate primary and secondary cell-mediated immune responses.

**T Lymphocytes and Cell-Mediated Immunity**

T lymphocytes function in the activation of other T cells and B cells, in the control of intracellular viral infections, in the rejection of foreign tissue grafts, and in delayed hypersensitivity reactions (see Chapter 16). Collectively, these immune responses are referred to as cell-mediated or cellular immunity.

T lymphocytes arise from bone marrow stem cells, but unlike B cells, pre-T cells migrate to the thymus for their maturation. There the immature T lymphocytes undergo rearrangement of the genes needed for expression of a unique T-cell antigen receptor similar to but distinct from the B-cell receptor. The T-cell receptor is composed of two polypeptide chains that form a groove that recognizes the processed antigen peptide–MHC molecules (Fig. 15-12). Maturation of subpopulations of T cells (i.e., CD4+ and CD8+) also occurs in the thymus. Mature T cells migrate to the peripheral lymphoid tissues and, upon encountering antigen, multiply and differentiate into memory T cells and various mature T-cell populations. The two main populations of mature T cells are CD4+ (helper) and CD8+ (cytotoxic) T cells.

**Helper T Cells**

The CD4+ helper T cell serves as a master regulator for the immune system. Activation of CD4+ helper T cells depends on the recognition of antigen in association with class II MHC molecules. Once activated, the helper T cells secrete cytokines that influence the function of nearly all other cells of the immune system. Differences in the types of cytokines made by the CD4+ helper T cell produce different types of immune responses. These cytokines activate and regulate B cells, cytotoxic T cells, NK cells, macrophages, and other immune cells.

The activated CD4+ helper T cell can differentiate into distinct subpopulations of helper T cells (e.g., T\(_{H1}\), T\(_{H2}\), and T\(_{H17}\)) based on the cytokines secreted by the antigen-presenting cell at the site of activation. The cytokine IL-12 produced by macrophages and dendritic cells directs the maturation of CD4+ helper T cells toward T\(_{H1}\) cells. The cytokine IL-4 produced by mast cells and T cells induces differentiation toward T\(_{H2}\) cells. The cytokines IL-6 and transforming growth factor-beta (TGF-β), notably in the absence of either IL-4 or IL-12, will induce differentiation toward T\(_{H17}\) cells.

The distinct pattern of cytokines secreted by mature T\(_{H1}\) and T\(_{H2}\) cells defines these subpopulations of T cells and determines their functions. Activated T\(_{H1}\) cells stimulate phagocyte-mediated ingestion and killing of microbes. T\(_{H1}\) cells produce the cytokine IFN-γ,
which activates macrophages and stimulates B cells to produce IgG antibodies that activate complement and coat pathogens for phagocytosis. T_{H2} cells produce IL-4, which stimulates B cells to differentiate into IgE-secreting plasma cells; IL-5, which activates eosinophils; and IL-13, which activates mucosal epithelial cells to secrete mucus and expel microbes. Differentiated CD4^+ T cells of the T_{H1} subset recognize microbial peptides on macrophages and have the dual function of stimulating the production of IgG antibodies and eliminating cells infected with certain pathogenic intracellular microbes such as mycobacteria; whereas those of the T_{H2} subset tend to recognize protein antigens or chemicals that stimulate the production of IgE and development of allergies. Activated T_{H1} cells produce the cytokine IL-17, which promotes inflammation, and plays a role in the adaptive immune response and in some T cell–mediated inflammatory disorders.

In most immune responses, a balanced response of T_{H1} and T_{H2} cells occurs, but immunization or exposure to antigen can skew the response to one or the other subset. For example, the extensive exposure to an allergen in atopic individuals has been shown to shift the naive CD4^+ T cell toward a T_{H2} response, with the production of the cytokines that influence IgE production and mast cell priming. An appreciation of these processes has led to clinical research that suggests that redirection of an allergic T_{H2} response to a nonallergic T_{H1} response can occur in atopic individuals through modified immunization protocols.

**Cytotoxic T Cells**

Activated CD8^+ lymphocytes become cytotoxic T cells after recognition of class I MHC–antigen complexes on target cell surfaces, such as body cells infected by viruses or transformed by cancer (Fig. 15-13). The recognition of class I MHC–antigen complexes on infected target cells ensures that neighboring uninfected host cells, which express class I MHC molecules alone or with self-peptide, are not indiscriminately destroyed. The CD8^+ cytotoxic T cells perform their killing function by injecting preformed cytotoxic proteins into target cells, thereby triggering apoptosis or programmed cell death (see Chapter 2). Cytotoxic T cells also produce and release cytokines, such as IFN-γ, which inhibits viral replication and is an important inducer of MHC class I molecule expression and macrophage activation. The CD8^+ cytotoxic T cells are especially important in controlling replicating viruses and intracellular bacteria because antibodies cannot readily penetrate the membrane of living cells.

**Regulatory T Cells**

A recently defined type of T lymphocyte is the regulatory T cell, which has CD4 and CD25 expressed on its cell membrane. Regulatory T cells, in contrast to CD4^+ helper T cells, suppress immune responses by inhibiting the proliferation of other potentially harmful self-reactive lymphocytes. The actions of regulatory T cells are antigen specific. Activation of a regulatory T-cell receptor by the antigen prompts the secretion of the cytokine IL-10 and transforming growth factor-β (TGF-β). These cytokines inhibit the proliferation and activation of lymphocytes and macrophages. There is also recent evidence that regulatory CD8^+ T cells can selectively down-regulate T cells that are activated by either self or foreign antigens. These cells are thought to differentiate into effector cells during the primary immune response and function as suppressor cells during the secondary or memory phases of immunity, and are primarily involved in self–nonself discrimination. The potential clinical importance of regulatory T cells is suggested from animal studies showing inhibition of inflammatory bowel disease, experimental allergic encephalitis, and autoimmune diabetes by increased activity of regulatory T cells.

**Cell-Mediated Immunity**

Cell-mediated immunity functions against microbes, including bacteria, parasites, and all viruses that replicate inside cells where they cannot be destroyed by antibodies. Both CD8^+ and CD4^+ cells contribute to the response, with each having different effector mechanisms for the eradication of the infection.

The effector functions of CD8^+ cytotoxic T cells, which act against cells infected with viruses, are the most direct. Antigens derived from the virus multiply inside
the infected cell and are displayed on the target cell’s surface, where they are recognized by antigen receptors on the cytotoxic T cell (see Fig. 15-12). Cytotoxic T cells perform their killing function by releasing preformed cytotoxic proteins that induce apoptosis or programmed cell death of the target cell (see Chapter 2).

The principal function of CD4+ cells of the T,1 subset involves the defense against intracellular pathogens, such as mycobacteria, which grow primarily in phagosomes of macrophages, shielding them from the effects of both antibodies and cytotoxic T cells. These cells secrete the cytokine IFN-γ, a potent macrophage activator, which stimulates the induction of microbicidal substances in macrophages, leading to the destruction of the ingested microbes. CD4+ T,1 cells also produce a range of other cytokines, chemokines, and surface molecules that do not activate infected macrophages, but instead kill chronically infected senescent macrophages, stimulate the production of new macrophages in bone marrow, and recruit fresh macrophages to sites of infection. Thus, the CD4+ T,1 cell controls and coordinates host defenses against certain intracellular pathogens, a function that helps to explain why a decreased CD4+ T,1 count in persons with acquired immunodeficiency syndrome (AIDS) places them at high risk for intracellular pathogen infections.

**Active Versus Passive Immunity**

Adaptive, or specific, immune responses are designed to protect the body against potentially harmful foreign substances, infections, and other sources of non–self antigens. It is the specific protection that is acquired through exposure to antigens (active immunity) or through transfer of protective antibodies against an antigen (passive immunity).

*Active immunity* is acquired through immunization or actually having a disease. It is called *active immunity* because it depends on a response to the antigen by the person’s immune system. Active immunity, although long lasting once established, requires a few days to weeks after a first exposure before the immune response is sufficiently developed to contribute to the destruction of the pathogen. However, the immune system usually is able to react within hours to subsequent exposure to the same agent because of the presence of memory B and T lymphocytes and circulating antibodies. The process of acquiring the ability to respond to an antigen after its administration by vaccine is known as *immunization*. An acquired immune response can improve on repeated exposures to an injected antigen or a natural infection.

*Passive immunity* is immunity transferred from another source. An infant receives passive immunity naturally from the transfer of antibodies from its mother in utero and through breast milk. Maternal IgG crosses the placenta and protects the newborn during the first few months of life. Normally, an infant has few infectious diseases during the first 3 to 6 months owing to the protection provided by the mother’s antibodies. Passive immunity also can be artificially provided by the transfer of antibodies produced by other people or animals. Some protection against infectious disease can be provided by the injection of hyperimmune serum, which contains high concentrations of antibodies for a specific disease, or immune serum or gamma globulin, which contains a pool of antibodies from many individuals providing protection against many infectious agents. Passive immunity produces only short-term protection that lasts weeks to months.

**Regulation of the Immune Response**

Self-regulation is an essential property of the immune system. An inadequate immune response may lead to immunodeficiency, but an inappropriate or excessive response may lead to conditions varying from allergic reactions to autoimmune diseases. This regulation is not well understood and involves all aspects of the immune response—antigen, antibody, cytokines, regulatory T cells, and the neuroendocrine system.

With each exposure to antigen, the immune system must determine the branch of the immune system to be activated and the extent and duration of the immune response. After exposure to an antigen, the immune response to that antigen develops after a brief lag, reaches a peak, and then recedes. Normal immune responses are self-limited because the response eliminates the antigen, and the products of the response, such as cytokines and antibodies, have a limited life span and are secreted only for brief periods after antigen recognition. Evidence suggests that cytokine feedback from the helper T or regulatory T cells controls several aspects of the immune response.

Another facet of immune self-regulation is inhibition of immune responses by tolerance. The term *tolerance* is used to define the ability of the immune system to be nonreactive to self-antigens while producing immunity to foreign agents. Tolerance to self-antigens protects an individual from harmful autoimmune reactions (see Chapter 16). Exposure of an individual to foreign antigens may lead to tolerance and the inability to respond to potential pathogens that cause infection. Tolerance exists not only to self-tissues but also to maternal–fetal tissues. Special regulation of the immune system is evident in privileged sites such as the brain, testes, ovaries, and eyes. Immune damage in these areas could result in serious consequences to the individual and the species.
Developmental Aspects of the Immune System

Embryologically, the immune system develops in several stages, beginning at 5 to 6 weeks as the fetal liver becomes active in hematopoiesis. Development of the primary lymphoid organs (i.e., thymus and bone marrow) begins during the middle of the first trimester and proceeds rapidly. Secondary lymphoid organs (i.e., spleen, lymph nodes, and mucosa-associated lymphoid tissues) develop soon after. These secondary lymphoid organs are rather small but well developed at birth and mature rapidly after exposure to microbes during the postnatal period. The thymus is fully formed and functional and is the largest lymphoid tissue relative to body size at birth.

Transfer of Immunity from Mother to Infant

Protection of a newborn against antigens occurs through transfer of maternal antibodies. Maternal IgG antibodies cross the placenta during fetal development and remain functional in the newborn for the first few months of life (Fig. 15-14). IgG is the only class of immunoglobulins to cross the placenta. Levels of maternal IgG decrease significantly during the first 3 to 6 months of life, while infant synthesis of immunoglobulins increases. Maternally transmitted IgG is effective against most microorganisms and viruses. The largest amount of IgG crosses the placenta during the last weeks of pregnancy and is stored in fetal tissues; therefore, infants born prematurely may be deficient. Because of the transfer of IgG antibodies to the fetus, an infant born to a mother infected with HIV will have a positive HIV antibody test result, although the child may not necessarily be infected with the virus.

Cord blood does not normally contain IgM or IgA. If present, these antibodies are of fetal origin and represent exposure to intrauterine infection. The infant begins producing IgM antibodies shortly after birth, in response to the immense antigenic stimulation of his or her new environment. Premature infants appear to be able to produce IgM as well as term infants. At approximately 6 days of age the IgM rises sharply, and this rise continues until approximately 1 year of age, when the adult level is achieved.

![Graph showing Maternal/neonatal serum immunoglobulin G levels.](From J Pediatr. 1968;72(2):276–290.)
Serum IgA normally is first detected at approximately 13 days after birth. The level increases during early childhood until adult levels are reached between the sixth and seventh years. Maternal IgA also is transferred to the infant in breast milk. These antibodies provide local immunity for the intestinal system and have been shown to decrease diarrheal infections. These evolutionary adaptations of the immune system have increased the survival of our species and optimized the development of other important organs in the early months of life.

**Immune Response in the Elderly**

Aging is characterized by a declining ability to adapt to environmental stresses. One of the factors thought to contribute to this problem is a decline in immune responsiveness. This includes changes in cell-mediated and humoral immune responses. Elderly persons tend to become more susceptible to infections, have more evidence of autoimmune and immune complex disorders than younger persons, and have a higher incidence of cancer. Experimental evidence suggests that vaccination is less successful in inducing immunization in older persons than in younger adults. However, the effect of altered immune function on the health of elderly persons is clouded by the fact that age-related changes or disease may affect the immune response.

The alterations in immune function that occur with advanced age are not fully understood. There is a decrease in the size of the thymus gland, which is thought to affect T-cell function. The size of the gland begins to decline shortly after sexual maturity, and by 50 years of age, it usually has diminished to 15% or less of its maximum size. There are conflicting reports regarding age-related changes in the peripheral lymphocytes. A suggested biologic clock in T cells that determines the number of times it divides may regulate cell number with age. Some researchers have reported a decrease in the absolute number of lymphocytes, and others have found little, if any, change. The most common finding is a slight decrease in the proportion of T cells to other lymphocytes and a decrease in CD4+ and CD8+ T cells.

More evident are altered responses of the immune cells to antigen stimulation; increasing proportions of lymphocytes become unresponsive, whereas the remainder continue to function relatively normally. T and B cells show deficiencies in activation. In the T-cell types, the CD4+ subset is most severely affected. Evidence indicates that aged T cells have a decreased rate of synthesis of the cytokines that drive the proliferation of lymphocytes and a diminished expression of the receptors that interact with those cytokines. For example, it has been shown that IL-2, IL-4, and IL-12 levels decrease with aging. Although B-cell function is compromised with age, the range of antigens that can be recognized is not diminished. If anything, the repertoire, including outgrowths of autoreactive B-cell clones, is increased to the extent that B cells begin to recognize some self-antigens as foreign antigens. This may be the basis for the increased incidence of autoimmune disease in the elderly.

**SUMMARY CONCEPTS**

- Newborn infants are protected against antigens in early life by passive transfer of maternal antibodies through the placenta (IgG) and through breast feeding (IgA).
- The largest amount of IgG crosses the placenta during the last weeks of pregnancy and is stored in fetal tissues; therefore, infants born prematurely may be deficient. Because of the transfer of IgG antibodies to the fetus, an infant born to a mother infected with HIV will have a positive HIV antibody test result, although the child may not necessarily be infected with the virus.
- Aging is characterized by changes in immune responsiveness, including cell-mediated and humoral immune responses. Elderly persons tend to be more susceptible to infections, have more evidence of autoimmune and immune complex disorders than younger persons, and have a higher incidence of cancer.

**REVIEW EXERCISES**

1. The systemic manifestations (e.g., generalized muscle aches, chills and fever, loss of appetite) that accompany a severe sore throat or acute respiratory infection are stimulated by reactions to cytokines of the innate immune system rather than by the antibodies or cell-mediated responses of the adaptive immune response.
   
   A. Explain.

2. A nursing student is working in a community clinic as a volunteer. Each time she enters the clinic, she suffers bouts of sneezing and runny nose. She has a history of mold allergy and her younger brother has asthma. Analysis at the allergy clinic indicates a strong reaction to latex. She is advised to avoid exposure to all forms of latex.
   
   A. What class of immunoglobulin and what type of mediator cells are responsible for the symptoms expressed in this individual?
   
   B. What type of T-helper cell and cytokines direct the expression of this humoral immune response?
C. Is this an example of active or passive immunity? Is it a primary or secondary immune response?

3. A 5-month-old child presents with thrush, a yeast infection of the mouth. In the last 2 months, he has had recurrent bouts of otitis media. His tonsils are very small. Laboratory analysis indicates a low lymphocyte count and no T lymphocytes. Further analysis indicates a genetic mutation in the T-cell receptor that affects maturation of all T cells. The final diagnosis is severe combined immunodeficiency disease. A bone marrow transplant is being pursued with cells from his HLA-matched sibling.

A. Explain why infections were not present in the first few months of this child’s life.

B. What would be the impact of an absence of T cells on both humoral and cell-mediated immunity?

The immune system is a multifaceted defense network that has evolved to protect against invading microorganisms, prevent the proliferation of cancer cells, and mediate the healing of damaged tissue. Under normal conditions, the immune response deters or prevents disease. Occasionally, however, the inadequate, inappropriate, or misdirected activation of the immune system can lead to debilitating or life-threatening illnesses, typified by allergic or hypersensitivity reactions, transplantation rejection, autoimmune disorders, and immunodeficiency states.

### Hypersensitivity Disorders

Although activation of the immune system normally leads to production of antibodies and T-cell responses that protect the body against attack by microorganisms, it is also capable of causing tissue injury and disease. Disorders caused by immune responses are collectively referred to as hypersensitivity reactions, a term that arose from the observation that someone exposed to a particular antigen exhibited a detectable reaction or was “hypersensitive” to subsequent encounters with the same antigen.

Hypersensitivity disorders are commonly classified into four groups according to the type of immune response causing the injury and the nature and location of the antigen that is the target of the response: type I, immediate hypersensitivity disorders; type II, antibody-mediated disorders; type III, immune complex-mediated disorders; and type IV, T-cell-mediated disorders (Table 16-1).

### Type I, Immediate Hypersensitivity Disorders

Type I hypersensitivity reactions are IgE-mediated reactions that begin rapidly, often within minutes of an antigen challenge. Often, they are referred to as allergic reactions and the antigens are called allergens. Typical
Allergens include the proteins in plant pollens, house dust mites, animal dander, foods, and chemicals like the antibiotic penicillin. Exposure to the allergen can be through inhalation, ingestion, injection, or skin contact. Depending on the portal of entry, type I reactions may be limited to merely annoying (e.g., seasonal rhinitis), severely debilitating (asthma), or systemic and potentially life-threatening (anaphylaxis).

Two types of cells are central to a type I hypersensitivity reaction: type 2 helper T (T_H2) cells and granule-containing cells, such as mast cells and/or basophils. There are two subsets of helper T cells (T_H1 and T_H2) that develop from the same precursor CD4+ T lymphocyte (see Chapter 15). T_H1 cells differentiate in response to microbes and stimulate the differentiation of B cells into IgM- and IgG-producing plasma cells. T_H2 cell differentiation occurs in response to allergens and helminths (intestinal parasites). Cytokines secreted by T_H2 cells stimulate differentiation of B cells into IgE-producing plasma cells, act as growth factors for mast cells, and recruit and activate eosinophils.

The tissue-based mast cells and blood-based basophils are both derived from hematopoietic precursor cells in the bone marrow. Mast cells are widely distributed in connective tissue, especially in areas beneath the skin and mucous membranes of the respiratory, gastrointestinal, and genitourinary tracts and adjacent to blood and lymph vessels. This location places them near surfaces that are exposed to environmental antigens and parasites. Basophils, which share many features with mast cells, are granulocytes that circulate in the blood and represent less than 1% of peripheral leukocytes (white blood cells). Both mast cells and basophils contain preformed mediators of inflammation that are stored in granules and released at the time of activation, and both have high-affinity receptors for IgE antibodies on their surface.

Type I hypersensitivity reactions begin with mast cell or basophil sensitization. During the sensitization or priming stage, allergen-specific IgE antibodies attach to receptors on the surface of mast cells and basophils. With subsequent exposure, the sensitizing allergen binds to the cell-associated IgE and triggers a series of events that ultimately lead to degranulation of the sensitized mast cells or basophils, causing the release of their preformed mediators (Fig. 16-1). Mast cells are also the source of lipid-derived membrane products (e.g., prostaglandins and leukotrienes) and cytokines that participate in the continued response to the allergen.

Many type I hypersensitivity reactions, such as bronchial asthma, have two well-defined phases: (1) a primary or immediate-phase response characterized by vasodilation, vascular leakage, and smooth muscle contraction, and (2) a secondary or late-phase response characterized by more intense infiltration of tissues with eosinophils and other acute and chronic inflammatory cells, as well as tissue destruction in the form of epitelial cell damage.

The primary or immediate-phase response usually occurs within 5 to 30 minutes of exposure to antigen and subsides within 60 minutes. It is mediated by mast cell degranulation and the release of preformed mediators. These mediators include histamine, prostaglandins, leukotrienes, platelet activating-factor, interleukins, and enzymes such as chymase and trypsin that lead to the generation of kinins. Histamine is a potent vasodilator that increases the permeability of capillaries and venules and causes smooth muscle contraction and bronchoconstriction. The kinins, which are a group of potent inflammatory peptides, require activation through enzymatic modification. Once activated, these peptide mediators (e.g., bradykinin) produce vasodilation and smooth muscle contraction.

The secondary or late-phase response occurs about 2 to 8 hours later and lasts for several days. It results from the action of lipid mediators and cytokines involved in the inflammatory response. The lipid mediators are derived from mast cell membrane phospholipids, which are broken down to form arachidonic acid. Arachidonic acid, in turn, is the parent compound from which the leukotrienes and prostaglandins are synthesized.
(see Chapter 3). The leukotrienes and prostaglandins produce responses similar to histamine, although their effects are delayed and prolonged by comparison. Mast cells also produce cytokines and chemotactic factors that prompt the influx of eosinophils and leukocytes to the site of allergen contact, additionally contributing to the inflammatory response.

At this point, it is important to note that not all IgE-mediated responses produce discomfort and disease. Type I hypersensitivity, particularly the late-phase response, plays a protective role in the control of parasitic intestinal infections. IgE antibodies directly damage the larvae of these parasites by recruiting inflammatory cells and causing antibody-dependent cell-mediated cytotoxicity. This type of type I hypersensitivity reaction is particularly important in developing countries where much of the population is infected with intestinal parasites.

**Systemic (Anaphylactic) Reactions**

Anaphylaxis is a systemic life-threatening hypersensitivity reaction characterized by widespread edema, difficulty breathing, and vascular shock secondary to vasodilation (see section on anaphylactic shock, Chapter 20). It results from the presence of antigen introduced by injection, insect sting, or absorption across the epithelial surface of the skin or gastrointestinal mucosa. The level of severity depends on the level of sensitization. Even small amounts of antigen,
such as the presence of residual amounts of peanut that remain on equipment used for preparing foods containing peanuts, can be sufficient to cause anaphylaxis in an extremely sensitive person. Within minutes after exposure, itching, hives, and skin erythema develop, followed shortly by bronchospasm and respiratory distress. Vomiting, abdominal cramps, diarrhea, and laryngeal edema and obstruction follow, and the person may go into shock and die unless effective treatment is instituted.

The initial management of anaphylaxis focuses on the establishment of a stable airway and intravenous access, and the administration of epinephrine. Epinephrine produces relaxation of bronchial smooth muscle and inhibits the immediate life-threatening cardiovascular effects of anaphylaxis. Persons with a history of anaphylaxis should be provided with preloaded epinephrine syringes and instructed in their use. They should also be instructed to seek immediate professional help regardless of the initial response to self-treatment. Family members and caregivers of young children should be trained to inject epinephrine. Prevention of exposure to potential triggers that cause anaphylaxis is particularly important. Finally, all persons with potential for anaphylaxis should be advised to wear or carry a medical alert bracelet, necklace, or other identification to inform emergency personnel of the possibility of anaphylaxis.

Local (Atopic) Reactions

Local or atopic reactions usually occur when the antigen is confined to a particular site by virtue of exposure. The term atopic refers to a genetically determined hypersensitivity to common environmental allergens mediated by an IgE–mast cell reaction. Persons with atopic disorders commonly are allergic to more than one (often many) environmental allergens. The most common atopic disorders are urticaria (hives), allergic rhinitis (hay fever), atopic dermatitis, food allergies, and some forms of asthma. The discussion in this section focuses on allergic rhinitis and food allergy. Allergic asthma is discussed in Chapter 23 and atopic dermatitis in Chapter 46.

The susceptibility to immediate hypersensitivity disorders tends to be inherited. The genetic basis of atopy is unclear; however, linkage studies suggest an association with cytokine genes on chromosome 5q that regulate the expression of circulating IgE. Persons with atopic allergic conditions tend to have high serum levels of IgE and increased numbers of basophils and mast cells. Although the IgE-triggered response is likely a key factor in the pathophysiology of atopic allergic disorders, it is not the only factor and may not be solely responsible for conditions such as atopic dermatitis and certain forms of asthma.

Allergic Rhinitis. Allergic rhinitis is characterized by symptoms of sneezing, itching, and watery discharge from the nose and eyes (rhinoconjunctivitis). Allergic rhinitis not only produces nasal symptoms but frequently is associated with other chronic airway disorders, such as sinusitis and bronchial asthma. Severe attacks may be accompanied by malaise (general discomfort), fatigue, and muscle soreness from sneezing. Fever is absent. Sinus obstruction may cause headache. Typical allergens include pollens from ragweed, grasses, trees, and weeds; fungal spores; house dust mites; animal dander; and feathers. Allergic rhinitis can be divided into perennial and seasonal allergic rhinitis depending on the chronology of symptoms. Persons with the perennial type of allergic rhinitis experience symptoms throughout the year, whereas those with seasonal allergic rhinitis (e.g., hay fever) are plagued with intense symptoms in conjunction with periods of high allergen (e.g., pollens, fungal spores) exposure. Symptoms that become worse at night suggest a household allergen, and symptoms that improve or disappear on weekends suggest occupational exposure.

Diagnosis depends on a careful history and physical examination, microscopic identification of an increased number of eosinophils on a nasal smear, and skin or serum testing to identify the offending allergens. When possible, avoidance of the offending allergen is recommended. Treatment is symptomatic in most cases and includes the use of oral antihistamines and oral or topical decongestants. Intranasal corticosteroids often are effective when used appropriately. Intranasal cromolyn, a drug that stabilizes mast cells and prevents their degranulation, may be useful, especially when administered before expected contact with an offending allergen. A program of specific immunotherapy (“allergy shots”) may be used when symptoms are particularly bothersome. Desensitization involves frequent (often weekly) injections of the offending antigens. The antigens, which are given in increasing doses, stimulate production of high levels of IgG, which acts as a blocking antibody by combining with the antigen before it can combine with the cell-bound IgE antibodies.

Food Allergies. Virtually any food can produce atopic or nonatopic allergies. The primary target of food allergy may be the skin, the gastrointestinal tract, the respiratory system, or a combination thereof. The foods most commonly causing these reactions are milk, eggs, peanuts, tree nuts, fish, and shellfish (i.e., crustaceans and mollusks). The allergenicity of a food may be changed by heating or cooking. A person may be allergic to drinking milk but may not have symptoms when milk is included in cooked foods. Both acute reactions (hives and anaphylaxis) and chronic reactions (asthma, atopic dermatitis, and gastrointestinal disorders) can occur. Anaphylaxis occurs as a multiorgan response associated with IgE-mediated hypersensitivity. The foods most responsible for anaphylaxis are peanuts, tree nuts (e.g., walnuts, almonds, pecans, cashews, hazelnuts), and shellfish. One form of food-associated anaphylaxis occurs with exercise. It may occur when exercise follows ingestion of a particular food to which IgE sensitivity has been demonstrated,
or it may occur after ingestion of any food. Exercise without ingestion of the incriminated food does not produce symptoms.

Food allergies can occur at any age but, similar to atopic dermatitis and rhinitis, they tend to manifest during childhood. The allergic response is thought to occur when there is contact between specific food allergens and sensitizing IgE in the intestinal mucosa, thereby causing local and systemic release of histamine and other mediators of the allergic response. In this disorder, allergens usually are food proteins and partially digested food products. Carbohydrates, lipids, or food additives, such as preservatives, colorings, or flavorings, also are potential allergens. Closely related food groups can contain common cross-reacting allergens. For example, some persons are allergic to all legumes (i.e., beans, peas, and peanuts).

Diagnosis of food allergies usually is based on a careful food history and through provocative diet testing. Provocative testing involves careful elimination of a suspected allergen from the diet for a period of time to see if the symptoms disappear and reintroducing the food to see if the symptoms reappear. Only one food should be tested at a time. Treatment focuses on avoidance of the food or foods responsible for the allergy. However, avoidance may be difficult for persons who are exquisitely sensitive to a particular food protein because foods may be contaminated with the protein during processing or handling of the food. As mentioned previously, contamination may occur when chocolate candies without peanuts are processed with the same equipment used for making candies with peanuts.

Type II, Antibody-Mediated Disorders

Type II (antibody-mediated) hypersensitivity reactions are mediated by IgG or IgM antibodies directed against target antigens on cell surfaces or in connective tissues. The antigens may be endogenous antigens that are present on the membranes of body cells, or they may be exogenous antigens, such as drug metabolites, that are adsorbed on the membrane surface. Three different antibody-mediated mechanisms are involved in type II reactions: (1) complement- and antibody–mediated cell destruction, (2) complement- and antibody-mediated inflammation, and (3) antibody-mediated cellular dysfunction (Fig. 16-2).

![FIGURE 16-2. Type II, hypersensitivity reactions result from binding of antibodies to normal or altered surface antigens. (A) Opsonization and complement- or antibody receptor–mediated phagocytosis or cell lysis through membrane attack complex (MAC). (B) Complement- and antibody receptor–mediated inflammation resulting from recruitment and activation of inflammation-producing leukocytes (neutrophils and monocytes). Antibody-mediated cellular dysfunction, in which (C) antibody against the thyroid-stimulating hormone (TSH) receptor increases thyroid hormone production. (D) Antibody to acetylcholine receptor inhibits receptor binding of the neurotransmitter in myasthenia gravis.](image-url)
Complement- and Antibody-Mediated Cell Destruction

The deletion of antibody-targeted cells can occur by way of the complement system or by antibody-dependent cell-mediated cytotoxicity (ADCC), which does not require complement.\textsuperscript{2,3} Complement-mediated cell destruction can occur because the cells are coated with molecules (opsonized; see Fig. 16-2A) that make them attractive to phagocytes or because of the formation of membrane attack proteins that disrupt the integrity of the cell membrane and cause cell lysis (see Chapter 15, Understanding the Complement System). With ADCC destruction, cells that are coated with low levels of IgG antibody are killed by a variety of effector cells that bind to their target by their receptors for IgG, and cell lysis occurs without phagocytosis.

Examples of antibody-mediated cell destruction include mismatched blood transfusion reactions, hemolytic disease of the newborn due to ABO or Rh incompatibility (see Chapter 13), and certain drug reactions. In the latter, the binding of certain drugs or drug metabolites to the surface of red or white blood cells elicits an antibody response that lyses the drug-coated cell. Lytic drug reactions can produce transient anemia, leukopenia, or thrombocytopenia, which often are corrected by the removal of the offending drug.

Complement- and Antibody-Mediated Inflammation

When antibodies are deposited in extracellular tissue components, such as basement membranes and matrix, injury results from inflammation rather than phagocytosis or cell lysis (see Fig. 16-2B).\textsuperscript{2,3} In this case, the deposited antibodies activate complement, generating chemotactic by-products that recruit and activate neutrophils and monocytes. The activated leukocytes release injurious substances, such as enzymes and reactive oxygen intermediates, that cause inflammation and tissue damage. Antibody-mediated inflammation is responsible for the tissue injury seen in some forms of glomerulonephritis, vascular rejection of organ grafts, and other diseases. In Goodpasture syndrome, for example, antibody binds to a major structural component of pulmonary and glomerular basement membranes, causing pulmonary hemorrhage and glomerulonephritis (see Chapter 25).

Antibody-Mediated Cellular Dysfunction

In some type II reactions, antibody binding to specific target cell receptors does not lead to cell death, but to a change in cell function (see Figs. 16-2C, D). In Graves disease, for example, autoantibodies directed against thyroid-stimulating hormone (TSH) receptors on thyroid cells stimulates thyroxine production, leading to hyperthyroidism\textsuperscript{2,3} (see Chapter 32). In myasthenia gravis, autoantibodies to acetylcholine receptors on the neuromuscular endplates either block the action of acetylcholine or mediate internalization or destruction of receptors, leading to decreased neuromuscular function (see Chapter 36).

Type III, Immune Complex–Mediated Disorders

Immune complex allergic disorders are mediated by the formation of insoluble antigen–antibody complexes, complement fixation, and localized inflammation\textsuperscript{2,3} (Fig. 16-3). Immune complexes formed in the circulation produce damage when they come in contact with the vessel lining or are deposited in tissues, such as the renal glomerulus, skin venules, lung tissue, and joint synovium. Once deposited, the immune complexes elicit an inflammatory response by activating complement, thereby leading to chemotactic recruitment of neutrophils and other inflammatory cells. Activation of these inflammatory cells by immune complexes and complement, accompanied by the release of potent inflammatory mediators, is directly responsible for the injury.

Type III reactions are responsible for the vasculitis seen in certain autoimmune diseases such as systemic lupus erythematosus (SLE) or the kidney damage seen with acute glomerulonephritis. As with type I hypersensitivity reactions, type III immune complex disorders may present with systemic manifestations or as a local reaction.

Systemic Immune Complex Disorders

Serum sickness is a type III systemic immune complex disorder that is triggered by the deposition of insoluble antigen–antibody (IgM, IgG, and occasionally IgA)
complexes in blood vessels, joints, and heart and kidney tissue.\textsuperscript{2,3} The deposited complexes activate complement, increase vascular permeability, and recruit phagocytic cells, all of which can promote local tissue damage and edema. The term \textit{serum sickness} was originally coined to describe a syndrome consisting of rash, lymphadenopathy, arthralgias, and occasionally neurologic disorders that appeared 7 or more days after injections of horse antiserum (used in protecting against tetanus). Although this therapy is not used today, the name remains. Currently, the most common causes of this allergic disorder include antibiotics (especially penicillin) and other drugs, various foods, and insect venoms.

The signs and symptoms of systemic immune complex disorders include urticaria, patchy or generalized rash, extensive edema (usually of the face, neck, and joints), and fever. In most cases, the damage is temporary, and symptoms resolve within a few days. However, a prolonged and continuous exposure to the sensitizing antigen can lead to irreversible damage. In previously sensitized persons, severe and even fatal forms of serum sickness may occur immediately or within several days after the sensitizing drug or serum is administered. Treatment usually is directed toward removal of the sensitizing antigen and providing symptomatic relief. This may include aspirin for joint pain and antihistamines for pruritus (itching). Epinephrine or systemic corticosteroids may be used for severe reactions.

**Local Immune Complex Reactions**

\textit{Arthus reaction} is a term used by pathologists and immunologists to describe localized tissue necrosis (usually in the skin) caused by type III immune complexes. In the laboratory, an Arthus reaction can be produced by injecting an antigen preparation into the skin of an immune animal with high levels of circulating antibody. Within 4 to 10 hours, a red, raised lesion appears on the skin at the site of the injection.\textsuperscript{2} An ulcer often forms in the center of the lesion. It is thought that the injected antigen diffuses into local blood vessels, where it comes in contact with specific antibody (IgG) to incite a localized vasculitis (i.e., inflammation of a blood vessel). This experimental model of localized vasculitis is the prototype of many forms of vasculitis seen in humans, such as the cutaneous vasculitides that characterize certain drug reactions.

**Type IV, Cell-Mediated Hypersensitivity Disorders**

Type IV hypersensitivity reactions involve cell-mediated rather than antibody-mediated immune responses.\textsuperscript{2,3} Cell-mediated immunity is the principal mechanism of response to a variety of microorganisms, including intracellular pathogens such as \textit{Mycobacterium tuberculosis} and viruses, as well as extracellular agents such as fungi, protozoa, and parasites. It can also lead to cell death and tissue injury in response to chemical antigens (contact dermatitis) or self-antigens (autoimmunity).

Type IV hypersensitivity reactions, which are mediated by specifically sensitized T lymphocytes, can be divided into two basic types: direct cell-mediated cytotoxicity and delayed-type hypersensitivity (Fig. 16-4).

**Direct Cell-Mediated Cytotoxicity**

In direct cell-mediated cytotoxicity (see Fig. 16-4A), CD8\textsuperscript{+} cytotoxic T lymphocytes (CTLs) directly kill target cells that express peptides derived from cytosolic antigens that are presented in association with class I major histocompatibility complex (MHC) molecules (see Chapter 15). In viral infections, CTL responses can lead to tissue injury by killing infected target cells even if the virus itself has no cytotoxic effects.\textsuperscript{2} Because CTLs cannot distinguish between cytopathic and non-cytopathic viruses, they kill virtually all infected cells regardless of whether the infection is harmful. In certain forms of hepatitis, for example, the destruction of liver cells is due to the host CTL response and not the virus.
Delayed-Type Hypersensitivity Disorders

Delayed-type hypersensitivity (DTH) reactions (see Fig. 16-4B) occur in response to soluble protein antigens and primarily involve antigen-presenting cells such as macrophages and CD4+ helper T cells of the Th1 type. During the reaction Th1 cells are activated and secrete an array of cytokines that recruit and activate macrophages, lymphocytes, fibroblasts, and other inflammatory cells. These Th1-cell-mediated responses require the synthesis of effector molecules and take 24 to 72 hours to develop, which is why they are called “delayed-type” hypersensitivity disorders.

The best-known DTH response is the reaction to the tuberculin test, in which inactivated tuberculin or purified protein derivative is injected under the skin. In a person who has been sensitized by previous infection, a local area of redness and induration develops within 8 to 12 hours, reaching a peak in 24 to 72 hours. The tuberculin reaction is characterized by perivascular accumulation of Th1 cells and, to a lesser extent, macrophages. Local secretion of cytokines by these mononuclear inflammatory cells leads to increased microvascular permeability with local redness and swelling. The sequence of events in DTH, as demonstrated by the tuberculin reaction, begins with the first exposure to the tubercle bacilli (see Chapter 22). The Th1 cells recognize the peptide antigens of the tubercle bacilli in association with class II MHC antigens on the surface of monocytes and antigen-presenting cells that have processed the mycobacterial antigens. This process leads to formation of sensitized Th1 memory cells that remain in the circulation for years. Subsequent injection of tuberculin into such an individual results in the secretion of Th1 cell cytokines that are ultimately responsible for the DTH response.

In addition to its beneficial protective role, DTH can also be the cause of disease, including allergic contact dermatitis and hypersensitivity pneumonitis. It also can be involved in transplant rejection and autoimmune disorders.

Allergic Contact Dermatitis. Allergic contact dermatitis denotes an inflammatory response confined to the skin that is initiated by re-exposure to an allergen to which a person had previously become sensitized (e.g., cosmetics, hair dyes, metals, topical drugs). The most common form of this condition is the dermatitis that follows an encounter with poison ivy or poison oak antigens, although many other substances can trigger a reaction.

Contact dermatitis is characterized by erythematous, papular, and vesicular lesions associated with intense pruritus and weeping. The affected area often becomes swollen and warm, with exudation, crusting, and potentially the development of a secondary infection. The location of the lesions often provides a clue about the antigen causing the disorder. The severity of the reaction associated with contact dermatitis ranges from mild to intense, depending on the person and the allergen. Because this condition follows the mechanism of a DTH response, the reaction does not become apparent for at least 12 hours and usually more than 24 hours after exposure. Depending on the antigen and the duration of exposure, the reaction may last from days to weeks.

Diagnosis of contact dermatitis is made by observing the distribution of lesions on the skin surface and associating a particular pattern with exposure to possible allergens. If a particular allergen is suspected, a skin patch test can be used to confirm the suspicion. Treatment usually is limited to removal of the irritant and application of topical preparations (e.g., ointments, corticosteroid creams) to relieve symptomatic skin lesions and prevent secondary bacterial infections. Severe reactions may require systemic corticosteroid therapy.

Hypersensitivity Pneumonitis. Hypersensitivity pneumonitis, which is associated with exposure to inhaled organic dusts or related occupational antigens, is another example of a DTH reaction. The disorder is thought to involve a susceptible host and activation of pulmonary T cells, followed by the release of cytokine mediators of inflammation. The inflammatory response that ensues (usually several hours after exposure) produces labored breathing, dry cough, chills, fever, headache, and malaise. The symptoms usually subside within hours after the sensitizing antigens are removed. A primary example of hypersensitivity pneumonitis is “farmer’s lung,” a condition resulting from exposure to moldy hay. Other sensitizing antigens include tree bark, sawdust, animal dander, and Mycobacteria that are occasionally found in humidifiers, hot tubs, and swimming pools. Exposure to small amounts of antigen for a long period may lead to chronic lung disease with minimal reversibility. This can occur in persons exposed to avian or animal antigens or a contaminated home air humidifier.

The most important element in the diagnosis of hypersensitivity pneumonitis is to obtain a good history (occupational and otherwise) of exposure to possible antigens. Treatment consists of first identifying and then avoiding the offending antigens. Severe forms of the disorder may be treated with systemic corticosteroid therapy.
SUMMARY CONCEPTS (continued)

antibody complexes and are responsible for vasculitis (as seen in systemic lupus erythematosus or acute glomerulonephritis), systemic immune complex disease (serum sickness), and local immune complex disease (Arthus reaction).

Type IV cell-mediated hypersensitivity reactions include direct cell cytotoxicity, in which sensitized CD8+ T cells kill antigen-bearing target cells, and delayed-type hypersensitivity reactions, in which presensitized CD4+ T cells release cytokines that damage and kill antigen-containing cells.

Transplantation Immunopathology

Transplantation is the process of taking cells, tissues, or organs, called a graft, from one individual and placing them into another individual. Sometimes grafts are transplanted from another site in the same individual. The individual who provided the tissue is called the donor, and the individual who receives the graft is called either the recipient or the host. Transplantation rejection is discussed here because it involves several of the previously discussed immunologic reactions. A major barrier to transplantation is the process of rejection, in which the recipient’s immune system recognizes the graft as foreign and attacks it.

The cell surface antigens that determine whether the tissue of transplanted organs is recognized as foreign are the MHC or human leukocyte antigens (HLA) that were discussed in Chapter 15. Transplanted tissue can be categorized as an autologous graft if the donor and recipient are the same person, syngeneic graft if the donor and recipient are identical twins, and allogeneic (genetic variations of the same gene within a given species) if the donor and recipient—whether related or not—share similar HLA types. The molecules that are recognized as foreign on allografts are called alloantigens. Donors of solid organ transplants can be living or dead (cadaver) and related or nonrelated (heterologous). Rejection of allografts is a response to MHC molecules, which are so polymorphic that no two individuals are likely to express the same MHC molecules, unless they are identical twins. The likelihood of rejection varies indirectly with the degree of MHC or HLA relatedness between the donor and recipient.

Immune Recognition of Allografts

Rejection of allografts is a complex process that involves cell-mediated immunity and circulating antibodies. Although many cells may participate in the process of acute transplant rejection, only the T lymphocytes seem to be absolutely required. The recipient’s T cells recognize allogeneic antigens in the graft by two pathways: the direct and indirect recognition pathways.

In the direct pathway, T cells of the transplant recipient directly recognize donor MHC molecules of the surface of antigen-presenting cells in the graft. Both the CD4+ and CD8+ cells of the transplant recipient are involved in the reaction. Recipient CD8+ T cells recognize donor class I MHC molecules and differentiate into mature CTLs that kill cells in the grafted tissue (see type IV hypersensitivity reactions). The CD4+ helper T-cell subset is triggered into proliferation and differentiation into Th1 effector cells by recognition of donor class II MHC molecules. As with delayed hypersensitivity reactions, cytokines secreted by activated CD4+ cells cause increased vascular permeability and local accumulation and activation of macrophages, resulting in graft injury.

In the indirect pathway, recipient CD4+ T cells recognize donor MHC molecules after they have been picked up, processed, and presented by the recipient’s own antigen-presenting cells. Thus, the indirect pathway is similar to the physiologic processing and presentation of other foreign antigens. This form of recognition mainly activates DTH pathways of the type IV hypersensitivity reactions. This indirect pathway is also involved in the production of antibodies against graft alloantigens. If the alloantigens are proteins, they are picked up by host B cells and processed, and their peptides presented to helper T cells, which then stimulate antibody responses.

Patterns and Mechanisms of Solid Organ Graft Rejection

The basic patterns of transplant rejection have historically been classified based on the time course of the response and the pathologic mechanisms involved.

Based on experience with kidney transplants, which have been done for a longer time and more often than any other organ, the patterns of response are called hyperacute, acute, and chronic. In actual practice, however, there is often an overlap in features. The diagnosis is further complicated by the effects of immunosuppressant drugs or the possible recurrence of the original disease.

Hyperacute Rejection

Hyperacute rejection occurs almost immediately after transplantation. In kidney transplants, it can often be seen at the time of surgery. As soon as blood flow from the recipient to the donor kidney begins, it takes on a cyanotic, mottled appearance. At other times, the reaction may take hours or days to develop.

The hyperacute response is produced by existing recipient antibodies to graft antigens that initiate a type III, Arthus-type hypersensitivity reaction in the blood vessels of the graft. These antibodies usually have developed in response to previous blood transfusions, pregnancies in which the mother makes antibodies to fetal antigens, or infections with bacteria or viruses possessing antigens that mimic MHC antigens.

Acute Rejection

Acute rejection may occur within the first few days to weeks after transplantation, or it may occur suddenly...
months or even years later, after the discontinuation of immunosuppressants in the post-transplant period. Before modern immunosuppression, acute rejection would often begin several days to a few weeks after transplantation. The delayed time of onset of acute rejection reflects the time it takes for the recipient’s immune system to generate T cells and antibodies against the graft. In kidney transplantation it is characterized by abrupt onset of kidney failure, which may be associated with fever and graft tenderness.

Acute rejection most typically involves both cell-mediated and humoral mechanisms of tissue damage. In acute cell-mediated rejection the activated T cells cause direct lysis of graft cells and recruit and activate inflammatory cells that injure the graft. Acute antibody-mediated or humoral mechanisms involve blood vessel damage and intravascular thrombosis that leads to graft destruction.

**Chronic Rejection**

Chronic rejection develops insidiously over months and years and may or may not be preceded by episodes of acute rejection. In recent years, acute rejection has been significantly controlled by immunosuppressive therapy, and chronic rejection has emerged as an important cause of graft rejection. In kidney transplantation there are signs of progressive kidney failure.

The dominant lesion in chronic rejection is arterial occlusion resulting from the proliferation of vascular smooth muscle cells, with graft failure resulting from ischemic damage. These arterial changes are often referred to as graft vasculopathy or accelerated graft arteriosclerosis. The actual mechanism of this type of response is unclear but may include release of cytokines that stimulate proliferation of vascular endothelial and muscle cells; repair with fibrosis after repeated bouts of acute antibody-mediated or cellular rejection; and toxic effects of immunosuppressive drugs.

**Transplantation of Hematopoietic Cells**

Bone marrow transplantation is increasingly being used as therapy for hematopoietic and some nonhematopoietic malignancies, aplastic anemia, and immunodeficiency disorders. Hematopoietic stem cells can be collected from donor bone marrow or peripheral blood. Stem cell aspiration from the bone marrow is the most common form of allograft collection. Peripheral blood offers a less-invasive method for obtaining stem cells. Hematopoietic growth factors, such as granulocyte colony-stimulating factor, are often used to induce stem cells to move out of the bone marrow into the blood. Before either bone marrow or peripheral blood stem cells are infused, recipients receive pretreatment conditioning regimens (e.g., total-body irradiation or treatment with cytotoxic drugs) to destroy malignant cells (e.g., in leukemia) and to create a graft bed. Rejection of the allogeneic bone marrow transplant appears to be mediated by a combination of reactive T cells and natural killer (NK) cells that are resistant to radiation therapy and chemotherapy.

**Graft-Versus-Host Disease**

Graft-versus-host-disease (GVHD) occurs when immunologically competent cells or precursors are transplanted into recipients who are immunologically compromised. Although GVHD occurs most often in persons who have undergone allogeneic bone marrow transplantation, it may also follow transplantation of organs rich in lymphoid tissue (e.g., the liver) or follow transfusions with nonirradiated blood. Three basic requirements are necessary for GVHD to develop: (1) the transplant must have a functional cellular immune component, (2) the recipient tissue must bear antigens foreign to the donor tissue, and (3) recipient immunity must be compromised to the point that it cannot destroy the transplanted cells. The primary agents of GVHD are the donor immunocompetent T cells derived from the donor marrow and the recipient tissue that they recognize as foreign and react against. Graft-versus-host-disease results in activation of both CD4 and CD8 T cells, ultimately generating type IV cell-mediated DTH and CTL reactions. The greater the difference in tissue antigens between the donor and recipient, the greater the likelihood of GVHD.

Graft-versus-host-disease can occur as an acute or chronic reaction. Acute GVHD, which develops within days to weeks after transplantation, involves the epithelial cells of the skin, liver, and gastrointestinal tract. The organ most commonly affected in acute GVHD is the skin. There is development of a pruritic, maculopapular rash, which begins on the palms and soles and frequently extends over the entire body, with subsequent desquamation (sloughing off skin). Involvement of the gastrointestinal tract usually parallels the development of skin and liver involvement. Gastrointestinal symptoms include nausea, bloody diarrhea, and abdominal pain. Graft-versus-host-disease of the liver is heralded by painless jaundice, hyperbilirubinemia, and abnormal liver function test results. Liver involvement can progress to development of veno-occlusive disease, drug toxicity, viral infection, iron overload, extrahepatic biliary obstruction, sepsis, and coma. Chronic GVHD may follow acute GVHD or it may develop insidiously. Persons in whom chronic GVHD develops are profoundly immunocompromised, and they develop skin lesions resembling systemic sclerosis (discussed in Chapter 44) and manifestations mimicking other autoimmune diseases. As a result of the severely compromised immune system, recurrent and life-threatening infections are common.

### SUMMARY CONCEPTS

- Transplantation involves taking cells, tissues, or organs, called a graft, from one individual (a donor) and placing them into another individual (recipient).
- A major barrier to transplantation is the process of rejection in which the recipient’s immune system recognizes the graft as foreign and attacks it.
Autoimmune Disease

Autoimmune diseases represent a group of disorders that are caused by a breakdown in the ability of the immune system to differentiate between self- and nonself-antigens. They can affect almost any cell or tissue in the body. Some autoimmune disorders, such as Hashimoto thyroiditis, are tissue specific, whereas others, such as SLE, affect multiple organs and systems. Chart 16-1 lists some of the common autoimmune diseases. Many of these disorders are discussed elsewhere in this book.

Immunologic Tolerance

To function properly, the immune system must be able to differentiate foreign antigens from self-antigens in a process called self-tolerance. 1-3 It is the HLAs encoded by MHC genes that serve as recognition markers of self and nonself for the immune system (see Chapter 15). To elicit an immune response, an antigen must first be processed by an antigen-presenting cell (APC), such as a macrophage, which then presents the antigenic determinants along with a MHC II molecule to a CD4+ helper T cell. The dual recognition of the MHC–antigen complex by the T-cell receptor (TCR) of the CD4+ helper T cell acts like a security check. Similar recognition checks occur between CD8+ cytotoxic T cells and the MHC I–antigen complex of tissue cells that have been targeted for elimination. A number of chemical messengers (e.g., interleukins) and costimulatory signals are essential to the activation of immune responses and the preservation of self-tolerance.

Several mechanisms have been postulated to explain the tolerant state, including central tolerance and peripheral tolerance. 1,2,20-23 Central tolerance refers to the elimination of self-reactive T cells and B cells in the central lymphoid organs (i.e., the thymus for T cells and the bone marrow for B cells). Peripheral tolerance derives from the deletion or inactivation of autoreactive T cells or B cells that escaped elimination in the central lymphoid organs. Anergy represents the state of immunologic tolerance to specific antigens. It may take the form of diminished immediate hypersensitivity, delayed-type hypersensitivity, or both.

*Examples are not inclusive.
B-Cell Tolerance

Several mechanisms are available to filter autoreactive B cells out of the B-cell population: clonal deletion of immature B cells in the bone marrow; deletion of autoreactive B cells in the spleen or lymph nodes; functional inactivation or anergy; and receptor editing, a process that changes the specificity of a B-cell receptor when autoantigen is encountered. There is increasing evidence that B-cell tolerance is predominantly due to help from T cells. Loss of self-tolerance with development of autoantibodies is characteristic of a number of autoimmune disorders. For example, hyperthyroidism in Graves disease is due to autoantibodies to the TSH receptor (see Fig. 16-2 and Chapter 32).

T-Cell Tolerance

The central mechanisms of T-cell tolerance involve the deletion of self-reactive T cells in the thymus (Fig. 16-5). T cells develop from bone marrow–derived progenitor cells that migrate to the thymus, where they encounter self-peptides bound to MHC molecules. T cells that display the host's MHC antigens and T-cell receptors for a nonself-antigen are allowed to mature in the thymus (i.e., positive selection). T cells that have a high affinity for host cells are sorted out and undergo apoptosis or cell death (i.e., negative selection). The deletion of self-reactive T cells in the thymus requires the presence of autoantigens. Because many autoantigens are not present in the thymus, self-reactive T cells may escape the thymus, so peripheral mechanisms that participate in T-cell tolerance are required.

Several mechanisms are available to control the responsiveness of self-reactive T cells in the periphery. Sometimes the host antigens are not available in the appropriate immunologic form or are separated from the T cells (e.g., by the blood–brain barrier) so that corresponding T cells remain immunologically ignorant of their presence. In other cases, the autoreactive T cell encounters its corresponding antigen in the absence of T-cell tolerance.
the costimulatory signals that are necessary for its activation. The peripheral activation of T cells requires two signals: recognition of the peptide antigen in association with the MHC molecules on the APCs, and a set of secondary costimulatory signals. Because costimulatory signals are not strongly expressed on most normal tissues, the encounter of the autoreactive T cells and their specific target antigens frequently results in anergy.\(^1\)\(^2\)

Another self-tolerance mechanism involves the apoptotic death of autoreactive T cells.\(^20\)\(^21\)\(^24\) This type of apoptosis is mediated by an apoptotic cell surface receptor (called Fas) that is present on the T cell and a soluble membrane messenger molecule (Fas ligand) that binds to the apoptotic receptor and activates the death program (see Chapter 2). The expression of the apoptotic Fas receptor is markedly increased in activated T cells; thus, coexpression of the Fas messenger molecule by the same cohort of activated autoreactive T cells may serve to induce their death.

Suppressor T cells with the ability to down-regulate the function of autoreactive T cells are also thought to play an essential role in peripheral T-cell tolerance. These cells are believed to be a distinct subset of CD4\(^+\) and CD8\(^+\) T cells.\(^{25}\)\(^26\) The mechanism by which these T cells exert their suppressor function is unclear. They may secrete cytokines that suppress the activity of self-reactive immune cells, or they may delete the self-reactive T-cell clones.

**Mechanisms of Autoimmune Disease**

It is not known what triggers autoimmunity, but both genetic susceptibility and environmental factors, such as infectious agents, appear to play a role. Moreover, a number of autoimmune disorders such as SLE occur more commonly in women than men, suggesting that estrogens may play a role in their development. Evidence suggests that estrogens stimulate the immune response and androgens suppress it.\(^{27}\)\(^28\) For example, estrogen stimulates a DNA sequence that promotes the production of interferon-\(\gamma\), which is thought to assist in the induction of an autoimmune response.

**Genetic Susceptibility**

Genetic factors can increase the incidence and severity of autoimmune diseases, as shown by the familial clustering of several autoimmune diseases and the observation that certain inherited HLA types occur more frequently in persons with a variety of immunologic disorders.\(^2\)\(^22\)\(^23\) For example, 90% of persons with ankylosing spondylitis carry the HLA-B27 antigen, compared with 7% of persons without the disease.\(^2\) Other HLA-associated diseases include Reiter syndrome with HLA-B27, rheumatoid arthritis with HLA-DR4, and SLE with HLA-DR3 (see Chapter 44). The molecular basis for these associations is unknown. Because autoimmunity does not develop in all persons with genetic predisposition, it appears that other factors—such as a “trigger event”—interact to precipitate the altered immune state. The event or events that trigger the development of an autoimmune response are unknown. It has been suggested that the “trigger” may be a virus or other microorganism, a chemical substance, or a self-antigen from a body tissue that has been hidden from the immune system during development.

**Role of Infections**

Viral and bacterial infections may contribute to the development and exacerbations of autoimmunity. In many persons, the onset of autoimmunity is associated with or preceded by infection. In most of these cases, the infectious microorganisms are not present in lesions or detectable when autoimmunity develops.\(^1\)\(^3\) Therefore, the lesions of autoimmunity are not due to the infectious agent itself, but to the immune process that was triggered by the microbe. There are three proposed mechanisms through which infections can trigger autoimmunity: breakdown of T-cell anergy, molecular mimicry, and superantigens.

**Breakdown of T-Cell Anergy.** Infections of particular tissues may induce local innate immune responses that attract leukocytes into the tissue and result in the activation of antigen-presenting cells. These antigen-presenting cells begin to express costimulators and secrete T cell–activating cytokines, resulting in the breakdown of self-tolerance.\(^1\)\(^2\) Most normal tissues do not express the costimulatory molecules and thus are protected from autoreactive T cells. However, this protection can be lost if the cells that do not normally express the costimulatory molecules are induced to do so.

**Molecular Mimicry.** One proposed link between infections and autoimmunity is molecular mimicry, in which a microbe shares an immunologic epitope with the host.\(^29\)\(^30\) In rheumatic fever and acute glomerulonephritis, a protein in the cell wall of group A \(\beta\)-hemolytic streptococci has considerable similarity with antigens in heart and kidney tissue, respectively. After infection, antibodies directed against the microorganism cause a classic case of mistaken identity, which leads to inflammation of the heart or kidney. Not everyone exposed to group A \(\beta\)-hemolytic streptococci develops an autoimmune reaction. The reason that only certain persons are targeted for autoimmune reactions to a particular self-mimicry molecule may be determined by differences in HLA types. The HLA type determines exactly which fragments of a pathogen are displayed on the cell surface for presentation to T cells. One individual’s HLA may bind self-mimicry molecules for presentation to T cells, whereas another’s HLA type may not. In the spondyloarthropathies, particularly Reiter syndrome and reactive arthritis, there is a clear relationship between arthritis and a
prior bacterial infection, combined with the inherited HLA-B27 antigens.

Superantigens. Superantigens are a family of related substances, including staphylococcal and streptococcal exotoxins, that can short-circuit the normal sequence of events in an immune response, leading to inappropriate activation of CD4+ helper T cells. Superantigens do not require the typical processing and presentation of antigen by APCs to induce a T-cell response. Instead, they are able to interact with a T-cell receptor outside the normal antigen-binding site. This distinctive mode of activation, combined with the ability of superantigens to bind to a wide variety of MHC class II molecules, can lead to the activation of large numbers of T cells regardless of their MHC/peptide specificity. Superantigens are involved in several diseases, including food poisoning and toxic shock syndrome.

Release of Sequestered Antigens

Normally the body does not produce antibodies against self-antigens. Thus, any self-antigen that was completely sequestered during development and then reintroduced to the immune system is likely to be regarded as foreign. Among the sequestered tissues that could be regarded as foreign are spermatozoa and ocular antigens such as those found in uveal tissue. Posttraumatic uveitis and orchiditis after vasectomy may fall into this category. Changes in antigen structure or release of hidden antigens may also account for the persistence of autoimmune disorders. Once an autoimmune disorder has been induced, it tends to be progressive, sometimes with sporadic relapses and remissions. A possible mechanism for the persistence and evolution of autoimmunity is the phenomenon called epitope spreading. Infections, and even the initial autoimmune episode, may expose self-antigens that have been hidden from the immune system, resulting in continued activation of new lymphocytes that recognize the previously hidden epitopes.

Diagnosis and Treatment of Autoimmune Disease

Suggested criteria for determining whether a disorder is an autoimmune disease include the following: evidence of an autoimmune reaction, determination that the immunologic findings are not secondary to another condition, and no other identifiable causes for the disorder. Currently, the diagnosis of autoimmune disease is based primarily on clinical findings and serologic testing.

The basis for most serologic assays is the demonstration of antibodies directed against tissue antigens or cellular components. For example, an individual with a history of fever, arthritis, and a macular rash and who has high levels of antinuclear antibody has a probable diagnosis of SLE. The detection of autoantibodies in the laboratory usually is accomplished by one of three methods: indirect fluorescent antibody assay (IFA), enzyme-linked immunosorbent assay (ELISA), or particle agglutination of some kind. The rationale behind each of these methods is similar: the patient’s serum is diluted and allowed to react with an antigen-coated surface (e.g., whole, fixed cells for the detection of antinuclear antibodies). In the case of IFA and ELISA, a second “labeled” antibody is added, which binds to the patient’s antibody and can induce a visible reaction. Particle agglutination assays are much simpler—the binding of the patient’s antibody to antigen-coated particles causes a visible agglutination reaction. For most serologic assays, the patient’s serum is serially diluted until it no longer produces a visible reaction (e.g., 1:100 dilution). This is called a positive titer. Healthy persons sometimes have low titers of antibody against cellular and tissue antigens, but their titers usually are far lower than in patients with autoimmune disease.

Treatment of autoimmune disease is based on the tissue or organ that is involved, the effector mechanism involved, and the magnitude and chronicity of the effector processes. Ideally, treatment should focus on the mechanism underlying the autoimmune disorder. Corticosteroids and immunosuppressive drugs may be used to arrest or reverse the downhill course of some autoimmune disorders. Purging autoreactive cells from the immune repertoire through the use of plasmapheresis is also an option in some severe cases of autoimmunity.

Recent research has focused on the cytokines involved in the inflammatory response that accompanies many of the autoimmune disorders (e.g., interferon-β for multiple sclerosis and tumor necrosis factor-α [TNF-α] antibodies for rheumatoid arthritis and Crohn disease).

SUMMARY CONCEPTS

- Autoimmune diseases represent a disruption in self-tolerance that results in damage to body tissues by the immune system.
- Self-tolerance is maintained through central and peripheral mechanisms that delete autoreactive B or T cells or otherwise suppress or inactivate immune responses that would be destructive to host tissues. Defects in any of these mechanisms could impair self-tolerance and predispose to the development of autoimmune disease.
- Autoimmunity results from a failure of tolerance. Autoimmune disorders may be triggered by environmental stimuli, such as infections, in a genetically predisposed individual.
Immunodeficiency Disorders

Immunodeficiency can be defined as an abnormality in one or more components of the immune system that renders a person susceptible to diseases normally prevented by an intact immune system. These disorders can be broadly classified into two groups: primary and secondary. The primary or congenital immunodeficiencies are genetic defects that result in increased susceptibility to infection that is frequently manifested early in life. Secondary or acquired immunodeficiency is not inherited but develops as a consequence of malnutrition, selective loss of immunoglobulins through the gastrointestinal or genitourinary tracts, treatment with immunosuppressant drugs, or human immunodeficiency virus (HIV), the etiologic agent of acquired immunodeficiency syndrome (AIDS). Regardless of the cause, primary and secondary deficiencies can produce the same spectrum of disease. The severity and symptomatology of the various disorders depend on the type and extent of the deficiency.

Primary Immunodeficiency Disorders

Until recently, little was known about the causes of primary immunodeficiency diseases. However, this has changed with recent advances in genetic technology. To date, more than 180 primary immunodeficiency syndromes have been identified, and specific molecular defects have been identified in more than one third of these diseases. Most are transmitted as recessive traits, caused by mutations in genes on the X chromosome or autosomal chromosomes. Many of these disorders have been traced to mutations affecting signaling pathways (e.g., cytokines and cytokine signaling, receptor subunits, and metabolic pathways) that dictate immune cell development and function. Furthermore, it has been shown that the immune system is a carefully balanced system that is designed to distinguish between self and nonself; therefore, symptoms of autoimmunity often are observed with primary immunodeficiency disease.

Early detection, which is possible for most primary immunodeficiency diseases, is critical for the success of some treatments and can be lifesaving. For infants with severe combined T- and B-cell immunodeficiency, early diagnosis is essential in terms of not only preventing life-threatening infections, but also preventing administration of live attenuated virus vaccines (e.g., measles, mumps, rubella, varicella), which could prove fatal. The first clinical clue for the diagnosis of a primary immunodeficiency disease is usually a history of infections that are persistent, difficult to treat, or caused by unusual microbes. The Jeffrey Modell Foundation/Immune Deficiency Foundation has developed a set of warning signs that serve as an excellent tool for determining what should be considered abnormal (Chart 16-2). Because these disorders are frequently inherited, a positive family history is also a key diagnostic tool. The type of infection can provide information regarding the type of defect that is present. Infections with bacterial organisms are frequently observed in cases of antibody deficiency, whereas severe viral, fungal, and opportunistic infections characterize T-cell deficiencies. Recurrent Streptococcus pneumoniae or Neisseria infections characterize persons with complement deficiencies, and recurrent infections with staphylococcal and other catalase-positive organisms indicate disorders of phagocytosis.

Humoral (B-Cell) Immunodeficiency Disorders

Of all the primary immunodeficiency diseases, those affecting antibody production and humoral immunity are the most common. Antibody production depends on the differentiation of hematopoietic stem cells into mature B lymphocytes and the antigen-dependent generation of immunoglobulin-producing plasma cells (Fig. 16-6). This maturation cycle initially involves the production of surface IgM, migration from the bone marrow to the peripheral lymphoid tissue, and switching to the production of specialized IgM-, IgA-, IgD-, IgE-, or IgG-secreting plasma cells after antigenic stimulation. Primary humoral immunodeficiency disorders can interrupt the production of one or all of the immunoglobulins.

Defects in humoral immunity increase the risk of recurrent pyogenic infections, including those caused by S. pneumoniae, Haemophilus influenzae, Staphylococcus aureus, and Pseudomonas species. Humoral immunity usually is not as important in defending against intracellular bacteria (mycobacteria), fungi, and protozoa. Viruses usually are handled normally, except for the enteroviruses that cause gastrointestinal infections.
Transient Hypogammaglobulinemia of Infancy. During the first few months of life, infants are protected from infection by IgG antibodies that have been transferred from the maternal circulation during fetal life. Immunoglobulin A (IgA), IgM, IgD, and IgE do not normally cross the placenta. The presence of elevated levels of IgA or IgM in the infant cord blood suggests premature antibody production in response to an intrauterine infection. An infant’s level of maternal IgG gradually declines over a period of approximately 6 months (see Chapter 15, Fig. 15-14). Concomitant with the loss of maternal antibody, the infant’s immature humoral immune system begins to function, and between the ages of 1 and 2 years, the child’s antibody production reaches adult levels.

Any abnormality that interferes with the production of immunoglobulin-producing plasma cells can produce a state of immunodeficiency. For example, certain infants may experience a delay in IgG production (IgM and IgA levels are normal) beyond 6 months of age. The total number and antigenic response of circulating B cells are normal, but the chemical communication between B and T cells that leads to clonal proliferation of antibody-producing plasma cells seems to be reduced. This condition is referred to as transient hypogammaglobulinemia of infancy. The result of this condition usually is limited to repeated bouts of upper respiratory and middle ear infections. This condition usually resolves by 2 to 4 years of age.

X-Linked Agammaglobulinemia. X-linked (Bruton) agammaglobulinemia is a recessive trait that almost exclusively affects boys, as they have only one X chromosome. As the name implies, persons with this disorder have essentially undetectable levels of all serum immunoglobulins. Therefore, they are susceptible to meningitis, recurrent otitis media, and sinopulmonary infections with organisms such as S. pneumoniae, H. influenzae type b, S. aureus, and Neisseria meningitidis. The abnormal gene in X-linked agammaglobulinemia that maps to the long arm of the X chromosome has a role in all stages of B-cell development. Mutation in the gene results in an absence of mature circulating B cells and plasma cells. T lymphocytes, however, are normal in number and function.

Most boys with the disorder remain asymptomatic until 6 to 9 months of age because of the presence of maternal antibodies. A clue to the presence of the disorder is the failure of an infection to respond completely and promptly to antibiotic therapy. Diagnosis is based on demonstration of low or absent serum immunoglobulins. Therapy consists of prophylaxis with intravenous immunoglobulin (IVIG) and prompt antimicrobial therapy for suspected infections. The prognosis for this condition depends on the prompt recognition and treatment of infections. Chronic pulmonary disease is an ever-present danger.

Common Variable Immunodeficiency. A similar disorder of B-cell maturation is a condition called common variable immunodeficiency (CVID). In this syndrome, the terminal differentiation of mature B cells to plasma cells is blocked. More than 80% of persons with this disorder have a normal number of B lymphocytes, but they fail to differentiate into antibody-secreting cells when the lymphocytes are presented with antigen. Some persons may also have increased apoptosis of helper T cells and decreased T-cell function and signaling.

The symptomatology of CVID is similar to that of X-linked agammaglobulinemia (i.e., recurrent otitis
media and sinus and pulmonary infections), but the onset of infections occurs much later, usually between the ages of 15 and 35 years. In contrast to X-linked agammaglobulinemia, the sex distribution in CVID is almost equal. Most persons with CVID have no identified molecular diagnosis. Because the disorder occurs in first-degree relatives of persons with IgA deficiency, and some persons with IgA deficiency develop agammaglobulinemia, these disorders may have a common genetic basis.

Persons with CVID often have autoantibody formation and normal-sized or enlarged tonsils and lymph nodes, and approximately 25% have splenomegaly. They have an increased tendency toward development of interstitial lung disease, autoimmune disorders, hepati tis, and chronic diarrhea with associated intestinal malabsorption. There is also an increased risk of gastric cancer and non-Hodgkin B-cell lymphoma.

Treatment methods for CVID are similar to those used for X-linked agammaglobulinemia, with IVIG being the cornerstone of therapy. Anaphylaxis to IgA in the IVIG can occur in persons with CVID who are IgA deficient. The use of IgA-depleted IVIG has greatly reduced this risk.

**Selective Immunoglobulin A Deficiency.** Selective IgA deficiency is the most common type of immunoglobulin deficiency. The syndrome is characterized by moderate to marked reduction in levels of serum and secretory IgA, probably due to a block in the pathway that promotes terminal differentiation of mature B cells to IgA-secreting plasma cells. The occurrence of IgA deficiency in both men and women and in members of successive generations within families suggests autosomal inheritance with variable expressivity. The disorder has also been noted in persons treated with certain drugs (e.g., phenytoin, sulphasalazine), suggesting that environmental factors may trigger the disorder.

Although an IgA deficiency can occur in apparently healthy persons, it is commonly associated with repeated infections in the respiratory, gastrointestinal, and urogenital systems. Persons with IgA deficiency also can develop antibodies against IgA, which can lead to severe anaphylactic reactions when blood components containing IgA are given. Therefore, only specially washed erythrocytes from normal donors or erythrocytes from IgA-deficient donors should be used.

There is no specific treatment available for selective IgA deficiency unless there is a concomitant reduction in IgG levels. Administration of IgA immune globulin is of little benefit because IgA has a short half-life and is not secreted across the mucosa. There also is the risk of anaphylactic reactions associated with IgA antibodies in the immune globulin.

**Immunoglobulin G Subclass Deficiency.** An IgG subclass deficiency can affect one or more of the IgG subclasses, despite normal levels or elevated serum concentrations of IgG. In general, antibodies directed against protein antigens belong to the IgG1 and IgG3 subclasses, and antibodies directed against carbohydrate and polysaccharide antigens are primarily from the IgG2 subclass. As a result, persons who are deficient in IgG2 subclass antibodies can be at greater risk for development of sinusitis, otitis media, and pneumonia caused by polysaccharide-encapsulated microorganisms such as *S. pneumoniae, H. influenzae* type b, and *N. meningitidis.*

Children with mild forms of the deficiency can be treated with prophylactic antibiotics to prevent repeated infections. Intravenous immunoglobulin can be given to children with severe manifestations of this deficiency. The use of polysaccharide vaccines conjugated to protein carriers can provide protection against some of these infections, whereas protein vaccines conjugated to protein carriers would stimulate an IgG1 response.

**X-linked Immunodeficiency with Hyperimmunoglobulinemia M.** *Hyper-IgM syndrome* is characterized by low IgG and IgA levels with normal or, more frequently, high IgM concentrations. Being predominantly an X-linked recessive disorder, the disease is primarily seen in boys. Formerly classified as a B-cell defect, it now has been traced to a T-cell defect. The disorder results from the inability of T cells to signal B cells to undergo isotype switching to IgG and IgA; thus, they produce only IgM.

Like those with X-linked agammaglobulinemia, affected individuals become symptomatic during the first and second years of life. They have recurrent pyogenic infections, including otitis media, sinusitis, tonsillitis, and pneumonia. Persons with the syndrome are also at increased risk for development of autoimmune diseases of the formed elements of the blood, including hemolytic anemia, thrombocytopenia, and recurrent severe neutropenia.

**Cellular (T-Cell) Immunodeficiency Disorders**

Unlike B cells, in which a well-defined series of differentiation steps ultimately leads to the production of immunoglobulins, mature T lymphocytes consist of distinct subpopulations with diverse immunologic assignments. They protect against fungal, protozoan, viral, and intracellular bacterial infections; control malignant cell proliferation; and are responsible for coordinating the overall immune response.

In general, persons with T-cell–mediated immunodeficiency disorders have infections or other clinical problems that are more severe than those seen with antibody disorders. Children with defects in this branch of the immune response rarely survive beyond infancy or childhood unless immunologic reconstitution is achieved. However, exceptions are being recognized as newer T-cell defects, such as the X-linked hyper-IgM syndrome, are identified. Other recently identified primary T-cell immunodeficiency disorders result from defective expression of the TCR complex, defective cytokine production, and defects in T-cell activation.
Thymic Hypoplasia: DiGeorge Syndrome. DiGeorge syndrome stems from an embryonic developmental defect. The defect is thought to occur before the 12th week of gestation, when the thymus gland, parathyroid gland, and parts of the head, neck, and heart are developing. The disorder affects both males and females and is relatively more common than other T cell immunodeficiencies. Formerly thought to be caused by a variety of factors, including extrinsic teratogens, this defect has been traced to microdeletion of specific deoxyribonucleic acid (DNA) sequences from chromosome 22 (22q11).

Infants born with this defect have partial or complete failure in development of the thymus and parathyroid glands and have congenital defects of the head, neck, and/or heart. The extent of immune and parathyroid abnormalities is highly variable, as are the other defects. In some children, the thymus is not absent but is in an abnormal location and is extremely small. These infants can have partial DiGeorge syndrome, in which hypertrophy of the thymus occurs with development of normal immune function. The facial disorders can include hypertelorism (increased distance between the eyes); micrognathia (abnormally small jaw); low-set, posteriorly angulated ears; split uvula; and high-arched palate (Fig. 16-7). Urinary tract abnormalities also are common. The most frequent presenting sign is hypocalcemia and tetany that develop within the first 24 hours of life. It is caused by the absence of the parathyroid gland and is resistant to standard therapy.

Children who survive the immediate neonatal period may have recurrent or chronic infections because of impaired T-cell immunity. Children also may have an absence of immunoglobulin production, caused by a lack of helper T-cell function. For children who do require treatment, thymus transplantation can be performed to reconstitute T-cell immunity. Bone marrow transplantation also has been successfully used to restore normal T-cell populations. If blood transfusions are needed, as during corrective heart surgery, special processing is required to prevent graft-versus-host disease.

Severe Combined Immunodeficiency Disorders

Severe combined immunodeficiency (SCID) is a syndrome of diverse genetic causes characterized by profound deficiencies in T- and B-cell function, and in some cases NK cells and function. Mutations in 13 different genes have been found to cause the condition, which is usually fatal in the first 2 years of life unless reconstitution of the immune system can be accomplished. Although they appear normal at birth, affected infants begin to develop frequent episodes of diarrhea, pneumonia, otitis media, sepsis, and cutaneous lesions within the first few months of life. Growth may appear normal, but extreme wasting develops after infections and diarrhea begin. Exposure to live vaccines, nonirradiated blood products, and infections can prove life threatening.

Pathogenesis and Etiology. The most common form of SCID, accounting for about half of all cases in the United States, is X-linked, and hence is more common in boys than girls. These mutations are recessive so that heterozygous girls are usually normal carriers of the gene, whereas boys who inherit the abnormal chromosome manifest the disease. The genetic defect in the X-linked form of SCID is due to a mutation in a trans-membrane protein that is responsible for the survival and proliferation of T-lymphocyte precursors. T-cell numbers are greatly reduced in number and, although B cells are normal, antibody synthesis is greatly impaired because of a T-cell help. There may also be a deficiency in NK cells.

The remaining cases of SCID show an autosomal recessive pattern of inheritance, with the most common cause being mutations in the gene encoding adenosine deaminase (ADA), an enzyme involved in purine
metabolism. A deficiency in ADA leads to deoxyadenosine and its derivatives, which are toxic to immature lymphocytes, especially those of the T-cell lineage. Hence there is a greater reduction in T lymphocytes than B lymphocytes. Although the number of NK cells is low, their function is normal. Other distinguishing features of ADA deficiency include the presence of rib cage deformity and numerous skeletal deformities.

**Diagnosis and Treatment.** Severe combined immunodeficiency is a pediatric emergency. Because the disorder is not apparent at birth and early recognition is essential for lifesaving treatment, a recommendation to add SCID and other severe T-cell defects to the routine newborn screening panel was approved by the U.S. Department of Health and Human Services in 2010. All infants who test positive on the newborn screening test should receive rapid referral to an immunologist for a complete immune evaluation.

Bone marrow transplant is the mainstay treatment for all forms of SCID. Both HLA-identical and T-cell depleted HLA-haploidentical hematopoietic stem cell transplants have been very effective in reconstitution of the immune system, especially if performed within the first 3.5 months of life and without pretransplantation chemotherapy or posttransplantation drugs for graft-versus-host rejection prophylaxis. Enzyme replacement therapy also may be used in the management of persons ADA-deficient SCID. However, it should not be used if bone marrow transplantation is anticipated because it can predispose to graft rejection.

**Immune Deficiency with Thrombocytopenia and Eczema**

Immune deficiency with thrombocytopenia and eczema (Wiskott-Aldrich syndrome) is an X-linked recessive disorder characterized by thrombocytopenia, eczema, and marked susceptibility to bacterial infections. Bleeding episodes or symptoms due to infection usually begin within the first 6 months of life. Abnormalities of humoral immunity include decreased serum levels of IgM and markedly elevated serum IgA and IgE concentrations. T-cell dysfunction initially is mild but progressively deteriorates, and children with the disorder become increasingly susceptible to the development of malignancies of the mononuclear phagocytic system, including Hodgkin lymphoma and leukemia. Children with Wiskott-Aldrich syndrome typically are unable to produce antibody to polysaccharide antigens and therefore are susceptible to infections caused by encapsulated microorganisms, including septicemia and meningitis. Varicella infection can be lethal to children with this condition.

Management of children with Wiskott-Aldrich syndrome focuses on treatment of eczema, control of infections, and management of bleeding episodes. Bone marrow transplantation has been successful in children with Wiskott-Aldrich syndrome. Splenectomy, sometimes recommended for children with thrombocytopenia, effectively stops the bleeding episodes but increases the risk of septicemia.

**Acquired Immunodeficiency Syndrome**

Acquired immunodeficiency syndrome is a disease caused by infection with human immunodeficiency virus (HIV) and is characterized by profound immunosuppression with associated opportunistic infections, malignancies, wasting, and central nervous system degeneration. HIV is a retrovirus that selectively attacks the CD4+ T lymphocytes, the immune cells responsible for orchestrating and coordinating the immune response to infection. As a consequence, persons with HIV infection have a deteriorating immune system, and thus are more susceptible to severe infections from ordinarily harmless organisms.

As a national and global epidemic, the degree of morbidity and mortality caused by HIV, as well as its impact on health care resources and the economy, is tremendous and unrelenting. In 2011, it was estimated that there were nearly 34 million people worldwide living with HIV/AIDS and 1.7 million people died of HIV-related causes. During the same year, 2.5 million people were newly infected with HIV. Because the reporting of cases is not uniform throughout the world, many countries may not be accurately represented in this number.

**Transmission of HIV Infection**

Human immunodeficiency virus is transmitted through conditions that facilitate the exchange of blood or body fluids that contain the virus or virus-infected cells, the major routes being sexual contact; contaminated blood, either through sharing needles or syringes used for illicit drugs; or passage from infected mothers to their newborns. It is estimated that more than 90% of children living with HIV acquired the virus in utero, during the birth process, or through breastfeeding. Human immunodeficiency virus is not transmitted through casual contact. Several studies involving more than 1000 uninfected, nonsexual household contacts with persons with HIV infection (including siblings, parents, and children) have shown no evidence of casual transmission.

Sexual contact is the most frequent mode of HIV transmission. There is a risk of transmitting HIV when semen or vaginal fluids come in contact with a part of the body that lets them enter the bloodstream. This can include the vaginal mucosa, anal mucosa, and wounds or sores on the skin. Thus, the risk of infection is increased in the presence of ulcerative sexually transmitted infections (STIs) such as syphilis, herpes simplex virus infection, and chancre; however, it is also increased with nonulcerative STIs such as gonorrhea, chlamydial infection, and trichomoniasis. Condoms are highly effective in preventing the transmission of HIV. Unprotected sex between men is still the main mode of transmission in both Canada and the United States (48% of new HIV cases in Canada in 2011 and 63% in the United States in 2010). During the same years, 25% of newly diagnosed HIV/AIDS cases in the United States and 30% of newly diagnosed cases in Canada were attributable to high-risk heterosexual intercourse.
Transfusions of whole blood or blood products before 1985 resulted in the transmission of HIV. Since 1985, all blood donations in the United States have been screened for HIV, dramatically reducing the transmission risk to an extremely small number. Currently, all donated blood and plasma are screened for HIV-associated antigen and antibodies to HIV. Screening tests may be negative in the so-called window period, the 1 to 6 months following a new HIV infection and before seroconversion, the point at which HIV antibodies can be detected in the blood. Therefore, the U.S. Food and Drug Administration (FDA) requires blood collection centers to screen potential donors through interviews designed to identify behaviors known to present a risk for HIV infection. In addition, nucleic acid amplification testing (NAAT) of blood donors has reduced the risk of transfusion transmission of both HIV and hepatitis C virus to approximately 1 in 2 million blood units.

Occupational HIV infection among health care workers is uncommon. Universal blood and body fluid precautions should be used in encounters with all patients in the health care setting because HIV status is not always known. Occupational risk of infection for health care workers most often is associated with percutaneous inoculation (e.g., needle stick) of blood from a patient with HIV infection. Transmission is associated with the size of the needle, amount of blood present, depth of the injury, type of fluid contamination, stage of illness of the patient, and viral load of the patient. The average risk for HIV infection from percutaneous exposure to HIV-infected blood is about 0.3%, and about 0.09% after mucous membrane exposure.

The HIV-infected person is infectious even when no symptoms are present. The point at which an infected person converts from being negative for the presence of HIV antibodies in the blood to being positive is called seroconversion. Seroconversion typically occurs within 1 to 3 months after exposure to HIV, but rarely can take as long as 6 months. Recent data suggest that 50% of transmissions occur during primary HIV infection and early HIV infection. The time after infection and before seroconversion is known as the window period. During the window period, a person's HIV antibody test result will be negative but he or she can still transmit the virus.

Molecular and Biologic Features of HIV Infection

The primary etiologic agent of AIDS is HIV, an enveloped ribonucleic acid (RNA) retrovirus that carries its genetic material in RNA rather than DNA. Two genetically different but antigenically related forms of HIV—HIV-1 and HIV-2—have been isolated in people with AIDS. Human immunodeficiency virus-1 is the type most commonly associated with AIDS in the United States, Europe, and central Africa, whereas HIV-2 causes a similar disease principally in western Africa. Human immunodeficiency virus-2 spreads more slowly and causes disease more slowly than HIV-1. Specific tests are now available for HIV-2, and blood collected for transfusion is routinely screened for HIV-2. The remaining discussion focuses on HIV-1, but the information is generally applicable to HIV-2 as well.

HIV infects a limited number of cell types in the body, including CD4+ T lymphocytes, macrophages, and dendritic cells (see Chapter 15). The CD4+ T cells are necessary for recognition of foreign antigens, activating antibody-producing B lymphocytes, and orchestrating cell-mediated immunity, in which cytotoxic CD8+ T cells and NK cells directly destroy virus-infected cells, tubercle bacilli, and foreign antigens. The phagocytic function of monocytes and macrophages is also influenced by CD4+ T cells.

The HIV is spherical and contains an electron-dense core surrounded by a lipid envelope (Fig. 16-8A). The core contains an outer shell, or capsid, made up primarily of a protein called p24; two copies of the genomic RNA; and three viral enzymes (protease, reverse transcriptase, and integrase). The viral core is surrounded by a matrix protein called p17, which lies beneath the viral envelope, a structure studded with two viral glycoproteins, gp120 and gp41, which are critical for the infection of cells.

Replication of HIV occurs in eight steps (Fig. 16-8B). Each of these steps provides insights into the development of methods used for preventing or treating the infection. The first step involves the binding of the virus to the CD4+ T cell. Once HIV has entered the bloodstream, it attaches to the surface of a CD4+ T cell by binding to the CD4 molecule, which acts as a high-affinity receptor for the virus. This process is known as attachment. However, attaching to the CD4 molecule is not sufficient for infection; the virus must also bind with other surface molecules (chemokine coreceptors, such as CCR5 and CXCR4) that bind the gp120 and gp41 envelope glycoproteins. The chemokine coreceptors are critical components of the HIV infection process: the virus can only infect cells expressing CD4+ and the coreceptors. People with defective coreceptors are more resistant to development of HIV infection, despite repeated exposure. Research aimed at developing coreceptor-targeted viral entry inhibitors raises new hope for bridging the gap toward a cure of HIV infection.

The second step of the replication process allows for internalization of the virus. After attachment, the viral envelope peptides fuse to the CD4+ T-cell membrane. Fusion results in an uncoating of the virus, allowing the contents of the viral core (the two single strands of viral RNA and the reverse transcriptase, integrase, and protease enzymes) to enter the host cell. The third step consists of DNA synthesis. In order for HIV to reproduce, it must change its RNA into DNA. It does this using the reverse transcriptase enzyme. Reverse transcriptase makes a copy of the viral RNA, and then in reverse makes a complementary DNA (cDNA) strand. The result is a double-stranded DNA that carries instructions for viral replication.

The fourth step is called integration. In dividing cells, the cDNA enters the nucleus and, with the help of the enzyme integrase, is inserted into the cell's original DNA. The integrated virus is called a provirus.
T cells, the proviral cDNA may remain in the cytoplasm in a linear extrachromosomal form. The fifth step involves transcription of the double-stranded viral DNA to form a single-stranded messenger RNA (mRNA) with the instructions for building new viruses. Transcription involves activation of the T cell and induction of host cell transcription factors. Alternatively, the provirus may remain nontranscribed within infected cells for months or years, hidden from the host’s immune system and even from antiviral therapies. Long-lived reservoirs of HIV are established within the first month of acute infection. These reservoirs of latent infected cells do not spontaneously produce virus unless activated. Their long life span constitutes one of the main barriers to HIV eradication by current antiviral therapies.

Within 72 hours of a transmission event, local virus replication occurs at the site of infection and the draining lymph nodes. Infection becomes systemic by the end of the first week, as the virus disseminates to other lymphoid tissue compartments. By day 10 after infection, most circulating CD4\(^+\) T cells either have been infected with or have interacted with HIV. The availability and rapid consumption of targets during this early period leads to massive viral replication, accounting in part for the high levels of viremia and genital shedding achieved by the end of the first month. Once infection has become truly systemic, viral loads grow exponentially, with a
doubling time of approximately 0.3 days during the first 2 to 3 weeks of infection.

The problem is that, over years, the CD4+ T-cell count gradually decreases through this process, and the number of viruses detected in the blood of persons infected with HIV increases. The depletion of CD4+ T cells after infection is due to the cytopathic effect of the virus, resulting from production of viral particles, as well as death of unaffected cells. Other infected cells, such as macrophages and dendritic cells, may also die, resulting in destructive changes in the lymphoid organs. Until the CD4+ T-cell count falls to a very low level, a person infected with HIV can remain asymptomatic, although active viral replication is still taking place and serologic tests can identify antibodies to HIV. These antibodies, unfortunately, do not convey protection against the virus. Although symptoms are not evident, the infection proceeds on a microbiologic level, including the invasion and selective destruction of CD4+ T cells. The continual decline of CD4+ T cells, which are pivotal cells in the immune response, strips the HIV-infected person of protection against common organisms and cancerous cells.

Classification and Stages of HIV Infection

The definitions and classification systems for HIV and AIDS have been evolving, due in part to improvements in diagnostic and therapeutic capabilities, including increased use of new HIV-testing technologies. In 1993, the Centers for Disease Control and Prevention (CDC) developed a classification system that emphasized the clinical importance of the CD4+ T-cell count along with a list of AIDS-defining conditions (Chart 16-3).36 The 1993 classification system, which was revised in 2008, highlights the central importance of the CD4+ T-cell count and percentages, which are objective measures of immunosuppression routinely used in the care of HIV-infected persons67 (Table 16-2). It distinguishes three stages of HIV infection based on CD4+ T-cell counts and total T-cell percentages: stage one >500 cells/µL (29%); stage two 200 to 499 cells/µL (14% to 28%); and stage three (AIDS) <200 cells/µL (<14%). An undetermined stage has also been included.

Clinical Course. The typical course of HIV infection is characterized by three phases, which usually occur over a period of 8 to 12 years. These are the primary infection phase, chronic asymptomatic or latency phase, and overt AIDS phase (Fig. 16-9).56

When initially infected with HIV, many persons have an acute mononucleosis-like syndrome known as primary infection. This acute phase (stage 1) may include fever, fatigue, myalgias, sore throat, night sweats, gastrointestinal problems, lymphadenopathy, maculopapular rash, and headache. Fever and malaise are the symptoms most commonly associated with primary infection.46,57 During primary infection, there is an increase in viral replication, which leads to very high viral loads, sometimes greater than 1,000,000 copies/mL, and a decrease in the CD4+ T-cell count. The signs and symptoms of primary HIV infection usually appear 1 to 4 weeks after exposure to HIV, and have an average duration of 7 to 10 days. After several weeks, the immune system acts to control viral replication and reduces the viral load to a lower level, where it often remains for several years. This relatively stable level of virus is referred to as the set point. People who are diagnosed with HIV infection while they are in the primary infection phase may have a unique opportunity for treatment. Some experts hypothesize that treatment, if started early, may reduce the number of HIV-infected CD4+ memory T cells; protect the functioning of HIV-infected CD4+ T cells and cytotoxic T cells; and potentially help to maintain a homogeneous viral population that will be better controlled by antiretroviral therapy and the immune system.46,58

*Added to the 1993 expansion of the AIDS surveillance case definition.

The primary stage is followed by a latent period (stage 2) during which the person has no signs or symptoms of illness. The median time of the latent period is about 10 years. During this time, the CD4⁺ T-cell count falls gradually from the normal range of 800 to 1000 cells/µL to 200 to 499 cells/µL (14% to 28%). More recent data suggest that the CD4⁺ T-cell decline may not fall in an even slope based on HIV RNA levels, and factors related to the variability in the decline in CD4⁺ T cells are under investigation.

Lymphadenopathy (i.e., swollen lymph nodes) for more than 3 months in at least two locations (not including the groin) develops in some persons with HIV infection during this phase. The lymph nodes may be sore or visible externally.

Stage 3 (overt AIDS) occurs when a person has a CD4⁺ T-cell count of less than 200 cells/µL (<14%) or an AIDS-defining illness. Without antiretroviral therapy, this phase can lead to death within 2 to 3 years. The risk of opportunistic infections and death increases significantly when the CD4⁺ T-cell count falls below 200 cells/µL.

The clinical course of HIV varies from person to person. In the absence of treatment, most people with HIV infection progress to AIDS after 7 to 10 years. These people are the chronic or typical progressors. Another 10% to 20% are rapid progressors who develop AIDS within 2 to 3 years after primary infection. The final 5% to 15% are long-term nonprogressors, who remain asymptomatic for 10 years or more after seroconversion, with stable CD4⁺ T-cell counts and low plasma HIV RNA levels. A subset of these long-term nonprogressors, called elite controllers, have plasma HIV RNA levels that are below the level of detection. Studies of these individuals have helped to identify host and viral factors that influence disease progression.

One factor found to be important in elite control is a mutation in the genes coding for CCR5, a coreceptor used for HIV entry. Mutations in both genes result in CD4⁺ cells with a defective CCR5, thereby preventing HIV entry into those cells. Research in this area is ongoing.

* A confirmed case meets the laboratory diagnosis of HIV infection and one of the four stages. Although cases with no information on AIDS-defining characteristics can be classified as stage unknown, every effort should be made to obtain CD4⁺ T-cell counts and percentages and the presence of AIDS-defining conditions at the time of diagnosis.

**Opportunistic Infections**

Opportunistic infections involve common organisms that do not typically produce infection unless there is impaired immune function. As the number of CD4+ T cells declines, the risk of these infections increases. In addition, the baseline HIV RNA level contributes and serves as an independent risk factor.2,3

Opportunistic infections are most often categorized by the type of organism (e.g., fungal, protozoal, bacterial and mycobacterial, viral). Bacterial and mycobacterial opportunistic infections include bacterial pneumonia, salmonellosis, bartonellosis, *Mycobacterium tuberculosis* (TB), and *Mycobacterium avium* complex (MAC). Fungal opportunistic infections include candidiasis, coccidioidomycosis, cryptococcosis, histoplasmosis, penicilliosis, and pneumocystosis. Protozoal opportunistic infections include cryptosporidiosis, microsporidiosis, isosporiasis, and toxoplasmosis. Viral infections include those caused by cytomegalovirus (CMV), herpes simplex and zoster viruses, human papillomavirus, and JC virus, a virus that is the causative agent of progressive multifocal leukoencephalopathy (PML).

**Respiratory Tract Infections.** The most common causes of respiratory disease in persons with HIV infection are bacterial pneumonia, *Pneumocystis jiroveci* pneumonia, and pulmonary tuberculosis. Other organisms that cause opportunistic pulmonary infections in persons with AIDS include CMV, MAC, *Toxoplasma gondii*, and *Cryptococcus neoformans*. Pneumonia also may be caused by more common bacterial pulmonary pathogens, including *S. pneumoniae*, *Pseudomonas aeruginosa*, and *H. influenzae*. Some persons may become infected with multiple organisms, causing a polymicrobial infection. Kaposi sarcoma (to be discussed) also can occur in the lungs.

*P. jiroveci* (formerly known as *P. carinii*) pneumonia (PCP) was the most common presenting manifestation of AIDS during the first decade of the epidemic. *P. jiroveci* is an organism common in soil, houses, and many other places in the environment, and in healthy persons does not cause infection or disease. In persons with HIV infection, *P. jiroveci* can multiply quickly in the lungs and cause pneumonia. As the disease progresses, the alveoli become filled with a foamy exudate that forms cup-shaped cyst walls within the exudate (Fig. 16-10). Since highly active antiretroviral therapy (HAART) and prophylaxis for PCP were instituted, the incidence of PCP has decreased.4,5 *P. jiroveci* (formerly known as *P. carinii*) pneumonia still is common in people unaware of their HIV-infected status, in those who choose not to treat their HIV infection or take prophylaxis, and in those with poor access to health care. The best predictor of PCP is a CD4+ cell count below 200 cells/µL, and it is at this point that antiretroviral prophylaxis with trimethoprim-sulfamethoxazole or an alternative agent (in the case of adverse reactions to sulfa drugs) is strongly recommended. The symptoms of *P. jiroveci* pneumonia may be acute or gradually progressive. Patients may present with complaints of a mild cough, fever, shortness of breath, and weight loss. Diagnosis is made by identifying the organism in pulmonary secretions.

Tuberculosis (TB) is the leading cause of death for people with HIV infection worldwide, and is often the first manifestation of HIV infection. In 2011, 23% of those with TB tested positive for HIV.4 In the United States, the number of TB cases decreased from the 1950s to 1985; then, in 1986, the number began to increase (see Chapter 22).4,5 Several factors contributed to this increase, but the most profound factor was HIV infection. The lungs are the most common site of *M. tuberculosis* infection, but extrapulmonary infection of the kidney, bone marrow, and other organs also occurs in people with HIV infection. Whether a person has pulmonary or extrapulmonary TB, most persons present with fever, night sweats, cough, and weight loss. Persons infected with both HIV and TB are more likely to have a rapidly progressive form of TB, and usually have an increase in viral load, which decreases the success of TB therapy. They also have an increased number of other opportunistic infections and an increased mortality rate.

Since the late 1960s, most persons with TB have responded well to therapy. However, in 1991, there were outbreaks of multidrug-resistant (MDR) TB. Since the original outbreak of MDR TB in the early 1990s, new cases of MDR TB have declined, largely because of improved infection control practices and the expansion of directly observed therapy programs.

**Gastrointestinal Manifestations.** Diseases of the gastrointestinal tract are some of the most frequent complications of HIV infection and AIDS. Esophageal candidiasis, CMV infection, and herpes simplex virus infection commonly cause esophagitis in people with
HIV infection. Aphthous ulcers presumed secondary to HIV are also common. Persons experiencing these infections usually complain of painful swallowing or retrosternal pain. Endoscopy or barium esophagography is required for definitive diagnosis.

Diarrhea or gastroenteritis is a common complaint in persons with HIV infection. Although diarrhea is often a side effect of medications used to treat HIV, it should be evaluated for the same common causes as in the general population. The most common protozoal opportunistic infection that causes diarrhea is Cryptosporidium parvum. Clinical features of cryptosporidiosis can range from mild diarrhea to severe, watery diarrhea with a loss of up to several liters of water per day, as well as malabsorption, electrolyte disturbances, dehydration, and weight loss. Other organisms that cause gastroenteritis and diarrhea are Salmonella, CMV, Clostridium difficile, Escherichia coli, Shigella, Giardia, and microsporidia. These organisms are identified by examination of stool cultures or endoscopy.

Nervous System Manifestations. Human immunodeficiency virus infection, particularly in the late stages of severe immunocompromise, leaves the nervous system vulnerable to an array of neurologic disorders, including neurocognitive disorders, toxoplasmosis, and progressive multifocal leukoencephalopathy.

HIV-associated neurocognitive disorders (HANDs) is a syndrome of cognitive impairment with motor dysfunction or behavioral/psychosocial symptoms associated with HIV infection itself. In 2007, the National Institute of Mental Health and National Institute of Neurologic Diseases and Stroke developed a new classification with standardized diagnostic criteria for HANDs. The three conditions comprising HANDs are HIV-associated asymptomatic neurocognitive impairment, HIV-associated mild neurocognitive disorder, and HIV-associated dementia, formerly known as AIDS dementia complex. The clinical features of HIV-associated dementia, which is usually a late complication of HIV infection, include impairment of attention and concentration, slowing of mental and motor speed and agility, and apathetic behavior. There is no specific treatment for HAND, but HAART comprised of medications which penetrate the blood-brain barrier is considered the best therapeutic option at this time.

Toxoplasmosis is a common opportunistic infection in persons with AIDS. The organism responsible, T. gondii, is a parasite that most often affects the CNS. Toxoplasmosis usually is a reactivation of a latent T. gondii infection that has been dormant in the CNS. The typical presentation includes fever, headaches, and neurologic dysfunction, including confusion and lethargy, visual disturbances, and seizures. Computed tomography scans or, preferably, magnetic resonance imaging (MRI) should be performed immediately to detect the presence of neurologic lesions. Prophylactic treatment with trimethoprim-sulfamethoxazole or an alternative agent, which is also used for prevention of P. jiroveci pneumonia, is effective against T. gondii.

Progressive multifocal leukoencephalopathy (PML) is a demyelinating disease of the white matter of the brain caused by the JC virus, a DNA papovavirus that attacks the oligodendrocytes. PML advances slowly, and is characterized by progressive limb weakness, sensory loss, difficulty controlling the digits, visual disturbances, subtle alterations in mental status, hemiparesis, ataxia, diplopia, and seizures. The mortality rate is high, and the average survival time is 2 to 4 months after diagnosis. Diagnosis is suspected based on clinical findings and an MRI, and confirmed by the presence of the JC virus in the cerebrospinal fluid. There is no proven cure for PML, but improvement can occur after starting effective HAART.

Malignancies

Persons with AIDS have a high incidence of certain malignancies, especially Kaposi sarcoma (KS), non-Hodgkin lymphoma, and noninvasive cervical carcinoma. The increased incidence of malignancies probably is a function of impaired cell-mediated immunity. As persons with HIV infection are living longer, there has been increasing incidence of age- and gender-specific malignancies. Non–AIDS-defining malignancies account for more morbidity and mortality than AIDS-defining malignancies in the HAART era.

Kaposi sarcoma is a malignancy of the endothelial cells that line small blood vessels. An opportunistic cancer, KS occurs in immunosuppressed persons (e.g., transplant recipients or persons with AIDS). Kaposi sarcoma was one of the first and most common opportunistic cancers associated with AIDS. Since the introduction of HAART, the incidence of KS has decreased dramatically but has not reached zero. There is evidence linking KS to a herpesvirus (herpesvirus 8 [HHV-8], also called KS-associated herpes virus [KSHV]). The virus is readily transmitted through homosexual and heterosexual activities; however, there is a disproportionately higher incidence of KS in men who have sex with men compared with women and other men. Maternal–infant transmission also can rarely occur. The virus has been detected in saliva from infected persons, and other nonsexual modes of transmission are suspected.

The lesions of KS can be found on the skin and on any mucosal surface in the oral cavity, gastrointestinal tract, and lungs. More than 50% of people with skin lesions also have gastrointestinal lesions. The disease usually begins as one or more macules, papules, or purple skin lesions that enlarge and become darker (Fig. 16-11). Tumor nodules frequently are located on the trunk, neck, and head, especially the tip of the nose. They usually are painless in the early stages, but discomfort may occur as the tumor develops. Invasion of internal organs, including the lungs, gastrointestinal tract, and lymphatic system, commonly occurs. Gastrointestinal tract KS is often asymptomatic, but can cause pain, bleeding, or obstruction.
Pulmonary KS usually is a late development of the disease and causes dyspnea, cough, and hemoptysis (coughing up blood). With prolonged survival, the number of persons with AIDS who develop non-Hodgkin lymphoma has increased steadily. The clinical features are nonspecific and include fever, night sweats, and weight loss (see Chapter 11). Because the manifestations of non-Hodgkin lymphoma are similar to those of other opportunistic infections, diagnosis often is difficult. Diagnosis can be made by biopsy of the affected tissue.

The high prevalence of human papillomavirus (HPV) infection in persons with AIDS has been linked to the development of cervical carcinoma and anal carcinoma in both HIV-positive men and women. Gynecologic examination with cervical cytologic analysis for HPV should be part of the routine evaluation of HIV-infected women. Since HPV can also cause anal dysplasia, a precursor of anal carcinoma, cytologic evaluations of the anal canal are also recommended for both HIV-infected men and women. A quadrivalent vaccine to prevent HPV infection became available in 2007. The safety and immunogenicity of this vaccine among HIV-infected men and women are being studied.

**Wasting Syndrome and Metabolic Disorders**

**Wasting Syndrome.** The wasting syndrome, which is an AIDS-defining illness, is characterized by involuntary weight loss of at least 10% of baseline body weight in the presence of diarrhea, more than two stools per day, or chronic weakness and a fever. This diagnosis is made when no other opportunistic infections or neoplasms can be identified as causing these symptoms. Factors that contribute to wasting are anorexia, metabolic abnormalities, endocrine dysfunction, malabsorption, and cytokine dysregulation. Treatment for wasting includes nutritional interventions such as oral supplements or enteral or parenteral nutrition, as well as pharmacologic agents, including appetite stimulants, cannabinoids, and megestrol acetate.

**Metabolic Disorders.** A wide range of metabolic and morphologic disorders are associated with HIV infection, including insulin resistance and diabetes, lipodystrophy, hyperlipidemia, and mitochondrial disorders. It is not known why insulin resistance appears to be increased in people with HIV infection; however, most experts believe it is secondary to dysregulation of metabolic pathways or to indirect effects through mitochondrial toxicity linked to adipocyte toxicity. Moreover, metabolic complications among people with HIV infection have been increasing since the introduction of potent HAART.

The term lipodystrophy is frequently used to describe the body composition changes with or without the other metabolic derangements. Lipodystrophy related to HIV infection includes symptoms that fall into two categories: changes in body composition and metabolic changes. The alterations in body appearance are an increase in abdominal girth, buffalo hump development (abnormal distribution of fat in the dorsocralvical area), wasting of fat from the face and extremities, and breast enlargement in men and women. Most individuals experience either lipohypertrophy or lipoatrophy. Mixed patterns of fat changes are less common. The metabolic changes include elevated serum cholesterol, low HDL cholesterol, elevated triglyceride levels, and insulin resistance. Originally attributed solely to the use of protease inhibitors, the pathogenesis of these metabolic derangements is complex and there may be multiple confounding factors.
The mitochondria control many of the oxidative chemical reactions that release energy from glucose and other organic molecules and transform it into adenosine triphosphate (ATP), which cells use as an energy source. In the absence of normal mitochondrial function, cells revert to anaerobic metabolism, generating lactic acid. The mitochondrial disorders seen in persons with HIV infection are attributed to a class of drugs called the nucleoside/nucleotide analog reverse transcriptase inhibitors (NRTIs), particularly the thymidine analogs. The most common presentations are lipoatrophy and peripheral neuropathy, although patients may not experience both. Patients may also present with nonspecific gastrointestinal symptoms, including nausea, vomiting, and abdominal pain. They may develop altered liver function and lactic acidosis. Since the recognition of the ascending polynephropathy syndrome and reports of hepatic failure due to combination therapy with stavudine and didanosine, reports of life-threatening events due to mitochondrial toxicities have dramatically decreased.

**Diagnosis and Treatment**

A diagnosis of HIV infection may be prompted by a number of scenarios, including positive results of a screening test, accompanying signs and symptoms of an acute HIV infection, or manifestations of an immunodeficiency state. Unfortunately, there are approximately 250,000 persons living with HIV infection in the United States who are not aware of their infection or their risk of transmitting it, and therefore are missing the opportunity to benefit from early treatment.

**Diagnostic Methods.** The most accurate and inexpensive method for identifying HIV infection is the HIV antibody test. The first commercial assays for HIV were introduced in 1985 to screen donated blood. Since then, use of antibody detection tests has been expanded to include evaluating persons at increased risk for HIV infection. The HIV antibody test procedure consists of screening with an enzyme immunoassay (EIA), also known as enzyme-linked immunosorbent assay (ELISA), followed by a confirmatory test such as the Western blot assay, which is performed if the EIA is positive. The EIA detects antibodies produced in response to HIV infection. In an EIA, antibodies to HIV in the blood sample bind to HIV antigens in the test material. The Western blot is a more sensitive assay than the EIA that looks for the presence of antibodies to specific viral antigens. In the case of a false-positive EIA result, the Western blot test can identify the person as uninfected. Polymerase chain reaction (PCR) is a technique for detecting HIV DNA (see Chapter 14). Polymerase chain reaction detects the presence of the virus rather than the antibody to the virus, which the EIA and Western blot tests detect. Polymerase chain reaction is useful in diagnosing HIV infection in infants born to infected mothers because these infants have their mothers’ HIV antibodies regardless of whether the children are infected. Polymerase chain reaction is also useful in determining acute HIV infection as the antibody tests are negative in early infection.

Technologic advances have led to new forms of testing, such as the oral test, home testing kits, and the new rapid blood test. Oral fluids contain antibodies to HIV. In the late 1990s, the FDA approved the OraSure test. The OraSure uses a cotton swab, which is inserted into the mouth for 2 minutes, placed in a transport container with preservative, and then sent to a laboratory for EIA and Western blot testing. Home HIV testing kits can be bought over the counter. The kits, approved by the FDA, allow persons to collect their own blood sample through a finger-stick process, mail the specimen to a laboratory for EIA and confirmatory Western blot tests, and receive results by telephone in 3 to 7 days. In November 2002, the FDA approved the Ora Quick Rapid HIV-1 Antibody Test. The Ora Quick uses a whole-blood specimen from a fingerstick and can provide results in about 20 minutes. Reactive, or positive, test results require confirmation using Western blot testing on the serum. Persons with a reactive result need to be told that the preliminary test was positive and that they need a confirmatory test. The use of a rapid test should facilitate people receiving the results of their HIV test more regularly because they do not need to return for their test results 2 weeks later unless it is positive or there is concern that the person may be in the window period before seroconversion. The newest development in HIV testing is a combined antigen-antibody test (p24 antigen, HIV antibodies), which has the advantage of early detection of HIV, potentially within 2 weeks of infection.

**Treatment.** Currently, there is no cure for HIV infection. The medications that are currently available to treat HIV infection decrease the amount of virus in the body, but they do not eradicate HIV. The treatment of HIV infection is one of the most rapidly evolving fields in medicine.

There currently are five different classes of HIV antiretroviral medications: nucleoside and nucleotide analog reverse transcriptase inhibitors; nonnucleoside reverse transcriptase inhibitors; protease inhibitors; entry inhibitors; and the newest class, integrase inhibitors. Each class of agents attempts to interrupt the life cycle of the HIV at different points (see Fig. 16-8). Reverse transcriptase inhibitors inhibit HIV replication by acting on the enzyme reverse transcriptase. Nucleoside analog reverse transcriptase inhibitors and nucleotide reverse transcriptase inhibitors act by blocking the elongation of the DNA chain by stopping more nucleosides from being added. Nonnucleoside reverse transcriptase inhibitors work by binding to the reverse transcriptase enzyme so it cannot copy the virus’s RNA into DNA. Protease inhibitors bind to the protease enzyme and inhibit its action. This inhibition prevents cleavage of the polypeptide chain into individual proteins, which would be used to construct a new virus.
Two new classes of antiretroviral therapy are the *entry inhibitors* and *integrase inhibitors*. The entry inhibitors prevent HIV from entering or fusing with the CD4+ cell, thus blocking the virus from inserting its genetic information into the CD4+ T cell. The integrase inhibitors block the integration step of the viral cycle, thus preventing the HIV genome from integrating into the host’s genome.

Because different drugs act at different stages of the replication cycle, optimal treatment includes a combination of at least three antiretroviral drugs, referred to as *highly active antiretroviral therapy* (HAART). The goal of HAART is a sustained suppression of HIV replication, resulting in an undetectable viral load and increasing CD4+ cell count. In general, antiviral therapies are prescribed to slow the progression of AIDS and improve the overall quality of life and survival time of persons with HIV infection.

Preventive and therapeutic vaccines for HIV are also being investigated. The preventive vaccine would be given to someone who is HIV negative, with the goal of preventing infection if exposed to HIV. The therapeutic vaccine would be used in people who are already infected with HIV as a way to control HIV replication. In trials to date, these vaccines have not proven beneficial.

A new preventive strategy has been approved by the FDA in the United States. PrEP—pre-exposure prophylaxis—involves consistently taking antiretroviral medication that may interrupt infection if exposed to HIV in high-risk settings. It is not 100% effective at preventing HIV infection; routine counseling on reducing risky behaviors and routine evaluations for sexually transmitted infections are still paramount. Individuals taking PrEP also need to be routinely monitored for efficacy and side effects of the medication.

**HIV Infection in Pregnancy and in Infants and Children**

Transmission from mother to infant is the most common way that children become infected with HIV. Human immunodeficiency virus may be transmitted from infected women to their offspring in utero, during labor and delivery, or through breast-feeding.

Most transmissions from mother to child occur during childbirth when the mother’s infected blood in the birth canal infects the baby. Breast-feeding, particularly in poor countries, can account for one third to one half of all mother-to-child transmission. Screening programs for pregnant women and antiretroviral prophylaxis are available for preventing mother-to-child transmission in HIV-positive women. Epidemiologic estimates suggest that coverage for antiviral prophylaxis to HIV-positive women for prevention of mother-to-child transmission in low- to middle-income countries increased from 9% in 2004 to 33% in 2007 to 57% in 2011.

**Diagnosis and Treatment.** Diagnosis of HIV infection in children born to HIV-infected mothers is complicated by the presence of maternal anti-HIV IgG antibody, which crosses the placenta to the fetus. Consequently, infants born to HIV-infected women can be HIV antibody positive by ELISA up until 18 months of age even though they are not infected with HIV. Polymerase chain reaction testing for HIV DNA is used most often to diagnose HIV infection in infants younger than 18 months of age. Two positive PCR tests are needed for diagnosis. Children born to mothers with HIV infection are considered uninfected if they become HIV antibody negative after 18 months of age, have no other laboratory evidence of HIV infection, and have not met the case definition criteria for AIDS in children.

The landmark Pediatric AIDS Clinical Trials Group (PACTG) 076 study reported that perinatal transmission could be lowered by two-thirds, from 26% to 8%, by administering zidovudine to the mother during pregnancy and labor and delivery and to the infant when it is born. The U.S. Public Health Service therefore recommends that HIV counseling and testing should be offered to all pregnant women. The recommendations also stress that women who test positive for HIV antibodies should be informed of the perinatal prevention benefits of zidovudine therapy and offered HAART, which often includes zidovudine. This is done because it has been found that women receiving antiretroviral therapy who also have a viral load less than 1000 copies/mL have very low rates of perinatal transmission. Efavirenz, a non-nucleoside reverse transcriptase inhibitor, has the potential for causing neural tube defects within the first 6 weeks of pregnancy. HIV-infected women of child-bearing age should be tested for pregnancy and counseled regarding the potential adverse effects prior to initiating HAART with efavirenz. If a woman is taking an efavirenz-based regimen and pregnancy is determined after 6 weeks, then she may continue the regimen as long as virologic suppression is maintained and the pregnancy is monitored. Benefits of voluntary testing for mothers and newborns include reduced morbidity because of intensive treatment and supportive health care, the opportunity for early antiretroviral therapy for mother and child, and information regarding the risk of transmission from breast milk.

**Clinical Manifestations.** Children may have a different clinical presentation of HIV infection than adults. Failure to thrive, CNS abnormalities, and developmental delays are the most prominent primary manifestations of HIV infection in children. Children born with HIV infection usually weigh less and are shorter than noninfected infants. A major cause of early mortality for HIV-infected children is *P. jiroveci* pneumonia, which occurs early in children, with the peak age of onset at 3 to 6 months. For this reason, prophylaxis with trimethoprim-sulfamethoxazole should be started beginning at 4 to 6 weeks for all infants born to HIV-infected mothers, regardless of their CD4+ cell count or infection status.
SUMMARY CONCEPTS

- Immunodeficiency is an absolute or partial loss of the normal immune response, which places a person at increased risk for development of infections or malignant complications. It can be classified as primary (i.e., congenital or inherited) or secondary (i.e., due to another disease or condition).

- Immunodeficiency can affect the humoral or cellular components of the adaptive immune system. Defects in humoral immunity increase the risk of recurrent pyogenic infections but have less effect on the defense against intracellular bacteria (mycobacteria), fungi, protozoa, and viruses (except for the enteroviruses that cause gastrointestinal infections). Defects in cellular immunity increase the risk of developing fungal, protozoal, viral, and intracellular bacterial infections, and malignant cell proliferation.

- Acquired immunodeficiency syndrome (AIDS), the most common type of secondary immunodeficiency, is caused by infection with the human immunodeficiency virus (HIV), a retrovirus that infects the body's CD4+ T cells and macrophages. Destruction of CD4+ cells constitutes an attack on the entire immune system because this subset of lymphocytes exerts critical regulatory and effector functions that involve both humoral and cellular immunity.

- The clinical course of HIV infection can be divided into three phases: a primary phase that occurs shortly after infection and is usually manifested by mononucleosis-like symptoms, a latency phase that may last for years, and an overt AIDS phase that is characterized by a marked decrease in CD4+ T cells and the development of opportunistic infections, malignancies, wasting syndrome, and metabolic disorders. There is no cure for AIDS. Treatment largely involves the use of drugs that interrupt the replication of HIV and prevention or treatment of complications such as opportunistic infections.

- Women who are infected with HIV may transmit the virus to their offspring in utero, during labor and delivery, or through breast milk. Diagnosis of HIV infection in children born to HIV-infected mothers is complicated by the presence of maternal HIV antibody, which crosses the placenta to the fetus. This antibody usually disappears within 18 months in uninfected children.

REVIEW EXERCISES

1. A 32-year-old man presents in the allergy clinic with complaints of allergic rhinitis or hay fever. His major complaints are those of nasal pruritus (itching), nasal congestion with profuse watery drainage, sneezing, and eye irritation. The physical examination reveals edematous and inflamed nasal mucosa and redness of the ocular conjunctiva. He relates that this happens every fall during “ragweed season.”

   A. Explain the immunologic mechanisms that are responsible for this man’s symptoms.
   B. What type of diagnostic test might be used?
   C. What type(s) of treatment might be used to relieve his symptoms?

2. Persons with intestinal parasites and those with allergies may both have elevated levels of eosinophils in their blood.

   A. Explain.

3. A 20-year-old woman has been diagnosed with IgA deficiency. She has been plagued with frequent bouts of bronchitis and sinus infections.

   A. Why are these types of infections particularly prominent in persons with an IgA deficiency?
   B. She has been told that she needs to be aware that she could have a severe reaction when given unwashed blood transfusions. Explain.

4. Persons with impaired cellular immunity may not respond to the tuberculin test, even when infected with Mycobacterium tuberculosis.

   A. Explain.

5. A 29-year-old woman presents to the clinic for her initial obstetric visit about 10 weeks into her pregnancy.

   A. This woman is in a monogamous relationship. Should an HIV test be a part of her initial blood work? Why?
   B. The woman’s HIV test comes back positive. What should be done to decrease the risk of transmitting HIV to her child?
   C. The infant is born, and its initial antibody test is positive. Does this mean the infant is infected? How is the diagnosis of HIV infection in a child younger than 18 months made, and why is this different than the diagnosis for adults?

6. A 40-year-old man presents to the clinic very short of breath, and after a radiograph and an examination, he is diagnosed with PCP. His provider does an HIV test, which is positive. Upon further testing, the man’s CD4+ cell count is found to be 100 cells/µL and his viral load is 250,000 copies/mL.
A. Why did the provider do an HIV test after the man was diagnosed with PCP?

B. Is there a way to prevent PCP?

C. What classification does this man fall into based on his CD4+ count and symptomatology, and why?

REFERENCES

The main function of the cardiovascular or circulatory system, which consists of the heart and blood vessels, is transport. The circulatory system transports and distributes oxygen and nutrients needed for metabolic processes to the tissues, carries waste products from cellular metabolism to the kidneys and other excretory organs for elimination, and circulates fluids, electrolytes, and hormones needed to regulate body function. This process is carried out with exquisite precision so that oxygen and nutrient delivery is exactly matched to meet tissue needs.

Organization of the Circulatory System

The circulatory system can be divided into two parts: the pulmonary (or central) circulation, which moves blood through the lungs and creates a link with the gas exchange function of the respiratory system, and the systemic (or peripheral) circulation, which moves blood throughout all the other tissues of the body (Fig. 17-1).

Pulmonary and Systemic Circulations

The pulmonary circulation consists of the right side of the heart, the pulmonary arteries and arterioles, the pulmonary capillaries, and the pulmonary veins. The large pulmonary vessels are unique in that the
The pulmonary artery is the only artery that carries deoxygenated venous blood and the pulmonary veins are the only veins that carry oxygenated arterial blood. The systemic circulation consists of the left side of the heart, the aorta and its branches, the capillaries that supply the brain and peripheral tissues, and the systemic venous system and the vena cava. The veins from the lower portion of the body merge to form the inferior vena cava and those from the head and upper extremities form the superior vena cava, both of which empty into the right heart.

Although the pulmonary and systemic circulations function similarly, they have some important differences. The pulmonary circulation, which is the smaller of the two, is located in the chest near the heart and functions as a low-pressure system (mean arterial pressure of approximately 12 mm Hg). This low pressure allows blood to move through the lungs more slowly, providing more time for gas exchange. Because the systemic circulation must transport blood to distant parts of the body, often against the effects of gravity, it functions as a high-pressure system, with a mean arterial pressure of 90 to 100 mm Hg.

The heart, which propels blood through the circulatory system, consists of two pumps in series—the right heart, which propels blood through the gas exchange vessels in the lungs, and the left heart, which propels blood through the vessels that supply all the other tissues in the body. Both sides of the heart are further divided into two chambers, an atrium and a ventricle. The atria function as collection chambers for blood returning to the heart and as auxiliary pumps that assist in filling the ventricles. The ventricles are the main pumping chambers of the heart. The right ventricle pumps blood through the pulmonary artery to the lungs and the left ventricle pumps blood through the aorta into the systemic circulation. The ventricular chambers of the right and left heart have inlet and outlet valves that act reciprocally (i.e., one set of valves is open while the other is closed) to control the direction of blood flow through the cardiac chambers and out into the arteries.

Because the circulatory system is a closed system, both sides of the heart must pump the same amount of blood over time. If the output of the left heart were to fall below that of the right heart, blood would accumulate in the pulmonary circulation. Likewise, if the right heart were to pump less effectively than the left heart, blood would accumulate in the systemic circulation. However, the left and right heart seldom eject exactly the same amount of blood with each beat. This is because blood return to the heart is affected by activities such as taking a deep breath or moving from the seated to standing position. These beat-by-beat variations in stroke volume (amount of blood pumped with each beat) are accommodated by the large storage capabilities of the venous system that allow for temporary changes in blood volume. The accumulation of blood occurs only when the storage capacity of the venous system has been exceeded.

**Volume and Pressure Distribution**

Blood flow in the systemic circulatory system depends on a blood volume that is sufficient to fill the blood vessels in the systemic circulation and a pressure difference that provides the force needed to move blood forward. As shown in Figure 17-2, approximately 4% of the blood at any given time is in the left heart, 16% is in the arteries and arterioles, 4% is in the capillaries, 64% is in the venules and veins, and 4% is in the right heart. The arteries and arterioles, which have thick, elastic walls and function as a distribution system, have the highest pressure. The capillaries are small, thin-walled vessels that link the arterial and venous sides of the circulation. They serve as an exchange system where transfer of gases, nutrients, and wastes take place. Because of their small size and large surface area, the capillaries contain the smallest amount of blood. The venules and veins, which contain the largest amount of blood, are thin-walled, distensible vessels that function as a reservoir to collect blood from the capillaries and return it to the right heart.

Because the pulmonary and systemic circulations are connected and function as a closed system, blood can be shifted from one circulation to the other.
In the pulmonary circulation, the blood volume (approximately 450 mL in the adult) can vary from as low as 50% of normal to as high as 200% of normal. An increase in intrathoracic pressure, such as occurs when exhaling against a closed glottis, impedes venous return to the right heart. This can produce a transient shift from the pulmonary to the systemic circulation of as much as 250 mL of blood as blood backs up in the vena cava and large veins. Body position also affects the distribution of blood volume. In the recumbent position, approximately 25% to 30% of the total blood volume is in the pulmonary circulation. On standing, gravity causes a rapid displacement of this blood to the lower part of the body. Because the volume of the systemic circulation is approximately seven times that of the pulmonary circulation, a shift of blood from one system to the other has a much greater effect on the pulmonary than on the systemic circulation.

The movement of blood from the arterial to the venous side of the circulation depends on a pressure difference or gradient, moving from an area of higher pressure to one of lower pressure. The pressure distribution in different parts of the circulation is almost an inverse of the volume distribution (see Fig. 17-2). The pressure in the arterial side of the circulation, which contains only approximately one sixth of the blood volume, is much higher than the pressure on the venous side of the circulation, which contains approximately two thirds of the blood. This pressure and volume distribution is due in large part to the structure and relative elasticity of the arteries and veins. The pressure difference between the arterial and venous sides of the circulation (approximately 84 mm Hg) provides the driving force for the flow of blood in the systemic circulation. The pulmonary circulation has a similar arterial–venous pressure difference, albeit of a lesser magnitude, that facilitates blood flow.

**SUMMARY CONCEPTS**

- The cardiovascular or circulatory system, which consists of a pump (heart), a series of distributing (arteries and arterioles) and collecting (veins and venules) blood vessels, and an extensive system of exchange vessels (capillaries), functions mainly as a transport system that circulates nutrients and other materials to and removes waste products from tissues throughout the body.
- The circulatory system can be divided into two parts: the right heart and pulmonary circulation, which moves blood through the lungs and creates a link with the gas exchange function of the respiratory system; and the left heart and systemic circulation, which moves blood throughout all the other tissues of the body.
- Blood flow in the circulatory system depends on a blood volume that is sufficient to fill the blood vessels and a pressure difference across the system that provides the force that is needed to move blood forward. The venous system, which is a low pressure system designed to collect and return blood to the heart, contains about two-thirds of the blood; the arterial system, which is a high pressure distributive system, contains about one-sixth of the blood; and the capillaries, which have the lowest pressure and function as an exchange system for gases, nutrients, and wastes, contain the least amount of blood.
Principles of Blood Flow

The term hemodynamics refers to the principles that govern the flow of blood in the vascular system. The physics of fluid flow through rigid tubes provides the basis for understanding the flow of blood through blood vessels, even though blood vessels are not rigid tubes (they are distensible) and blood is not a simple homogenous fluid.

Pressure, Resistance, and Flow

Flow through the blood vessels in the circulatory system is determined almost entirely by two factors: the pressure difference (ΔP) between the two ends of a vessel or group of vessels and the resistance (R) that the blood must overcome as it moves through the vessel or vessels. Thus, the flow of blood through a vessel can be calculated using the equation: flow = ΔP/R. In the circulatory system, blood flow is represented by the cardiac output. Resistance is the opposition to flow caused by friction between the moving blood components and the stationary vessel wall. In the peripheral circulation, the collective resistance of all the vessels in that part of the circulation is referred to as the total peripheral vascular resistance.

The relationship between pressure and resistance can be quantified by what has become known as Poiseuille’s law. In the 1840s, Louis Poiseuille determined that the flow of fluid was determined by the pressure difference between the two ends of a tube (ΔP = P1 − P2), the fourth power of the radius (r⁴) of the tube, the viscosity (η) of the fluid, the tube length (l), and two constants (π and 8) using the following equation: flow = πΔP r⁴/8η. Simplifying the equation (i.e., flow = ΔP r⁴/η) by deleting the constants π and 8 along with the length, which usually does not change, makes it clear that flow will increase as the pressure gradient and vessel radius increase and decrease as the blood viscosity increases. Note particularly that the rate of flow is directly related to the fourth power of the radius, emphasizing the importance of vessel diameter in determining the rate of flow through the vessel. For example, if the pressure remains constant, the rate of flow is 16 times greater in a vessel with a radius of 2 mm (2 × 2 × 2 × 2 = 16) than in a vessel with a radius of 1 mm (1 × 1 × 1 × 1 = 1).

Viscosity generates resistance to flow by producing friction between the molecules of a liquid. Unlike water that flows through plumbing pipes, blood is a nonhomogeneous liquid. It contains blood cells, platelets, fat globules, and plasma proteins that increase its viscosity. It is mainly the hematocrit or percentage of suspended red cells in the blood that determines viscosity.

Flow in Series and Parallel Vessels

The interaction between pressure and resistance is determined by whether blood vessels are arranged in series or in parallel. In vessels such as arteries, arterioles, capillaries, venules, and veins, which are collectively arranged in series, flow through each vessel at any given pressure is the same; therefore, the total resistance is equal to the sum of the resistances (R) of each vessel (R₁ + R₂ + R₃).

In segments of the circulation where blood vessels branch extensively to form parallel circuits, as in those that supply blood to the many organs and tissues of the body, greater amounts of blood will flow through parallel vessels than through any of the individual vessels. Thus, for any given pressure, the total resistance to blood flow will be equal to the sum of the reciprocals of the individual resistances (1/R₁ + 1/R₂ + 1/R₃).

Velocity, Cross-Sectional Area, and Flow

In addition to the amount of blood flowing through a given organ or tissue, the rate or velocity at which the blood is moving is also important. Flow is a volume measurement (milliliters [mL] per second [sec]) that is determined by the cross-sectional area of a vessel and the velocity of flow. Velocity is a distance measurement; it refers to the speed or linear movement per unit time of blood as it flows through a vessel. When the flow through a given segment of the circulatory system is constant—as it must be for continuous flow—the velocity is inversely proportional to the cross-sectional area of the vessel (i.e., the smaller the cross-sectional area, the greater is the velocity of flow).

The linear velocity of blood flow in the circulatory system varies widely from 30 to 35 cm/second in the aorta to 0.2 to 0.3 mm/second in the capillaries. This is because even though each individual capillary is very small, the total cross-sectional area of all the systemic capillaries greatly exceeds the cross-sectional area of other parts of the circulation. As a result of this large surface area, the slower movement of blood allows ample time for exchange of nutrients, gases, and metabolites between the tissues and the blood.

Laminar Versus Turbulent Flow

Ideally, blood flow should be laminar or streamlined, with the blood components arranged in layers so that the plasma is adjacent to the smooth, slippery endothelial lining of the blood vessel, and the blood elements, including the platelets, are in the center or axis of the bloodstream. This arrangement reduces friction by allowing the blood layers to slide smoothly over one another, with the axial layer having the most rapid rate of flow.

Under certain conditions, however, blood flow can switch from laminar to turbulent. In turbulent flow the laminar stream is disrupted and the flow becomes mixed, moving both radially (crosswise) and axially (lengthwise). Turbulent flow can be caused by a number of factors, including high velocity of flow, change in vessel diameter, and low blood viscosity. The tendency for turbulence to occur is increased in direct proportion to the velocity of flow.

Because energy is used in propelling blood both radially and axially, more energy (pressure) is required to drive turbulent flow than laminar flow. Turbulence is often accompanied by vibrations of the blood and surrounding cardiovascular structures. Some of these vibrations are in the audible range and can be heard using a stethoscope. For example, a heart murmur results from turbulent flow through a diseased heart valve.
Wall Tension, Radius, and Pressure

In a blood vessel, wall tension is the force in the vessel wall that opposes the distending pressure inside the vessel. French astronomer and mathematician Pierre de Laplace described the relationship between wall tension, pressure, and the radius of a vessel or sphere more than 200 years ago. This relationship, which has come to be known as the law of Laplace, can be expressed by the equation \( P = T/r \), in which \( T \) is the wall tension, \( P \) is the intraluminal pressure or pressure within the vessel, and \( r \) is the vessel radius (Fig. 17-3A). Accordingly, the internal pressure expands the vessel until it is exactly balanced by the tension in the vessel wall. The smaller the radius, the greater is the pressure needed to balance the wall tension. The law of Laplace can also be used to express the effect of the vessel radius on wall tension (\( T = P \times r \)). This correlation can be compared with a partially inflated balloon (Fig. 17-3B). Because the pressure is equal throughout, the tension in the part of the balloon with the smaller radius is less than the tension in the section with the larger radius. The same holds true for an arterial aneurysm in which the tension and risk of rupture increase as the aneurysm grows in size (see Chapter 18).

The law of Laplace was later expanded to include wall thickness (\( T = P \times r/\text{wall thickness} \)). Wall tension is inversely related to wall thickness, such that the thicker the vessel wall, the lower the tension, and vice versa. In hypertension, for example, arterial vessel walls hypertrophy and become thicker, thereby reducing the tension and minimizing wall stress. The law of Laplace can also be applied to the pressure required to maintain the patency of small blood vessels. Provided that the thickness of a vessel wall remains constant, it takes more pressure to overcome wall tension and keep a vessel open as its radius decreases in size. The critical closing pressure refers to the point at which vessels collapse so that blood can no longer flow through them. In circulatory shock, for example, there is a decrease in blood volume and vessel radii, along with a drop in blood pressure. As a result, many of the small vessels collapse as the blood pressure drops to the point where it can no longer overcome the wall tension. The collapse of peripheral veins often makes it difficult to insert venous lines that are needed for fluid and blood replacement.

Vascular Distensibility

Distensibility refers to the ability of a blood vessel to be stretched and accommodate an increased volume of blood. It is normally expressed as the fractional increase in volume for each millimeter of mercury (mm Hg) increase in pressure. Vascular compliance or capacitance refers to the total quantity of blood that can be stored in a given portion of the circulation for each millimeter of mercury rise in pressure. Both compliance and capacitance can be used to as a measure of the distensibility or flexibility of a blood vessel. The most distensible of all vessels are the veins, which can increase their volume with only slight changes in pressure, allowing them to function as a reservoir for storing large quantities of blood that can be returned to the circulation when it is needed. Although arteries have a thicker muscular wall than veins, their distensibility allows them to store some of the blood that is ejected from the heart during systole, providing for continuous flow through the capillaries as the heart relaxes during diastole.

**SUMMARY CONCEPTS**

- Blood flow is determined largely by the pressure difference between the two ends of a vessel or group of vessels and the resistance that the blood must overcome as it moves through the vessel or vessels. The resistance or opposition to blood flow, which is directly related to the viscosity of the blood as determined by the percentage of red blood cells and inversely related to the fourth power of the vessel radius, increases as the viscosity of the blood increases and decreases as the radius of a vessel increases and vice versa.

- The relationship between the wall tension of a vessel, its intraluminal pressure, and its radius can be described using the law of Laplace (wall tension = pressure × radius). Thus, at any given

*Text continues on page 382*
The term hemodynamics is used to describe factors such as (1) pressure and resistance, (2) vessel radius, (3) cross-sectional area and velocity of flow, and (4) laminar versus turbulent flow that affect blood flow through the blood vessels in the body.

**Pressure, Resistance, and Flow.** The flow of fluid through a tube, such as blood through a blood vessel, is directly related to a pressure difference \((P_1 - P_2)\) between the two ends of the tube and inversely proportional to the resistance \((R)\) that the fluid encounters as it moves through the tube.

The resistance to flow, in peripheral resistance units (PRUs), is determined by the blood viscosity, vessel radius, and whether the vessels are aligned in series or in parallel. In vessels aligned in series, blood travels sequentially from one vessel to another such that the resistance becomes additive (e.g., \(2 + 2 + 2 = 6\) PRU). In vessels aligned in parallel, such as capillaries, the blood is not confined to a single channel but can travel through each of several parallel channels such that the resistance becomes the reciprocal of the total resistance (i.e., \(1/R\)). As a result, there is no loss of pressure, and the total resistance (e.g., \(1/2 + 1/2 + 1/2 = 3/2\) PRU) is less than the resistance of any of the channels.

**Vessel Radius.** In addition to pressure and resistance, the rate of blood flow through a vessel is affected by the fourth power of its radius (the radius multiplied by itself four times). Thus, blood flow in vessel B with a radius of 2 mm will be 16 times greater than in vessel A with a radius of 1 mm.
Blood Flow

3 Cross-Sectional Area and Velocity of Flow. The velocity or rate of forward movement of the blood is affected by the cross-sectional area of a blood vessel. As the cross-sectional area of a vessel increases (Sections 1 and 3), blood must flow laterally as well as forward to fill the increased area. As a result, the mean forward velocity decreases. In contrast, when the cross-sectional area is decreased (Section 2), the lateral flow decreases and the mean forward velocity is increased.

4 Laminar and Turbulent Flow. Blood flow is normally laminar, with platelets and blood cells remaining in the center or axis of the bloodstream. Laminar blood flow can be described as layered flow in which a thin layer of plasma adheres to the vessel wall, while the inner layers of blood cells and platelets shear against this motionless layer. This allows each layer to move at a slightly faster velocity, with the greatest velocity occurring in the central part of the bloodstream.

Turbulent blood flow is flow in which the blood elements do not remain confined to a definite lamina or layer, but develop vortices (i.e., a whirlpool effect) that push blood cells and platelets against the wall of the vessel. More pressure is required to force a given flow of blood through the same vessel (or heart valve) when the flow is turbulent rather than laminar. Turbulence can result from an increase in velocity of flow, a decrease in vessel diameter, or low blood viscosity. Turbulence is usually accompanied by vibrations of the fluid and surrounding structures. Some of these vibrations in the cardiovascular system are in the audible frequency range and may be detected as murmurs or bruits.
SUMMARY CONCEPTS (continued)

Intraluminal pressure, wall tension becomes greater as the radius of a vessel increases; and more pressure will be needed to overcome the contractile tension in a vessel wall as the diameter decreases. Wall tension is also affected by wall thickness, increasing as the wall becomes thinner and decreasing as it becomes thicker.

- The velocity or speed of blood flow through a vessel is greatly affected by its cross-sectional area, increasing as the cross-sectional area decreases and decreasing as it increases. High velocity can create turbulent blood flow, in which the blood moves crosswise and lengthwise in blood vessels; as opposed to laminar or layered flow, in which the blood components are arranged so that the plasma is adjacent to the smooth surface of the inner lining of the vessel wall and the blood components are in the center of the bloodstream.

- Vascular compliance or capacitance reflects the distensibility of blood vessels and total quantity of blood that can be stored in a given part of the circulatory system for a given change in pressure. It is greater in the thin-walled vessels of the venous system than in the thick-walled vessels of the arterial system.

The Heart as a Pump

The heart is a four-chambered muscular pump approximately the size of a fist that beats an average of 70 times each minute, 24 hours each day, 365 days each year for a lifetime. In 1 day, this pump moves more than 1800 gallons of blood throughout the body, and the work performed by the heart over a lifetime would lift 30 tons to a height of 30,000 ft.

Functional Anatomy of the Heart

The heart, which is enclosed in a loose-fitting sac called the pericardium, is located between the lungs in the mediastinal space of the intrathoracic cavity. It is located posterior to the sternum and anterior to the vertebral column and extends about 5 inches from the second to fifth vertebrae (Fig. 17-4A). The heart is suspended by the great vessels, with its broader side (i.e., base) facing upward and its tip (i.e., apex) pointing downward, forward, and to the left. The heart is positioned obliquely, so that the right side of the heart is almost fully in front of the left side of the heart, with only a small portion of the lateral left ventricle on the frontal plane of the heart (Fig. 17-4B). When the hand is placed on the thorax, the main impact of the heart’s contraction is felt against the chest wall at a point between the fifth and sixth ribs, a little below the nipple and approximately 3 inches to the left of the midline. This is called the point of maximum impulse.

The wall of the heart is composed of an outer epicardium, which lines the pericardial cavity; the myocardium or muscle layer; and the smooth endocardium, which lines the chambers of the heart (Fig. 17-5). A fibrous skeleton separates the atria and ventricles and forms a rigid support for attachment of the heart valves. The interatrial and interventricular septa divide the heart into a right and a left pump, each composed of two muscular chambers: a thin-walled atrium, which serves as a reservoir for blood coming into the heart, and a thick-walled ventricle, which pumps blood out of the heart. The increased thickness of the left ventricular wall compared to the right ventricle (Fig. 17-4C) results from the additional work this ventricle is required to perform.

Pericardium

The pericardium forms a fibrous covering around the heart, holding it in a fixed position in the thorax and providing physical protection and a barrier to infection. The pericardium consists of a tough outer fibrous layer and a thin inner serous layer. The outer fibrous layer is attached to the great vessels that enter and leave the heart, the sternum, and the diaphragm. The fibrous pericardium is highly resistant to distention; it prevents acute dilatation of the heart chambers and exerts a restraining effect on the left ventricle. The inner serous layer consists of a visceral layer and a parietal layer. The visceral layer, also known as the visceral pericardium or epicardium, covers the entire heart and great vessels and then folds over to form the parietal layer that lines the fibrous pericardium (see Fig. 17-5). Between the visceral and parietal layers is the pericardial cavity, a potential space that contains 30 to 50 mL of serous fluid. This fluid acts as a lubricant to minimize friction between the two layers as the heart contracts and relaxes.

Myocardium

The myocardium, or muscular portion of the heart, forms the walls of the atria and ventricles. Cardiac muscle cells, like skeletal muscle, are striated and composed of sarcomeres that contain actin and myosin filaments (see Chapter 1). They are smaller and more compact than skeletal muscle cells and contain many large mitochondria, reflecting their continuous energy needs.

The contractile properties of cardiac muscle are similar to those of skeletal muscle, except the contractions are involuntary and the duration of contraction is much longer. Unlike the orderly longitudinal arrangement of skeletal muscle fibers, cardiac muscle cells are arranged as an interconnecting latticework, with their fibers dividing, recombining, and then dividing again (Fig. 17-6A). The fibers are separated from neighboring cardiac muscle cells by dense structures called intercalated disks. The intercalated disks, which are unique to cardiac muscle,
contain gap junctions that serve as low-resistance pathways for passage of ions and electrical impulses from one cardiac cell to another (Fig. 17-6B). Thus, the myocardium behaves as a single unit, or syncytium, rather than as a group of isolated units, as does skeletal muscle. When one myocardial cell becomes excited, the impulse travels rapidly so the heart can beat as a unit.

As in skeletal muscle, cardiac muscle cells contain actin and myosin filaments, which interact and slide along one another during muscle contraction. A number of important proteins regulate the interaction between the actin and myosin filaments. These include the tropomyosin and the troponin complex, which consists of three subunits (troponin T, troponin I, and troponin C) that regulate calcium-mediated muscle contraction (see Chapter 1, Fig. 1-19). In clinical practice, the serum levels of specific cardiac forms of troponin T and troponin I, released from injured heart muscle, are used in the diagnosis of myocardial infarction (see Chapter 19).
Although cardiac muscle cells require calcium for contraction, they have a less well-defined sarcoplasmic reticulum for storing calcium than skeletal muscle cells. Thus, cardiac muscle relies more heavily than skeletal muscle on an influx of extracellular calcium ions for contraction. The cardiac glycosides (e.g., digoxin) are inotropic drugs that enhance cardiac contractility by increasing the free intracellular calcium concentration in cardiac muscle.

**Endocardium**

The endocardium is a thin, three-layered membrane that lines the heart and covers the valves. The innermost layer, which lines the heart chambers, consists of smooth endothelial cells supported by a thin layer of connective tissue. The endothelial lining of the endocardium is continuous with the lining of the blood vessels that enter and leave the heart. The middle layer consists of dense connective tissue with elastic fibers. The outer layer, which is composed of irregularly arranged connective tissue cells, contains blood vessels and branches of the conduction system and is continuous with the myocardium.

**Heart Valves and Fibrous Skeleton**

An important structural feature of the heart is its fibrous skeleton, which consists of four interconnecting valve rings and surrounding connective tissue (Fig. 17-7). The fibrous skeleton separates the atria and ventricles and forms a rigid support for attachment of the valves and insertion of the cardiac muscle. The tops of the valve rings are attached to the muscle tissue of the atria,
pulmonary trunks, and aorta. The bottoms are attached to the ventricular walls. For the heart to function effectively, blood must flow in one direction only, moving forward through the chambers of the right heart to the lungs and then through the chambers of the left heart to the systemic circulation. This unidirectional flow is provided by the heart’s paired atrioventricular (i.e., tricuspid and mitral) valves and two semilunar (i.e., pulmonic and aortic) valves (Fig. 17-8).

The atrioventricular (AV) valves control the flow of blood between the atria and the ventricles (Fig. 17-9). The thin edges of the AV valves form cusps, two on the left side of the heart (i.e., bicuspid or mitral valve) and three on the right side (i.e., tricuspid valve). The AV valves are supported by the papillary muscles, which project from the wall of the ventricles, and the chordae tendineae, which attach to the valve. Contraction of the papillary muscles at the onset of systole ensures closure by producing tension on the leaflets of the AV valves before the full force of ventricular contraction pushes against them. The chordae tendineae are cordlike structures that support the AV valves and prevent them from evert ing into the atria during systole.

The aortic and pulmonic valves control the movement of blood out of the ventricles (Fig. 17-10). The pulmonic valve, which is located between the right ventricle and the pulmonary artery, controls the flow of blood into the pulmonary circulation; and the aortic valve, located between the left vent ricle and the aorta, controls the flow of blood into the systemic circulation. Because their flaps are shaped like half-moons, they are often referred to as the semilunar valves (Fig. 17-10B). The semilunar valves have three cuplike cusps that are attached to the valve rings. These cuplike structures collect the retrograde, or backward, flow of blood that occurs toward the end of systole, enhancing closure. For the development of a perfect seal along the free edges of the semilunar valves, each valve cusp must have a triangular shape, which is
facilitated by a nodular thickening at the apex of each leaflet (Fig. 17-10C). Immediately behind each of the semilunar cusps, the walls of the pulmonary trunk and aorta are slightly dilated, forming a sinus (Fig. 17-10A). In these sinuses, eddy currents develop that tend to keep the valve cusps away from the vessel wall. The opening for the right coronary artery is located in the right aortic sinus, and the opening for the left coronary artery is located in the left aortic sinus. Were it not for the presence of the sinuses and eddy currents, the coronary artery openings would be blocked by the valve cusps.

There are no valves at the atrial sites (i.e., venae cavae and pulmonary veins) where blood enters the heart (see Fig. 17-8). This means that excess blood is pushed back into the veins when the atria become distended. For example, the jugular veins typically become distended when inflow into the right atria is impeded in right-sided heart failure, whereas normally they are flat or collapsed. Likewise, the pulmonary venous system becomes congested when outflow from the left atrium is impeded.

**Electrical Activity of the Heart**

Heart muscle is unique among other muscles in that it is capable of generating and rapidly conducting its own electrical impulses or action potentials. These action potentials result in excitation of muscle fibers throughout the myocardium. Impulse formation and conduction result in weak electrical currents that spread through the entire body.

**Cardiac Conduction System**

In certain areas of the heart, the myocardial cells have been modified to form the specialized cells of the conduction system (Fig. 17-11). Although most myocardial cells are capable of initiating and conducting impulses, it is this specialized conduction system that maintains the pumping efficiency of the heart. Specialized pacemaker cells generate impulses at a faster rate than other myocardial cells, and the cells of the conduction system transmit impulses at a faster rate than other myocardial cells. Because of these properties, the conduction system normally controls the rhythm of the heart.

The conduction system consists of (1) the sinoatrial (SA) node, where the rhythmic impulse is generated; (2) the internodal pathways, which conduct the impulse from the SA node to the AV node; (3) the AV node, in which the impulse from the atria is delayed before passing to the ventricles; (4) the AV bundle, which conducts the impulse from the atria to the ventricles; and the (5) left and right bundles of the Purkinje system, which conduct the impulses to all parts of the ventricles.

The SA node has the fastest intrinsic rate of firing (60 to 100 beats per minute) and normally functions as the pacemaker of the heart. From the SA node, the impulse travels radially throughout the right atrium, ultimately reaching the AV node. A special pathway, the anterior interatrial pathway, conducts the impulse to the left atrium.

The heart essentially has two conduction systems: one that controls atrial activity and one that controls ventricular activity. The AV node connects the two systems and normally provides for a one-way conduction between the atria and ventricles. Within the AV node, atrial fibers connect with very small junctional fibers in the node itself. Because of these connections, the zone surrounding and including the AV node and the adjacent atrial and ventricular conduction pathways is often referred to as the AV junctional area. The velocity of conduction through these fibers is very slow (approximately one-half that of normal cardiac muscle), which greatly
delays impulse transmission. A further delay occurs as the impulse travels through the transitional fibers and into the AV bundle, also known as the bundle of His. This delay provides a mechanical advantage whereby the atria can complete their ejection of blood before ventricular contraction begins. Under normal circumstances, the AV node provides the only connection between the atrial and ventricular conduction systems. The atria and ventricles would beat independently of each other if the transmission of impulses through the AV node were blocked.

The Purkinje system, which supplies the ventricles, has large specialized fibers that allow for rapid conduction and almost instantaneous excitation of both the right and left ventricles. This rapid rate of conduction is necessary for the swift and efficient ejection of blood from the heart. Fibers of the Purkinje system originate in the AV node and then travel downward in the AV bundle into the ventricular septum, where they divide to form the right and left bundle branches that lie beneath the endocardium on the two respective sides of the ventricular septum. The main trunk of the left bundle branch extends for approximately 1 to 2 cm before fanning out as it enters the septal area and divides further into two segments: the left posterior and anterior fascicles.

The AV nodal fibers, when not stimulated, discharge at an intrinsic rate of 45 to 50 times a minute, and the Purkinje fibers discharge at 15 to 40 times per minute. Although the AV node and Purkinje system have the ability to control the rhythm of the heart, they do not normally do so because the discharge rate of the SA node is considerably faster. Each time the SA node discharges, its impulses are conducted into the AV nodal and Purkinje fibers, causing them to fire. Should the SA node fail to discharge, the AV node can assume the pacemaker function of the heart, and the Purkinje system can assume the pacemaker function of the ventricles should the AV junction fail to conduct impulses from the atria to the ventricles. Under these circumstances, the heart rate reflects the intrinsic firing rate of the prevailing structures.

**Action Potentials**

An action potential represents the sequential change in electrical potential that occurs across a cell membrane when excitation occurs (see Chapter 1, “Understanding Membrane Potentials”). Action potentials can be divided into three parts: the resting or unexcited state during which the membrane is polarized (positive on the outside and negative on the inside of the membrane), depolarization or change in the direction of polarity (positive on the inside and negative on the outside), and repolarization or reestablishment of polarity of the resting membrane potential. The sodium (Na⁺), potassium (K⁺), and calcium (Ca²⁺) ions are the major electrical charge carriers in cardiac muscle cells. Disorders of the ion channels along with disruption in the flow of these current-carrying ions are increasingly being linked to the generation of cardiac arrhythmias and conduction disorders.

The action potential of cardiac muscle is divided into five phases: phase 0—the upstroke or rapid depolarization; phase 1—early repolarization; phase 2—the plateau; phase 3—rapid repolarization; and phase 4—the resting membrane potential (Fig. 17-12A). Cardiac muscle has three types of membrane ion channels that contribute to the voltage changes that occur during these phases of the action potential. They are the (1) fast sodium (Na⁺) channels, (2) slow calcium (Ca²⁺) channels, and (3) potassium (K⁺) channels.

During phase 0 in atrial and ventricular muscle and in the Purkinje conduction system, opening of the fast Na⁺ channels for a few ten-thousandths of a second is responsible for the spike-like onset of the action potential. The point at which the Na⁺ gates open is called the depolarization threshold. When the cell has reached this threshold, a rapid influx of Na⁺ to the interior of the cell membrane causes the membrane potential to shift from a resting membrane potential of approximately −90 mV to +20 mV.

Phase 1 occurs at the peak of the action potential and signifies inactivation of the fast Na⁺ channels with an
returns to the normal resting state. *Phase 4* is the resting membrane potential. During phase 4, the Na\(^+\)–K\(^+\) adenosine triphosphate (ATPase) pump is activated, transporting Na\(^+\) out of the cell and moving K\(^+\) back into the cell.

There are two main types of action potentials in the heart—the slow response and the fast response. The slow response, which is initiated by the slow Ca\(^{2+}\) channels, is found in the SA node, which is the natural pacemaker of the heart, and the conduction fibers of the AV node (Fig. 17-12B). The fast response, which is characterized by the opening of the fast Na\(^+\) channels, occurs in the myocardial cells of the atria, the ventricles, and the Purkinje fibers (Fig. 17-12A). The fast-response cardiac cells do not normally initiate cardiac muscle action potentials. Instead, these impulses originate in the specialized slow-response cells of the SA node and are conducted to the fast-response myocardial cells in the atria and ventricles, where they effect a change in membrane potential to the threshold level. On reaching threshold, the voltage-dependent Na\(^+\) channels open to initiate the rapid upstroke of the phase 1 action potential. The amplitude and rate of rise in the action potential during phase 1 are important to the conduction velocity of the fast response.

The hallmark of the pacemaker cells in the SA and AV nodes is a spontaneous phase 4 depolarization. The membrane permeability of these cells allows a slow inward leak of current to occur through the slow channels during phase 4. This leak continues until the threshold for firing is reached, at which point the cell spontaneously depolarizes. The rate of pacemaker cell discharge varies with the resting membrane potential and the slope of phase 4 depolarization (Fig. 17-12B). The catecholamines, the sympathetic nervous system neurotransmitters epinephrine and norepinephrine, increase the heart rate by increasing the slope or rate of phase 4 depolarization. Acetylcholine, the parasympathetic neurotransmitter released during vagal stimulation of the heart, slows the heart rate by decreasing the slope of phase 4.

**Absolute and Relative Refractory Periods**

There is a period in the action potential curve during which no stimuli can generate another action potential (Fig. 17-13). This period, which is known as the *absolute refractory period*, includes phases 0, 1, 2, and part of phase 3. During this time, the cell cannot depolarize again under any circumstances. In skeletal muscle, the refractory period is very short compared with the duration of muscle contraction such that a second contraction can be initiated before the first is over, resulting in a summated tetanized contraction. In cardiac muscle, the absolute refractory period is almost as long as the contraction and a second contraction cannot be stimulated until the first is over. The longer length of the absolute refractory period of cardiac muscle is important in maintaining the alternating contraction and relaxation that are essential to the pumping action of the heart and for the prevention of fatal arrhythmias. When repolarization has returned the membrane potential to a level below
Arrhythmias and Conduction Disorders

Arrhythmias represent disorders of cardiac rhythm. Cardiac arrhythmias are commonly divided into two categories: supraventricular and ventricular arrhythmias. The supraventricular arrhythmias include those that originate in the SA node, atria, AV node, and junctional tissues. The ventricular arrhythmias include those that originate in the ventricular conduction system and ventricular muscle. Because the ventricles are the pumping chambers of the heart, ventricular arrhythmias (e.g., ventricular tachycardia and fibrillation) are the most serious in terms of immediate life-threatening events.

Conduction disorders disrupt the flow of impulses through the conduction system of the heart. Heart block occurs when the conduction of impulses is blocked, often in AV nodal fibers. Under normal conditions, the AV node provides the only connection for transmission of impulses between the atrial and ventricular conduction systems; in complete heart block, the atria and ventricles beat independently of each other. The most serious effect of some forms of AV block is a slowing of heart rate to the extent that circulation to the brain is compromised.

An ectopic pacemaker is an excitable focus outside the normally functioning SA node. A premature ventricular complex (PVC) occurs when an ectopic ventricular pacemaker initiates a beat. The occurrence of frequent PVCs in the diseased heart predisposes to the development of other more serious arrhythmias, including ventricular tachycardia and ventricular fibrillation.

Fibrillation is the result of disorganized current flow within the atria (atrial fibrillation) or ventricle (ventricular fibrillation). Fibrillation interrupts the normal contraction of the atria or ventricles. In ventricular fibrillation, the ventricles quiver but do not contract. Thus, there is no cardiac output, and there are no palpable or audible pulses. Ventricular fibrillation is a fatal event unless treated with immediate defibrillation.

Electrocardiography

The electrocardiogram (ECG) is a recording of the electrical activity of the heart. The electrical currents generated by the heart spread through the body to the skin, where they can be sensed by appropriately placed electrodes, amplified, and viewed on an oscilloscope or chart recorder. Figure 17-14 depicts the electrical activity of the conduction system on an ECG tracing. The deflection points of an ECG are designated by the letters P, Q, R, S, and T. Sinoatrial node depolarization does not have sufficient current to be revealed on the ECG. The P wave represents atrial depolarization; the QRS complex (i.e., beginning of the Q wave to the end of the S wave), ventricular depolarization; and the T wave, ventricular repolarization. Atrial repolarization occurs during ventricular depolarization and is hidden in the QRS complex.

On the horizontal axis of the ECG, the unit of measurement is time in seconds, and on the vertical axis the unit of measurement is the amplitude of the impulse in millivolts (mV). The vertical lines are time calibration lines, with five 0.04-second vertical lines representing 0.20 seconds (see Fig. 17-14). The horizontal lines are arranged so that five lines of upward or downward deflection in the ECG tracing represent 0.50 mV.

The ECG records the potential difference in charge between two electrodes as the depolarization and repolarization waves move through the heart and are conducted to the skin surface. The shape of the tracing is determined by the direction in which the impulse spreads through the heart muscle in relation to electrode placement. A depolarization wave that moves toward the recording electrode registers as a positive, or upward, deflection. Conversely, if the impulse moves away from the recording electrode, the deflection is downward, or negative. When there is no flow of charge between electrodes, the potential is zero, and a straight line is recorded at the baseline of the chart.

Conventionally, 12 leads or electrodes are used for recording a diagnostic ECG, each providing a unique view of the electrical forces of the heart from a different position on the body’s surface. Six limb leads view the electrical forces as they pass through the heart on the frontal or vertical plane. The electrodes for the limb leads are attached to the four extremities or representative areas on the body near the shoulders and lower chest or abdomen. Chest electrodes provide a view of the electrical forces as they pass through the heart on the
horizontal plane. They are applied to different positions on the chest, including the right and left sternal borders and the left anterior surface. When indicated, additional electrodes may be applied to other areas of the body, such as the posterior or right anterior chest.

Cardiac Cycle

The term cardiac cycle, which is used to describe the rhythmic pumping action of the heart, is divided into two parts: systole, the period during which the ventricles are contracting, and diastole, the period during which the ventricles are relaxed and filling with blood. Simultaneous changes occur in atrial pressure, ventricular pressure, aortic or pulmonary artery pressure, ventricular volume, the ECG, and heart sounds that occur during the cardiac cycle (Fig. 17-15). Four heart sounds are usually generated by closure of the heart valves during the cardiac cycle, but only two (the first and second) are ordinarily heard through a stethoscope. The first heart sound is initiated at the onset of systole and reflects the closure of AV valves. The second heart sound occurs at the end of systole with abrupt closure of the semilunar valves.

Ventricular Systole and Diastole

Ventricular systole is divided into two periods: the isovolumetric (iso, meaning same) contraction period and the ejection period. The isovolumetric contraction period, which begins with the closure of the AV valves and occurrence of the first heart sound, heralds the onset of systole (see Fig. 17-15A). Immediately after closure of the AV valves, there is an additional 0.02- to 0.03-second period during which the pulmonic and aortic valves remain closed. During this period, the ventricular volume remains the same while the ventricles contract, producing an abrupt increase in pressure. The ventricles continue to contract until left ventricular pressure is slightly higher than aortic pressure and right ventricular pressure is higher than pulmonary artery pressure. At this point, the aortic and pulmonic valves open, signaling the onset of the ejection period. Approximately 60% of the stroke volume is ejected during the first quarter of systole, and the remaining 40% is ejected during the next two quarters of systole. Little blood is ejected from the heart during the last quarter of systole, although the ventricles remain contracted. At the end of systole, the ventricles relax, causing a precipitous fall in intraventricular pressures. As this occurs, blood from the large arteries flows back toward the ventricles, causing the aortic and pulmonic valves to snap shut—an event that is marked by the second heart sound.

The aortic pressure reflects changes in the ejection of blood from the left ventricle. There is a rise in pressure and stretching of the elastic fibers in the aorta as blood is ejected into the aorta at the onset of the ejection period. The aortic pressure continues to rise and then begins to fall during the last quarter of systole as blood flows out of the aorta into the peripheral vessels. The incisura, or notch, in the aortic pressure tracing represents closure of the aortic valve. The aorta is highly elastic and as such stretches during systole to accommodate the blood that is being ejected from the left heart during systole. During diastole, recoil of the elastic fibers in the aorta serves to maintain the arterial pressure.

Diastole is marked by ventricular relaxation and filling. After closure of the semilunar valves, the ventricles continue to relax for another 0.03 to 0.06 second.
During this time, which is called the isovolumetric relaxation period, ventricular volume remains the same but ventricular pressure drops until it becomes less than atrial pressure (see Fig. 17-15B). As this occurs, the AV valves open, and the blood that has been accumulating in the atria during systole flows into the ventricles. Most of ventricular filling occurs during the first third of diastole, which is called the rapid filling period. During the middle third of diastole, inflow into the ventricles is almost at a standstill. The last third of diastole is marked by atrial contraction, which gives an additional thrust to ventricular filling. When audible, the third heart sound is heard at the end of the rapid filling period due to vibrations that are caused by the abrupt cessation of ventricular distension and by the deceleration of blood entering the ventricles. A third heart sound is sometimes heard in children with thin chest walls and in persons with a distended or noncompliant ventricle. A fourth heart sound, when present, occurs during the last third of diastole as the atria contract (see Fig. 17-15C).

During diastole, the ventricles increase their volume to approximately 120 mL (i.e., the end-diastolic volume), and at the end of systole, approximately 50 mL of blood (i.e., the end-systolic volume) remains in the ventricles. The difference between the end-diastolic and end-systolic volumes (approximately 70 mL) is called the
stroke volume. The ejection fraction, which is the stroke volume divided by the end-diastolic volume, represents the fraction or percentage of the diastolic volume that is ejected from the heart during systole. One of the signs of heart failure is a decrease in the ejection fraction, which reflects the diminished function of the left ventricle.

Atrial Filling and Contraction

Because there are no valves between the junctions of the central veins (i.e., venae cavae and pulmonary veins) and the atria, atrial filling occurs during both systole and diastole. During normal quiet breathing, right atrial pressure usually varies between −2 and +2 mm Hg. It is this low atrial pressure that maintains the movement of blood from the systemic veins into the right atrium and from the pulmonary veins into the left atrium.

Three main atrial pressure waves occur during the cardiac cycle (see Fig. 17-15). The first, or c wave, occurs as the ventricles begin to contract and their increased pressure causes the AV valves to bulge into the atria. The second, or v wave, occurs toward the end of systole when the AV valves are still closed and results from a slow buildup of blood in the atria. The third, or a wave, occurs during the last part of diastole and is caused by atrial contraction. The right atrial pressure waves are transmitted to the internal jugular veins as pulsations. These pulsations can be observed visually and may be used to assess cardiac function. For example, exaggerated waves occur when the volume of the right atrium is increased because of impaired emptying into the right ventricle.

Right atrial pressure and filling is regulated by a balance between the ability of the right ventricle to move blood out of the right heart and the pressures that move blood from the venous circulation into the right atrium (venous return). When the heart pumps strongly, right atrial pressure is decreased and atrial filling is enhanced. Right atrial pressure is also affected by changes in intrathoracic pressure. It is decreased during inspiration when intrathoracic pressure becomes more negative, and it is increased during coughing or forced expiration when intrathoracic and right atrial pressures become more positive.

Although the main function of the atria is to store blood as it enters the heart, these chambers also act as pumps that aid in ventricular filling. Atrial contraction occurs during the last third of diastole. Atrial contraction becomes more important during periods of increased activity when the diastolic filling time is decreased because of an increase in heart rate or when heart disease impairs ventricular filling. In these two situations, the cardiac output would fall drastically were it not for the action of the atria. It has been estimated that atrial contraction can contribute as much as 30% to cardiac reserve during periods of increased need, while having little or no effect on cardiac output during rest.

Regulation of Cardiac Performance

The efficiency and work of the heart as a pump often is measured in terms of cardiac output or the amount of blood the heart pumps each minute. The cardiac output (CO) is the product of the stroke volume (SV) or amount of blood that the heart ejects with each beat and the heart rate (HR) or number of times the heart beats each minute (i.e., CO = SV x HR). The cardiac output varies with body size and the metabolic needs of the tissues. It increases with physical activity and decreases during rest and sleep. The average cardiac output in normal adults ranges from 3.5 to 8.0 L/minute. In the highly trained athlete, this value can increase to levels as high as 32 L/minute during maximum exercise.

The cardiac reserve refers to the maximum percentage of increase in cardiac output that can be achieved above the normal resting level. The normal young adult has a cardiac reserve of approximately 300% to 400%. Cardiac performance is influenced by the work demands of the heart and the ability of the coronary circulation to meet its metabolic needs. The heart’s ability to increase its output according to body needs mainly depends on four factors: the preload or ventricular filling, the afterload or resistance to ejection of blood from the heart, cardiac contractility, and the heart rate. Heart rate and cardiac contractility are strictly cardiac factors, meaning they originate in the heart, although they are controlled by various neural and humoral mechanisms. Preload and afterload, on the other hand, are mutually dependent on the behavior of both the heart and blood vessels.

Preload

The preload represents the volume work of the heart. It is called the preload because it is the work or load imposed on the heart before the contraction begins. It is the amount of blood that the heart must pump with each beat and represents the volume of blood stretching the ventricular muscle fibers at the end of diastole (i.e., end-diastolic volume). It is determined by the amount of the blood that remains in the ventricle at the end of systole (end-systolic volume) plus the amount of venous blood returning to the heart during diastole.

The increased force of contraction that accompanies an increase in ventricular end-diastolic volume is referred to as the Frank-Starling mechanism or Starling law of the heart (Fig. 17-16). The anatomic arrangement of the actin and myosin filaments in the myocardial muscle fibers is such that the tension or force of contraction is greatest when the muscle fibers are optimally stretched just before the heart begins to contract. The maximum force of contraction and cardiac output is achieved when the muscle fibers are stretched about two and one-half times their normal resting length. When the muscle fibers are stretched to this degree, there is optimal overlap of the actin and myosin filaments needed for maximal contraction.

The Frank-Starling mechanism allows the heart to adjust its pumping ability to accommodate various levels of venous return. Cardiac output is less when decreased filling causes excessive overlap of the actin and myosin filaments or when excessive filling causes the filaments to be pulled too far apart. The Frank-Starling mechanism also plays an important role in balancing the output of the two ventricles.
Afterload

The afterload is the pressure or tension work of the heart. It is the pressure that the heart must generate to move blood into the aorta. It is called the afterload because it is the work presented to the heart after the contraction has commenced. The systemic arterial blood pressure is the main source of afterload work for the left heart, and the pulmonary arterial pressure is the main source of afterload work for the right heart. The afterload work of the left ventricle is also increased with narrowing (i.e., stenosis) of the aortic valve.

Cardiac Contractility

Cardiac contractility refers to the ability of the heart to change its force of contraction without changing its resting or diastolic length (see Fig. 17-16 upper curve). The contractile state of the myocardial muscle is determined by biochemical and biophysical properties that govern the interaction between the actin and myosin filaments in the myocardial cells. It is strongly influenced by the number of calcium ions that are available to participate in the contractile process.

An inotropic influence is one that modifies the contractile state of the myocardium independent of the Frank-Starling mechanism. For example, sympathetic stimulation produces a positive inotropic effect by increasing the calcium that is available for interaction between the actin and myosin filaments. Hypoxia exerts a negative inotropic effect by interfering with the generation of ATP, which is needed for muscle contraction.

Heart Rate

The heart rate influences cardiac output and the work of the heart by determining the frequency with which the ventricles contract and blood is ejected from the heart. Heart rate also determines the time spent in diastolic filling. Although systole and the ejection period remain fairly constant across heart rates, the time spent in diastole and filling of the ventricles becomes shorter as the heart rate increases. This leads to a decrease in stroke volume and, at high heart rates, may produce a decrease in cardiac output. One of the dangers of ventricular tachycardia is a reduction in cardiac output because the heart does not have time to fill adequately.

SUMMARY CONCEPTS

- The heart is a four-chambered pump consisting of two atria (the right atrium, which receives blood returning to the heart from the systemic circulation, and the left atrium, which receives oxygenated blood from the lungs) and two ventricles (a right ventricle, which pumps blood into the pulmonary circulation, and a left ventricle, which pumps blood into the systemic circulation).

- The myocardium or muscle layer of the atria and ventricles produces the pumping action of the heart and the heart valves control the directional flow of blood, with the AV valves controlling flow between the atria to the ventricles; the pulmonic valve, flow between the right side of the heart to the lungs; and the aortic valve, flow between the left side of the heart and the systemic circulation.

- Specialized cells in the heart’s conduction system control the rhythmic contraction and relaxation of the heart. The SA node, which has the fastest inherent rate of impulse generation, acts as the pacemaker of the heart. Impulses from the SA node travel through the atria to the AV node, then to the ventricular Purkinje system. Disorders of the cardiac conduction system include arrhythmias and conduction defects. Ventricular arrhythmias are generally more serious than atrial arrhythmias because they afford the potential for disrupting the pumping ability of the heart.
SUMMARY CONCEPTS (continued)

- The cardiac cycle, which describes the pumping action of the heart, is divided into two parts: systole, during which the ventricles contract and blood is ejected from the heart; and diastole, during which the ventricles relax and allow for filling to occur. The cardiac output, or amount of blood that the heart pumps each minute, represents the stroke volume, or amount of blood pumped with each beat; and the heart rate, the number of times the heart beats each minute. Cardiac reserve refers to the maximum percentage of increase in cardiac output that can be achieved above the normal resting level.

- The heart’s ability to increase its output according to body needs depends on: (1) the preload, or filling of the ventricles (i.e., end-diastolic volume); (2) the afterload, or resistance to ejection of blood from the heart; (3) cardiac contractility, which is determined by the interaction of the actin and myosin filaments of cardiac muscle fibers; and (4) the heart rate, which determines the frequency with which blood is ejected from the heart.

The Systemic Circulation and Control of Blood Flow

The systemic vascular system is a closed system of vessels that distributes blood from the heart to the tissues and returns blood to the heart. Its three divisions include the arterial system, which delivers blood to the tissues; the venous system, which returns blood to the heart; and the capillaries of the microcirculation, which separate the arterial and venous systems and is the site where nutrients and gas exchange take place.

Blood Vessels

All blood vessels, except the capillaries, have walls composed of three layers, or coats, called tunicae (Fig. 17-17). The outermost layer of a vessel, called the tunica externa or tunica adventitia, is composed primarily of loosely woven collagen fibers that protect the blood vessel and anchor it to the surrounding structures. The middle layer, the tunica media, is largely a smooth muscle layer that constricts to regulate and control the diameter of the vessel. Larger arteries have an external elastic lamina that separates the tunica media from the tunica externa. The innermost layer, the tunica intima, consists of a single layer of flattened endothelial cells with minimal underlying subendothelial connective tissue. The endothelial layer provides a smooth and slippery inner surface for the vessel that prevents platelet adherence and blood clotting.

The layers of the different types of blood vessels vary with vessel function. The walls of the arterioles, which control blood pressure, have large amounts of smooth muscle. Veins are thin-walled, distensible, and collapsible vessels. Capillaries are single-cell–thick vessels designed for the exchange of gases, nutrients, and waste materials.

Vascular smooth muscle cells, which form the predominant cellular layer in the tunica media, produce vasoconstriction or dilation of blood vessels. Smooth muscle contracts slowly and generates high forces for long periods with low energy requirements; using only 1/10 to 1/300 the energy of skeletal muscle. These characteristics are important in blood vessels that must maintain their tone day in and day out.

Compared with skeletal and cardiac muscle, smooth muscle has a less–well-developed sarcoplasmic reticulum for storing intracellular calcium, and it has very few fast sodium channels. Therefore, depolarization of smooth muscle relies largely on extracellular calcium, which enters through calcium channels in the muscle membrane. Sympathetic nervous system control of vascular smooth muscle tone occurs by way of receptor-activated opening and closing of the calcium channels. In general, α-adrenergic receptors are excitatory, in that they causing the channels to open and produce vasoconstriction, and β-adrenergic receptors are inhibitory, in that they causing the channels to close and produce vasodilation. Calcium channel–blocking drugs cause vasodilation by blocking calcium entry through the calcium channels.

Smooth muscle contraction and relaxation also occur in response to local tissue factors such as lack of oxygen, increased hydrogen ion concentrations, and
excess carbon dioxide. Nitric oxide (formerly known as the endothelial relaxing factor) acts locally to produce smooth muscle relaxation and regulate blood flow. These factors are discussed more fully in the section on local control of blood flow.

**Arterial System**

The arterial system consists of the large and mediumsized arteries and the arterioles. Arteries are thick-walled vessels with large amounts of elastic fibers. The elasticity of these vessels allows them to stretch during cardiac systole, when the heart contracts and blood is ejected into the circulation, and to recoil during diastole, when the heart relaxes. The arterioles, which are predominantly smooth muscle, serve as resistance vessels for the circulatory system. They act as control valves through which blood cause them to constrict or relax as needed to maintain blood pressure. The regulation of arterial blood pressure is discussed further in Chapter 18.

The delivery of blood to the tissues of the body is dependent on pressure pulsations or waves of pressure that are generated by the intermittent ejection of blood from the left ventricle into the distensible aorta and large arteries of the arterial system. The arterial pressure pulse represents the energy that is transmitted from molecule to molecule along the length of the vessel (Fig. 17-18). In the aorta, this pressure pulse is transmitted at a velocity of 4 to 6 m/second, which is approximately 20 times faster than the flow of blood. Therefore, the pressure pulse has no direct relation to blood flow and could occur if there were no flow at all. When taking a pulse, it is the pressure pulses that are felt, and it is the pressure pulses that produce the Korotkoff sounds heard during blood pressure measurement. The tip or maximum deflection of the pressure pulse coincides with the systolic blood pressure, and the minimum point of deflection coincides with the diastolic pressure. The pulse pressure is the difference between systolic and diastolic pressure. If all other factors are equal, the magnitude of the pulse pressure reflects the volume of blood ejected from the left ventricle in a single beat.

Both the pressure values and the conformation of the pressure wave change as it moves though the peripheral arteries, such that the systolic and pulse pressures are higher in the large arteries than in the aorta (see Fig. 17-18). The increase in pulse pressure in the “downstream” arteries is due to the fact that immediately following ejection from the left ventricle, the pressure wave travels at a higher velocity than the blood itself, augmenting the downhill pressure. Furthermore, at branch points of arteries, the forward-moving pressure waves are reflected backward, which also tends to augment the pressure. With peripheral arterial disease, there is a delay in the transmission of the reflected wave so that the pulse decreases rather than increases in amplitude.

After its initial amplification, the pressure pulse becomes smaller and smaller as it moves through the smaller arteries and arterioles, until it disappears almost entirely in the capillaries. This dampening of the pressure pulse is caused by the resistance and distensibility characteristics of these vessels. The increased resistance of these small vessels impedes the transmission of the pressure waves, whereas their distensibility is great enough so that any small change in flow does not cause a pressure change. Although the pressure pulses usually are not transmitted to the capillaries, there are situations in which this does occur. For example, injury to a finger or other area of the body often results in a throbbing sensation. In this case, extreme dilatation of the small vessels in the injured area produces a reduction in the dampening of the pressure pulse.

**Venous System**

The venous system is a low-pressure system that returns blood to the heart. The venules collect blood from the capillaries, and the veins transport blood back to the right heart. Blood from the systemic veins flows into the right atrium of the heart; therefore, the pressure in the right atrium is called the central venous pressure. Right atrial pressure is regulated by the ability of the right ventricle to pump blood into the pulmonary circulation and the tendency of blood to flow from the peripheral veins into the right atrium. The normal right atrial pressure is about 0 mm Hg, which is equal to atmospheric pressure. It can increase to 20 to 30 mm Hg in conditions such as right heart failure or when the rapid infusion of blood or intravenous fluids greatly increases the total blood
volume and causes blood to accumulate in the systemic veins and right heart.

The veins and venules are thin-walled, distensible, and collapsible vessels. The veins are capable of enlarging and storing large quantities of blood, which can be made available to the circulation as needed. Even though the veins are thin walled, they are muscular. This allows them to contract or expand to accommodate varying amounts of blood. Veins are innervated by the sympathetic nervous system. When blood is lost from the circulation, the veins constrict as a means of maintaining the circulating blood volume.

Because the venous system is a low-pressure system, blood flow must oppose the effects of gravity. In a person in the standing position, the weight of the blood in the vascular column causes an increase of 1 mm Hg in pressure for every 13.6 mm of distance below the level of the heart. Were it not for the valves in the veins and the action of the skeletal muscles, the venous pressure in the feet would be about +90 mm Hg in the standing adult. Gravity has no effect on the venous pressure in a person in the recumbent position because the blood in the veins is then at the level of the heart.

Valves in the veins of extremities counteract the effects of gravity (Fig. 17-19), and with the help of skeletal muscles that surround and intermittently compress the leg veins in a milking manner, move blood forward to the heart. This pumping action is known as the venous or muscle pump and is efficient enough that under normal circumstances, the pressure in the feet of a walking adult remains less than 20 mm Hg. There are no valves in the abdominal or thoracic veins, and blood flow in these veins is heavily influenced by the pressure in the abdominal and thoracic cavities, respectively.

**Capillaries**

Capillaries are microscopic, single-cell–thick vessels that connect the arterial and venous segments of the circulation. The capillary wall is composed of a single layer of endothelial cells surrounded by a basement membrane or basa lamina (Fig. 17-20). Intercellular junctions join the capillary endothelial cells; these are called the capillary pores. Lipid-soluble materials diffuse directly through the capillary cell membrane. Water and water-soluble materials leave and enter the capillary through the capillary pores. The size of the capillary pores varies with capillary function. In the brain, the endothelial cells are joined by tight junctions that form the blood–brain barrier. This prevents substances that would alter neural excitability from leaving the capillary. In organs that process blood contents, such as the liver, capillaries have large pores so that substances can pass easily through the capillary wall. In the kidneys, the glomerular capillaries have small openings called fenestrations that pass directly through the middle of the endothelial cells, a feature that is consistent with the filtration function of the glomerulus.

**Lymphatic System**

The lymphatic system, commonly called the lymphatics, represents an accessory route through which fluid can flow through the tissue spaces into the blood and then...
back to the heart. Importantly, the lymphatics can carry proteins and large particulate matter away from the tissue spaces, neither of which can be removed by absorption into the venous system. The lymphatic system is also the main route for absorption of fats and fat soluble vitamins from the gastrointestinal tract.

The lymphatic system is made up of vessels similar to those of the blood vessels in the circulatory system. These vessels commonly travel along with an arteriole or venule or with a companion artery and vein. The terminal lymphatic vessels are made up of a single layer of connective tissue with an endothelial lining and resemble blood capillaries. The lymphatic vessels lack tight junctions and are loosely anchored to the surrounding tissues by fine filaments (Fig. 17-21). The loose junctions permit the entry of large particles, and the filaments hold the vessels open under conditions of edema, when the pressure of the surrounding tissues would otherwise cause them to collapse. The lymph capillaries drain into larger lymph vessels that ultimately empty into the right and left thoracic ducts (Fig. 17-22). The thoracic ducts empty into the circulation at the junctions of the subclavian and internal jugular veins.

Although the divisions are not as distinct as in the circulatory system, the larger lymph vessels show evidence of having intimal, medial, and adventitial layers similar to those of blood vessels. Contraction of the smooth muscle in the medial layer of the larger collecting lymph channels assists in propelling lymph fluid toward the thorax. External compression of the lymph channels by active and passive movements of body parts also aids in forward propulsion of lymph fluid. The rate of flow through the lymphatic system by way of all of the various lymph channels, approximately 120 mL/hour, is determined by the interstitial fluid pressure and the activity of lymph pumps.

### The Microcirculation

The most important function of the circulatory system occurs in the microcirculation, which consists of the arterioles, capillaries, and venules. It is here that the transport of nutrients to the tissues and removal of metabolites takes place. Blood enters the microcirculation through an arteriole, passes through the capillaries, and leaves by way of a small venule (Fig. 17-23). Small cuffs of smooth muscle, the precapillary sphincters, are positioned at the arterial end of the capillary. The smooth muscle tone of the arterioles, precapillary sphincters, and venules controls blood flow through the capillary bed. Depending on venous pressure, blood flows through the capillary channels when the precapillary sphincters are open.

An important aspect of the circulatory system, which occurs at the level of the microcirculation, is the ability of organs and tissues to regulate their blood flow based on metabolic needs. Local control is particularly important in tissues such as skeletal muscle and in the heart, organs in which the metabolic activity and need for blood flow vary extensively; and in the brain where metabolic activity and need for blood flow remain relatively constant.

### Autoregulation of Blood Flow

**Autoregulation** is a local control mechanism that automatically adjusts tissue blood flow independent of systemic factors. For example, blood flow to organs such as the heart, brain, and kidneys remains relatively constant, although blood pressure may vary over a range of 60 to 180 mm Hg. In contrast to the mean arterial pressure, which is controlled by systemic mechanisms that adjust the cardiac output to maintain that pressure, changes in blood flow to the individual body tissues are controlled intrinsically by modifying the diameter of local arterioles feeding the capillaries.

There are two mechanisms that control autoregulation: metabolic and myogenic. In most tissues, declining levels of nutrients, particularly oxygen, are the strongest stimuli for autoregulation. Substances released by metabolically active tissues (such as potassium and hydrogen ions, lactic acid, and adenosine, which is a breakdown product of ATP) serve as autoregulation stimuli. Whatever the precise stimuli, the net result is an immediate vasodilation of the arterioles serving the capillaries of the metabolically deprived tissues. Inadequate blood perfusion to an organ is quickly followed by a decline in its metabolic rate and, if prolonged, death of its cells. Likewise, excessively high arterial pressure and tissue perfusion can be dangerous because it may damage the more fragile blood vessels. The *myogenic* (myo = muscle; gen = organ) control mechanisms rely on stretch of the vascular smooth muscle in the vessel wall.
Therefore, it has been proposed that when the arterial pressure stretches the vessel, this in turn causes reactive vascular constriction that reduces the blood flow nearly back to normal. Conversely, at low pressures, the degree of stretch of the vessel is less, so that the smooth muscle relaxes, reducing vascular resistance and helping to return blood flow toward normal.

A phenomenon called reactive hyperemia is a manifestation of local metabolic regulation of blood flow. When the blood supply to an area has been occluded and then restored, local blood flow through the tissues increases within seconds to restore the metabolic equilibrium of the tissues. This increased flow is called reactive hyperemia. The transient redness seen on an arm after leaning on a hard surface is an example of reactive hyperemia. Local control mechanisms rely on a continuous flow from the main arteries; therefore, hyperemia cannot occur when the arteries that supply the capillary beds are narrowed. For example, if a major coronary artery becomes occluded, the opening of channels supplied by that vessel cannot restore blood flow.

**Endothelial Control of Blood Flow**

One of the important functions of the endothelial cells lining the arterioles and small arteries is the synthesis and release of factors that can affect the degree of relaxation or contraction of the arterial wall. The most important of the endothelial relaxing factors is nitric oxide. The normal endothelium maintains a continuous release of nitric oxide, which is synthesized from the amino acid arginine and oxygen and reduction of inorganic nitrate. The production of nitric oxide can be stimulated by a variety of endothelial agonists, including acetylcholine, bradykinin, histamine, and thrombin. Shear stress on the endothelium resulting from an increase in blood flow or blood pressure also stimulates...
Nitric oxide production and vessel relaxation. Nitric oxide also inhibits platelet aggregation and secretion of platelet contents, many of which cause vasoconstriction. Nitroglycerin, a drug used in treatment of angina, produces its effects by releasing nitric oxide in vascular smooth muscle of the target tissues.

The endothelium also produces a number of vasoconstrictor substances, including angiotensin II, vasoconstrictor prostaglandins, and a family of peptides called endothelins. There are at least three endothelins. Endothelin-1 is the most potent endogenous vasoconstrictor known.

**Humoral Control of Blood Flow**

Humoral control of blood flow involves the effect of vasodilator and vasoconstrictor substances in the blood. Some of these substances are formed by special glands and transported in the blood throughout the entire circulation. Others are formed in local tissues and aid in the local control of blood flow. Among the most important of the humoral factors are norepinephrine and epinephrine, angiotensin II, histamine, serotonin, bradykinin, and the prostaglandins.

**Norepinephrine and Epinephrine.** Norepinephrine is an especially powerful vasoconstrictor hormone; epinephrine is less so and in some tissues (e.g., skeletal muscle) even causes mild vasodilation. Stimulation of the sympathetic nervous system during stress or exercise causes local constriction of veins and arterioles due to the release of norepinephrine from sympathetic nerve endings. In addition, sympathetic stimulation causes the adrenal medullae to secrete both norepinephrine and epinephrine into the blood. These hormones then circulate in the blood, causing direct sympathetic stimulation of blood vessels in all parts of the body.

**Angiotensin II.** Angiotensin II, another powerful vasoconstrictor, is produced as a part of the renin-angiotensin-aldosterone system. It normally acts on many arterioles at the same time to increase the peripheral vascular resistance, thereby increasing the arterial blood pressure (discussed in Chapter 18).

**Histamine.** Histamine has a powerful vasodilator effect on arterioles and has the ability to increase capillary permeability, allowing leakage of both fluid and plasma proteins into the tissues. Histamine is largely derived from mast cells in injured tissues and basophils in the blood. In certain tissues, such as skeletal muscle, the activity of the mast cells is mediated by the sympathetic nervous system; when sympathetic control is withdrawn, the mast cells release histamine.

**Serotonin.** Serotonin, which is liberated from aggregating platelets during the clotting process, causes vasoconstriction and plays a major role in control of bleeding. Serotonin is found in brain and lung tissues, and there is some speculation that it may be involved in the vascular spasm associated with some allergic pulmonary reactions and migraine headaches.

**Bradykinin.** The kinins (i.e., kallidins and bradykinin) are small polypeptides that are liberated from the globulin kininogen, which is present in body fluids. They cause powerful vasodilation when formed in the blood and tissue fluids of organs. Bradykinin causes intense dilation of arterioles, increased capillary permeability, and constriction of venules. It is thought that the kinins play special roles in regulating blood flow and capillary leakage in inflamed tissues. It is also believed that bradykinin plays a major role in regulating blood flow in the skin as well in the salivary and gastrointestinal glands.

**Prostaglandins.** Prostaglandins are synthesized from constituents of the cell membrane (i.e., the long-chain fatty acid arachidonic acid). Tissue injury incites the release of arachidonic acid from the cell membrane, which initiates prostaglandin synthesis (see Chapter 3, Fig. 3-4). There are several prostaglandins (e.g., E2, F2, D2), which are subgrouped according to their solubility; some produce vasoconstriction and some produce vasodilation. As a general rule, those in the E group are vasoconstrictors and those in the F group are vasoconstrictors. The corticosteroid hormones produce an anti-inflammatory response by blocking the release of arachidonic acid, thereby preventing prostaglandin synthesis.

**Collateral Circulation**

Collateral circulation is a mechanism for the long-term regulation of local blood flow. In the heart and other vital structures, anastomotic channels exist between some of the smaller arteries. These channels permit perfusion of an area by more than one artery. When one artery becomes occluded, these anastomotic channels increase in size, allowing blood from a patent artery to perfuse the area supplied by the occluded vessel. For example, persons with extensive obstruction of a coronary blood vessel may rely on collateral circulation to meet the oxygen needs of the myocardial tissue normally supplied by that vessel. As with other long-term compensatory mechanisms, the recruitment of collateral circulation is most efficient when the obstruction to flow is gradual, rather than sudden.

**Neural Control of Blood Flow**

The neural control of the circulation occurs primarily through the sympathetic and parasympathetic divisions of the autonomic nervous system (ANS). The ANS contributes to the control of cardiovascular function through modulation of cardiac function (i.e., heart rate and cardiac contractility) and peripheral vascular resistance.

The neural control centers for the integration and modulation of cardiac function and blood pressure are located bilaterally in the medulla oblongata of the brain. The medullary cardiovascular neurons are grouped into three distinct pools that lead to sympathetic innervation of the heart and blood vessels and parasympathetic innervation of the heart. The first two, which control
sympathetic-mediated acceleration of heart rate and blood vessel tone, are called the vasomotor center. The third, which controls parasympathetic-mediated slowing of heart rate, is called the cardioinhibitory center. These brain stem centers receive information from many areas of the nervous system, including the hypothalamus. The arterial baroreceptors and chemoreceptors provide the medullary cardiovascular center with continuous information regarding changes in blood pressure (see Chapter 18).

The sympathetic nervous system serves as the final common pathway for controlling the smooth muscle tone of the blood vessels. Most of the sympathetic preganglionic fibers that control vessel function originate in the vasomotor center of the brain stem, travel down the spinal cord, and exit in the thoracic and lumbar (T1 to L2) segments. The sympathetic neurons that supply the blood vessels maintain them in a state of tonic activity, so that even under resting conditions, the blood vessels are partially constricted. Vessel constriction and relaxation are accomplished by altering this basal input. Increasing sympathetic activity causes constriction of some vessels, such as those of the skin, the gastrointestinal tract, and the kidneys. Blood vessels in skeletal muscle are supplied by both vasoconstrictor and vasodilator fibers. Activation of sympathetic vasodilator fibers causes vessel relaxation and provides the muscles with increased blood flow during exercise. Although the parasympathetic nervous system contributes to the regulation of heart function, it has little or no control over blood vessels.

The actions of the ANS are mediated by chemical neurotransmitters. Acetylcholine is the postganglionic neurotransmitter for parasympathetic neurons and norepinephrine is the main postganglionic neurotransmitter for sympathetic neurons. Sympathetic neurons also respond to epinephrine, which is released into the bloodstream by the adrenal medulla. The neurotransmitter dopamine can also act as a neurotransmitter for some sympathetic neurons. The synthesis, release, and inactivation of the autonomic neurotransmitters are discussed in Chapter 34.

**SUMMARY CONCEPTS**

- The systemic circulation consists of arteries and arterioles, capillaries, and venules and veins. The walls of the blood vessels, except the capillaries, are composed of three layers: an outer layer, the tunica externa, composed of large collagen fibers that protect the vessel and anchor it to the surrounding structures; a middle layer, the tunica media, composed of smooth muscle that constricts to regulate vessel diameter; and an inner layer, the tunica intima, of flattened endothelial cells that provide a smooth and slippery surface for blood flow.

**REVIEW EXERCISES**

1. In persons with atherosclerosis of the coronary arteries, symptoms of myocardial ischemia do not usually occur until the vessel has been 75% occluded. Use Poiseuille law to explain.

2. Once an arterial aneurysm has begun to form, it will continue to enlarge as the result of the increased tension in its wall.

A. Explain the continued increase in size using the law of Laplace.

B. Using information related to cross-sectional area and velocity of flow, explain why there is stasis of blood flow with the tendency to form clots in aneurysms with a large cross-sectional area.
3. Use events in the cardiac cycle depicted in Figure 17-11 to explain:
   A. The effect of hypertension on the isovolumetric contraction period.
   B. The effect of an increase in heart rate on the time spent in diastole.
   C. The effect of an increase in the isovolumetric relaxation period on the diastolic filling of the ventricle.

4. Use the Frank-Starling ventricular function curve depicted in Figure 17-16 to explain the changes in cardiac output that occur with the following changes in respiratory effort:
   A. What happens to cardiac output during increased inspiratory effort in which a marked decrease in intrathoracic pressure produces an increase in venous return to the right heart?
   B. What happens to cardiac output during increased expiratory effort in which a marked increase in intrathoracic pressure produces a decrease in venous return to the right heart?
   C. Given these changes in cardiac output that occur during increased respiratory effort, what would you propose as one of the functions of the Frank-Starling curve?

isorders of the blood vessels are directly or indirectly responsible for many human diseases. Arterial diseases, such as stroke and coronary heart disease, are responsible for more morbidity and mortality than any other type of disease. Hypertension, or elevation of the arterial blood pressure, is probably the most common of all health problems in adults and is the leading risk factor for cardiovascular disorders. Although venous diseases are less common, they also cause clinically significant problems. The discussion in this chapter is organized into four parts: blood vessel structure and function, disorders of the arterial circulation, disorders of the arterial blood pressure, and disorders of the venous circulation.

**Blood Vessel Structure and Function**

The walls of arteries and veins are composed of three layers called tunica: an outer layer called the *tunica externa*, a middle layer called the *tunica media*, and an inner layer called the *tunica intima* (Fig. 18-1). The tunica externa is composed primarily of loosely woven collagen fibers that protect the blood vessel and anchor it to the surrounding structures. It is infiltrated with nerve fibers and, in larger vessels, a system of tiny blood vessels called the *vasa vasorum*. The tunica media is composed mainly of circularly arranged smooth muscle cells and sheets of elastin. Larger arteries have an external elastic lamina that separates the tunica media from the tunica externa. The tunica intima consists of a single layer of flattened endothelial cells with minimal underlying subendothelial connective tissue. As the main cellular component of the blood vessel wall, the endothelial and smooth muscle cells play an important role in the pathogenesis of many blood vessel diseases.
Endothelial cells form a continuous lining for the entire vascular system called the endothelium. Once thought to be nothing more than a lining for blood vessels, it is now known that the endothelium is a versatile, multi-functional tissue that plays an active role in controlling vascular function⁴ (Table 18-1). As a selectively permeable monolayer, the endothelium controls the transfer of molecules across the vessel wall. The endothelium also plays a role in the modulation of blood flow and vascular resistance; control of platelet adhesion and blood clotting; metabolism of hormones; regulation of immune and inflammatory reactions; and elaboration of factors that influence the growth of other cell types, especially vascular smooth muscle cells.

Structurally intact endothelial cells respond to various abnormal stimuli by adjusting their usual functions and by expressing newly acquired functions.⁶ The term endothelial dysfunction describes several types of potentially reversible changes in endothelial function that occur in response to environmental stimuli. Endothelial cell dysfunction has been implicated in a number of pathologies including thrombosis, atherosclerosis, and hypertensive vascular lesions.⁴ There is also evidence that the dysfunction contributes to conditions such as erectile dysfunction, disorders of the retina, kidney disease, pulmonary hypertension, and septic shock.

Inducers of endothelial dysfunction include cardiovascular risk factors such as smoking, hyperlipidemia, hypertension, insulin resistance and diabetes, and aging that contribute to the development of atherosclerosis. Dysfunctional endothelial cells, in turn, produce pro-inflammatory cytokines, growth factors (e.g., vascular endothelial growth factor), reactive oxygen species, procoagulant or anticoagulant substances, and a variety of other disease-producing products. They also influence the reactivity of underlying smooth muscle cells through production of both relaxing factors (e.g., nitric oxide) and contracting factors (e.g., endothelins; see Chapter 17).

### Vascular Smooth Muscle Cells

Vascular smooth muscle cells, which form the predominant cellular layer in the tunica media, produce vasoconstriction or vasodilation. A network of vasomotor nerves of the sympathetic component of the autonomic nervous system supplies the smooth muscle in the blood vessels. These nerves are responsible for constriction of the vessel walls. Because they do not enter the tunica media of the blood vessel, the nerves do not synapse directly on the smooth muscle cells. Instead, they release the neurotransmitter norepinephrine, which diffuses into the media and acts on the nearby smooth muscle cells. The resulting impulses are propagated along the smooth muscle cells, causing contraction of the entire smooth muscle cell layer and thus reducing the radius of the vessel lumen.

Vascular smooth muscle cells also synthesize collagen, elastin, and other components of the extracellular matrix; elaborate growth factors and cytokines; and after vascular injury migrate into the intima and proliferate. Thus, smooth muscle cells are important in both normal vascular repair and pathologic processes such as atherosclerosis. The migratory and proliferative activities of vascular smooth muscle cells are stimulated by growth promoters and inhibitors, such as platelet-derived growth factor, thrombin, fibroblast growth factor, cytokines, and nitric oxide.

**SUMMARY CONCEPTS**

- The walls of blood vessels are composed of an inner layer of endothelial cells, a middle layer of vascular smooth muscle, and an outer layer of loosely woven collagen tissue.
- The endothelium, which forms a continuous lining for the entire vascular system, controls the transfer of molecules across the vascular wall and plays a role in the control of platelet adhesion and blood clotting, modulation of blood flow and vascular resistance, metabolism of hormones, regulation of immune and inflammatory reactions, and elaboration of factors that influence the growth of other cell types, particularly the smooth muscle cells.
- The term endothelial dysfunction describes changes in endothelial function that occur in response to stimuli derived from cardiovascular risk factors such as smoking, hyperlipidemia, hypertension, insulin resistance and diabetes, and obesity.
- Vascular smooth muscle cells, which form the middle layer of blood vessels, control the dilation and constriction of blood vessels, elaborate growth factors, and synthesize collagen, elastin, and other components of the extracellular matrix that are important in both normal vascular repair and pathologic processes such as atherosclerosis.

**Disorders of the Arterial Circulation**

The arterial system distributes blood to all the tissues in the body. There are three types of arteries: large elastic arteries, including the aorta and its distal branches; medium-sized arteries, such as the coronary and renal arteries; and small arteries and arterioles that pass through the tissues. Each of these different types of arteries tends to be affected by different disease processes. The discussion in this section focuses on hyperlipidemia and atherosclerosis, the vasculitides, arterial disease of the extremities, and arterial aneurysms.

**Hyperlipidemia**

Hyperlipidemia is a medical condition characterized by an elevation of any or all lipid profiles and/or lipoproteins in the blood. Hyperlipidemias can be classified as either primary or secondary. Primary hyperlipidemias are probably genetically based, but the genetic defects are known for only a minority of patients. Secondary hyperlipidemia may result from diseases such as diabetes, thyroid disease, renal disorders, liver disorders, and Cushing syndrome, as well as obesity, alcohol consumption, estrogen administration, and other drug-associated changes in lipid metabolism. Besides the primary and secondary hyperlipidemia subtypes, hyperlipidemia is also classified according to the type of lipid that is elevated—hypercholesterolemia, hypertriglyceridemia, or both in combined hyperlipidemia. The condition, specifically hypercholesteremia, is strongly associated with the development of atherosclerosis, which causes more morbidity and mortality in the Western world than any other disorder. By the year 2025, it is predicted that cardiovascular mortality will likely exceed that of every other major disease group including infections, cancer, and trauma.

**Lipoprotein Metabolism and Transport**

Because lipids, namely cholesterol and triglycerides, are insoluble in plasma, they are encapsulated by special fat-carrying proteins called lipoproteins for transport in the blood. There are five main types of lipoproteins, classified by their protein content or densities: chylomicrons, very-low-density lipoprotein (VLDL), intermediate-density lipoprotein (IDL), low-density lipoprotein (LDL), and high-density lipoprotein (HDL). Thus, VLDLs carry large amounts of triglycerides and much less cholesterol and protein. Low-density lipoprotein is the main carrier of cholesterol, whereas HDL is about 50% protein and carries less cholesterol and little triglyceride (Fig. 18-2).

Lipoproteins are macromolecules made up of a hydrophobic core of insoluble cholesterol esters and triglycerides, surrounded by a hydrophilic outer shell of soluble phospholipids, and nonesterified cholesterol (Fig. 18-3). In addition, the shell contains a variety of apolipoproteins, proteins that bind lipids, thereby increasing the stability and water solubility of the resulting lipoprotein. The apolipoproteins also activate certain enzymes required for normal lipoprotein metabolism, and they serve as reactive sites that specific receptors on peripheral tissues can recognize and use in the endocytosis and metabolism of the lipoproteins. Apolipoproteins can be grouped into two classes: exchangeable and nonexchangeable. Exchangeable apolipoproteins (e.g., apoA-I, apoC-II, and apoE) are able to dissociate from one lipoprotein and associate with another, whereas the nonexchangeable apolipoproteins (e.g., apoB-48 and...
apoB-100) remain attached to the same lipoprotein particle from biosynthesis to breakdown.

There are two pathways involved in the generation and transport of lipoproteins: the exogenous intestinal and endogenous hepatic pathways. The exogenous pathway is involved in the transport of dietary triglycerides and cholesterol from the intestines to the liver. The chylomicrons, which are the largest of the lipoprotein molecules, are synthesized in the wall of the small intestine. These triglyceride-rich lipoproteins transfer their triglycerides to peripheral tissues, especially adipose tissue and skeletal muscle, for energy and storage. The remnant chylomicron particles, which contain cholesterol, are then taken up by the liver and the cholesterol is used in the synthesis of VLDL or excreted in the bile.

**Endogenous Pathway.** The liver is the central site for handling of lipids: it is able to store glycerols and fats in its cells; synthesize triglycerides; and use esterified cholesterol and triglycerides to form VLDL. Like chylomicrons, VLDLs carry their triglycerides to fat and muscle cells, where the triglycerides are removed. The resulting IDL particles, which are reduced in triglyceride content and enriched in cholesterol, are then taken to the liver and recycled to form VLDL or converted to LDL.

**Low-Density Lipoproteins**

Sometimes called *bad cholesterol*, LDL is the main carrier of cholesterol. Low-density lipoprotein particles are rich in cholesterol and cholesterol esters. Approximately 60% of the LDL is transported back to the liver, where its apoB-100 binds to specific LDL receptors on liver cells, allowing the particles to be internalized. The remaining 40% of LDL particles are carried to extrahepatic tissues, such as those of the adrenal cortex and gonads, which also have apoB-100 receptors that allow them to internalize the LDL particles and use the cholesterol in the synthesis of their cell membranes and steroid hormones.

There are different types of LDL, and some people with markedly elevated LDL do not develop atherosclerotic vascular disease, whereas other people with only modest elevations in LDL develop severe disease. This can be partially explained by the quality and size of the LDL particles. Small, dense LDL is more toxic or atherogenic to the endothelium than large, buoyant LDL. It is more likely to enter the vessel wall, become oxidized, and trigger the atherosclerotic process.

**High-Density Lipoproteins**

Often referred to as the *good cholesterol*, HDL is synthesized by several pathways, including direct secretion by the intestine and liver and transfer of lipid constituents released during lipolysis of lipoproteins that contain apoB100. It participates in reverse cholesterol transport see Fig. 18-4—that is, carrying cholesterol from the peripheral tissues back to the liver. Epidemiologic studies show an inverse relation between HDL levels and the development of atherosclerosis. It is thought that HDL, which is low in cholesterol and rich in surface phospholipids,
facilitates the clearance of cholesterol from atheromatous plaques and transports it to the liver, where it may be excreted rather than reused in the formation of VLDL. The mechanism whereby HDL takes up cholesterol from peripheral cells has recently been elucidated. A lipid transporter (adenosine triphosphate [ATP]-binding cassette transporter A class 1, or ABCA1) promotes the movement of cholesterol from peripheral cells to the lipid-poor HDL cholesterol. Defects in this system (resulting from mutations in the ABCA1 transporter gene) are responsible for a condition called Tangier disease, which is characterized by accelerated atherosclerosis and little or no HDL cholesterol.

**Hypercholesterolemia**

Hypercholesterolemia refers to increased levels of cholesterol in the blood. The Third Report of the National Cholesterol Educational Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults classification system describes optimal to very high levels of LDL cholesterol and triglycerides, and low and high levels of HDL cholesterol (Table 18-2).

Several factors, including nutrition, genetics, comorbid conditions, medications, and metabolic diseases, can raise blood lipid levels. Most cases of elevated levels of cholesterol are probably multifactorial. Hypercholesterolemia can be divided into two types: primary or secondary. In primary hypercholesteremia elevated cholesterol levels develop independent of other causes. Secondary hypercholesterolemia is associated with other health problems and behaviors. Many types of primary hypercholesterolemia have a genetic basis. There may be a defective synthesis of the apolipoproteins, a lack of lipoprotein receptors, defective receptors, or defects in the handling of cholesterol in the cell that are genetically determined. For example, the LDL receptor is deficient or defective in the genetic disorder known as familial hypercholesterolemia (type 2A). This autosomal dominant type of hyperlipidemia results from a mutation in the gene specifying the receptor for LDL. It is one of the most common of all Mendelian disorders, with heterozygotes having one defective gene representing about 1 in 500 persons in the general population. Because most of the circulating cholesterol is removed by receptor-dependent mechanisms, blood cholesterol levels are markedly elevated in persons with this disorder. Plasma LDL levels in heterozygotes range between 250 and 500 mg/dL, whereas in homozygotes LDL cholesterol levels may rise to 1000 mg/dL. Although heterozygotes commonly have an elevated cholesterol level from birth, the disorder does not typically manifest until adult life, when xanthomas (i.e., cholesterol deposits) develop along the tendons, and atherosclerosis appears (Fig. 18-5). Myocardial infarction before 40 years of age is common. Homozygotes are much more severely affected; they have cutaneous xanthomas in childhood and may experience myocardial infarction by as early as 1 to 2 years of age.

Secondary causes of hypercholesterolemia include obesity with high-calorie intake, sedentary lifestyle, and diabetes mellitus. High-calorie diets increase the production of VLDL, with triglyceride elevation and high conversion of VLDL to LDL. Excess ingestion of cholesterol may reduce the formation of LDL receptors and thereby decrease LDL removal from the blood. Diets that are high in saturated fats increase cholesterol synthesis and suppress LDL receptor activity. A sedentary lifestyle influences interactions among lipids and lipoproteins. Diabetes mellitus and the metabolic syndrome are associated with elevated triglycerides, low HDL, and minimal or modest elevation of LDL. Other systemic disorders that can elevate lipids include hypothyroidism, the nephrotic syndrome, and obstructive liver disease. Medications such as beta-blockers, estrogens, and protease inhibitors (used in the treatment of human immunodeficiency virus [HIV] infection) can also increase lipid levels.

Diagnosis of Hyperlipidemia. Diagnosis of hyperlipidemia depends on a person’s complete lipid profile (total cholesterol, LDL, HDL, and triglyceride levels) after an overnight fast. Most clinical laboratories measure the total serum cholesterol, total triglycerides, and the amount of cholesterol carried in the HDL fraction. The LDL is then estimated by subtracting the HDL from the total serum cholesterol and the triglycerides divided by 5 (i.e., LDL [mg/dL] = total cholesterol [mg/dL] − HDL [mg/dL] − triglycerides [mg/dL]/5). The relationship between the different lipid fractions can then be used as a means for determining an individual’s risk for developing coronary heart disease and other atherosclerosis-related diseases. Cholesterol is carried in the blood as VLDL, LDL, and HDL, with the total serum cholesterol being equal to the sum of these three components. Thus, total serum cholesterol levels may

---

*When using SI units (expressed in mmol/L), the triglycerides are divided by 2.2.*
be elevated as a result of an increase in any of the lipoproteins. For example, two persons with the same total serum cholesterol of 275 mg/dL may have very different lipid profiles. One person may have a favorable lipid profile with an HDL of 110 mg/dL, a triglyceride level of 175 mg/dL, and an LDL of 130 mg/dL, whereas another person with an HDL of 40 mg/dL, a triglyceride level of 150 mg/dL, and an LDL cholesterol of 205 mg/dL would be at much greater risk for cardiovascular disease.

Management of Hyperlipidemia. A reduction in LDL cholesterol continues to be the primary target for cholesterol-lowering therapy, particularly in people at risk for coronary artery disease (CAD). The major risk factors for CAD, exclusive of LDL cholesterol levels, include cigarette smoking, hypertension, family history of premature CAD in a first-degree relative, age (men ≥ 45 years; women ≥ 55 years), an HDL cholesterol level less than 40 mg/dL, and diabetes mellitus. Guidelines recommend that persons with none of the major risk factors should have an LDL cholesterol goal of 160 mg/dL or less; those with two or more of the major risk factors should have an LDL cholesterol goal of less than 130 mg/dL; persons with high-risk factors (i.e., those with CAD, other forms of atherosclerotic disease, or diabetes) should have an LDL cholesterol goal of less than 100 mg/dL; and persons with very–high-risk factors (i.e., acute coronary syndromes or CAD with other risk factors) should have an LDL cholesterol goal of less than 70 mg/dL. It is also recommended that persons with a greater than 20% 10-year risk of experiencing myocardial infarction or coronary death, as determined by the risk assessment tool developed from Framingham Heart Study data, should have an LDL cholesterol goal of less than 100 mg/dL (to calculate a risk score, go to http://hp2010.nhlbihin.net/atpIII/calculator.asp?userertype=prof).

The management of hypercholesterolemia focuses on dietary and therapeutic lifestyle changes; when these are unsuccessful, pharmacologic treatment may be necessary. Therapeutic lifestyle changes include an increased emphasis on physical activity, dietary measures to reduce LDL levels, smoking cessation, and weight reduction for people who are overweight.

Several dietary elements affect cholesterol and its lipoprotein fractions: (1) excess calorie intake, (2) saturated and trans fats, and (3) cholesterol. Excess calories consistently lower HDL and less consistently elevate LDL. Saturated fats in the diet can strongly influence cholesterol levels. Depending on individual differences, they raise VLDL and LDL levels. Trans fats, which are manufactured from vegetable oils and are used to enhance the taste and extend the shelf life of fast foods, are more atherogenic than saturated fats. Dietary cholesterol tends to increase LDL cholesterol.

Lipid-lowering drugs work in several ways, including decreasing cholesterol production, decreasing cholesterol absorption from the intestine, and removing cholesterol from the bloodstream. Drugs that act to directly decrease cholesterol levels also indirectly lower cholesterol levels by stimulating the production of additional LDL receptors. There currently are five major types of medications available for treating hypercholesterolemia: 3-hydroxy-3-methyl-glutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins), bile acid–binding resins, cholesterol absorption inhibitor agents, niacin and its congeners, and the fibrates. Inhibitors of HMG-CoA reductase, a key enzyme in the cholesterol biosynthetic pathway, can reduce or block the hepatic synthesis of cholesterol and are the cornerstone of LDL-reducing therapy. Statins also reduce triglyceride levels. The bile acid–binding resins bind and sequester cholesterol-containing bile acids in the intestine. This leads to increased production of LDL receptors by the liver, with resulting increased removal of cholesterol from the blood for synthesis of new bile acids. The cholesterol absorption inhibitor (ezetimibe) interferes with the absorption of cholesterol. Nicotinic acid, a niacin congener, blocks the synthesis and release of VLDL by the liver, thereby lowering not only VLDL levels but also IDL and LDL levels. Nicotinic acid also increases HDL concentrations up to 30%. The fibrates decrease the synthesis of VLDL by the liver and also enhance the clearance of triglycerides from the circulation.

Atherosclerosis

Atherosclerosis is a condition in which an artery wall thickens as a result of the accumulation of fatty materials. The term atherosclerosis, which comes from the Greek words atheros (“gruel” or “paste”) and sclerosis (“hardness”), denotes the formation of fibrous plaque in the intimal lining of the large and medium-sized arteries such as the aorta and its branches, the coronary arteries, and the cerebral arteries that supply the brain (Fig. 18-6). The disorder, which remains a leading cause of coronary artery disease, stroke, and peripheral artery disease, can begin in the late teens, but usually takes decades to cause symptoms. Some people experience rapidly progressing atherosclerosis during their 30s, others during their 50s or 60s.

Epidemiology and Risk Factors

Atherosclerosis is a complex disorder. Although its exact cause is unknown, epidemiologic studies have identified predisposing risk factors (Chart 18-1). Some of these are constitutional and cannot be changed, but others are affected by lifestyle and can be modified. The major risk factor, hypercholesterolemia, has both constitutional and lifestyle components.

Constitutional risk factors such as increasing age, male gender, and family history of premature coronary artery disease cannot be changed. The tendency toward the development of atherosclerosis appears to run in families. Persons who come from families with a strong history of heart disease or stroke due to atherosclerosis are at greater risk for developing atherosclerosis than those with a negative family history. Several genetically
determined alterations in lipoprotein and cholesterol metabolism have been identified, and it seems likely that others will be identified in the future. The incidence of atherosclerosis increases with age. Other factors being equal, men are at greater risk for the development of CAD than are premenopausal women, probably because of the protective effects of natural estrogens. After menopause, the incidence of atherosclerotic-related diseases in women increases, and by the seventh to eighth decade of life, the frequency of myocardial infarction in the two genders tends to equalize.

The major risk factors that can be modified by a change in health care behaviors include cigarette smoking, obesity, hypertension, hyperlipidemia and elevated LDL cholesterol, and diabetes mellitus, all of which are traditional cardiovascular risk factors. Smoking affects atherosclerosis by several mechanisms other than its unfavorable effects on blood pressure, sympathetic vascular tone, and reduction in myocardial oxygen supply. It has adverse hemostatic and inflammatory effects and it may enhance the oxidation of LDL cholesterol, causing damage to the endothelial lining of blood vessels. Obesity, type 2 diabetes, high blood pressure, high blood triglycerides and low HDL levels (all components of the metabolic syndrome; see Chapter 33) often can be controlled with a change in health care behaviors and medications.

However, not all cases of atherosclerosis can be explained by the established genetic and environmental risk factors. Other so-called nontraditional risk factors have been associated with increased risk for development of atherosclerosis, including C-reactive protein (CRP), serum homocysteine, and lipoprotein (a). There has been increased interest in the possible connection between infectious agents (e.g., Chlamydia pneumoniae, herpesvirus, cytomegalovirus) and the development of vascular disease. Genomic evidence of these organisms has been found in atherosclerotic lesions, but whether they are causally associated with lesions or simply enter the diseased vessel is unknown.

Considerable interest in the role of inflammation in the etiology of atherosclerosis has emerged over the past two decades. C-reactive protein is an acute-phase reactant synthesized in the liver that is a marker for systemic inflammation (see Chapter 3). A number of population-based studies have demonstrated that baseline CRP levels can predict future cardiovascular events among apparently healthy individuals. High-sensitivity CRP (hs-CRP) may be a better predictor of cardiovascular risk than lipid measurement alone. Because CRP is an acute inflammatory phase reactant, major infections, trauma, or acute hospitalization can elevate CRP levels (usually 100-fold or more). Thus, CRP levels to determine cardiovascular risk should be performed when the person is clinically stable.

---

**CHART 18-1 Risk Factors for Atherosclerosis**

**Nonmodifiable**
- Increasing age
- Male gender
- Genetic disorders of lipid metabolism
- Family history of premature coronary artery disease

**Potentially Modifiable**
- Cigarette smoking
- Obesity
- Hypertension
- Hyperlipidemia with elevated low-density lipoprotein and low high-density lipoprotein cholesterol
- Diabetes mellitus

**Additional Nontraditional**
- Inflammation marked by elevated C-reactive protein levels
- Hyperhomocysteinemia
- Increased lipoprotein (a) levels

---

Homocysteine is derived from the metabolism of dietary methionine, an amino acid that is abundant in animal protein. Homocysteine inhibits elements of the anticoagulant cascade and is associated with endothelial damage, which is thought to be an important first step in the development of atherosclerosis.\textsuperscript{1,6} The normal metabolism of homocysteine requires adequate folate and vitamin B\textsubscript{6} intake, although the jury is still out on whether supplemental folate and vitamin B\textsubscript{6} can reduce the incidence of cardiovascular disease.\textsuperscript{1}

Homocystinuria, due to rare hereditary errors of metabolism, results in elevated homocysteine levels and premature cardiovascular disease.\textsuperscript{1}

Lipoprotein(a) (Lp[a]), which is an altered form of LDL that contains apoB-100 linked to apoA, is considered to be an independent risk factor for the development of atherosclerosis.\textsuperscript{1,2} Lp(a) enhances cholesterol delivery to injured blood vessels, suppresses the generation of plasmin, and promotes smooth muscle proliferation. Lipoprotein(a) levels are heritable and are not altered by most cholesterol-lowering drugs.\textsuperscript{2}

Pathogenesis and Mechanisms of Development

The lesions associated with atherosclerosis are of three different stages or subtypes: fatty streaks, fibrous atheromatous plaques, and complicated lesions. The latter two are responsible for the clinically significant manifestations of the disease.\textsuperscript{1,2,14}

Fatty streaks appear as thin yellow lines running along the major arteries, such as the aorta. The streak consists of smooth muscle cells filled with cholesterol and macrophages (a type of immune system “scavenger” cell that removes harmful substances, such as excess cholesterol particles, from the bloodstream). The first evidence of atherosclerosis, fatty streaks can be found in children 10 to 14 years of age regardless of gender or race.\textsuperscript{1,2} They increase in number until about 20 years of age, and then remain static or regress. The fatty streak alone does not cause any symptoms but, over time, can develop into a more advanced form of atherosclerosis called an atheroma or fibrous plaque.

The fibrous atheromatous plaque is the basic lesion of clinical atherosclerosis. It is characterized by the accumulation of intracellular and extracellular lipids, proliferation of vascular smooth muscle cells, formation of scar tissue, and calcification. The lesions begin as a gray to pearly white, elevated thickening of the vessel intima with a core of extracellular lipid covered by a fibrous cap of connective tissue and smooth muscle (Fig. 18-7). As the lesions increase in size, they encroach on the lumen of the artery and eventually may occlude the vessel or predispose to thrombus formation, causing a reduction of blood flow. Because blood flow is related to the fourth power of the vessel radius (see Chapter 17),...
the reduction in blood flow becomes increasingly greater as the disease progresses. Complicated atherosclerotic lesions develop when the fibrous plaque breaks open, producing hemorrhage, ulceration, and scar tissue deposits. Thrombosis is the most important complication of atherosclerosis. It is caused by slowing and turbulence of blood flow in the region of the plaque and ulceration of the plaque.

Although the risk factors associated with atherosclerosis have been identified through epidemiologic studies, many unanswered questions remain regarding the mechanisms that contribute to the development of atherosclerotic lesions. The vascular endothelial layer, which consists of a single layer of cells with cell-to-cell attachments, normally serves as a selective barrier that protects the subendothelial layers by interacting with blood cells and other blood components. One hypothesis of plaque formation suggests that injury to the endothelial vessel layer is the initiating factor. A number of factors are regarded as possible injurious agents, including products associated with smoking, immune mechanisms, and mechanical stress such as that associated with hypertension. The fact that atherosclerotic lesions tend to form where vessels branch or where there is turbulent flow suggests that hemodynamic factors may also play a role.

Hyperlipidemia, particularly elevated LDL, is also believed to play an active role in the pathogenesis of the atherosclerotic lesion. Interactions between the endothelial layer of the vessel wall and white blood cells, particularly the monocytes (blood macrophages), normally occur throughout life; these interactions increase when blood cholesterol levels are elevated. One of the earliest responses to elevated cholesterol levels is the attachment of monocytes to the endothelium. The monocytes have been observed to move through the cell-to-cell attachments of the endothelial layer into the subendothelial spaces, where they are transformed into macrophages.

Activated macrophages release free radicals that oxidize LDL, which in turn is toxic to the endothelium, causing endothelial cell loss and exposure of the subendothelial tissue to blood components. This leads to platelet adhesion and aggregation and fibrin deposition. Platelets and activated macrophages release various factors that are thought to modulate the proliferation of smooth muscle cells and the deposition of extracellular matrix in the lesions. Activated macrophages also ingest the oxidized LDL to become foam cells, which are present in all stages of atherosclerotic plaque formation. Some of these cells die in place, releasing their fat and cholesterol-laden membranes into the intercellular space. This attracts more macrophages. Lipids released from necrotic foam cells accumulate to form unstable plaques (also known as vulnerable plaque). Unstable plaques typically are characterized histologically by a large central lipid core, an inflammatory infiltrate, and a thin fibrous cap. These vulnerable plaques are at risk of rupture, often at the shoulder of the plaque (see Fig. 18-7A) where the fibrous cap is thinnest and the mechanical stresses highest.

Clinical Manifestations
Atherosclerosis usually doesn’t cause signs and symptoms until it severely narrows or totally blocks an artery. Many people don’t know they have the disease until they have a medical emergency, such as a heart attack or stroke. Signs and symptoms will depend on the vessels involved and the extent of vessel obstruction. Atherosclerotic lesions produce their effects through narrowing of the vessel and production of ischemia; sudden vessel obstruction due to plaque hemorrhage or rupture; thrombosis and formation of emboli resulting from damage to the vessel endothelium; and aneurysm formation due to weakening of the vessel wall. In larger vessels, such as the aorta, the important complications are those of thrombus formation and weakening of the vessel wall. In medium-sized arteries, such as the coronary and cerebral arteries, ischemia and infarction due to vessel occlusion are more common. Although atherosclerosis can affect any organ or tissue, the arteries supplying the heart, brain, kidneys, lower extremities, and small intestine are most frequently involved (see Fig. 18-6).

Vascularitis
The vasculitides are a group of vascular disorders that cause inflammatory injury and necrosis of the blood vessel wall. Vessels of any type in virtually any organ can be affected, resulting in a broad spectrum of signs and symptoms. Because they may affect veins and capillaries, the terms vasculitis, angiitis, and arteritis often are used interchangeably. Besides the finding referable to the specific tissue or organ involved, the clinical manifestations typically include constitutional signs and symptoms such as fever, myalgia, arthralgia, and malaise.

The two most common pathogenic mechanisms of vasculitis are direct invasion of the vascular wall by an infectious agent and immune-mediated inflammation. The most common mechanisms that initiate noninfectious vasculitis are pathological immune responses that result in endothelial activation, with subsequent vessel obstruction, and ischemia of the dependent tissue. In almost all forms of vasculitis, the triggering event initiating and driving the inflammatory process is unknown.

A number of persons with vasculitis have circulating antibodies called antineutrophil cytoplasmic antibodies (ANCA) that react with antigens in the cytoplasm of neutrophils. Although the precise pathologic mechanism is unknown, these antibodies may serve to initiate an inflammatory state that continually recruits and stimulates neutrophils to release reactive oxygen species and proteolytic enzymes. Serum ANCA titers, which can correlate with disease activity, may serve as a useful quantitative diagnostic marker for ANCA-associated vasculitides.

The vasculitides are commonly classified based on etiology, pathologic findings, and prognosis. One
Atherosclerosis is characterized by the development of atheromatous lesions within the intimal lining of the large- and medium-sized arteries that protrude into and can eventually obstruct blood flow. The development of atherosclerotic lesions is a progressive process involving (1) endothelial cell injury, (2) migration of inflammatory cells, (3) smooth muscle cell proliferation and lipid deposition, and (4) gradual development of the atheromatous plaque with a lipid core.

1. **Endothelial Cell Injury.** The vascular endothelium consists of a single layer of cells with cell-to-cell attachments, which normally resist attachment of the white blood cells and other blood components streaming past them. Agents such as smoking, elevated low-density lipoprotein (LDL) levels, immune mechanisms, and mechanical stress associated with hypertension share the potential for causing endothelial injury with adhesion of monocytes and platelets.

2. **Migration of Inflammatory Cells.** Early in the development of atherosclerotic lesions, endothelial cells begin to express selective adhesion molecules that capture monocytes and other inflammatory cells that initiate the development of atherosclerotic lesions. After monocytes adhere to the endothelium, they migrate between the endothelial cells to localize in the intima, transform into macrophages, and engulf lipoproteins, largely LDL particles.
**Atherosclerosis**

3. **Lipid Accumulation and Smooth Muscle Cell Proliferation.** Although the recruitment of monocytes to the arterial wall and their subsequent differentiation into activated macrophages that remove LDL from the circulation is protective, it also contributes to the development of atherosclerosis. Activated macrophages release toxic oxygen species that oxidize LDL. The oxidized LDL is then aggressively ingested by the macrophages through scavenger receptors on their plasma membrane, resulting in the formation of foam cells, which are the primary component of atherosclerotic lesions. Activated macrophages also produce growth factors that contribute to the migration and proliferation of smooth muscle cells (SMCs) and the elaboration of extracellular matrix (ECM).

4. **Plaque Structure.** Atherosclerotic plaques consist of an aggregation of SMCs, macrophages, and other leukocytes; ECM, including collagen and elastic fibers; and intracellular and extracellular lipids. Typically, the superficial fibrous cap is composed of SMCs and dense ECM. Immediately beneath and to the side of the fibrous cap is a cellular area (the shoulder) consisting of macrophages, SMCs, and lymphocytes. Below the fibrous cap is a central core of lipid-laden foam cells and fatty debris. Rupture, ulceration, or erosion of an unstable or vulnerable fibrous cap may lead to hemorrhage into the plaque or thrombotic occlusion of the vessel lumen.
classification system divides the conditions into three groups: (1) small vessel, (2) medium-sized vessel, and (3) large vessel vasculitides (Table 18-3).\textsuperscript{1,2}

Small vessel refers to small arteries, arterioles, venules, and capillaries; medium vessel refers to small and medium–sized arteries and arterioles; and large vessel refers to the aorta and its major tributaries. The small vessel ANCA-associated vasculitides are involved in a number of different diseases, including Wegener granulomatosis, which is characterized by a triad of acute granulomatous lesions of the upper respiratory tract (ear, nose, sinuses, and throat), necrotizing vasculitis of the affected small to medium-sized vessels of the lungs and upper airways, and renal disease in form of necrotizing glomerulonephritis.\textsuperscript{1} Acute Wegener granulomatosis is potentially life-threatening and requires initial treatment with corticosteroids combined with a cytotoxic agent.

Medium-sized vessel vasculitides produce necrotizing damage to medium-sized muscular arteries of major organ systems. This group includes polyarteritis nodosa, Kawasaki disease (discussed in Chapter 19), and thromboangiitis obliterans (discussed in the section on arterial disease of the extremities). Polyarteritis nodosa is an uncommon, acute multisystem inflammatory disease of small and medium-sized blood vessels of the kidney, liver, intestine, peripheral nerves, skin, and muscle. The usual course of the disease is progressive with various signs and symptoms according to the pattern of organ involvement. Most cases were fatal before corticosteroid and immunosuppressant agents became available for use in treatment of the disorder.\textsuperscript{1}

Large vessel vasculitides involve large elastic arteries; they commonly are called giant cell arteritides because they involve infiltration of the vessel wall with giant cells and mononuclear cells. Giant cell (temporal) arteritis, the most common of the large vessel vasculitides, is an acute and chronic inflammation of the medium- to small-sized arteries, principally the temporal and frontal arteries but sometimes extending to the veins and nerves of the extremities; occurs almost exclusively in men who are heavy smokers.

(text continued from page 411)
Arterial Disease of the Extremities

Disorders of the circulation in the extremities often are referred to as peripheral vascular disorders. In many respects, the disorders that affect arteries in the extremities are the same as those affecting the coronary and cerebral arteries in that they produce ischemia, pain, impaired function, and in some cases infarction and tissue necrosis. Not only are the effects similar, but the pathologic conditions that impair circulation in the extremities are also identical. This section focuses on peripheral arterial disease, thromboangiitis obliterans, and Raynaud phenomenon.

Peripheral Arterial Disease

Peripheral artery disease (PAD) refers to the obstruction of large arteries that supply the body’s peripheral structures rather than its central structures such as the heart or brain. Often PAD is a term used to refer to atherosclerotic blockages found in the lower extremities. Peripheral artery disease can result from atherosclerosis, inflammatory processes leading to stenosis, embolism, or thrombus formation. It causes either acute or chronic ischemia. The disease is seen most commonly in men in their 60s and 70s. The risk factors for PAD are similar to those for coronary artery disease. Cigarette smoking and diabetes mellitus are the strongest risk factors, with more than 80% of persons with the disorder being current or former smokers.

As with atherosclerosis in other locations, the signs and symptoms of vessel occlusion are gradual. The primary symptom of chronic obstructive arterial disease is pain with walking or claudication (from the Latin verb claudicare, “to limp”). Typically, persons with the disorder complain of calf pain because the gastrocnemius muscle has the highest oxygen consumption of any muscle group in the leg during walking. Some persons may complain of a vague aching feeling or numbness, rather than pain. Other activities such as swimming, bicycling, and climbing stairs use other muscle groups and may not incite the same degree of discomfort as walking. Other signs of ischemia include atrophic changes and thinning of the skin and subcutaneous tissues of the lower leg and diminution in the size of the leg muscles. The foot often is cool, and the popliteal and pedal pulses are weak or absent. Limb color blanches with elevation of the leg because of the effects of gravity on perfusion pressure and becomes deep red when the leg is in the dependent position because of an autoregulatory increase in blood flow and a gravitational increase in perfusion pressure.

When blood flow is reduced to the extent that it no longer meets the minimal needs of resting muscle and nerves, ischemic pain at rest, ulceration, and gangrene develop. As tissue necrosis develops there typically is severe pain in the region of skin breakdown, which is worse at night with limb elevation and is improved with standing.

Diagnostic methods include inspection of the limbs for signs of chronic low-grade ischemia such as subcutaneous atrophy, brittle toenails, hair loss, pallor, coolness, or dependent rubor. Palpation of the femoral, popliteal, posterior tibial, and dorsalis pedis pulses allows for an estimation of the level and degree of obstruction. The ratio of ankle to arm (i.e., tibial and brachial arteries) systolic blood pressure is used to detect significant obstruction, with a ratio of less than 0.9 indicating occlusion. Blood pressures may be taken at various levels on the leg to determine the level of obstruction. A Doppler ultrasound stethoscope may be used for detecting pulses and measuring blood pressure. Ultrasound imaging, magnetic resonance imaging (MRI) arteriography, spiral computed tomographic (CT) arteriography, and invasive contrast angiography also may be used as diagnostic methods.

Treatment includes measures directed at protection of the affected tissues and preservation of functional capacity. Walking (slowly) to the point of claudication usually is encouraged because it increases collateral circulation. Avoidance of injury is important because tissues of extremities affected by atherosclerosis are easily injured and slow to heal. It is important to address other cardiovascular risk factors such as smoking, hypertension, hyperlipidemia, and diabetes. Drug therapy includes antiplatelet therapy (e.g., aspirin or clopidogrel). Other medications that are useful include statins, cilostazol (a vasodilator with antiplatelet properties), and pentoxifylline (an antiplatelet agent that decreases blood viscosity and improves erythrocyte flexibility). Percutaneous or surgical intervention is typically reserved for the patient with disabling claudication or limb-threatening ischemia. Surgery (i.e., femoropopliteal bypass grafting using a section of saphenous vein) may be indicated in severe cases. Percutaneous transluminal angioplasty and stent placement, in which a balloon catheter is inserted into the area of stenosis and the balloon inflated to increase vessel diameter, is another form of treatment.

Thromboangiitis Obliterans

Thromboangiitis obliterans, also known as Buerger disease, is a recurring progressive, nonatherosclerotic inflammation and thrombosis of small and medium-sized arteries and veins, usually the plantar and digital vessels in the foot and lower leg. Arteries in the arm and hand also may be affected. Although primarily an arterial disorder, the inflammatory process often extends to involve adjacent veins and nerves. Usually it is a disease of young, heavy cigarette smokers, occurring before the age of 35. The pathogenesis of Buerger disease remains elusive, though cigarette smoking and in some instances tobacco chewing seem to be involved. It has been suggested that the tobacco may trigger an immune response in susceptible persons or it may unmask a clotting defect, either of which could incite an inflammatory reaction of the vessel wall. It is more common in the Mediterranean region, Middle East, and Asia.

Pain is the predominant symptom of the disorder. It usually is related to distal arterial ischemia. During the early stages of the disease, there is intermittent claudication in the arch of the foot and the digits. In severe cases, pain is present even when the person is at rest.
The impaired circulation increases sensitivity to cold. The peripheral pulses are diminished or absent, and there are changes in the color of the extremity. In moderately advanced cases, the extremity becomes cyanotic when the person assumes a dependent position, and the digits may turn reddish-blue even when in a nondependent position. With lack of blood flow, the skin becomes thin and shiny, hair growth slows, and nail growth is impaired. Chronic ischemia causes thick, malformed nails. If the disease continues to progress, tissues eventually ulcerate and gangrenous changes arise that may necessitate amputation (Fig. 18-8).

Diagnostic methods are similar to those for atherosclerotic disease of the lower extremities. It is essential that the person stop smoking cigarettes or using tobacco. Even passive smoking and nicotine replacement therapy should be eliminated. Other treatment measures are of secondary importance and focus on methods for producing vasodilation and preventing tissue injury. Sympathectomy, or excision of a segment of a sympathetic nerve, may be done to alleviate the vasospastic manifestations of the disease. As the distal arterial tree is occluded, revascularization is not possible. If smoking cessation is not achieved, then the prognosis is generally poor, with amputation of both lower and upper extremities the eventual outcome.

**Raynaud Phenomenon**

Raynaud phenomenon is a functional disorder caused by intense vasospasm of the arteries and arterioles in the fingers and, less often, the toes. The disorder is divided into primary and secondary types.

Primary Raynaud phenomenon is seen in otherwise healthy young women, and it often is precipitated by exposure to cold or by strong emotions and usually is limited to the fingers. The cause of vasospasm in primary Raynaud phenomenon is unknown or idiopathic. Hyperreactivity of the sympathetic nervous system has been suggested as a contributing cause. Secondary Raynaud phenomenon is associated with previous vessel injury, such as frostbite, occupational trauma associated with the use of heavy vibrating tools, collagen diseases, neurologic disorders, chronic arterial occlusive disorders, and drugs, such as bleomycin. Another occupation-related cause is the exposure to alternating hot and cold temperatures such as that experienced by butchers and food preparers. Raynaud phenomenon often is the first symptom of collagen diseases. It occurs in almost all persons with scleroderma and can precede the diagnosis of scleroderma by many years.

The ischemic phase of Raynaud phenomenon is manifested by changes in skin color that progress from pallor to cyanosis, a sensation of cold, and changes in sensory perception, such as numbness and tingling. The color changes usually are first noticed in the tips of the fingers, later moving into one or more of the distal phalanges (Fig. 18-9). After the ischemic episode, there is a period of hyperemia with intense redness, throbbing, and paresthesias. The period of hyperemia is followed by a return to normal color. Primary Raynaud phenomenon attacks typically involve all fingers in a symmetric fashion and are associated with minimal pain, whereas asymmetric finger involvement and intense pain suggest secondary Raynaud phenomenon.

In severe progressive cases, trophic skin changes may develop. The nails may become brittle, and the skin over the tips of the affected fingers may thicken. Ulceration and superficial gangrene of the fingers, although infrequent, may occur.

The initial diagnosis is based on a history of vasospastic attacks supported by other evidence of the disorder. Immersion of the hand in cold water may be used to initiate an attack as an aid to diagnosis. Laser Doppler flow velocimetry may be used to quantify digital blood flow during changes in temperature. Primary Raynaud phenomenon is differentiated from secondary Raynaud...
phenomenon by excluding other disorders known to cause vasospasm.

Treatment measures are directed toward eliminating factors that cause vasospasm and protecting the digits from trauma during an ischemic episode. Abstinence from smoking and protection from cold are priorities. The entire body must be protected from cold, not just the extremities. Avoidance of emotional stress is another important factor in controlling the disorder because anxiety and stress may precipitate a vascular spasm in predisposed persons. Vasoconstrictor medications, such as the decongestants contained in allergy and cold preparations, should be avoided. Treatment with vasodilator drugs may be indicated, particularly if episodes are frequent, because frequency encourages the potential for development of thrombosis and gangrene. A recent advancement in the treatment of Raynaud phenomenon therapy is phosphodiesterase inhibitors (e.g., sildenafil, tadalafil, vardenafil) that produce arterial vasodilation. Surgical interruption of sympathetic nerve pathways (sympathectomy) may be used for persons with severe symptoms.\(^\text{21}\)

**Aneurysms and Dissection**

*Aneurysm* is a pathological outpouching or sac-like dilatation in the wall of a blood vessel usually caused by weakening of the vessel wall. Aneurysms can occur in arteries and veins, but they are most common in the arteries. There are two types of aneurysms.\(^\text{1,2}\) A *true aneurysm* is bounded by a complete vessel wall. The blood in a true aneurysm remains within the vascular compartment. A *false aneurysm* represents a localized dissection or tear in the inner wall of the artery with formation of an extravascular hematoma that causes vessel enlargement (Fig. 18-10B). Unlike true aneurysms, false aneurysms are bounded only by the outer layers of the vessel wall or supporting tissues.

Aneurysms can assume several forms and may be classified according to their cause, location, and anatomic features (Fig. 18-10). A *berry aneurysm* consists of a small, spherical dilation of the vessel at a bifurcation (Fig. 18-10A).\(^\text{1,2}\) This type of aneurysm usually is found in the circle of Willis in the cerebral circulation. A *fusiform aneurysm* involves the entire circumference of the vessel and is characterized by a gradual and progressive dilation of the vessel (Fig. 18-10C). These aneurysms, which vary in diameter (up to 20 cm) and length, may involve the entire ascending and transverse portions of the thoracic aorta or may extend over large segments of the abdominal aorta. A *saccular aneurysm* extends over part of the circumference of the vessel and appears saclike. A *dissecting aneurysm* is a false aneurysm resulting from a tear in the intimal layer of the vessel that allows blood to enter the vessel wall, dissecting its layers to create a blood-filled cavity.

The weakness that leads to aneurysm formation may be caused by a number of factors, including congenital defects, trauma, infections, and atherosclerosis. Once initiated, the aneurysm grows larger as the tension in the vessel increases. This is because the tension in the wall of a vessel is equal to the pressure multiplied by the radius (i.e., tension = pressure × radius; see Chapter 17). In this case, the pressure in the segment of the vessel affected by the aneurysm does not change but remains the same as that of adjacent portions of the vessel. As an aneurysm increases in diameter, the tension in the wall of the vessel increases in direct proportion to its increased size. If untreated, the aneurysm may rupture because of the increased tension. Even an unruptured aneurysm can cause damage by exerting pressure on adjacent structures and interrupting blood flow.

**Aortic Aneurysms**

Aortic aneurysms may involve any part of the aorta: the ascending aorta, aortic arch, descending aorta, thoracoabdominal aorta, or abdominal aorta. Multiple aneurysms may be present. The signs and symptoms of aortic aneurysms depend on the size and location. With both thoracic and abdominal aneurysms, the most dreaded complication is rupture. The likelihood of rupture correlates with increasing aneurysm size. The risk of rupture rises from less than 2% for small abdominal aneurysms
Thoracic aneurysms, which are less common than abdominal aortic aneurysms, may involve one or more aortic segments. Most thoracic aneurysms are due to atherosclerosis. Disorders of connective tissue, such as Marfan syndrome (Chapter 6), are rare causes but of important clinical significance. The majority of thoracic aneurysms are asymptomatic. When symptoms occur, they depend largely on the size and position of the aneurysm. Substernal, back, or neck pain may occur. There may be dyspnea, stridor, or a brassy cough caused by pressure on the trachea. Hoarseness may result from pressure on the recurrent laryngeal nerve, and there may be difficulty swallowing because of pressure on the esophagus. The aneurysm also may compress the superior vena cava, causing distention of neck veins and edema of the face and neck.

Abdominal aortic aneurysms, which are the most common type of aneurysm, usually develop after age 50 and are associated with severe atherosclerosis. They occur more frequently in men than women, and over half of affected persons are hypertensive. Although abdominal aortic aneurysms usually occur in the context of atherosclerosis, it is thought that other factors such as smoking and a genetic predisposition may play a role.

Abdominal aortic aneurysms are most commonly located below the level of the renal artery (>90%) and involve the bifurcation of the aorta and proximal end of the common iliac arteries. They can involve any part of the vessel circumference (saccular) or extend to involve the entire circumference (fusiform). Most abdominal aneurysms are asymptomatic. Because an aneurysm is of arterial origin, a pulsating mass may provide the first evidence of the disorder. Typically, aneurysms larger than 4 cm are palpable. The mass may be discovered during a routine physical examination or the affected person may complain of its presence. Calcification, which frequently exists on the wall of the aneurysm, may be detected during abdominal radiologic examination. Pain may be present and varies from mild midabdominal or lumbar discomfort to severe abdominal and back pain. As the aneurysm expands, it may compress the lumbar nerve roots, causing lower back pain that radiates to the posterior aspects of the legs. The aneurysm may extend to and impinge on the renal, iliac, or mesenteric arteries, or to the vertebral arteries that supply the spinal cord. An abdominal aneurysm also may cause erosion of vertebrae. Stasis of blood favors thrombus formation along the wall of the vessel (Fig. 18-11), and peripheral emboli may develop, causing symptomatic arterial insufficiency.

Diagnostic methods include ultrasonography, echocardiography, CT scans, and MRI. Unruptured aneurysms are generally asymptomatic and are often diagnosed incidentally during clinical examination. Measures to slow aneurysm growth and lower the risk of rupture include risk factor modification. Hypercholesterolemia and high blood pressure should be controlled and smoking discontinued. Surgical repair, in which the involved section of the aorta is replaced with a synthetic graft of woven Dacron, frequently is the treatment of choice.

Aortic Dissection

Aortic dissection (dissecting aneurysm) is an acute, life-threatening condition. It involves hemorrhage into the vessel wall with longitudinal tearing of the vessel wall to form a blood-filled channel (see Fig. 18-10B). Unlike atherosclerotic aneurysms, aortic dissection often occurs without evidence of previous vessel dilatation. The dissection can originate anywhere along the length of the aorta but most often involves the ascending aorta.

Aortic dissection is caused by conditions that weaken or cause degenerative changes in the elastic and smooth muscle layers of the aorta. There are two risk factors that predispose to aortic dissection: hypertension and degeneration of the medial layer of the vessel wall. It is most common in 40- to 60-year-old men with an antecedent history of hypertension. Aortic dissection also is associated with connective tissue diseases, such as 1
Marfan syndrome. It also may occur during pregnancy because of changes in the aorta that occur during this time. Other factors that predispose to dissection are congenital defects of the aortic valve (i.e., bicuspid or unicuspid valve structures) and aortic coarctation.

Aortic dissections are commonly classified into two types, A and B, as determined by the level of dissection. Type A aneurysms, which involve the proximal aorta (ascending aorta only or both the ascending and the descending aorta), are the most common and potentially serious in terms of complications. Type B aneurysms usually begin distal to the subclavian artery and do not involve the ascending aorta. Dissections usually extend distally from the intimal tear. When the ascending aorta is involved, expansion of the wall of the aorta may impair closure of the aortic valve. There also is the risk of aortic rupture with blood moving into the pericardium and compressing the heart. Although the length of dissection varies, it is possible for the abdominal aorta to be involved with progression into the renal, iliac, or femoral arteries. Partial or complete occlusion of the arteries that arise from the aortic arch or the intercostal or lumbar arteries may lead to stroke, ischemic peripheral neuropathy, or impaired blood flow to the spinal cord.

A major symptom of a dissecting aneurysm is the abrupt presence of excruciating pain, described as tearing or ripping. Pain associated with dissection of the ascending aorta frequently is located in the anterior chest, and pain associated with dissection of the descending aorta often is located in the back. In the early stages, blood pressure typically is moderately or markedly elevated. Later, the blood pressure and pulse rate become unobtainable in one or both arms as the dissection disrupts arterial flow to the arms. Syncope, hemiplegia, or paralysis of the lower extremities may occur because of occlusion of blood vessels that supply the brain or spinal cord. Heart failure may develop when the aortic valve is involved.

Diagnosis of aortic dissection is based on history and physical examination. Aortic angiography, transesophageal echocardiography, CT scans, and MRI studies aid in the diagnosis. The treatment of dissecting aortic aneurysm may be medical or surgical. Aortic dissection is a life-threatening emergency; persons with a probable diagnosis are stabilized medically even before the diagnosis is confirmed. Two important factors that participate in propagating the dissection are high blood pressure and the steepness of the pulse wave. Without intervention, these forces produce continued extension of the dissection. Medical treatment therefore focuses on control of hypertension and the use of drugs that lessen the force of systolic blood ejection from the heart. Two commonly used drugs, often given in combination, are an intravenous β-adrenergic blocking drug and sodium nitroprusside (a vasodilator). Adequate pain control is necessary to alleviate anxiety and relieve sympathetic stimulation, which will raise blood pressure. Surgical treatment consists of resection of the involved segment of the aorta and replacement with a prosthetic graft. Despite recent advances in diagnosis and treatment, the mortality rate in acute aortic dissection remains high.
Disorders of Arterial Blood Pressure

The arterial blood pressure reflects the rhythmic ejection of blood from the left ventricle into the aorta. It rises as the left ventricle contracts and falls as it relaxes. In healthy adults, the highest pressure, called the systolic pressure, is ideally less than 120 mm Hg and the lowest pressure, called the diastolic pressure, is less than 80 mm Hg (Fig. 18-12). The difference between the systolic and diastolic pressure is called the pulse pressure (approximately 40 mm Hg). The pulse pressure reflects the pulsatile nature of arterial blood flow. It rises when the stroke volume is increased and falls when the resistance to outflow is decreased. The mean arterial pressure represents the average pressure (approximately 90 to 100 mm Hg) in the arterial system during ventricular contraction and relaxation and is a good indicator of tissue perfusion. Mean arterial pressure can be estimated using the following equation: mean arterial pressure = 1/3 systolic + 2/3 diastolic pressures.

The systolic and diastolic components of blood pressure are determined by cardiac output and total peripheral vascular resistance and can be expressed as the product of the two (blood pressure = cardiac output × total peripheral resistance). The cardiac output is the product of the stroke volume (amount of blood ejected from the heart with each beat) and the heart rate: cardiac output = stroke volume × heart rate. The total peripheral resistance reflects changes in the radius of the arterioles as well as the viscosity or thickness of the blood. The arterioles often are referred to as the resistance vessels because they can selectively constrict or relax to control the resistance to outflow of blood into the capillaries. The body maintains its blood pressure by adjusting the cardiac output to compensate for changes in peripheral vascular resistance, and it changes the peripheral vascular resistance to compensate for changes in cardiac output.

In hypertension and disease conditions that affect blood pressure, changes in blood pressure usually are described in terms of the systolic and diastolic pressures, pulse pressure, and mean arterial pressure. These pressures are influenced by the stroke volume, the rapidity with which blood is ejected from the heart, the elastic properties of the aorta and large arteries and their ability to accept various amounts of blood as it is ejected from the heart, and the properties of the resistance blood vessels that control the runoff of blood into the smaller vessels and capillaries that connect the arterial and venous circulations.

Mechanisms of Blood Pressure Regulation

An adequate systemic arterial pressure is perhaps the single most important requirement for proper functioning of the cardiovascular system. Although different tissues in the body are able to regulate their own blood flow, without sufficient arterial pressure the brain and the heart do not receive adequate blood flow, no matter what adjustments are made in their vascular resistance by local control mechanisms. The mechanisms used to regulate the arterial pressure depend on whether short-term or long-term adaptation is needed (Fig. 18-13).

Short-Term Regulation

The mechanisms for short-term regulation of blood pressure, those acting over seconds or minutes, are intended to correct temporary imbalances in blood pressure, such as occur during physical exercise and changes in body position. These mechanisms also are responsible for maintenance of blood pressure at survival levels during life-threatening situations such as during an acute hemorrhagic incident. The short-term regulation of blood pressure relies mainly on neural and humoral mechanisms, the most rapid of which are the neural mechanisms.

Neural Mechanisms. The neural control of blood pressure is vested in centers that are located in the reticular formation of the medulla and lower third of the pons, where integration and modulation of autonomic nervous system (ANS) responses occur. This area of the brain contains the vasomotor and cardiac control centers and is often collectively referred to as the cardiovascular center. The cardiovascular center transmits parasympathetic impulses to the heart through the vagus nerve and sympathetic impulses to the heart and blood vessels through the spinal cord and peripheral sympathetic nerves. Parasympathetic stimulation of the heart produces a slowing of heart rate, whereas sympathetic
stimulation produces an increase in heart rate and cardiac contractility. Blood vessels are mainly innervated by the sympathetic nervous system, which produces constriction of the small arteries and arterioles with a resultant increase in peripheral vascular resistance.

The ANS control of blood pressure is mediated through both intrinsic and extrinsic cardiovascular reflexes, as well as higher neural control centers. The intrinsic reflexes, including the baroreceptor and chemoreceptor reflexes, respond to stimuli originating from within the cardiovascular system and are essential to rapid and short-term regulation of blood pressure. The extrinsic reflexes mediate the cardiovascular response to stimuli originating from outside the cardiovascular system. They mediate blood pressure responses associated with factors such as pain and temperature changes. The neural pathways for these reactions are more diffuse, and their responses are less consistent than those of the intrinsic reflexes. Many of these responses are channeled through the hypothalamus, which plays an essential role in the control of sympathetic nervous system responses.

The baroreceptors are pressure-sensitive receptors located in the walls of blood vessels and the heart. They can be classified as high-pressure and low-pressure baroreceptors based on the type of blood vessel in which they are located. The high-pressure carotid and aortic baroreceptors are located in strategic position between the heart and the brain (Fig. 18-14). They respond to changes in the stretch of the vessel wall by sending impulses to cardiovascular centers in the brain stem to effect appropriate changes in heart rate and vascular smooth muscle tone. For example, the fall in blood pressure that occurs on moving from the lying to the standing position produces a decrease in the stretch of the baroreceptors with a resultant increase in heart rate and sympathetically induced vasoconstriction that produces an increase in peripheral vascular resistance. The low-pressure baroreceptors, which are located in large systemic veins, pulmonary vessels, and walls of the right atrium and ventricles of the heart, have both circulatory and renal effects. They produce changes in antidiuretic hormone (ADH) secretion, resulting in profound effects on the retention of salt and water.

The arterial chemoreceptors are cells that monitor the oxygen, carbon dioxide, and hydrogen ion content of the blood. They are located in the carotid bodies, which lie in the bifurcation of the two common carotids, and in the aortic bodies of the aorta (see Fig. 18-14). Because of their location, these chemoreceptors are always in close contact with the arterial blood. Although the main function of the chemoreceptors is to regulate ventilation, they also communicate (text continues on page 423)
The arterial blood pressure, which is the force that moves blood through the arterial system, reflects the intermittent contraction and relaxation of the left ventricle. It is determined by (1) the properties of the arterial system and the factors that maintain (2) the systolic and (3) the diastolic components of the blood pressure. These factors include the blood volume, elastic properties of the blood vessels, cardiac output, and peripheral vascular resistance.

1. **Arterial Pressure Regulation.** The arterial blood pressure represents the force that distributes blood throughout the capillaries of the body. The aorta and large arteries have large amounts of elastin in their walls that allow them to stretch and store energy during ventricular systole and recoil during diastole. The arterioles, which are the terminal components of the arterial system, serve as resistance vessels that regulate blood pressure by controlling the distribution of blood to the capillary beds. The elastic properties of the aorta and large arteries, coupled with the high resistance properties of the arterioles, allow the arterial system to act as a filter that converts the intermittent flow generated by the heart to virtually steady flow in the capillaries. The low-pressure venous system collects blood from the capillaries and returns it to the heart as a means of maintaining the cardiac output needed to sustain the arterial pressure.

2. **Systolic Pressure.** The systolic blood pressure reflects the amount of blood (stroke volume) that is ejected from the heart with each beat, the rate and force with which it is ejected, and the elasticity or compliance of the aorta and large arteries. The blood that is ejected from the heart during systole does not move directly through the circulation. Instead, a substantial fraction of the stroke volume is stored in large arteries. Because the walls of these vessels are elastic, they can be stretched to accommodate a large volume of blood without an appreciable change in pressure. The systolic pressure often increases with aging as the aorta and large arteries lose their elasticity and become more rigid.
Diastolic Pressure. The diastolic blood pressure reflects the closure of the aortic valve, the energy that has been stored in the elastic fibers of the large arteries during systole, and the resistance to flow through arterioles into the capillaries. Closure of the aortic valve at the onset of diastole and recoil of the elastic fibers in the aorta and large arteries continue to drive the blood forward, even though the heart is not pumping. These effects, largely restricted to the elastic vessels, convert the discontinuous systolic flow in the ascending aorta into a continuous flow in the peripheral arteries.

Humoral Mechanisms. The humoral control of blood pressure relies on a number of mechanisms, including the renin-angiotensin-aldosterone system and vasopressin. Other humoral substances, such as epinephrine, a sympathetic neurotransmitter released from the adrenal gland, have the effect of directly producing an increase in blood pressure because of the hypoxemia that occurs during the apneic periods.

Angiotensin II functions in both the short- and long-term regulation of blood pressure. It is a strong vasoconstrictor, particularly of arterioles and, to a lesser extent, of veins. Constriction of the arterioles increases the peripheral vascular resistance, thereby contributing to the short-term regulation of blood pressure. Angiotensin II also reduces sodium excretion by increasing sodium reabsorption by the proximal tubules of the kidney. A second major function of angiotensin II, stimulation of aldosterone secretion from the adrenal gland, contributes to the long-term regulation of blood pressure by increasing salt and water retention by the kidney.
Vasopressin, also known as antidiuretic hormone (ADH), is released from the posterior pituitary gland in response to decreases in blood volume and blood pressure, an increase in the osmolality of body fluids, and other stimuli. The antidiuretic actions of vasopressin are discussed in Chapter 8. Vasopressin has a direct vasoconstrictor effect, particularly on the vessels of the splanchnic circulation that supplies the abdominal viscera. However, long-term increases in vasopressin cannot maintain an increase in blood pressure, and vasopressin does not enhance hypertension produced by sodium-retaining hormones or other vasoconstricting substances. It has been suggested that vasopressin plays a permissive role in hypertension through its water-retaining properties or as a neurotransmitter that serves to modify ANS function.

**Long-Term Regulation**

Long-term mechanisms, which are responsible for the hourly, daily, weekly, and monthly regulation of blood pressure, are largely vested in the kidneys and their role in regulation of extracellular fluid volume. These mechanisms function largely by regulating the blood pressure around an equilibrium point, which represents the normal pressure for a given individual. Accordingly, when the body contains too much extracellular fluid, the arterial pressure rises and the rate at which water (i.e., pressure diuresis) and sodium (i.e., pressure natriuresis) are excreted by the kidney is increased. When blood pressure returns to its equilibrium point, water and sodium excretion return to normal. A fall in blood pressure due to a decrease in extracellular fluid volume has the opposite effect. In persons with hypertension, renal control mechanisms are often altered such that the equilibrium point for blood pressure regulation is maintained at a higher level of sodium and water elimination.

There are two general mechanisms by which an increase in fluid volume can elevate blood pressure—
Hypertension

Hypertension, or high blood pressure, is probably the most common of all health problems in adults and is the leading risk factor for cardiovascular disorders. It affects approximately 50 million individuals in the United States and approximately 1 billion persons worldwide. Hypertension is more common in younger men compared with younger women in the United States, in blacks compared with whites, in persons from lower socioeconomic groups, and in older persons. Men have higher blood pressures than women up until the time of menopause, at which point women quickly lose their protection. The prevalence of hypertension increases with age. Thus, the problem of hypertension can be expected to become even greater with the aging of the “baby-boomer” population.

Hypertension commonly is divided into the categories of primary and secondary hypertension. In primary, or essential, hypertension, the chronic elevation of blood pressure occurs without evidence of other disease conditions. Primary hypertension accounts for approximately 90% to 95% of all cases of hypertension. In secondary hypertension, the elevation of blood pressure results from some other disorder, such as kidney disease.

Hypertension is diagnosed when the systolic pressure is consistently elevated above 140 mm Hg, or the diastolic blood pressure is 90 mm Hg or higher. Hypertension is further divided into stages 1 and 2 based on systolic and diastolic blood pressure measurements (Table 18-4).

### Measurement of Blood Pressure

The diagnosis of blood pressure disorders is facilitated by blood pressure measurements, which should be obtained with a well-calibrated sphygmomanometer. Accuracy of the measurements requires that persons taking the pressure are adequately trained in blood pressure measurement, the equipment is properly maintained, and the cuff bladder is appropriate for the upper arm measurement, the equipment is properly maintained, and when the flow is deficient, the local vessels dilate. In situations of increased extracellular fluid volume and a resultant increase in cardiac output, all of the tissues of the body are exposed to the same increase in flow. This results in a generalized constriction of arterioles and an increase in peripheral vascular resistance and blood pressure.

The role that the kidneys play in long-term regulation of blood pressure is emphasized by the fact that many antihypertensive medications produce their blood pressure-lowering effects by increasing sodium and water elimination.

### TABLE 18-4 Classification of Blood Pressure for Adults and Recommendations for Follow-up

*Initial blood pressure: If systolic and diastolic categories are different, follow recommendations for shorter follow-up (e.g., 160/86 mm Hg should be evaluated or referred to source of care within 1 month).

†Follow-up blood pressure: Modify the scheduling of follow-up according to reliable information about past blood pressure measurements, other cardiovascular risk factors, or target-organ disease.

‡Provide advice about lifestyle modification.

A systolic pressure of less than 120 mm Hg and a diastolic pressure of less than 80 mm Hg are normal, and systolic pressures between 120 and 139 mm Hg and diastolic pressures between 80 and 89 mm Hg are considered prehypertensive. For adults with diabetes mellitus, the blood pressure goal has been lowered to less than 130/80 mm Hg. A single elevated blood pressure reading is not sufficient to make a diagnosis of hypertension. Rather, the diagnosis depends on a series of measurements, since readings can vary from time to time.

Systolic hypertension has been defined as a systolic pressure of 140 mm Hg or greater and a diastolic pressure of less than 90 mm Hg. Historically, diastolic hypertension was thought to confer a greater risk for cardiovascular events than systolic hypertension. However, there is mounting evidence that elevated systolic blood pressure is at least as important, if not more so. There are two aspects of systolic hypertension that confer increased risk for cardiovascular events—one is the actual elevation in systolic pressure and the other is the disproportionate rise in pulse pressure. Elevated pressures during systole favor the development of left ventricular hypertrophy, increased myocardial oxygen demands, and eventual left heart failure. At the same time, the absolute or relative lowering of diastolic pressure is a limiting factor in coronary perfusion because coronary perfusion is greatest during diastole. Elevated pulse pressures produce greater stretch of arteries, causing damage to the elastic elements of the vessel and thus predisposing to aneurysms and development of the intimal damage that leads to atherosclerosis and thrombosis.

**Primary (Essential) Hypertension**

Essential (primary) hypertension is the term applied to hypertension for which no cause can be identified. Although the cause or causes of essential hypertension are largely unknown, both constitutional and lifestyle factors have been implicated, either singly or collectively, as contributing factors.

**Constitutional Risk Factors.** Constitutional risk factors include family history of hypertension, race, and age-related increases in blood pressure. The inclusion of heredity as a contributing factor in the development of hypertension is supported by the fact that hypertension is seen most frequently among persons with a family history of hypertension. The inherited predisposition does not seem to rely on other risk factors, but when they are present, the risk apparently is additive. Hypertension not only is more prevalent in blacks than whites, but also is more severe, tends to occur earlier, and often is not treated early enough or aggressively enough. Blacks also tend to experience greater cardiovascular and renal damage at any level of pressure.

Maturation and growth are known to cause predictable increases in blood pressure. For example, the arterial blood pressure in the newborn is approximately 50 mm Hg systolic and 40 mm Hg diastolic. Sequentially, blood pressure increases with physical growth from a value of 78 mm Hg systolic at 10 days of age to 120 mm Hg at the end of adolescence. Diastolic pressure increases until 50 years of age and then declines from the sixth decade onward, whereas systolic blood pressure continues to rise with age.

Another factor that is thought to contribute to the development of hypertension is insulin resistance and the hyperinsulinemia that occurs in persons with diabetes. This clustering of cardiovascular risk factors has been named the insulin resistance syndrome, cardiometabolic syndrome, or metabolic syndrome (see Chapter 33).

**Lifestyle Risk Factors.** Lifestyle factors can contribute to the development of hypertension by interacting with other risk factors. These lifestyle factors include high salt intake, excessive calorie intake and obesity, and excessive alcohol consumption. Although stress can raise blood pressure acutely, there is less evidence linking it to chronic elevations in blood pressure. Smoking and a diet high in saturated fats and cholesterol, although not identified as primary risk factors for hypertension, are independent risk factors for coronary heart disease and should be avoided.

Increased sodium intake has long been suspected as an etiologic factor in the development of hypertension, although just how it contributes to the development of hypertension is still unclear. It may be that sodium causes an elevation in blood volume, increases the sensitivity of cardiovascular or renal mechanisms to sympathetic nervous system influences, or exerts its effect through some other mechanism such as the renin-angiotensin-aldosterone system. Regardless of the mechanism, numerous studies have shown that a reduction in salt intake can lower blood pressure.

Excessive weight commonly is associated with hypertension. It has been suggested that fat distribution might be a more critical indicator of hypertension risk than actual overweight. The waist-to-hip ratio commonly is used to differentiate central or upper body obesity, with fat deposits located in the abdomen and visceral fat, from peripheral or lower body obesity, with fat deposits in the buttocks and legs (see Chapter 10). Abdominal or visceral fat seems to be more insulin resistant than fat deposited over the buttocks and legs. The mechanisms involved in obesity-related hypertension are complex and involve multiple organ systems. They include increased sympathetic nervous system activation, increased activity of the angiotensin-aldosterone system, and insulin resistance. Recent evidence indicates that leptin, an adipocyte-derived hormone, may represent a link between adiposity and increased cardiovascular sympathetic activity. Besides its effect on appetite and metabolism, leptin is thought to act on the hypothalamus to increase blood pressure through activation of the sympathetic nervous system. High levels of circulating free fatty acids in obese people also appear to participate in activation of the sympathetic nervous system. There is also research supporting activation of the renin-angiotensin-aldosterone system by adipocyte-derived...
angiotensinogen and the ability of adipose tissue to increase aldosterone levels through the production of factors that induce aldosterone production.\textsuperscript{40} Regular alcohol consumption plays a role in the development of hypertension.\textsuperscript{41} The effect is seen with different types of alcoholic drinks, in men and women, and in a variety of ethnic groups. One of the first reports of a link between alcohol consumption and hypertension came from the Oakland-San Francisco Kaiser Permanente Medical Care Program study that correlated known drinking patterns and blood pressure levels of 84,000 persons.\textsuperscript{42} This study revealed that the regular consumption of three or more drinks per day increases the risk for hypertension. Systolic pressures were more markedly affected than diastolic pressures. Blood pressure may improve or return to normal when alcohol consumption is decreased or eliminated.

**Secondary Hypertension**

Secondary hypertension, which describes an elevation in blood pressure due to another disease condition, accounts for 5\% to 10\% of hypertension cases.\textsuperscript{43} Unlike essential hypertension, many of the conditions causing secondary hypertension can be corrected or cured by surgery or specific medical treatment. Secondary hypertension tends to be seen in persons younger than 30 and older than 50 years of age. Among the most common causes of secondary hypertension are kidney disease (i.e., renovascular hypertension), adrenal cortical disorders, pheochromocytoma, and coarctation of the aorta. Oral contraceptive agents are also implicated as a cause of secondary hypertension. Cocaine, amphetamines, and other illicit drugs can also cause a significant elevation in blood pressure, as can sympathomimetic agents (decongestants, anorectics), erythropoietin, and licorice (including some chewing tobacco with licorice as an ingredient). Obstructive sleep apnea is an independent risk factor for secondary hypertension.

**Renal Hypertension.** With the dominant role that the kidney assumes in blood pressure regulation, it is not surprising that the largest single cause of secondary hypertension is renal disease. Most acute kidney disorders result in decreased urine formation, retention of salt and water, and hypertension. This includes acute glomerulonephritis, acute renal failure, and acute urinary tract obstruction. Hypertension also is common among persons with chronic pyelonephritis, polycystic kidney disease, diabetic nephropathy, and end-stage kidney disease, regardless of cause. In older persons, the sudden onset of secondary hypertension often is associated with atherosclerotic disease of the renal blood vessels.

Renovascular hypertension refers to hypertension caused by reduced renal blood flow and activation of the renin-angiotensin-aldosterone mechanism. It is the most common cause of secondary hypertension, accounting for 1\% to 2\% of all cases of hypertension.\textsuperscript{44} The reduced renal blood flow that occurs with renovascular disease causes the affected kidney to release excessive amounts of renin, increasing circulating levels of angiotensin II. Angiotensin II, in turn, acts as a vasoconstrictor to increase peripheral vascular resistance and as a stimulus for increased aldosterone levels and sodium retention by the kidney. One or both of the kidneys may be affected. When the renal artery of only one kidney is involved, the unaffected kidney is subjected to the detrimental effects of the elevated blood pressure.

There are two major types of renovascular disease: (1) atherosclerosis of the proximal renal artery, and (2) fibromuscular dysplasia, a noninflammatory vascular disease that affects the renal arteries and branch vessels.\textsuperscript{44,45} Atherosclerotic stenosis of the renal artery accounts for 70\% to 90\% of cases and is seen most often in older persons, particularly those with diabetes, aortoiliac occlusive disease, coronary artery disease, or hypertension.\textsuperscript{44} Fibromuscular dysplasia is more common in women and tends to occur in younger age groups, often persons in their third decade.\textsuperscript{35} Genetic factors may be involved, and the incidence tends to increase with risk factors such as smoking and hyperlipidemia.

Diagnostic tests for renovascular hypertension may include studies to assess overall renal function, physiologic studies to assess the renin-angiotensin system, perfusion studies to evaluate renal blood flow, and imaging studies to identify renal artery stenosis.\textsuperscript{44} Renal arteriography remains the definitive test for identifying renal artery disease. Duplex ultrasonographic scanning, contrast-enhanced CT scans, and magnetic resonance angiography (MRA) are other tests that can be used to screen for renovascular hypertension.\textsuperscript{44}

The goal of treatment for renal hypertension is to control the blood pressure and stabilize renal function. Angioplasty or revascularization has been shown to be an effective long-term treatment for the disorder. Angiotensin-converting enzyme (ACE) inhibitors may be used in medical management of renal stenosis. However, these agents must be used with caution because of their ability to produce marked hypotension and renal dysfunction.

**Disorders of Adrenocortical Hormones.** Increased levels of adrenocortical hormones also can give rise to hypertension. Primary hyperaldosteronism (excess production of aldosterone due to adrenocortical hyperplasia or adenoma) and excess levels of glucocorticoid (Cushing disease or syndrome) tend to raise the blood pressure\textsuperscript{30,46} (see Chapter 32). These hormones facilitate sodium and water retention by the kidney; the hypertension that accompanies excessive levels of either hormone probably is related to this factor. For patients with primary hyperaldosteronism, a sodium-restricted diet often produces a reduction in blood pressure. Because aldosterone acts on the distal renal tubule to increase sodium absorption in exchange for potassium elimination in the urine, persons with hyperaldosteronism usually have decreased potassium levels. Screening tests for primary hyperaldosteronism involve the determination of plasma aldosterone concentration and plasma renin activity. Computed tomography and magnetic resonance imaging scans are used to localize the lesion. Persons with solitary adenomas are usually treated surgically. Potassium-sparing
diuretics, such as spironolactone, which is an aldosterone antagonist, often are used in the medical management of persons with bilateral hyperplasia.

**Pheochromocytoma.** Pheochromocytomas are rare catecholamine-secreting tumors of adrenal chromaffin cells. They can occur at any age, including infancy, but are uncommon after 60 years of age. They can occur as part of hereditary syndromes, but most are sporadic. Of the sporadic tumors, about 10% are malignant.

Like adrenal medullary cells, the tumor cells of a pheochromocytoma produce and secrete the catecholamines epinephrine and norepinephrine. The hypertension that develops is a result of the massive release of these catecholamines. Their release may be paroxysmal rather than continuous, causing periodic episodes of headache, excessive sweating, and palpitations. Headache is the most common symptom and can be quite severe. Nervousness, tremor, facial pallor, weakness, fatigue, and weight loss occur less frequently. Marked variability in blood pressure between episodes is typical.

Diagnostic methods include urinary and blood assays for catecholamines and their metabolites and CT and MRI studies to locate tumors and possible metastases. Surgical removal of the tumor or tumors is the treatment of choice. If the tumor is not resectable, treatment with drugs that block the action or synthesis of catecholamines can be used. When correctly diagnosed and treated, most pheochromocytomas are curable. When they are undiagnosed or improperly treated, they can be fatal.

**Coarctation of the Aorta.** Coarctation of the aorta or aortic coarctation is a congenital condition in which a narrowing or constriction of the lumen of the aorta exists. In the adult form, narrowing most commonly occurs just distal to the origin of the subclavian (see Chapter 19). The ejection of a large stroke volume into a narrowed aorta results in an increase in systolic blood pressure and blood flow to the upper part of the body. Blood pressure in the lower extremities may be normal, although it frequently is low. It has been suggested that the increase in cardiac output and maintenance of the blood pressure to the lower part of the body is achieved through the renin-angiotensin-aldosterone mechanism in response to a decrease in renal blood flow.

Coarctation of the aorta should be considered as a cause of secondary hypertension in young people with an elevation in blood pressure. Because the aortic capacity is diminished in coarctation of the aorta, there usually is a marked increase in pressure (measured in the arms) during exercise, when the stroke volume and heart rate are exaggerated. Pulse pressure in the legs almost always is narrowed, and the femoral pulses are weak. It is important that blood pressure be measured in both arms and one leg when coarctation of the aorta is suspected. A pressure in the arms 20 mm Hg or more higher than in the legs suggests coarctation of the aorta.

Treatment consists of surgical repair or balloon angioplasty. Although balloon angioplasty is a relatively recent form of treatment, it has been used in children and adults with good results. However, there are few data on long-term follow-up.

**Oral Contraceptive Drugs.** The use of oral contraceptive pills is probably the most common cause of secondary hypertension in young women. Women taking oral contraceptives should have their blood pressure taken regularly. The cause of the increased blood pressure is largely unknown, although it has been suggested that the probable cause is volume expansion because both estrogens and synthetic progestational agents used in oral contraceptive pills cause sodium retention. Various contraceptive drugs contain different amounts and combinations of estrogen and progestational agents, and these differences may contribute to the occurrence of hypertension in some women but not others. Fortunately, the hypertension associated with oral contraceptives usually disappears after the drug has been discontinued, although it may take as long as 3 months for this to occur. However, in some women the blood pressure may not return to normal, and they may be at risk for development of hypertension. The risk for hypertension-associated cardiovascular complications is found primarily in women older than 35 years of age and in those who smoke.

**Target-Organ Damage**

Hypertension is typically an asymptomatic disorder. When symptoms do occur, they are usually related to the long-term effects of hypertension on other organ systems, termed target organs, such as the kidneys, heart, eyes, and blood vessels (Chart 18-2). The excess morbidity and mortality related to hypertension is progressive over the whole range of systolic and diastolic pressures, with target-organ damage varying markedly among persons with similar levels of hypertension.

Hypertension is a major risk factor for atherosclerosis; it predisposes to all major atherosclerotic cardiovascular disorders, including coronary heart disease, heart failure, stroke, and peripheral artery disease. The risk for coronary artery disease and stroke depends to a great extent on other risk factors, such as obesity, smoking, and elevated cholesterol levels. In clinical

trials, antihypertensive therapy has been associated with reductions in stroke incidence averaging 30% to 40%; myocardial infarction, 20% to 25%; and heart failure, more than 50%.29

Hypertension increases the workload of the left ventricle by increasing the pressure against which the heart must pump as it ejects blood into the systemic circulation.30 As the workload of the heart increases, the left ventricular wall hypertrophies to compensate for the increased pressure work. Despite its adaptive advantage, left ventricular hypertrophy is a major risk factor for coronary heart disease, cardiac arrhythmias, sudden death, and congestive heart failure. Hypertensive left ventricular hypertrophy regresses with therapy. Regression is most closely related to systolic pressure reduction and does not appear to reflect the particular type of medication used.

Chronic hypertension can lead to nephrosclerosis, a common cause of chronic kidney disease (see Chapter 25). Hypertensive kidney disease is more common in blacks than whites. Hypertension also plays an important role in accelerating the course of other types of kidney disease, particularly diabetic nephropathy. Because of the risk for diabetic nephropathy, the American Diabetes Association recommends that persons with diabetes maintain their blood pressure at levels less than 130/80 mm Hg31 (see Chapter 33).

Dementia and cognitive impairment occur more commonly in persons with hypertension.29 Hypertension, particularly systolic hypertension, is a major risk factor for ischemic stroke and intracerebral hemorrhage29 (see Chapter 37). Narrowing and sclerosis of small penetrating arteries in the subcortical regions of the brain are common findings on autopsy in persons with chronic hypertension.29 These changes are thought to contribute to hypoperfusion, loss of autoregulation of blood flow, and impairment of the blood–brain barrier, ultimately leading to subcortical white matter demyelination. Magnetic resonance imaging studies have revealed more extensive white matter lesions and brain atrophy in hypertensive versus normotensive persons. Effective antihypertensive therapy strongly reduces the risk of development of significant white matter changes; however, existing white matter changes, once established, do not appear to be reversible.29

**Diagnosis and Treatment**

Unlike disorders of other body systems that are diagnosed by methods such as radiography and tissue examination, hypertension and other blood pressure disorders are determined by repeated blood pressure measurements. Laboratory tests, x-ray films, and other diagnostic tests usually are done to exclude secondary hypertension and determine the presence or extent of target-organ damage.

The increased availability of hypertensive screening clinics provides one of the best means for early detection. Because blood pressure in many individuals is highly variable, unless the pressure is extremely elevated or associated with symptoms it should be measured on different occasions over a period of several months before a diagnosis of hypertension is made.

Ambulatory and self/home measurement of blood pressure may provide valuable information outside the clinician’s office regarding a person’s blood pressure and response to treatment. Self/home measurement can help detect “white coat hypertension,” a condition in which the blood pressure is consistently elevated in the health care provider’s office but normal at other times; it can also be used to assess the response to treatment measure, motivate adherence to treatment regimes, and eventually reduce health care costs.29,30

The main objective for treatment of hypertension is to achieve and maintain arterial blood pressure below 140/90 mm Hg, with the goal of preventing morbidity and mortality. In persons with hypertension and diabetes or renal disease, the goal is blood pressure below 130/80 mm Hg. Treatment methods include lifestyle modification and, when necessary, pharmacologic agents to achieve and maintain blood pressure within an optimal range.29

**Lifestyle Modification.** Lifestyle modification has been shown to reduce blood pressure, enhance the effects of antihypertensive drug therapy, and prevent cardiovascular risk. Major lifestyle modifications shown to lower blood pressure include weight reduction in persons who are overweight or obese, regular physical activity, reduction of dietary sodium intake, and limitation of alcohol intake to no more than two drinks per day for most men and one drink for women and persons of lighter weight.38

**Pharmacologic Treatment.** The decision to initiate pharmacologic treatment is based on the severity of the hypertension, the presence of target-organ disease, and the existence of other conditions and risk factors.29,48

Drug selection is based on the stage of hypertension. Among the drugs used in the treatment of hypertension are diuretics, β-adrenergic receptor inhibitors, ACE inhibitors or angiotensin II receptor blockers, calcium channel blockers, central α2-adrenergic agonists, α1-adrenergic receptor blockers, and vasodilators.

The physiologic mechanisms whereby the different antihypertension drugs produce a reduction in blood pressure differ among agents. Diuretics lower blood pressure initially by decreasing vascular volume (by suppressing renal reabsorption of sodium and increasing sodium and water excretion) and cardiac output. With continued therapy, a reduction in peripheral resistance becomes a major mechanism of blood pressure reduction. The β-adrenergic receptor inhibitors are effective in treating hypertension because they decrease heart rate, cardiac output, and renin release by the kidney. The ACE inhibitors act by inhibiting the conversion of angiotensin I to angiotensin II, thus decreasing angiotensin II levels and reducing its effect on vasoconstriction, aldosterone levels, intrarenal blood flow, and glomerular filtration rate. The calcium channel blockers decrease peripheral vascular resistance by inhibiting the movement of calcium into arterial smooth muscle cells. The centrally
is associated with autoregulatory changes in coronary artery, cerebral artery, and kidney blood flow, care should be taken to avoid excessively rapid decreases in blood pressure, which can lead to hypoperfusion and ischemic injury. Therefore, the goal of initial treatment measures should be to obtain a partial reduction in blood pressure to a safer, less critical level, rather than to normotensive levels.

**Hypertension in Special Populations**

### High Blood Pressure in Pregnancy

Hypertensive disorders complicate 5% to 10% of pregnancies and remain a major cause of maternal and neonatal morbidity and mortality in the United States and worldwide. In 2000, the National Institutes of Health Working Group on High Blood Pressure in Pregnancy published a revised classification system for high blood pressure in pregnancy that included preeclampsia–eclampsia, gestational hypertension, chronic hypertension, and preeclampsia superimposed on chronic hypertension. Most adverse events are attributable directly to the preeclampsia syndrome, characterized by new-onset hypertension with proteinuria that develops in the last half of pregnancy. Women with chronic hypertension can also manifest adverse events.

**Preeclampsia–Eclampsia.** Preeclampsia–eclampsia is a pregnancy-specific syndrome with both maternal and fetal manifestations. It is defined as an elevation in blood pressure (systolic blood pressure $>140$ mm Hg or diastolic blood pressure $>90$ mm Hg) and proteinuria ($\geq 300$ mg in 24 hours) developing after 20 weeks of gestation. The presence of a systolic blood pressure of $160$ mm Hg or higher or a diastolic pressure of $110$ mm Hg or higher, proteinuria greater than $2$ g in 24 hours, serum creatinine greater than $1.2$ mg/dL, platelet counts less than $100,000$ cells/mm$^3$, elevated liver enzymes (alanine aminotransferase [ALT] or aspartate aminotransferase [AST]), persistent headache or cerebral or visual disturbances, and persistent epigastric pain serve to reinforce the diagnosis. Preeclampsia occurs primarily during first pregnancies and during subsequent pregnancies in women with multiple fetuses, diabetes mellitus, collagen vascular disease, or underlying kidney disease. It is also associated with a condition called a hydatidiform mole, an abnormal mass of cysts that develops due to an abnormal pregnancy caused by a pathologic ovum. Women with chronic hypertension who become pregnant have an increased risk for preeclampsia and adverse neonatal outcomes, particularly when associated with proteinuria early in pregnancy. Eclampsia is the occurrence, in a woman with preeclampsia, of seizures that cannot be attributed to other causes.

The cause of pregnancy-induced hypertension is largely unknown. Considerable evidence suggests that the placenta is a key factor in all the manifestations because delivery is the only definitive cure for this disease. Pregnancy-induced hypertension is thought to
involve a decrease in placental blood flow leading to the release of toxic mediators that alter the function of endothelial cells in blood vessels throughout the body, including those of the kidney, brain, liver, and heart. The endothelial changes result in signs and symptoms of preeclampsia and, in more severe cases, of intravascular clotting and hyperperfusion of vital organs.

**Gestational Hypertension.** Gestational hypertension is defined as the development of new hypertension without proteinuria occurring after 20 weeks' gestation, which resolves within 12 weeks of termination of the pregnancy. The final diagnosis of gestational hypertension is made only postpartum. Women with gestational hypertension progress to preeclampsia in 15% to 45% of cases and often require early delivery. Surveillance for development of preeclampsia and close fetal monitoring are recommended.

**Chronic Hypertension.** Chronic hypertension in pregnancy is considered to be hypertension that is unrelated to the pregnancy. It is defined as a blood pressure of 140/90 or greater on two separate occasions before 20 weeks' gestation or persisting beyond 12 weeks postpartum. In women with chronic hypertension, blood pressure often decreases in early pregnancy and increases during the last trimester (3 months) of pregnancy, resembling preeclampsia. Consequently, women with undiagnosed chronic hypertension who do not present for medical care until the later months of pregnancy may be incorrectly diagnosed as having preeclampsia.

**Preeclampsia Superimposed on Chronic Hypertension.** Women with chronic hypertension are at increased risk for the development of preeclampsia, in which case the prognosis for the mother and fetus tends to be worse than for either condition alone. Superimposed preeclampsia should be considered in women with hypertension before 20 weeks of gestation who develop new-onset proteinuria, women with hypertension and proteinuria before 20 weeks of gestation, women with previously well-controlled hypertension who experience a sudden increase in blood pressure, and women with chronic hypertension who develop thrombocytopenia or an increase in serum ALT or AST to abnormal levels.

**Diagnosis and Treatment.** Early prenatal care is important in the detection of high blood pressure during pregnancy. It is recommended that all pregnant women, including those with hypertension, refrain from alcohol and tobacco use. A low-sodium diet usually is not recommended during pregnancy because pregnant women with hypertension tend to have lower plasma volumes than normotensive pregnant women, and because the severity of hypertension may reflect the degree of volume contraction. The exception is women with preexisting hypertension who have been following a low-sodium diet.

In women with preeclampsia, delivery of the fetus is curative. The timing of delivery becomes a difficult decision in preterm pregnancies because the welfare of both the mother and the infant must be taken into account. Bed rest is a traditional therapy. Antihypertensive medications, when required, must be carefully chosen because of their potential effects on uteroplacental blood flow and on the fetus. For example, the ACE inhibitors can cause injury and even death of the fetus when given during the second and third trimesters of pregnancy.

**High Blood Pressure in Children and Adolescents**

High blood pressure in children and adolescents is a growing health problem. In persons 3 to 18 years of age, the prevalence of hypertension is 3% to 4% in the United States. This may be due in part to increasing prevalence of obesity and other lifestyle factors, such as decreased physical activity and increased intake of foods that are high in calories and sodium content.

**Normative Values.** Blood pressure is known to increase from infancy to late adolescence. The average systolic pressure at 1 day of age is approximately 70 mm Hg and increases to approximately 85 mm Hg at 1 month of age. Systolic blood pressure continues to increase with physical growth to about 120 mm Hg at the end of adolescence. During the preschool years, blood pressure begins to follow a pattern that tends to be maintained as the child grows older. This pattern continues into adolescence and adulthood, suggesting that the roots of primary hypertension have their origin early in life. A familial influence on blood pressure often can be identified early in life. Children of parents with high blood pressure tend to have higher blood pressures than do children with normotensive parents.

Blood pressure norms for children are based on age-, height-, and gender-specific percentiles (Table 18-5). The National High Blood Pressure Education Program (NHBPEP) first published its recommendations in 1977. The fourth task force report (revised in 2005) recommended classification of blood pressure as normal (systolic or diastolic) for age, height, and gender into four categories: normal (less than the 90th percentile), high normal (between the 90th and 95th percentiles), stage 1 hypertension (between the 95th and 99th percentiles plus 5 mm Hg), and stage 2 hypertension (greater than the 99th percentile plus 5 mm Hg). The height percentile is determined using the revised Centers for Disease Control and Prevention (CDC) growth charts. As with the seventh report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) of the National Institutes of Health, high normal is now considered to be “prehypertensive” and is an indication for lifestyle modification. Children and adolescents with hypertension should be evaluated for target-organ damage.

**Pathogenesis and Risk Factors.** Secondary hypertension is the most common form of high blood pressure in infants and children. In later childhood and adolescence, essential hypertension is more common. Approximately 75% to 80% of secondary hypertension in children is caused by kidney abnormalities. Coarctation of the
aorta is another cause of hypertension in children and adolescents. Endocrine causes of hypertension, such as pheochromocytoma and adrenal cortical disorders, are rare. Hypertension in infants is most commonly associated with high umbilical catheterization and renal artery obstruction caused by thrombosis. Most cases of essential hypertension are associated with obesity or a family history of hypertension.

A number of drugs of abuse, therapeutic agents, and toxins also may increase blood pressure. Alcohol should be considered as a risk factor in adolescents. Oral contraceptives may be a cause of hypertension in adolescent girls. The nephrotoxicity of the drug cyclosporine, an immunosuppressant used in transplant therapy, may cause hypertension in children (and adults) after bone marrow, heart, kidney, or liver transplantation. The coadministration of corticosteroid drugs appears to increase the incidence of hypertension.

**Diagnosis and Treatment.** Children 3 years of age through adolescence should have their blood pressure taken once each year. The auscultatory method using a cuff of an appropriate size for the child’s upper arm is recommended. Repeated measurements over time, rather than a single isolated determination, are required to establish consistent and significant observations. Children with high blood pressure should be referred for medical evaluation and treatment as indicated. Treatment includes nonpharmacologic methods and, if necessary, pharmacologic therapy.

**High Blood Pressure in the Elderly**

The prevalence of hypertension increases with advancing age to the extent that half of people aged 60 to 69 years and approximately three fourths of people 70 years and older are affected. The age-related rise in systolic blood pressure is primarily responsible for the increase in hypertension that occurs with increasing age.

**Pathogenesis and Risk Factors.** Among the aging processes that contribute to an increase in blood pressure are a stiffening of the large arteries, particularly

The height percentile is determined using the newly revised CDC growth charts. Blood pressure levels are based on data from the 1999–2000 National Health and Nutritional Examination Survey (NHANES) that have been added to the childhood BP database.

the aorta; decreased baroreceptor sensitivity; increased peripheral vascular resistance; and decreased renal blood flow. Systolic blood pressure rises almost linearly between 30 and 84 years of age, whereas diastolic pressure rises until 50 years of age and then levels off or decreases. This rise in systolic pressure is thought to be related to increased stiffness of the large arteries. With aging, the elastin fibers in the walls of the arteries are gradually replaced by collagen fibers that render the vessels stiffer and less compliant. Differences in the central and peripheral arteries relate to the fact that the larger vessels contain more elastin, whereas the peripheral resistance vessels have more smooth muscle and less elastin. Because of increased wall stiffness, the aorta and large arteries are less able to buffer the increase in systolic pressure that occurs as blood is ejected from the left heart, and they are less able to store the energy needed to maintain the diastolic pressure. As a result, the systolic pressure increases, the diastolic pressure remains unchanged or actually decreases, and the pulse pressure or difference between the systolic pressure and diastolic pressure widens.

Isolated systolic hypertension (systolic pressure ≥140 mm Hg and diastolic pressure <90 mm Hg) is recognized as an important risk factor for cardiovascular morbidity and mortality in older persons. The treatment of hypertension in the elderly has beneficial effects in terms of reducing the incidence of cardiovascular events such as stroke. Studies have shown a reduction in stroke, coronary heart disease, and congestive heart failure in persons who were treated for hypertension compared with those who were not.

**Diagnosis and Treatment.** The recommendations for measurement of blood pressure in the elderly are similar to those for the rest of the population. Blood pressure varies among older persons, so it is especially important to obtain multiple measurements on different occasions to establish a diagnosis of hypertension. The effects of food, position, and other environmental factors are also exaggerated in older persons. Although sitting has been the standard position for blood pressure measurement, it is recommended that blood pressure also be taken in the supine and standing positions in the elderly. In some elderly persons with hypertension, a silent interlude is recognized as an important risk factor for cardiovascular morbidity and mortality in older persons. The treatment of hypertension in the elderly has beneficial effects in terms of reducing the incidence of cardiovascular events such as stroke. Studies have shown a reduction in stroke, coronary heart disease, and congestive heart failure in persons who were treated for hypertension compared with those who were not.

**Orthostatic Hypotension**

Orthostatic hypotension refers to an abnormal drop in blood pressure that occurs when a person stands after having been in the seated or supine position. After the assumption of the upright posture from the supine position, approximately 500 to 700 mL of blood is momentarily shifted to the lower part of the body, with an accompanying decrease in central blood volume and arterial pressure. Normally, this decrease in blood pressure is transient, lasting through several cardiac cycles, because the baroreceptors located in the thorax and carotid sinus area sense the decreased pressure and initiate reflex constriction of the veins and arterioles and an increase in heart rate, which brings the blood pressure back to normal. Within a few minutes of a change to the standing position, blood levels of the sympathetic neuromediators and antidiuretic hormone increase as a secondary means of ensuring maintenance of normal blood pressure in the standing position. Muscle movement in the lower extremities also aids venous return to the heart by pumping blood out of the legs.

**Etiology**

A wide variety of conditions, acute and chronic, are associated with orthostatic hypotension. These include reduced blood volume, drug-induced hypotension, altered vascular responses associated with aging, bed rest, and autonomic nervous system dysfunction.

**Reduced Blood Volume.** Orthostatic hypotension often is an early sign of reduced blood volume or fluid deficit. When blood volume is decreased, the vascular compartment is only partially filled; although cardiac...
output may be adequate when a person is in the recumbent position, it often decreases to the point of causing weakness and fainting when the person assumes the standing position. Common causes of orthostatic hypotension related to hypovolemia are excessive use of diuretics, excessive diaphoresis, loss of gastrointestinal fluids through vomiting and diarrhea, and loss of fluid volume associated with prolonged bed rest.

**Drug-Induced Hypotension.** Antihypertensive drugs and psychotropic drugs are a common cause of chronic orthostatic hypotension. In most cases, the orthostatic hypotension is well tolerated. If postural hypotension is severe enough to cause light-headedness or dizziness, it is recommended that the dosage of the drug be reduced or a different drug be used.

**Aging.** Weakness and dizziness on standing are common complaints of elderly persons. Orthostatic tolerance is usually well maintained until the age of 70 years, after which there is an increasing tendency toward arterial pressure instability and postural hypotension. Although orthostatic hypotension may be either systolic or diastolic, hypertension associated with aging seems more often to be systolic. Several deficiencies in the circulatory response may predispose the elderly to this problem, including diminished ability to produce an adequate increase in the heart rate, ventricular stroke volume, or peripheral vascular resistance; decreased function of the skeletal muscle pumps; and decreased blood volume. Because cerebral blood flow primarily depends on systolic pressure, persons with impaired cerebral circulation may experience symptoms of weakness, ataxia, dizziness, and syncope when their arterial pressure falls even slightly. This may occur in older persons who are immobilized for even brief periods or whose blood volume is decreased owing to inadequate fluid intake or overzealous use of diuretics.

Postprandial blood pressure often decreases in elderly persons. The greatest postprandial changes occur after a high-carbohydrate meal. Although the mechanism responsible for these changes is not fully understood, it is thought to result from glucose-mediated impairment of baroreflex sensitivity and increased splanchnic blood flow mediated by insulin and vasoactive gastrointestinal hormones.

**Bed Rest and Immobility.** Prolonged bed rest promotes a reduction in plasma volume, a decrease in venous tone, failure of peripheral vasoconstriction, and weakness of the skeletal muscles that support the veins and assist in returning blood to the heart. Physical deconditioning follows even short periods of bed rest. After 3 to 4 days, the blood volume is decreased. Loss of vascular and skeletal muscle tone is less predictable but often becomes maximal after approximately 2 weeks of bed rest. Orthostatic intolerance is a recognized problem of space flight—a potential risk after reentry into the earth’s gravitational field.

**Disorders of Autonomic Nervous System Function.** The sympathetic nervous system plays an essential role in adjustment to the upright position. Sympathetic stimulation increases heart rate and cardiac contractility and causes constriction of peripheral veins and arterioles. Orthostatic hypotension caused by altered ANS function is common in peripheral neuropathies associated with diabetes mellitus, after injury or disease of the spinal cord, or as the result of a cerebral vascular accident in which sympathetic outflow from the brain stem is disrupted. The American Autonomic Society and the American Academy of Neurology have distinguished three forms of primary ANS dysfunction: (1) pure autonomic failure, which is defined as a sporadic, idiopathic cause of persistent orthostatic hypotension and other manifestations of autonomic failure such as urinary retention, impotence, or decreased sweating; (2) Parkinson disease with autonomic failure; and (3)
multiple-system atrophy (Shy-Drager syndrome). The Shy-Drager syndrome usually develops in middle to late life as orthostatic hypotension associated with uncoordinated movements, urinary incontinence, constipation, and other signs of neurologic deficits referable to the corticospinal, extrapyramidal, corticobulbar, and cerebellar systems.

**Diagnosis and Treatment**

Orthostatic hypotension can be assessed with the auscultatory method of blood pressure measurement. A reading should be made when the person is supine, immediately after assumption of the seated or upright position, and 3 minutes after assumption of the standing position. A tilt table also can be used for this purpose. When the table is tilted, the recumbent person can be moved to a head-up position without voluntary movement. The tilt table also has the advantage of rapidly and safely returning persons with a profound postural drop in blood pressure to the horizontal position. Persons with a drop in blood pressure to orthostatic levels should be evaluated to determine the cause and seriousness of the condition. A history should be taken to elicit information about symptoms, particularly dizziness and history of syncope and falls; medical conditions, particularly those such as diabetes mellitus that predispose to orthostatic hypotension; use of prescription and over-the-counter drugs; and symptoms of ANS dysfunction, such as impotence or bladder dysfunction. A physical examination should document blood pressure in both arms and the heart rate while the person is in the supine, sitting, and standing positions and note the occurrence of symptoms. Noninvasive, 24-hour ambulatory blood pressure monitoring may be used to determine blood pressure responses to other stimuli of daily life, such as food ingestion and excretion.

Treatment of orthostatic hypotension usually is directed toward alleviating the cause, or if this is not possible, toward helping the person learn to cope with the disorder and prevent falls and injuries. Medications that predispose to postural hypotension should be avoided. Correcting the fluid deficit and trying a different antihypertensive medication are examples of measures designed to correct the cause. Measures designed to help persons prevent symptomatic orthostatic drops in blood pressure include gradual ambulation to allow the circulatory system to adjust (i.e., sitting on the edge of the bed for several minutes and moving the legs to initiate skeletal muscle pump function before standing); avoidance of situations that encourage excessive vasodilation (e.g., drinking alcohol, exercising vigorously in a warm environment); and avoidance of excess diuresis (e.g., use of diuretics), diaphoresis, or loss of body fluids. Tight-fitting elastic support hose or an abdominal support garment may help prevent pooling of blood in the lower extremities and abdomen.

Pharmacologic treatment may be used when nonpharmacologic methods are unsuccessful. A number of types of drugs can be used for this purpose. Medications that predispose to postural hypotension should be avoided. Correcting the fluid deficit and trying a different antihypertensive medication are examples of measures designed to correct the cause. Measures designed to help persons prevent symptomatic orthostatic drops in blood pressure include gradual ambulation to allow the circulatory system to adjust (i.e., sitting on the edge of the bed for several minutes and moving the legs to initiate skeletal muscle pump function before standing); avoidance of situations that encourage excessive vasodilation (e.g., drinking alcohol, exercising vigorously in a warm environment); and avoidance of excess diuresis (e.g., use of diuretics), diaphoresis, or loss of body fluids. Tight-fitting elastic support hose or an abdominal support garment may help prevent pooling of blood in the lower extremities and abdomen.

**SUMMARY CONCEPTS**

- Arterial blood pressure reflects the rhythmic ejection of blood from the left ventricle, rising as the ventricle contracts and falling as it relaxes; with the systolic blood pressure or highest pressure representing the amount of blood that is ejected from the heart with each beat and the diastolic pressure or lowest pressure representing the energy that has been stored in the large arteries during systole.

- Hypertension, which represents an elevation in systolic and/or diastolic blood pressure, is one of the most common health problems. It may occur as a primary disorder or as a sign of some other disorder, such as kidney disease (i.e., secondary hypertension).

- The pathogenesis of primary hypertension is thought to include constitutional and environmental factors involving the kidney and its role in regulating extracellular fluid volume, intracellular sodium and calcium levels, sympathetic nervous system activity, and regulation of the renin-angiotensin-aldosterone system.

- Uncontrolled hypertension increases the risk of heart disease, renal complications, retinopathy, and stroke. Treatment of primary hypertension focuses on nonpharmacologic methods such as weight reduction, reduction of sodium intake, and regular physical activity.

- Hypertension that occurs during pregnancy can be divided into four categories: preeclampsia-eclampsia, gestational hypertension, chronic hypertension, and chronic hypertension with superimposed preeclampsia-eclampsia. Preeclampsia-eclampsia is hypertension that develops after 20 weeks’ gestation and is accompanied by proteinuria, posing a particular threat to the mother and the fetus. Chronic hypertension is hypertension that is present before 20 weeks’ gestation.
SUMMARY CONCEPTS (continued)

- Blood pressure is known to increase from infancy through late adolescence. Among infants and children, secondary hypertension is the most common form of high blood pressure. In later childhood and adolescence, essential hypertension is more common.
- Isolated systolic hypertension, the most common type of hypertension in the elderly, represents the effects of aging on the distensibility of the aorta and its ability to stretch and accommodate blood being ejected from the left heart during systole. Untreated systolic hypertension is recognized as an important risk factor for stroke and other cardiovascular morbidity and mortality in older persons.
- Orthostatic hypotension, which is an abnormal decrease in systolic and diastolic blood pressures that occurs on assumption of the upright position, is an important consideration in the occurrence of dizziness and syncope. Among the factors that contribute to its occurrence are decreased fluid volume, medications, aging, defective function of the autonomic nervous system, and the effects of immobility. Treatment includes correcting the reversible causes and assisting the person to compensate for the disorder and prevent falls and injuries.

Disorders of the Venous Circulation

Veins are low-pressure, thin-walled vessels that rely on the ancillary action of skeletal muscle pumps and changes in abdominal and intrathoracic pressure to return blood to the heart. Unlike the arterial system, the venous system is equipped with valves that prevent retrograde flow of blood (see Chapter 17). Although its structure enables the venous system to serve as a storage area for blood, it also renders the system susceptible to problems related to stasis and venous insufficiency. This section focuses on three common problems of the venous system: varicose veins, venous insufficiency, and venous thrombosis.

Venous Circulation of the Lower Extremities

The venous system in the lower extremities consists of two components: the superficial veins (i.e., saphenous vein and its tributaries) and the deep venous channels (Fig. 18-17A). Perforating or communicating veins connect these two systems. Blood from the skin and subcutaneous tissues in the leg collects in the superficial veins and is then transported across the communicating veins into the deeper venous channels for return to the heart. Venous valves prevent the retrograde flow of blood and play an important role in the function of the venous system. Although these valves are irregularly located along the length of the veins, they almost always are found at junctions where the communicating veins merge with the larger deep veins and where two veins meet. The number of venous valves differs somewhat from one person to another, as does their structural competence, factors that may help explain the familial predisposition to development of varicose veins.

The action of the leg muscles assists in moving venous blood from the lower extremities back to the heart. When a person walks, the action of the leg muscles serves to increase flow in the deep venous channels and return venous blood to the heart (Fig. 18-18). The function of the so-called muscle pump, located in the gastrocnemius and soleus muscles of the lower extremities, can be compared with the pumping action of the heart.

During muscle contraction, which is similar to systole, valves in the communicating channels close to prevent backward flow of blood into the superficial system, as blood in the deep veins is moved forward by the action of the contracting muscles. During muscle relaxation, which is similar to diastole, the communicating valves open, allowing blood from the superficial veins to move into the deep veins.

Varicose Veins and Venous Insufficiency

The venous system of the lower limbs is associated with a wide clinical spectrum of disorders ranging from cosmetic problems of superficial varicose veins to severe symptoms, including ulceration.

Varicose Veins

Varicose, or dilated, tortuous veins of the lower extremities are common and often lead to secondary problems of venous insufficiency 1–7 (see Fig. 18-17B). The prevalence of varicose veins in Western populations is about 25% to 30% in women and 10% to 20% in men. The condition is more common after 50 years of age and in obese persons, and it occurs more often in women, probably because of venous stasis caused by pregnancy. 2

Varicose veins are described as being primary or secondary. Primary varicose veins originate in the superficial saphenous veins, and secondary varicose veins result from impaired flow in the deep venous channels. Approximately 80% to 90% of venous blood from the lower extremities is transported through the deep channels. The development of secondary varicose veins becomes inevitable when flow in these deep channels is impaired or blocked. The most common cause of secondary varicose veins is deep vein thrombosis. Other causes include congenital or acquired arteriovenous fistulas, congenital venous malformations, and pressure on the abdominal veins caused by pregnancy or a tumor.
**Etiology.** Prolonged standing and increased intra-abdominal pressure are important contributing factors in the development of primary varicose veins. Because there are no valves in the inferior vena cava or common iliac veins, blood in the abdominal veins must be supported by the valves located in the external iliac or femoral veins. When intra-abdominal pressure increases, as it does during pregnancy, or when the valves in these two veins are absent or defective, the stress on the saphenofemoral junction is increased. The high incidence of varicose veins in women who have been pregnant also suggests a hormonal effect on venous smooth muscle contributing to venous dilation and valvular incompetence. Lifting also increases intra-abdominal pressure and decreases flow of blood through the abdominal veins. Occupations that require repeated heavy lifting predispose to development of varicose veins.

Prolonged exposure to increased pressure causes the venous valves to become incompetent so they no longer close properly. When this happens, the reflux of blood causes further venous enlargement, pulling the valve leaflet apart and causing more valvular incompetence in sections of adjacent distal veins. Another consideration in the development of varicose veins is the fact that the superficial veins have only subcutaneous fat and superficial fascia for support, whereas the deep venous channels are supported by muscle, bone, and connective tissue. Obesity reduces the support provided by the superficial fascia and tissues, increasing the risk for development of varicose veins.

**Clinical Manifestations.** The signs and symptoms associated with primary varicose veins vary. Most women with superficial varicose veins complain of their unsightly appearance. In many cases, aching in the lower extremities and edema, especially after long periods of standing, may occur. The edema usually subsides at night when the legs are elevated. When the communicating veins are incompetent, symptoms are more common.
Diagnosis and Treatment. The diagnosis of varicose veins often can be made after physical inspection. Primary varicose veins should be differentiated from those secondary to chronic venous insufficiency, retroperitoneal venous obstruction, or congenital venous malformations. The Doppler ultrasonic flow probe also may be used to assess flow in the large vessels. Angiographic studies using a radiopaque contrast medium also are used to assess venous function.

Treatment measures for varicose veins focus on improving venous flow and preventing tissue injury. When correctly fitted, elastic support stockings or leggings compress the superficial veins and prevent distention. The most precise control is afforded by prescription stockings, measured to fit properly. These stockings should be applied before the standing position is assumed, when the leg veins are empty. Sclerotherapy, which often is used in the treatment of small residual varicosities, involves the injection of a sclerosing agent into the collapsed superficial veins to produce fibrosis of the vessel lumen. Surgical treatment consists of removing the varicosities and the incompetent perforating veins, but it is limited to persons with patent deep venous channels.

Chronic Venous Insufficiency

Chronic venous disease of the lower extremities is manifested by venous hypertension and a range of signs, the most obvious of which are varicose veins and venous ulcers due to venous insufficiency. Venous hypertension represents a sustained increase in venous blood pressures.

Etiology. Chronic venous insufficiency is most commonly caused by reflux through incompetent veins, but can also be caused by venous outflow obstruction and impaired function of the skeletal muscle pumps. Pressure in the veins of the legs is determined by two components: a hydrostatic component related to the weight of a column of blood below the level of the heart, and a hydrodynamic component related to the action of the skeletal muscle pump. Prolonged standing increases venous pressure and causes dilation and stretching of the vessel wall. When a person is in the erect position, the full weight of the venous columns of blood is transmitted to the leg veins. The effects of gravity are compounded in persons who stand for long periods without using their leg muscles to assist in pumping blood back to the heart.

Clinical Manifestations. Chronic venous insufficiency is characterized by signs and symptoms associated with impaired venous blood flow. In contrast to the ischemia caused by arterial insufficiency, venous insufficiency leads to tissue congestion, edema, and eventual impairment of tissue nutrition. The edema is exacerbated by long periods of standing. Necrosis of subcutaneous fat deposits occurs, followed by skin atrophy. Brown pigmentation of the skin caused by hemosiderin deposits resulting from the breakdown of red blood cells is common. Secondary lymphatic insufficiency occurs, with progressive sclerosis of the lymph channels in the face of increased demand for clearance of interstitial fluid.

In advanced venous insufficiency, impaired tissue nutrition causes stasis dermatitis and the development of stasis or venous ulcers (Fig. 18-19). Stasis dermatitis is characterized by the presence of thin, shiny, bluish brown, irregularly pigmented, desquamative skin that lacks the support of the underlying subcutaneous tissues. Minor injury leads to relatively painless ulcers that are difficult to heal. The lower part of the leg is particularly prone to development of stasis dermatitis and venous ulcers. Most lesions are located medially over the ankle and lower leg, with the highest frequency just above the medial malleolus.

Treatment of venous ulcers includes compression therapy with dressings and inelastic or elastic bandages.
Occasionally skin grafting is required for large or slow-healing venous ulcers. Growth factors (which are administered topically or by perilesional injection) may also be warranted.76

**Venous Thrombosis**

The term *venous thrombosis, or thrombophlebitis*, describes the presence of thrombus in a vein and the accompanying inflammatory response in the vessel wall.77,78 Thrombi can develop in the superficial or the deep veins. Deep venous thrombosis (DVT) most commonly occurs in the lower extremities. Deep venous thrombosis of the lower extremity is a serious disorder, complicated by pulmonary embolism (see Chapter 23), recurrent episodes of DVT, and development of chronic venous insufficiency. Isolated calf thrombi often are asymptomatic. If left untreated, they may extend to the larger, more proximal veins, with an increased risk of pulmonary emboli (up to 50% risk from proximal DVTs).

**Etiology**

In 1846, German pathologist Rudolf Virchow described the triad that has come to be associated with venous thrombosis: stasis of blood, increased blood coagulability, and vessel wall injury.79 Risk factors for venous thrombosis are summarized in Chart 18-3. Stasis of blood occurs with immobility of an extremity or the entire body. Bed rest and immobilization are associated with decreased blood flow, venous pooling in the lower extremities, and increased risk of DVT. Persons who are immobilized by a hip fracture, joint replacement, or spinal cord injury are particularly vulnerable to DVT. The risk of DVT is increased in situations of impaired cardiac function. This may account for the relatively high incidence in persons with acute myocardial infarction and congestive heart failure. Elderly persons are more susceptible than younger persons, probably because disorders that produce venous stasis occur more frequently in older persons. Long airplane travel poses a particular threat in persons predisposed to DVT because of prolonged sitting and increased blood viscosity due to dehydration.80

Hypercoagulability is a homeostatic mechanism designed to increase clot formation, and conditions that increase the concentration or activation of clotting factors predispose to DVT. Thrombosis also can be caused by inherited or acquired deficiencies in certain plasma proteins that normally inhibit thrombus formation, such as antithrombin III, protein C, and protein S. However, the most common inherited risk factors are the factor V Leiden and prothrombin gene mutations (see Chapter 12). The postpartum state is associated with increased levels of fibrinogen, prothrombin, and other coagulation factors. The use of oral contraceptives and hormone replacement therapy appear to increase coagulability and predispose to venous thrombosis, a risk that is further increased in women who smoke. Certain cancers are associated with increased clotting tendencies, and although the reason for this is largely unknown, substances that promote blood coagulation may be produced by the tumor cells or released from the surrounding tissues in response to the cancerous growth. Immune interactions with cancer cells can result in the release of cytokines that can cause endothelial damage and predispose to thrombosis. When body fluid is lost because of injury or disease, the resulting hemoconcentration causes clotting factors to become more concentrated. Other important risk factors include the antiphospholipid syndrome (discussed in Chapter 12) and hyperhomocysteinemia.

Vessel injury can result from a trauma situation or from surgical intervention. It also may occur secondary to infection or inflammation of the vessel wall. Persons undergoing hip surgery and total hip replacement are at particular risk because of trauma to the femoral and iliac veins and, in the case of hip replacement, thermal damage from heat generated by the polymerization of the acrylic cement that is used in the procedure. Venous catheters are another source of vascular injury.

**Clinical Manifestations**

Many persons with venous thrombosis are asymptomatic, probably because the vein is not totally occluded or because of collateral circulation.81–83 When present, the most common signs and symptoms of venous thrombosis are those related to the inflammatory process: pain, swelling, and deep muscle tenderness. Fever, general
Diagnosis and Treatment

The risk of pulmonary embolism emphasizes the need for early detection and treatment of DVT. Several tests are useful for this purpose: ascending venography, ultrasonography (e.g., real time, B mode, duplex), and plasma d-dimer (a degradation product of fibrin) assessment (see Chapter 23).

Whenever possible, venous thrombosis should be prevented in preference to being treated. Early ambulation after childbirth and surgery is one measure that decreases the risk of thrombus formation. Exercising the legs and wearing support stockings improve venous flow. A further precautionary measure is to avoid assuming body positions that favor venous pooling. Antiembolism stockings of the proper fit and length should be used routinely in persons at risk for DVT. Another strategy used for immobile persons at risk for development of DVT is a sequential pneumatic compression device. This consists of a plastic sleeve that encircles the legs and provides alternating periods of compression on the lower extremity. When properly used, these devices enhance venous emptying to augment flow and reduce stasis.

The objectives of treatment of venous thrombosis are to prevent the formation of additional thrombi, prevent extension and embolization of existing thrombi, and minimize venous valve damage. Anticoagulation therapy (i.e., warfarin and low–molecular-weight warfarin) is used to treat and prevent venous thrombosis (see Chapter 12). A 15- to 20-degree elevation of the legs prevents stasis. It is important that the entire lower extremity or extremities be carefully extended to avoid acute flexion of the knee or hip. Heat often is applied to the leg to relieve venospasm and to aid in the resolution of the inflammatory process. Bed rest usually is maintained until local tenderness and swelling have subsided. Gradual ambulation with elastic support is then permitted. Standing and sitting increase venous pressure and are to be avoided. Elastic support is needed for 3 to 6 months to permit recanalization and collateralization and to prevent venous insufficiency.
3. A 34-year-old, otherwise healthy woman complains of episodes lasting several hours in which her fingers become pale and numb. This is followed by a period during which the fingers become red, throbbing, and painful.
   A. What do you think is causing this woman’s problem?
   B. She relates that the episodes often occur when her fingers become cold or when she becomes upset. Explain the possible underlying mechanisms.
   C. What types of measures could be used to treat this woman?

4. A 47-year-old African-American man who is an executive in a law firm has his blood pressure taken at a screening program and is told that his pressure is 142/90 mm Hg. His father and older brother have hypertension, and his paternal grandparents had a history of stroke and myocardial infarction. The man enjoys salty foods and routinely uses a salt shaker to add salt to meals his wife prepares, drinks about four beers while watching television in the evening, and has gained 15 pounds in the past year. Although his family has encouraged him to engage in physical activities with them, he states he is either too busy or too tired.
   A. According to the JNC 7 guidelines, into what category does the patient’s blood pressure fall?
   B. What are his risk factors for hypertension?
   C. Explain how an increased salt intake might contribute to his increase in blood pressure.
   D. What lifestyle changes would you suggest to the patient? Explain the rationale for your suggestions.

5. A 36-year-old woman enters the clinic complaining of headache and not feeling well. Her blood pressure is 175/90 mm Hg. Her renal test results are abnormal, and follow-up tests confirm that she has a stricture of the left renal artery.
   A. Would this woman’s hypertension be classified as primary or secondary?
   B. Explain the physiologic mechanisms underlying her blood pressure elevation.

6. A 75-year-old woman residing in an extended care facility has multiple health problems, including diabetes, hypertension, and heart failure. Lately, she has been feeling dizzy when she stands up, and she has almost fallen on several occasions. Her family is concerned and wants to know why this is happening and what they can do to prevent her from falling and breaking her hip.
   A. How would you go about assessing this woman for orthostatic hypotension?
   B. What are the causes of orthostatic hypotension in elderly persons?
   C. How might this woman’s medical conditions and their treatment contribute to her orthostatic hypotension?
   D. The woman tells you that she feels particularly dizzy after she has eaten, yet staff members insist that she sit up and socialize with the other residents even though she would rather lie down and rest until the dizziness goes away. Explain the possible reason for her dizziness and what measures might be used to counteract the dizziness.
   E. The woman recently had an episode of vomiting and diarrhea on an extremely hot day. She told her family that she was so dizzy that she was sure she would fall. Explain why her dizziness was more severe under these conditions and what might be done to alleviate the situation.

Heart disease affects persons of all ages and ethnicities and remains the leading cause of death in developed countries, including the United States. Heart disease accounts for approximately 30% of deaths worldwide, including nearly 40% in high-income countries and approximately 28% in low- and middle-income countries. Experts predict that heart disease will become the leading cause of death worldwide by 2020 and will surpass death rates from infectious diseases as a result of economic advances, social structures, and demographics.

In an attempt to focus on common health problems that affect persons of all age groups, the chapter has been organized into five sections: coronary artery disease, endocardial and valvular disorders, disorders of the pericardium, cardiomyopathies, and heart disease in infants and children.

**Coronary Artery Disease**

Coronary artery disease (CAD) describes heart disease caused by impaired coronary blood flow. Diseases of the coronary arteries can cause a spectrum of ischemic disorders ranging from angina to myocardial infarction (i.e., heart attack), as well as conduction defects, heart failure, and sudden cardiac death.

**Coronary Circulation**

The coronary arteries and coronary veins comprise the blood vessels of the heart that carry blood to and from most of the myocardium (Fig. 19-1). The coronary vessels lay across the surface of the heart and are embedded in adipose tissue just under the epicardium.

There are two main coronary arteries, the left and the right, which arise from the aortic sinus. The left main coronary artery extends approximately 4 cm and then divides into the left anterior descending and circumflex branches. The left anterior descending artery passes through the groove between the two ventricles, giving off diagonal branches, which supply the anterior wall of the left ventricle, and perforating branches, which supply the anterior portion of the interventricular septum.
and the anterior papillary muscle of the left ventricle. The circumflex branch of the left coronary artery passes to the left and moves posteriorly in the groove that separates the left atrium and ventricle, giving off branches that supply the left lateral wall of the left ventricle. The right coronary artery lies in the right atrioventricular groove, and its branches supply the right ventricle. The right coronary artery usually crosses to the back of the heart, where this vessel forms the posterior descending artery, which, in most individuals, supplies the posterior portion of the heart, interventricular septum, sinoatrial (SA) and atrioventricular (AV) nodes, and posterior papillary muscle.4,6

The right and left coronary arteries or epicardial arteries branch into smaller intramyocardial arteries, which penetrate the myocardium before merging with a
network or plexus of subendocardial vessels. Although there are no connections between the large coronary arteries, there are anastomotic channels that join the small arteries. If larger vessels gradually become occluded, the smaller collateral vessels increase in size and provide alternative channels for blood flow. One of the reasons individuals with CAD may not experience any symptoms until the disease is advanced is due to the development of collateral channels occurring in concert with atherosclerotic changes (see Chapter 18).

Physical, metabolic, and neural factors control blood flow in the coronary arteries. The openings for the coronary arteries originate in the root of the aorta outside the aortic valve. Thus, aortic blood pressure is the major factor controlling the perfusion pressure in the coronary arteries; aortic pressure is generated by the heart itself. Myocardial blood flow, in turn, is largely regulated by the metabolic activity of the myocardium and autoregulatory mechanisms that control vessel dilation. In addition to generating the aortic pressure that propels blood through the coronary vessels, the contracting heart muscle influences its own blood supply by compressing the intramyocardial and subendocardial blood vessels during systole.

Coronary blood flow is regulated by oxygen demand of the cardiac muscle. Under resting conditions, the heart extracts and utilizes 60% to 80% of oxygen in the blood flowing through the coronary arteries, as compared with the 25% to 30% extracted by skeletal muscle. There is little oxygen reserve in the blood, and therefore, the coronary arteries vasodilate to meet the metabolic needs of the myocardium during periods of increased activity. Metabolic activity is a major determinant of coronary blood flow. Numerous substances (i.e., metabolites), which include potassium ions, lactic acid, carbon dioxide, and adenosine, are released from working myocardial cells and mediate the vasodilation that accompanies increased cardiac work. Of these substances, adenosine has the greatest vasodilator effect and is perhaps the most critical mediator of local blood flow in coronary circulation.

Endothelial cells, which make up the inner lining of all blood vessels including the coronary arteries, play an active role in the control of blood flow. These cells function as a selectively permeable barrier, which allows for the movement of small and large molecules from the blood to the tissues and also from the tissues to the blood. In addition, endothelial cells synthesize and release substances that affect relaxation or constriction of the vascular smooth muscle cells in the arterial wall. Potential vasodilators produced by the endothelium include nitric oxide (NO), prostacyclin, and endothelium-dependent hyperpolarizing factor (EDHF). The most important of these is nitric oxide. Most vasodilating stimuli exert their effects through nitric oxide pathways. The endothelium also is the source of endothelium-dependent constricting factors, the best known of which are the endothelins. Coagulation factors (e.g., thrombin), inflammatory mediators (e.g., histamine), and mechanical factors (e.g., increased shear force exerted on the vessel wall) and ischemia contribute to flow-mediated vasodilation, and stimulate the synthesis and release of nitric oxide.

Pathogenesis of Coronary Artery Disease

The most common cause of CAD is atherosclerosis (discussed in Chapter 18). Atherosclerosis may affect one or all three of the major epicardial coronary arteries and their branches. Clinically significant lesions may be located anywhere in these vessels, but tend to predominate in the first several centimeters of the left anterior descending and left circumflex artery or along the entire length of the right coronary artery. In some cases the major secondary branches also are involved.

Coronary heart disease is commonly divided into two broad disorders: acute coronary syndromes and chronic ischemic heart disease. The acute coronary syndromes represent a spectrum ranging from unstable angina to myocardial infarction that is caused by acute plaque disruption, whereas chronic ischemic heart disease is caused by atherosclerosis or vasospasm of the coronary arteries.

Plaque Disruption and Thrombus Formation

There are two types of atherosclerotic lesions: (1) the fixed or stable plaque, which obstructs blood flow, and (2) the vulnerable or unstable plaque, which can rupture, activating a cascade of events leading to thrombus formation.

The fixed or stable plaque is commonly associated with stable angina, and the unstable plaque is implicated in unstable angina and myocardial infarction (MI). In most cases the myocardial ischemia underlying unstable angina and acute MI is precipitated by plaque disruption, followed by thrombosis. The major determinants of plaque vulnerability to disruption include the size of its lipid-rich core, lack of stabilizing smooth muscle cells, presence of inflammation with plaque degradation, and stability and thickness of its fibrous cap (Fig. 19-2). Plaques with a thin fibrous cap overlying a large lipid core are at high risk for rupture.

Although plaque disruption may occur spontaneously, this event is often triggered by hemodynamic factors, such as blood flow characteristics and vessel tension. For example, an elevated risk for plaque disruption may result from physiologic events including increased sympathetic activity elicited by rising blood pressure, heart rate, or cardiac contractility. Plaque disruption is also associated with diurnal variation, which commonly occurs within an hour of rising. This phenomenon suggests that physiologic factors (e.g., coronary artery tone and blood pressure) may promote atherosclerotic plaque disruption and subsequent platelet deposition. The elevated sympathetic activity associated with wakefulness and being active may promote platelet aggregation and fibrinolytic activity that favor plaque disruption and thrombosis.

Local thrombosis occurring after plaque disruption results from a complex interaction among the contents
of the lipid core, smooth muscle cells, macrophages, and collagen. The lipid core provides a stimulus for platelet aggregation and thrombus formation. Both smooth muscle and foam cells in the lipid core contribute to the expression of tissue factor in unstable plaques. Once exposed to blood, tissue factor initiates the extrinsic coagulation pathway, resulting in the local generation of thrombin and deposition of fibrin (see Chapter 12).

Platelets are critical to the events following plaque disruption in acute CAD. Platelets adhere to the endothelium and release substances (i.e., adenosine diphosphate [ADP], thromboxane A₂, and thrombin) that promote further aggregation of platelets and thrombus formation. Glycoprotein receptors expressed on the platelet surface bind fibrinogen and cross-link platelets, contributing to thrombus formation. Platelet adhesion and aggregation occurs in several steps. First, release of ADP, thromboxane A₂, and thrombin initiates the aggregation process. Second, activation of glycoprotein IIb/IIIa receptors on the platelet surface occurs. Third, fibrinogen binds to the activated glycoprotein receptors, forming bridges between adjacent platelets.

Acute Coronary Syndrome

Acute coronary syndrome (ACS) represents a spectrum of acute ischemic heart diseases ranging from unstable ischemia to acute MI based on the presence or absence of an ST-segment elevation or depression on the ECG. This criterion allows for immediate classification of risk and guides whether a person should be considered for acute reperfusion therapy. The evaluation of serum biomarkers (e.g., troponin I) is then used to determine whether an acute MI has occurred.

Electrocardiographic Changes

The classic ECG changes that occur with ACS include ST-segment elevation, T-wave inversion, and development of an abnormal Q wave (Fig. 19-3). These changes may not be present immediately after the onset of symptoms and vary considerably depending on the duration of the ischemic event (acute versus evolving), its extent (subendocardial versus transmural), and its location (anterior versus inferior posterior). Because these changes usually occur over time and are seen on the ECG leads that view the involved area of the myocardium, provision for continuous and serial 12-lead ECG monitoring is indicated.

The T wave and ST segment, which represent the ventricular repolarization phase of the cardiac action potential on the ECG, are usually the first to be involved during myocardial ischemia and injury. During myocardial ischemia, repolarization is altered as the involved area becomes ischemic. This leads to T wave abnormalities, such as T-wave inversion. ST-segment changes also occur with acute ischemic myocardial injury. Normally, the ST segment of the ECG is nearly isoelectric (i.e., does not deviate from the baseline) because healthy myocardial cells attain the same resting membrane potential during early repolarization. Acute ischemia reduces the resting membrane potential and shortens the duration of the action potential of the cells within the ischemic area. The voltage difference in the cell membranes between the normal and ischemic areas of the myocardium leads to a “current of injury” between these regions.
Blood flow in the coronary vessels that supply the myocardium is influenced by (1) the aortic pressure, (2) autoregulatory mechanisms, and (3) compression of the intramyocardial vessels by the contracting heart muscle.

1. **Aortic Pressure.** The two main coronary arteries that supply blood flow to the myocardium arise in the sinuses behind the two cusps of the aortic valve. Because of their location, the pressure and flow of blood in the coronary arteries reflects that of the aorta. During systole, when the aortic valve is open, the velocity of blood flow and position of the valve cusps cause the blood to move rapidly past the coronary artery inlets, and during diastole, when the aortic valve is closed, blood flow and the aortic pressure are transmitted directly into the coronary arteries.

2. **Autoregulatory Mechanisms.** The heart normally extracts 60% to 80% of the oxygen in the blood delivered to it, leaving little in reserve. Accordingly, oxygen delivery during periods of increased metabolic demand depends on autoregulatory mechanisms that regulate blood flow through a change in vessel tone and diameter. During increased metabolic demand, vasodilation produces an increase in blood flow; during decreased demand, vasoconstriction or return of vessel tone to normal produces a reduction in flow. The mechanisms that link the metabolic activity of the heart to changes in vessel tone result from vasoactive mediators released from myocardial cells and the vascular endothelium.
**Vessel Compression.** The large coronary arteries lie on the epicardial surface of the heart, with the smaller intramyocardial vessels branching off and moving through the myocardium before merging with a plexus of vessels that supply the subendocardial muscle with blood. During systole, the contracting cardiac muscle has a squeezing effect on the intramyocardial vessels while at the same time producing an increase in intraventricular pressure that pushes against and compresses the subendocardial vessels. As a result, blood flow to the subendocardial muscle is greatest during diastole. Because the time spent in diastole becomes shortened as the heart rate increases, myocardial blood flow can be greatly reduced during sustained periods of tachycardia.

These currents of injury are represented as a deviation of the ST segment on the ECG. When the acute injury is transmural, the overall ST vector is shifted in the direction of the outer epicardium, resulting in an elevation of the ST segment (see Fig. 19-3). When the injury is confined primarily to the subendocardium, the ST vector is shifted toward the inner ventricular layer, resulting in an overall depression of the ST segment. Additional ventricular depolarization (QRS) changes may follow the T-wave and ST-segment abnormalities. With actual infarction, depolarization (QRS) changes often follow the T-wave and ST-segment abnormalities.

**Serum Biomarkers**

Serum biomarkers for ACS, referred to as a cardiac panel, include cardiac-specific troponin I (TnI) and troponin T (TnT), creatine kinase MB (CK-MB), and myoglobin. As myocardial cells become necrotic, their intracellular contents diffuse into the surrounding interstitium and into the blood. The rate at which the enzymes appear in the blood depends on their intracellular location, molecular weight, and local blood flow. For example, they may appear at an earlier-than-predicted time in patients who have undergone successful reperfusion therapy.

The *troponin assays* have high specificity for myocardial tissue and are the primary biomarker tests for the diagnosis of MI. The troponin complex, which is part of the actin filament, consists of three subunits (i.e., TnC, TnT, and TnI) that regulate the calcium-mediated actin–myosin contractile process in striated muscle (see Chapter 1, Fig. 1-19). Troponin I and troponin T, which are present in cardiac muscle, begin to rise within 3 hours after the onset of myocardial infarction and may remain elevated for 7 to 10 days after the event. This is especially useful in the late diagnosis of MI. *Creatine kinase* is an intracellular enzyme found in muscle cells. There are three isoenzymes of CK, with the MB isoenzyme being highly specific for injury to myocardial tissue. Serum levels of CK-MB exceed normal ranges within 4 to 8 hours of myocardial injury and decline to normal within 2 to 3 days. *Myoglobin* is an oxygen-carrying protein, similar to hemoglobin, expressed in cardiac and skeletal muscle. This small molecule is released quickly from infarcted myocardial tissue, and elevated levels can be detected in the blood within 1 hour after myocardial cell death with peak levels reached within 4 to 8 hours. Because myoglobin is present in both cardiac and skeletal muscle, this molecule is not specific to cardiac injury.
Unstable Angina/Non–ST Elevation Myocardial Infarction

Unstable angina/non–ST elevation myocardial infarction (UA/NSTEMI) is a clinical syndrome of myocardial ischemia ranging from angina to myocardial infarction. Typically, unstable angina and NSTEMI differ in whether the ischemia is severe enough to cause sufficient myocardial damage to release detectable quantities of serum cardiac markers. Persons who have no evidence of serum markers for myocardial damage are considered to have unstable angina, whereas a diagnosis of NSTEMI is indicated when there are detectable serum markers of myocardial injury.

The pain associated with unstable angina typically has a persistent and severe course and is characterized by at least one of three features: (1) it occurs at rest (or with minimal exertion), usually lasting more than 20 minutes if untreated (i.e., without nitroglycerine); (2) it is severe and described as frank pain and of new onset (i.e., within 1 month); and (3) it is more severe, prolonged, or frequent than previously experienced.

The risk of acute MI in an individual diagnosed with UA/NSTEMI is classified as low, intermediate, or high based upon the clinical history, ECG pattern, and serum biomarkers. The ECG pattern associated with in NSTEMI may display normal or ST-segment depression (or transient ST-segment elevation) and T-wave changes. The degree of ST-segment deviation from baseline is an important measure of ischemia and indicator of prognosis.

ST Elevation Myocardial Infarction

Acute ST elevation MI (STEMI) is characterized by the necrosis of myocardial tissue and a consequence of atherosclerotic disease of the coronary arteries. The specific area of infarction is determined by the affected coronary artery and its distribution of blood flow (Fig. 19-4).

Pathologic Changes. The size and pattern of the infarct depends on the location and extent of occlusion, amount of heart tissue supplied by the vessel, duration of the occlusion, metabolic needs of the affected tissue, extent of collateral circulation, and other factors such as heart rate, blood pressure, and cardiac rhythm. An infarct may involve the endocardium, myocardium, or epicardium, or a combination of these tissue layers. Transmural infarcts involve the full thickness of the ventricular wall and most commonly occur when there is obstruction of a single artery (Fig. 19-5). Subendocardial infarcts involve the inner one third to one half of the ventricular wall and occur more frequently in the presence of severely narrowed but still patent arteries.

The principal biochemical consequence of MI is the conversion from aerobic to anaerobic metabolism with inadequate production of energy to sustain normal myocardial function. As a result, a striking loss of contractile function occurs within 60 seconds of onset. Changes in cell structure (i.e., glycogen depletion and mitochondrial swelling) develop within several minutes. These early changes are reversible if blood flow is restored. Although gross tissue changes are not apparent for hours after the onset of MI, the ischemic area ceases to function within a matter of minutes, and damage to cells occurs in approximately 40 minutes. Irreversible myocardial cell death (necrosis) occurs after 20 to 40 minutes of severe ischemia (Fig. 19-6).

The term reperfusion refers to the reestablishment of blood flow using fibrinolytic therapy or revascularization procedures. Early reperfusion after onset of occlusion can prevent necrosis and improve myocardial perfusion in the infarct zone. Reperfusion after a
longer interval can salvage some ischemic myocardial cells. Reestablishing blood flow may also prevent the microvascular injury that occurs over a longer period.

Even though much of the viable myocardium existing at the time reperfusion recovers, critical abnormalities in biochemical function may persist, and these changes can lead to chronic impairment of ventricular function. The recovering area of the heart is often referred to as a **stunned myocardium**. Because myocardial function is lost before cell death occurs, a stunned myocardium may not be capable of sustaining life, and persons with large areas of dysfunctional myocardium may require supportive care until the stunned regions regain their function.

The onset of STEMI involves abrupt and significant chest pain. The pain typically is severe, often described as being constricting, suffocating, and crushing. Substernal pain that radiates to the left arm, neck, or jaw is common, although it may be experienced in other areas of the chest and back. Unlike that of angina, the pain associated with MI is more prolonged and not relieved by rest or nitroglycerin; this pain frequently requires morphine for relief. Some persons may not describe it as “pain,” but as “discomfort.” Women may experience atypical ischemic-type chest pain, whereas the elderly may complain of shortness of breath more frequently than chest pain.

Complaints of fatigue and weakness, especially of the arms and legs, are common. Pain and elevated sympathetic activity invoke tachycardia, anxiety, and restlessness, as well as emotional responses (e.g., a feeling of impending doom). Impairment of myocardial function may lead to hypotension and shock. In addition, gastrointestinal complaints are common with acute MI. There may be a sensation of epigastric distress; nausea and vomiting may occur. These symptoms are thought to be related to the severity of the
pain and vagal stimulation. The epigastric distress may be mistaken for indigestion, and the person may seek relief with antacids or other home remedies; this behavior may delay medical interventions.

Sudden death from acute MI is death that occurs within 1 hour of symptom onset. It usually is attributed to fatal arrhythmias, which may occur without evidence of infarction. Early hospitalization after onset of symptoms greatly improves the chances of averting sudden death because appropriate resuscitation equipment and personnel are immediately available should a ventricular arrhythmia occur. The recent distribution of automatic external defibrillators in multiple public arenas highlights the importance of immediately available should a ventricular arrhythmia occur. Furthermore, the development of procedures—specifically defibrillation and expeditious transport to a hospital equipped to initiate reperfusion therapy, manage arrhythmias, and provide advanced cardiac life support—is crucial.

The emergency department goals for management of ACS include rapid identification of persons who are candidates for reperfusion therapy. Evaluation of the person’s chief complaint, typically chest pain, along with other associated symptoms is essential in differentiating ACS from other diagnoses. For any person presenting with symptoms of ACS, providers should perform a 12-lead ECG and continuous ECG monitoring. Treatment regimens also include administration of oxygen, aspirin, nitrates, morphine, antiplatelet and anticoagulant therapy, beta-adrenergic blocking agents (beta blockers), and an angiotensin-converting enzyme (ACE) inhibitor.

The administration of oxygen augments the oxygen content of inspired air and increases the oxygen saturation of hemoglobin. Arterial oxygen levels may fall precipitously after acute MI, and oxygen administration maintains oxygen content of the blood perfusing the myocardial tissue. Platelets play a major role in the thrombotic response to atherosclerotic plaque disruption; therefore, inhibition of platelet aggregation is an important aspect in the early treatment of both unstable angina/NSTEMI and STEMI. Aspirin (i.e., acetylsalicylic acid) is the preferred antiplatelet agent for preventing platelet aggregation in persons with ACS. Aspirin, which acts by inhibiting synthesis of the prostaglandin thromboxane A2, is thought to promote reperfusion and reduce the likelihood of re-thrombosis. For patients who are aspirin-intolerant, another antiplatelet drug such as clopidogrel may be prescribed. Clopidogrel exerts its effects by inhibiting the ADP pathway in platelets (see Chapter 12).

The severe pain of acute MI gives rise to anxiety and recruitment of autonomic nervous system responses, both of which increase the work demands on the heart. Control of pain in acute MI is accomplished through a combination of nitrates, analgesics (e.g., morphine), and beta-blocking agents. Nitroglycerin is administered because of its vasodilating effect and ability to relieve coronary pain. The vasodilating effects of the drug decrease venous return (i.e., reduce preload) and arterial blood pressure (i.e., reduce afterload), thereby reducing oxygen consumption. Although a number of analgesic agents have been used to treat the pain of acute MI, morphine is usually the drug of choice to be given intravenously for rapid onset of action. Beta antagonists block beta-receptor-mediated functions of the sympathetic nervous system and thus decrease myocardial oxygen demand by reducing heart rate, cardiac contractility (i.e., inotropy), and systemic arterial blood pressure.

Immediate reperfusion therapy through use of pharmacologic agents (fibrinolytic therapy), percutaneous coronary intervention, or coronary artery bypass grafting is usually indicated for persons with ECG evidence of STEMI. Fibrinolytic drugs degrade blood and platelet clots, and their use is associated with positive outcomes such as reduced mortality and incidence of lethal
arrhythmias, limited infarct size, improved infarct healing, and myocardial remodeling. These agents interact with plasminogen to generate plasmin, which lyses fibrin clots and digests clotting factors V and VIII, prothrombin, and fibrinogen (see Chapter 12). The person must be at low risk for complications caused by bleeding, with no intracranial hemorrhage or significant trauma within the last 3 months.

Percutaneous coronary intervention (PCI) is indicated as an early invasive procedure for patients with unstable angina/NSTEMI. Percutaneous coronary intervention includes percutaneous transluminal coronary angioplasty (PTCA) and stent implantation. Balloon PTCA involves dilating the coronary artery with an inflatable balloon positioned at the narrowing of stenotic atherosclerotic plaque within the vessel (Fig. 19-7). Similar to an angiogram, the procedure is performed under local anesthesia in the cardiac catheterization laboratory. Balloon PTCA is almost exclusively used in conjunction with coronary stenting. The addition of coronary stenting significantly improved short- and long-term outcomes for patients with ACS compared with PTCA alone but patients remain at risk for restenosis and thrombosis following the procedure. Persons undergoing stent procedures must be treated with antiplatelet and anticoagulant drugs to prevent thrombosis and restenosis. Drug-eluting stents that provide sustained delivery of an antiproliferative pharmacologic agent may be used to decrease the risk of thrombosis.

Coronary artery bypass grafting (CABG) may be the treatment of choice for people with significant CAD who do not respond to medical treatment and who are not suitable candidates for PCI. It may also be indicated as an emergent treatment for STEMI, in which case the surgery should be done within 4 to 6 hours of symptom onset if possible. The procedure involves revascularization of the affected myocardium by attaching a saphenous vein graft between the aorta and the affected coronary artery distal to the site of occlusion, or by using the internal mammary artery to revascularize the left anterior descending artery or its branches (Fig. 19-8). This procedure often involves one to five distal anastomoses. Using emergent or urgent CABG as a reperfusion strategy is indicated in situations such as failed PCI with persistent pain or hemodynamic instability, or for patients who are not candidates for PCI or fibrinolytic therapy.

Myocardial Postinfarction Recovery Period. After a MI, there usually are three zones of tissue damage: a zone of myocardial tissue that becomes necrotic because of an absolute lack of blood flow; a surrounding zone of injured or hypoxic cells, some of which will recover; and an outer zone in which cells are ischemic and can be salvaged if blood flow can be reestablished. The boundaries of these zones may change with respect to the timeliness of treatment to successfully reestablish blood flow. If blood flow can be restored within 20 to 40 minutes, loss of cell viability is minimized. The process of ischemic necrosis usually begins in the subendocardial area of the
therapy, this complication has been greatly reduced.

Because of reperfusion and this pain increases with inspiration. The pain may with MI, the pain with pericarditis is sharp and stabbing, immune mechanisms. In contrast to the pain associated Descr. syndrome is thought to be mediated by autoimmu complications of MI are life-threatening arrhythmias, pericarditis, stroke, thromboemboli, and mechanical defects that have been replaced with scar tissue. An acute inflammatory response develops in the area of necrosis approximately 2 to 3 days after infarction. After, macrophages begin phagocytizing the damaged necrotic tissue; the infarcted area is gradually replaced with an ingrowth of highly vascularized granulation tissue, which in turn becomes less vascular and more fibrous in composition. At approximately 3 to 7 days, the center of the infarcted area remains soft and yellow; therefore, if rupture of the ventricle, interventricular septum, or valve structures occurs, it will usually happen at this time. Replacement of the necrotic myocardial tissue usually is complete by the 7th week. Importantly, areas of the myocardium that have been replaced with scar tissue lack the ability to contract and initiate or conduct action potentials.

The stages of recovery from MI are closely related to the size of the infarct. Fibrous scar tissue lacks the contractile, elastic, and conductive properties of normal myocardial cells; the residual effects and the complications of the MI are determined essentially by the extent and location of the injury. Among the numerous complications of MI are life-threatening arrhythmias, pericarditis, stroke, thromboemboli, and mechanical defects (e.g., mitral valve regurgitation, ventricular septal rupture, left ventricular wall rupture, and left ventricular aneurysm). Depending on its severity, MI has the potential for compromising cardiac contractility resulting in cardiogenic shock or heart failure (see Chapter 20). These serious complications are discussed later.

Pericarditis tends to occur in patients with large infarcts, a lower ejection fraction, and a higher occurrence of heart failure. It may appear as early as the 2nd or 3rd day postinfarction or up to several weeks later. Pericarditis that occurs weeks to months after MI or Dessler syndrome is thought to be mediated by autoimmune mechanisms. In contrast to the pain associated with MI, the pain with pericarditis is sharp and stabbing, and this pain increases with inspiration. The pain may be relieved by positional changes. Because of reperfusion therapy, this complication has been greatly reduced.

Mechanical defects result from changes that occur in the necrotic and subsequently inflamed myocardium and include rupture of the ventricular septum, papillary muscle, or free ventricular wall (Fig. 19-9). Partial or complete rupture of a papillary muscle is a rare but often fatal complication of transmural myocardial infarction. It is detected by the presence of a new systolic murmur and clinical deterioration, often with pulmonary edema. Ventricular septal rupture occurs less frequently than in the past because of reperfusion therapy. Previously thought to require surgical intervention only in symptomatic patients, surgical repair is now recommended for all patients with ventricular septal rupture. Complete rupture of the free wall of the infarcted ventricle occurs in up to 10% of patients and usually results in immediate death. It usually occurs 3 to 7 days postinfarction, usually involves the anterior wall, and is more frequent in older women. A more common mechanical postinfarction complication is mitral valve regurgitation, which results from early ischemic dysfunction of the papillary muscle and underlying myocardium.

A left ventricular aneurysm is a sharply delineated area of scar tissue that bulges paradoxically during systole. This section of the myocardium does not contract with the rest of the ventricle during systole. Instead, it diminishes the pumping efficiency of the heart and increases the work of the left ventricle, predisposing the patient to heart failure. Ischemia in the surrounding area predisposes the patient to development of arrhythmias, and stasis of blood in the aneurysm can lead to thrombus formation. Surgical resection may be performed to prevent these complications when other treatment measures fail.

**Chronic Ischemic Heart Disease**

Myocardial ischemia is defined as the inability of the coronary arteries to supply blood to meet the metabolic demands of the heart. Most often limitations in coronary blood flow are the result of atherosclerosis, but vasospasm may serve as an initiating or contributing factor. Coronary artery disease is divided into three
classifications: chronic stable angina, silent myocardial ischemia, and variant or vasospastic angina.

**Chronic Stable Angina**

Angina pectoris is a symptomatic paroxysmal chest pain or pressure sensation associated with transient myocardial ischemia. Chronic stable angina is associated with a fixed coronary obstruction that produces an imbalance between coronary blood flow and the metabolic demands of the myocardium. Stable angina is the initial manifestation of ischemic heart disease in approximately half of persons with CAD. Although most persons with stable angina have atherosclerotic heart disease, angina is not a clinical manifestation in a considerable number of persons with advanced coronary atherosclerosis. Some persons may not report severe pain, perhaps because they are physically inactive, have collateral circulation, or do not feel pain due to neuropathy.

Angina pectoris usually is precipitated by situations that increase the work demands of the heart, such as physical exertion, exposure to cold, and emotional stress. The pain is typically described as a steady constricting, squeezing, or a suffocating sensation, increasing in intensity only at the onset and end of the episode. This pain is commonly located in the precordial or substernal area of the chest; it is similar to sensations associated with myocardial infarction in that it may radiate to the left shoulder, jaw, arm, or other areas of the chest or back (Fig. 19-11). In some persons, the arm or shoulder pain may be confused with arthritis; in others, epigastric pain is confused with indigestion. Angina commonly is categorized according to whether it occurs with physical activity, occurs during rest, is of new onset, or is of increasing severity.

Typically, chronic stable angina is provoked by exertional activity or emotional stress and relieved within minutes by rest or by nitroglycerin. A delay of more than 5 to 10 minutes before relief is obtained suggests that the symptoms result from severe ischemia. Angina that occurs at rest, is of new onset, or is increasing in intensity or duration denotes an increased risk for myocardial infarction and should be evaluated using the criteria for ACS.

**FIGURE 19-10.** Paradoxical movement of a left ventricular aneurysm during systole.

**FIGURE 19-11.** Areas of pain due to Angina including anterior and posterior views.
Silent Myocardial Ischemia

Silent myocardial ischemia occurs in the absence of anginal pain. The factors associated with asymptomatic ischemia appear to be the same as those responsible for angina: impaired blood flow from the effects of coronary atherosclerosis or vasospasm. Silent myocardial ischemia affects three populations—persons who are asymptomatic without other evidence of CAD, persons who have had a myocardial infarct and continue to have episodes of silent ischemia, and persons with angina who also have episodes of silent ischemia. The reason for the painless episodes of ischemia is unclear. The ischemic episodes may be shorter and involve less myocardial tissue than those producing pain. Another explanation is that persons with silent angina have defects in pain threshold or pain transmission, or an autonomic neuropathy with sensory denervation. For example, asymptomatic ischemia is observed in persons with diabetes mellitus, probably the result of autonomic neuropathy, which is a common complication of diabetes. Silent myocardial ischemia makes up a significant proportion of all STEMIs in the elderly.

Variant (Vasospastic) Angina

Variant angina, also known as vasospastic or Prinzmetal angina, is caused by coronary artery spasm. The causes of variant angina are not completely understood, but a combination of pathologic processes may be responsible. Endothelial dysfunction, hyperactive sympathetic nervous system responses, defective handling of calcium by vascular smooth muscle, or altered nitric oxide production may all contribute. In some persons it is associated with hypercontractility of vascular smooth muscle, as well as with migraine headaches or Raynaud phenomenon. Unlike stable angina that occurs with exertion or stress, variant angina usually occurs during rest or with minimal exercise and frequently occurs nocturnally (between midnight and 8 AM).

Rhythm disturbances often occur when the pain is severe, and most persons are aware of their presence during an attack. Electrocardiographic changes are transient and include ST-segment elevation or depression, T-wave peaking, and inversion of U waves. Persons with variant angina who have serious arrhythmias during spontaneous episodes of pain are at a higher risk of sudden death.

Diagnosis and Treatment

The diagnosis of chronic ischemic heart disease is based on a detailed pain history, the presence of risk factors, invasive and noninvasive studies, and laboratory studies. It is important to rule out non-coronary causes of chest pain, such as esophageal reflux or musculoskeletal disorders. Noninvasive testing for chronic stable angina includes ECG, echocardiography, exercise stress testing, nuclear imaging studies, computed tomography (CT) scan, and possibly cardiac magnetic resonance imaging (MRI). Because the resting ECG is often normal, exercise testing is important for evaluating persons with angina. Although noninvasive testing is valuable in the diagnosis of chronic stable angina, cardiac catheterization and coronary arteriography are often needed for a definitive diagnosis.

The treatment goals for stable angina are directed toward symptom reduction and prevention of myocardial infarction through nonpharmacologic strategies, pharmacologic therapy, and coronary interventions. Nonpharmacologic methods are aimed at symptom control and lifestyle modifications to reduce risk factors for coronary disease. They include smoking cessation in persons who smoke, stress reduction, a regular exercise program, limiting dietary intake of foods high in cholesterol and saturated fats, weight reduction if obesity is present, and avoidance of cold or other stresses that produce vasoconstriction. Immediate cessation of activity often is sufficient to abort the onset of anginal pain. Sitting down or standing quietly may be preferable to lying down because these positions decrease preload by producing pooling of blood in the lower extremities.

Pharmacologic agents used in the treatment of chronic stable angina include nitrates, beta blockers, and calcium channel blockers. Nitrates, both short- and long-acting, are vasodilators used in the treatment of chronic stable angina and in silent myocardial ischemia. Nitrates exert their effect mainly through a decrease in venous return to the heart with a resultant decrease in intraventricular volume. Arterial pressure also decreases. Decreased intraventricular pressure and volume are associated with decreased wall tension and myocardial oxygen requirement. Although they are not vasodilators, beta blockers are extremely useful in management of angina associated with effort. The benefits of beta blockers are due primarily to their hemodynamic effects—decreased heart rate, blood pressure, and myocardial contractility—which decrease myocardial oxygen requirements at rest and during exercise. The calcium channel-blocking agents, also called calcium antagonists, block activated and inactivated L-type calcium channels in cardiac and smooth muscle. The therapeutic effects of the calcium channel blockers result from coronary and peripheral artery dilation and from decreased myocardial metabolism associated with the decrease in myocardial contractility. Percutaneous coronary intervention relieves symptoms for patients with chronic stable angina, but does not appear to extend the life span. Coronary artery bypass grafting is usually indicated in patients with double- or triple-vessel disease.

SUMMARY CONCEPTS

- Coronary artery disease is a disorder of impaired coronary blood flow, usually caused by atherosclerosis.
- The acute coronary syndromes (ACS) include unstable angina/non-ST elevation myocardial infarction (UA/NSTEMI) and ST elevation myocardial infarction (STEMI), which differ in severity based on the absence or presence of electrocardiograph ST segment changes.
Infective endocarditis (IE) is a serious and potentially life-threatening infection of the inner surface of the heart including the cardiac valves. Although rare in most contemporary population surveys (annual incidence 3 to 7 per 100,000 persons),

IE is associated with significant mortality. Infective endocarditis is characterized by colonization or invasion of the valves and the mural endocardium by a microbial agent, leading to vegetations and destruction of underlying cardiac tissues. Although other microorganisms, such as fungi, can cause endocarditis, the vast majority of cases are caused by bacteria.

Infective endocarditis is commonly classified into acute or subacute–chronic forms, depending on the onset, etiology, and severity of the disease. The onset of acute IE is usually rapid and occurs in patients with previously normal cardiac valves who are healthy and perhaps have a history of intravenous drug abuse, whereas subacute-chronic IE evolves over months, usually in persons who have underlying heart valve abnormalities.

Etiology and Pathogenesis. Two factors contribute to the development of IE: a portal of entry by which the organism gains access to the circulatory system and a damaged endocardial surface. The portal of entry into the bloodstream may be an obvious infection, a dental or surgical procedure that causes transient bacteremia, intravenous injection of a contaminated substance directly into the blood, or an occult source such as the oral cavity, gut, or a subcutaneous injury. Although infective endocarditis can develop in individuals with normal heart valves, persons with structural abnormalities of the valves, such as mitral valve prolapse or congenital heart disease, are at significantly higher risk. Host factors such as neutropenia, immunodeficiency, malignancy, therapeutic immunosuppression, diabetes, and alcohol or intravenous drug use are predisposing factors. Infections may also be associated with cardiovascular prostheses and devices, such as pacemakers, defibrillators, and left ventricular assist devices.

Staphylococcal infections are the leading cause of IE, with streptococci and enterococci as the other two most common infectious agents. Other bacterial agents include the so-called HACEK group (Haemophilus species, Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens, and Kingella kingae), all commensals in the oral cavity. Less commonly, gram-negative bacteria and fungi are involved. The causative agents differ somewhat in high-risk groups. For example, Staphylococcus aureus is the major offender in intravenous drug users, whereas prosthetic heart valve infective endocarditis tends to be caused by coagulase-negative staphylococci (e.g., Staphylococcus epidermidis).

In both acute and subacute–chronic forms of IE, friable, bulky, and potentially destructive vegetative lesions form on the heart valves (Fig. 19-12). The aortic and mitral valves are the most common sites of infection, although the right heart may also be involved, particularly in intravenous drug abusers. The vegetative lesions consist of a collection of infectious organisms and cellular debris enmeshed in the fibrin strands of clotted blood. The lesions may be singular or multiple, may grow as large as several centimeters, and usually are found loosely attached to the free edges of the valve surface. The infectious loci continuously release bacteria into the bloodstream and are a source of persistent bacteremia, sometimes contributing to pericarditis.

Disorders of the Endocardium

Among the disorders that affect the endocardium are infective endocarditis, rheumatic fever, and valvular heart disorders.

Infective Endocarditis

Infective endocarditis (IE) is a serious and potentially life-threatening infection of the inner surface of the heart including the cardiac valves. Although rare in most contemporary population surveys (annual incidence 3 to 7 per 100,000 persons),

IE is associated with significant mortality.
As the lesions grow, they cause valve destruction and dysfunction such as regurgitation, ring abscesses with heart block, and perforation. The loose organization of these lesions permits the organisms and fragments of the lesions to form emboli and travel in the bloodstream, causing cerebral, systemic, or pulmonary emboli. The fragments may lodge in small blood vessels, causing small hemorrhages, abscesses, and infarction of tissue. The bacteremia also can initiate immune responses thought to be responsible for skin manifestations, polyarthritis, glomerulonephritis, and other immune disorders.

**Manifestations.** Signs and symptoms of IE can include fever and signs of systemic infection, development of a new heart murmur, change in the character of an existing heart murmur, and evidence of embolic distribution of the vegetative lesions. In the acute form, the person is likely to develop a high fever accompanied by chills. In the subacute form, the fever usually is low grade, of gradual onset, and frequently accompanied by other systemic signs of inflammation, such as anorexia, malaise, and lethargy. Small petechial hemorrhages frequently result when emboli lodge in the small vessels of the skin, nail beds, and mucous membranes. Splinter hemorrhages (i.e., dark red lines) under the nails of the fingers and toes are common. Cough, dyspnea, arthralgia or arthritis, diarrhea, and abdominal or flank pain may occur as the result of systemic emboli.

**Diagnosis and Treatment.** Infective endocarditis continues to pose major challenges in terms of diagnosis and treatment. The blood culture remains the most definitive diagnostic procedure and is essential for guiding the treatment. However, the indiscriminate use of antibiotics has made identifying the causative organism much more difficult. Negative blood cultures can occur in up to 30% of cases of IE, delaying diagnosis and treatment and consequently having a profound effect on outcome. This may result from the prior administration of antibiotics, because the infection is growing slowly, or because it is challenging to culture in a laboratory (i.e., the organism requires a special culture medium). Transthoracic and transesophageal echocardiography are the primary techniques for detection of vegetation and cardiac complications resulting from IE and are important tools in the diagnosis and management of the disease.

Treatment of IE focuses on identifying and eliminating the causative microorganism, minimizing the residual cardiac effects, and treating the pathologic effect of emboli. The choice of antimicrobial therapy depends on the organism cultured and whether the infection involves a native or prosthetic valve. The widespread emergence of multidrug-resistant organisms, including *S. aureus*, poses a serious challenge in the treatment of IE. In addition to antibiotic therapy, surgery may be needed for unresolved infection, severe heart failure, and significant emboli.

Prevention of IE through the use of prophylactic antibiotics is controversial. The current recommendations conclude that only a very small number of IE cases might be prevented by antibiotic prophylaxis for dental procedures. Therefore, prophylaxis is recommended only for patients with predisposing congenital or valvular disorders undergoing select dental and surgical procedures.

**Rheumatic Heart Disease**

Rheumatic fever (RF) is an immune-mediated, multisystem inflammatory disease (involving heart, skin, and connective tissue) that occurs a few weeks after a group A (β-hemolytic) streptococcal (GAS) pharyngitis (sore throat) in children and young adults. It rarely occurs with streptococcal infections at other sites (e.g., skin). Acute rheumatic heart disease (RHD) is the cardiac manifestation of RF and is associated with inflammation of all three layers of the heart (myocardium, pericardium, and endocardium including the heart valves). Chronic deformity and impairment of one or more of the heart valves is the most important consequence of RHD. Although RF and RHD are rare in developed countries, the disorders continue to be major health problems in underdeveloped countries, where inadequate health care, poor nutrition, and crowded living conditions still prevail. Data from recent studies that used echocardiography to screen for RHD indicate that the prevalence of RHD is increasing in these regions. As a result, there has been an increased awareness and interest in RF and RHD.

**Pathogenesis.** The pathology of RF does not involve direct bacterial infection of the heart. Rather, the time frame for development of symptoms relative to the onset of pharyngitis and the presence of antibodies to the GAS organism strongly suggests an immunologic response. It is thought that antibodies directed against the M protein of certain strains of streptococci cross-react with glycoprotein antigens in the heart, joints, and other...
tissues to produce an autoimmune response through a phenomenon called molecular mimicry\(^3\) (see Chapter 16). Although only a small percentage of persons with untreated GAS pharyngitis develop RF, the incidence of recurrence with a subsequent untreated infection is substantially greater. These observations and more recent studies suggest a genetic predisposition to development of the disease.\(^6\)

**Clinical Features.** Rheumatic fever can manifest as an acute, recurrent, or chronic disorder. The acute stage of rheumatic fever includes a history of an initiating streptococcal infection and subsequent development of discrete inflammatory lesions seen on histopathologic exam within the connective tissue elements of the heart, blood vessels, joints, and subcutaneous tissues. Within the heart these lesions are called Aschoff bodies.\(^5\) The recurrent phase usually involves extension of the cardiac effects of the disease. The chronic phase is characterized by permanent deformity of the heart valves. Chronic rheumatic heart disease usually does not appear until at least 10 years after the initial attack, sometimes decades later.

Most persons with rheumatic fever have a history of sore throat, headache, fever, abdominal pain, nausea, vomiting, swollen glands (usually at the angle of the jaw), and other signs and symptoms of streptococcal infection. Other clinical features are related to the acute inflammatory process and the structures involved in the disease process. The course of the disease is characterized by a constellation of findings that includes carditis, migratory polyarthritis of the large joints, erythema marginatum, subcutaneous nodules, and Sydenham chorea.\(^5,35\)

Acute *rheumatic carditis*, which complicates the acute phase of rheumatic fever, is a pancarditis involving all three layers of the heart. In some cases, the myocardiurn can be so severely affected that the resulting cardiac dilation causes functional mitral insufficiency and even heart failure. Clinical features include pericardial friction rubs, arrhythmias, and a new heart murmur. Usually, both the pericarditis and myocarditis are self-limited manifestations of the acute stage of the rheumatic fever. Involvement of the endocardium and valvular structures produces the permanent and disabling effects of disease. Although any of the four valves can be involved, the mitral and aortic valves are affected most often. During the acute inflammatory stage, the valvular structures become red and swollen, and small vegetative lesions develop on the valve leaflets. These changes gradually proceed to the development of fibrous scar tissue, which tends to contract and cause permanent deformity of the valve leaflets and shortening of the chordae tendineae. In some cases, the edges or commissures of the valve leaflets fuse together as healing occurs.

**Polyarthritis** is the most common manifestation of rheumatic fever. It may be the only major diagnostic criterion in adolescents and adults. The arthritis most often involves larger joints, particularly the knees and ankles, and is almost always migratory, affecting one joint and then moving to another. Untreated, it lasts approximately 4 weeks, but it typically responds within 48 hours to salicylates. Polyarthritis usually heals completely.

**Erythema marginatum** lesions are commonly seen on the trunk or inner aspects of the upper arm and thigh, but never on the face. These transitory skin lesions occur early in the course of a rheumatic attack and usually with subcutaneous nodules, which are hard, painless, and freely movable masses that usually occur over the extensor muscles of the wrist, elbow, ankle, and knee joints.

Chorea (i.e., Sydenham chorea) is the major central nervous system manifestation of rheumatic fever. It is rarely seen after 20 years of age. The onset is typically insidious: the child often is fidgety, cries easily, drops things, and walks clumsily. The choreiform movements are spontaneous, rapid, jerking movements that interfere with voluntary activities. Facial grimaces are common, and speech may be affected. The chorea is self-limited, usually running its course within a matter of weeks or months, but recurrences are not uncommon.

**Diagnosis.** Diagnosis of acute rheumatic fever is made using serologic evidence of GAS infection along with a consideration of the cardinal symptoms and clinical manifestations or Jones criteria, which were developed to assist in standardizing the diagnosis of RF. Serologic tests for streptococcal antibodies (antistreptolysin O and antideoxyribonuclease B) can provide retrospective confirmation of recent streptococcal infection in persons thought to have rheumatic fever. Laboratory markers of acute inflammation include an elevated white blood cell count, erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP). The Jones criteria divide the clinical features of RF into major and minor categories, based on prevalence and specificity.\(^34,36\) The presence of two major signs (i.e., carditis, polyarthritis, chorea, erythema marginatum, and subcutaneous nodules) or one major and two minor signs (i.e., arthralgia, fever, elevated ESR, CRP, or leukocyte count and prolonged PR interval on EKG), accompanied by evidence of a preceding GAS infection (antistreptolysin 0 antibodies, positive throat culture for GAS) indicates a high probability of RF.

The use of echocardiography has enhanced the understanding of both acute and chronic RHD. It is useful in assessing the severity of valvular stenosis and regurgitation, chamber size and ventricular function, and the presence and size of pleural effusions. Doppler ultrasonography may be useful in identifying cardiac lesions in persons who do not show typical signs of cardiac involvement during an attack of RF.\(^34,36\)

**Treatment and Prevention.** It is important that GAS infections be promptly diagnosed and treated to prevent RF. The gold standard for detecting a GAS infection is a throat culture. However, it takes 24 to 48 hours to produce a result, which may delay treatment. Rapid tests for direct detection of GAS antigens are highly specific for GAS infection but are limited in terms of their sensitivity (i.e., the person may have a negative test result but
have a streptococcal infection). Thus a negative antigen test result should be confirmed with a throat culture when a streptococcal infection is suspected.36

Treatment of acute RF is designed to control the acute inflammatory response and prevent cardiac complications and recurrence of the disease. During the acute phase, antibiotics, anti-inflammatory drugs, and selective restriction of activities are prescribed. Penicillin, or another antibiotic in penicillin-sensitive patients, is the treatment of choice.36 Salicylates and corticosteroids can be used to suppress the inflammatory response, but should not be given until the diagnosis of RF is confirmed. Surgery, including valve repair and replacement, is indicated for chronic rheumatic valve disease and is determined by the severity of the symptoms or cardiac dysfunction.

Persons who had RF are at high risk for recurrence after subsequent GAS throat infections. Penicillin is the treatment of choice for secondary prophylaxis, but sulfadiazine or erythromycin may be used in those who are allergic to penicillin. The duration of prophylaxis depends on whether residual valvular disease is present or absent. It is recommended that persons who have persistent valvular disease receive low-dose antibiotic prophylaxis for at least 5 years after the acute episode of RF or until age 21 years if there is no evidence of carditis.35

**Valvular Heart Disease**

The past several decades have brought remarkable advances in the treatment of valvular heart disease. This is undoubtedly due to improved methods for noninvasive monitoring of ventricular function, improvement in prosthetic valves, advances in valve reconstruction, and the development of guidelines to improve the timing of surgical interventions.37 Nevertheless, valvular heart disease continues to produce considerable mortality and morbidity.

**Hemodynamic Derangements**

The function of the heart valves is to promote unidirectional flow of blood through the chambers of the heart. Dysfunction of the valves can result from a number of disorders including congenital defects, trauma, ischemia, degenerative changes, and inflammation. Although any of the heart valves can become diseased, the most commonly involved are the mitral and aortic valves. Disorders of the pulmonary and tricuspid valves are less common, probably because of the low pressure in the right side of the heart.

The heart valves consist of thin leaflets of tough, flexible, endothelium-covered fibrous tissue firmly attached at the base to the fibrous valve rings (see Chapter 17). The leaflets of the heart valves may be damaged or inflamed, which can deform their line of closure. Healing of the valve leaflets is associated with increased collagen content and scarring, causing the leaflets to shorten and stiffen. Another problem is that the edges of the healing valve leaflets can fuse together so that the valve does not open or close properly.

Two types of mechanical disruption occur with valvular heart disease: narrowing of the valvular opening, so it does not open properly, and distortion of the valve, so it does not close properly (Fig. 19-13). **Stenosis** refers to a narrowing of the valve orifice and failure of the valve leaflets to open normally (Fig. 19-14). Significant narrowing of the valve orifice increases the resistance to blood flow through the valve, converting the normally smooth laminar flow to a less efficient turbulent flow. This increases the work and volume of the chamber emptying through the narrowed valve—the left atrium in the case of mitral stenosis and the left ventricle in aortic stenosis. An **incompetent or regurgitant valve** does not close properly, thereby permitting the backward flow of blood to occur when the valve should be closed. When the aortic valve is affected, blood flows back into the left ventricle during diastole. When the mitral valve is affected, blood flows back into the left atrium during systole. Stenosis and regurgitation can occur in various forms, or these abnormalities may exist in the same valve. Alterations in hemodynamic function that accompany aortic and mitral valve stenosis and regurgitation are illustrated in Figure 19-15.
The effects of valvular heart disease depend on the valve involved, the degree of involvement, the rapidity of onset, and the rate and adequacy of compensatory mechanisms. For example, sudden destruction of an aortic valve cusp by infection can cause massive regurgitation and rapid heart failure, whereas rheumatic mitral stenosis usually develops over years without obvious symptoms. Abnormal turbulent flow through diseased valves typically produces abnormal heart sounds called murmurs.

**Mitral Valve Disorders**

The mitral or left atrioventricular (AV) valve controls the directional flow of blood between the left atrium and the left ventricle. The edges or cusps of both AV valves, which are thinner than those of the semilunar (i.e., pulmonic and aortic) valves, are anchored to the papillary muscles by the chordae tendineae. During much of systole, the mitral valve is subjected to the high pressure generated by the left ventricle as it pumps blood into the systemic circulation. During this period of increased pressure, the chordae tendineae prevent the eversion of the valve leaflets into the left atrium.

**Mitral Valve Stenosis.** Mitral valve stenosis represents the incomplete opening of the mitral valve during diastole, with left atrial distension and impaired filling of the left ventricle (see Fig. 19-15). Mitral valve stenosis is most commonly the result of rheumatic fever. Less frequently, the defect is congenital and manifests during infancy or early childhood or calcification in elderly patients. Mitral valve stenosis is a continuous, progressive, lifelong disorder consisting of a slow, stable course in the early years and progressive acceleration in later years.

Mitral valve stenosis is characterized by fibrous replacement of valvular tissue, along with stiffness and fusion of the valve apparatus (see Fig. 19-14). Typically, the mitral cusps fuse at the edges and the chordae tendineae thicken and shorten pulling the valvular structures into the ventricles. As the resistance to flow through the valve increases, the left atrium dilates and left atrial pressure increases. The increased left atrial pressure eventually is transmitted to the pulmonary venous system, causing pulmonary congestion. A characteristic auscultatory finding in mitral stenosis is an opening snap following the second heart sound, which is caused by the stiff mitral valve. As the stenosis worsens, there is a localized low-pitched diastolic murmur that increases in duration with the severity of the stenosis.

The clinical presentation of mitral valve stenosis depends on the severity of the obstruction or the degree of reduction in the valve area—the more severe the stenosis, the greater the symptoms. Manifestations are related to the elevation in left atrial pressure and pulmonary congestion such as dyspnea with exertion, decreased cardiac output owing to impaired left ventricular filling, and left atrial enlargement with the development of atrial arrhythmias and mural thrombi. More severe stenosis is associated with symptoms of pulmonary congestion, including paroxysmal nocturnal dyspnea (PND) and orthopnea. Palpitations, chest pain, weakness, and fatigue are common complaints.

**FIGURE 19-15.** Alterations in hemodynamic function that accompany aortic valve stenosis, mitral valve regurgitation, mitral valve stenosis, and aortic valve regurgitation. The thin arrows indicate direction of normal flow, and thick arrows the direction of abnormal flow. Expand description.
Paroxysmal atrial tachycardia and atrial fibrillation develop in 30% to 40% of persons with symptomatic mitral stenosis. Together, fibrillation and distention of the atria predispose the person to mural thrombus formation. The risk of arterial embolization, particularly stroke, is significantly increased in persons with atrial fibrillation.

Mitral Valve Regurgitation. Mitral valve regurgitation is characterized by incomplete closure of the mitral valve, with the left ventricular stroke volume being divided between the forward stroke volume that moves blood into the aorta and the regurgitant stroke volume that moves it back into the left atrium during systole (see Fig. 19-15). Mitral valve regurgitation can result from many processes that result in a rigid and thickened valve that does not open or close completely, such as IE or RHD. It can also result from rupture of the chordae tendineae or papillary muscles due to an MI, papillary muscle dysfunction, or stretching of the valve structures due to dilation of the left ventricle or valve orifice. Mitral valve prolapse is a common cause of mitral valve regurgitation in lean, thin women.

The hemodynamic changes associated with chronic mitral valve regurgitation occur gradually, allowing the left atrium to undergo compensatory responses. An increase in left ventricular end-diastolic volume permits an increase in total stroke volume, with restoration of forward flow into the aorta. Augmented preload and reduced or normal afterload (provided by unloading the left ventricle into the left atrium) facilitate left ventricular ejection. At the same time, a gradual increase in left atrial size allows for accommodation of the regurgitant volume at a lower filling pressure. A characteristic feature of mitral valve regurgitation is an enlarged or hypertrophied left ventricle, a hyperdynamic left ventricular impulse, and a pansystolic (throughout systole) heart murmur. Mitral regurgitation, like mitral stenosis, predisposes to atrial fibrillation.

The increased volume work associated with mitral regurgitation is relatively well tolerated, and many persons with the disorder remain asymptomatic for many years, developing symptoms between 6 and 10 years after diagnosis. The severity of regurgitation reflects the degree of left ventricular enlargement and may correlate with murmur intensity and typically correlates with the patients’ symptoms. As the disorder progresses, left ventricular function becomes impaired, the forward (aortic) stroke volume decreases, and the left atrial pressure increases, with the subsequent development of pulmonary congestion. It is usually recommended that valve surgery be performed before the onset of these symptoms.

Mitral Valve Prolapse. Sometimes referred to as floppy mitral valve syndrome, mitral valve prolapse occurs in 1% to 2.5% of the general population. The disorder is seen more frequently in thin women, and there may be a familial basis. Familial mitral valve prolapse is transmitted as an autosomal dominant trait, and several chromosomal loci have been identified. Although the exact cause of the disorder usually is unknown, it has been associated with Marfan syndrome, osteogenesis imperfecta, and other connective tissue disorders, and with cardiac, hematologic, neuroendocrine, metabolic, and psychological disorders.

Pathologic findings in persons with mitral valve prolapse include a myxedematous (mucinous) degeneration of mitral valve leaflets that causes them to become enlarged and floppy so that they prolapse or balloon back into the left atrium during systole. Secondary fibrotic changes reflect the stresses and injury that these ballooning movements impose on the valve. Certain forms of mitral valve prolapse may arise from disorders of the myocardium that place undue stress on the mitral valve because of abnormal movement of the ventricular wall or papillary muscle. Mitral valve prolapse may or may not cause mitral regurgitation.

Most people with mitral valve prolapse are asymptomatic and the disorder is discovered during a routine physical examination. A minority of people have symptoms such as chest pain, dyspnea, fatigue, anxiety, palpitations, and light-headedness. Unlike angina, the chest pain often is prolonged, ill defined, and not associated with exercise or exertion. The pain has been attributed to ischemia resulting from traction of the prolapsing valve leaflets. Palpitations, arrhythmias, and anxiety may result from abnormal autonomic nervous system function that commonly accompanies the disorder. Rare cases of sudden death have been reported for persons with mitral valve prolapse, mainly those with a family history of similar occurrences.

The disorder is characterized by a spectrum of auscultatory findings, ranging from a silent form to one or more middiastolic clicks followed by a late systolic or pansystolic murmur heard best at the apex. The clicks are caused by the sudden tensing of the mitral valve.

Aortic Valve Disorders

The aortic valve, which is located between the left ventricle and aorta, has three cuplike cusps and sometimes is referred to as the aortic semilunar valve because its leaflets are crescent or moon shaped. The aortic valve has no chordae tendineae. Although their structures are similar, the edges of the aortic valve leaflets are thicker than those of the mitral valve, particularly at the middle of the leaflet (see Chapter 17, Fig. 17-10). The mechanism of action of the aortic valve is also different from that of the mitral valve. During ventricular systole when the ventricles contract and blood is being ejected into the aorta, the cusps of the valve are flattened against the aortic wall and blood rushes past them; when the ventricles relax and the blood (no longer propelled forward by the pressure of ventricular contraction) begins to flow backward toward the heart, it fills the cusps and this closes the valve.

An important feature of the aortic valve is the location of the orifices for the two main coronary arteries, which are located behind the valve and at right angles to the direction of blood flow. It is the lateral pressure in the aorta that propels blood into the coronary arteries. During the ejection phase of the cardiac cycle, the lateral pressure is diminished by conversion of potential energy to kinetic energy as blood moves forward into the aorta. This process is grossly exaggerated in aortic valve stenosis because of the high flow velocities.

Aortic Valve Stenosis. Aortic valve stenosis is characterized by narrowing of the valve orifice with increased resistance to ejection of blood from the left ventricle into the aorta (see Fig. 19-15). The most common causes of aortic valve stenosis are congenital valve malformations and acquired calcification of a normal aortic valve. Congenital malformations may result in unicuspid, bicuspid, or misshapen valve leaflets. Acquired aortic stenosis is usually the consequence of calcification associated with age-related degenerative changes or the normal “wear and tear” of either previously normal aortic valves or congenitally bicuspid valves with which approximately 1% of the population are born. The incidence of acquired aortic valve stenosis is increasing with the rising average age of the population.

The progression of calcific aortic stenosis is usually slow and varies widely among individuals. It usually becomes clinically evident in the sixth and seventh decades in persons with bicuspid aortic valves, and not until the eighth and ninth decades in those with previously normal valves. Valve changes range from mild thickening without obstruction to severe calcification with impaired leaflet motion and obstructed left ventricular outflow. Processes in the development of calcific aortic valve disease have been shown to be similar to those in CAD. Both conditions are more common in men, older persons, and persons with hypercholesterolemia, and both derive in part from an active inflammatory process.

Early lesions of aortic sclerosis show focal subendothelial plaquelike lesions, similar to the initial phases of an atherosclerotic lesion. Aortic sclerosis is distinguished from aortic stenosis by the degree of valve impairment. In aortic sclerosis the valve leaflets are abnormally thickened, but the obstruction to outflow is minimal, whereas in aortic stenosis the functional area of the valve has decreased enough to cause measurable obstruction to outflow. Calcification of the aortic valve progresses from the base of the cusps to the leaflets. This reduces leaflet motion and effective valve area, but without commissural fusion. As calcification progresses, the leaflets become more rigid, there is worsening of obstruction to left ventricular outflow, and fusion of the commissures leads to aortic stenosis.

Because aortic stenosis usually develops gradually, the left ventricle has time to adapt. With increased systolic pressure from obstruction, the left ventricular wall becomes thicker, or hypertrophies, but a normal chamber volume is maintained. With this increase in wall thickness, called concentric remodeling, the left ventricular ejection fraction is maintained within normal limits. Hemodynamic variables remain stable even though the valve opening area is reduced to half of its normal size. However, an additional reduction in the valve opening area from one half to one fourth of its normal size produces severe obstruction to flow and a progressive increase in the pressure overload on the left ventricle. At this point, the increased work of the heart begins to exceed the coronary blood flow reserve, causing both systolic and diastolic dysfunction and signs of heart failure.

Aortic stenosis is usually first diagnosed with auscultation of a loud systolic ejection murmur or a single or paradoxically split-second heart sound. Eventually, the classic symptoms of advanced aortic stenosis such as angina, syncope, and heart failure develop, although more subtle signs of a decrease in exercise tolerance or exertional dyspnea should be monitored closely. Angina occurs in approximately two thirds of
persons with advanced aortic stenosis and is similar to that observed in CAD. Dyspnea, marked fatigability, peripheral cyanosis, and other signs of heart failure usually are not prominent until late in the course of the disease. Syncope (fainting) is most commonly due to the reduced cerebral circulation that occurs during exertion when the arterial pressure declines consequent to vasodilation in the presence of a fixed cardiac output.

**Aortic Valve Regurgitation.** Aortic valve regurgitation or aortic insufficiency is the result of an incompetent aortic valve that allows blood to flow back to the left ventricle during diastole (see Fig. 19-15). As a result, the left ventricle increases its stroke volume to accommodate blood entering from the pulmonary veins in addition to the volume of blood leaking back through the regurgitant valve. This defect may result from conditions that cause scarring of the valve leaflets or from enlargement of the valve orifice to the extent that the valve leaflets no longer meet. There are various causes of aortic regurgitation, including rheumatic fever, idiopathic dilation of the aorta, congenital abnormalities, infective endocarditis, and Marfan syndrome. Other causes include hypertension, trauma, and failure of a prosthetic valve.

Acute aortic regurgitation is characterized by a sudden, large regurgitant volume to a left ventricle of normal size that has not had time to adapt to the volume overload. It is caused by disorders such as infective endocarditis, trauma, or aortic dissection. Using the Frank-Starling mechanism, the heart responds by increasing heart rate, but the compensatory mechanisms fail to maintain the cardiac output. As a result, there is severe elevation in left ventricular end-diastolic pressure, which is transmitted to the left atrium and pulmonary veins, culminating in pulmonary edema. A decrease in cardiac output leads to sympathetic activation and a resultant increase in heart rate and peripheral vascular resistance that cause the regurgitation to worsen. Death from pulmonary edema, ventricular arrhythmias, or circulatory collapse is common in severe acute aortic regurgitation.

Chronic aortic regurgitation, which usually has a gradual onset, represents a condition of combined left ventricular volume and pressure overload. As the valve deformity increases, regurgitant flow into the left ventricle increases, diastolic blood pressure falls, and the left ventricle progressively enlarges or eccentrically hypertrophies. Hemodynamically, the increase in left ventricular volume results in the ejection of a large stroke volume that usually is adequate to maintain the forward cardiac output until late in the course of the disease. Most persons remain asymptomatic during this compensated phase, which may last decades. The only sign for many years may be a soft systolic aortic murmur.

As the disease progresses, signs and symptoms of left ventricular failure begin to appear. These include exertional dyspnea, orthopnea, and paroxysmal nocturnal dyspnea. In aortic regurgitation, failure of aortic valve closure during diastole causes an abnormal drop in diastolic pressure. Because coronary blood flow is greatest during diastole, the drop in diastolic pressure produces a decrease in coronary perfusion. Although angina is rare, it may occur when the heart rate and diastolic pressure fall to low levels. Persons with severe aortic regurgitation often complain of an uncomfortable awareness of heartbeat, particularly when lying down, and chest discomfort due to pounding of the heart against the chest wall. Tachycardia, occurring with emotional stress or exertion, may produce palpitations, head pounding, and premature ventricular contractions.

The major physical findings relate to the widening of the arterial pulse pressure, a hallmark of chronic aortic regurgitation. The pulse has a rapid rise and fall (Corrigan pulse), with an elevated systolic pressure and low diastolic pressure owing to the large stroke volume and rapid diastolic runoff of blood back into the left ventricle. Korotkoff sounds may persist to zero, even though intra-arterial pressure rarely falls below 30 mm Hg.\(^{37}\) The large stroke volume and wide pulse pressure may result in prominent carotid pulsations in the neck, throbbing peripheral pulses, and a left ventricular impulse that causes the chest to move with each beat. The hyperkinetic pulse of more severe aortic regurgitation, called a water-hammer pulse, is characterized by distention and quick collapse of the artery. On auscultation, the turbulence of flow across the aortic valve during diastole produces a high-pitched or blowing sound.

**Diagnosis and Treatment**

Valvular defects usually are detected through cardiac auscultation (i.e., heart sounds). Echocardiography provides a means of visualizing valvular motion, patterns of flow, and closure patterns. Pulsed Doppler ultrasound provides a semiquantitative or qualitative estimation of the severity of transvalvular gradients, right ventricular systolic pressure, and valvular regurgitation. Color flow Doppler provides a visual pattern of flow velocities over the anatomic 2-D echocardiographic image. This allows for demonstration of turbulence from stenotic and regurgitant valves. Transesophageal echocardiography with Doppler ultrasound is used to obtain echocardiographic data when surface sound transmission is poor, particularly of the AV valves and prosthetic heart valves. Cardiac catheterization may be used to further describe the effects of the defect.

The treatment of valvular defects consists of medical management of heart failure and associated problems and surgical valve repair or replacement, if warranted by the extent of deformity. Valvular replacement with a prosthetic device or a homograft usually is reserved for severe disease because the ideal substitute valve has not as yet been developed. Percutaneous balloon valvuloplasty involves the opening of a stenotic valve by guiding an inflated balloon through the valve orifice. The procedure is done in the cardiac catheterization laboratory and involves the insertion of a balloon catheter into the heart through a peripheral blood vessel.
Disorders of the Pericardium

The pericardium is a double-layered fibroserosous sac that encircles the heart. It isolates the heart from other thoracic structures, maintains its position in the thorax, prevents it from overfilling, and serves as a barrier to infection. The pericardium consists of two layers: a thin inner layer, called the visceral pericardium, adheres to the epicardium; and an outer fibrous layer, called the parietal pericardium, is attached to the great vessels that enter and leave the heart (see Chapter 17, Fig. 17-15). The two layers of the pericardium are separated by a thin layer of serous fluid, which prevents frictional forces from developing as the heart contracts and relaxes. Although the fibrous tissue outer layer of the pericardium allows for moderate changes in cardiac size, it cannot stretch sufficiently to accommodate rapid dilation of the heart or accumulation of pericardial fluid without increasing pericardial and intracardiac pressures.

The pericardium is subject to many of the same pathologic processes (e.g., congenital disorders, infections, trauma, and immune mechanisms) that affect other structures of the body. Pericardial disorders frequently are associated with other diseases in the heart or surrounding structures (Chart 19-1). The most common disorder of the pericardium is acute pericarditis.

Acute Pericarditis

Acute pericarditis, defined as signs and symptoms resulting from pericardial inflammation of less than 2 weeks’ duration, may result from an infection or noninfectious disease. Viral infections (especially infections with coxsackieviruses and echoviruses) are the most common cause of pericarditis and probably are responsible for many cases of idiopathic or pericarditis of unknown etiology. Other causes of acute pericarditis include bacterial or

**SUMMARY CONCEPTS**

- Infective endocarditis involves the invasion of the endocardium by pathogens that produce vegetative lesions on the endocardial surface. The loose organization of these lesions permits the organisms and fragments of the lesions to be disseminated throughout the systemic circulation. Although several organisms can cause the condition, staphylococci have become the leading cause. Treatment of infective endocarditis focuses on identifying and eliminating the causative microorganism, minimizing the residual cardiac effects, and treating the pathologic effect of emboli.

- Rheumatic fever, an immune-mediated, multisystem inflammatory disease associated with group A (β-hemolytic) streptococcal (GAS) pharyngitis, can result in serious and disabling impairment of the heart valves. Primary and secondary prevention strategies focus on appropriate antibiotic therapy.

- Dysfunction of the heart valves can result from a number of disorders, including congenital defects, rheumatic heart disease, trauma, ischemic heart disease, degenerative changes, and inflammation. Valvular heart disease causes disturbances of blood flow. A stenotic valvular defect is one that causes a decrease in blood flow through a valve, resulting in impaired emptying and increased work demands on the heart chamber that pushes blood across the diseased valve. A regurgitant valve permits blood flow to continue despite closure of the valve. Valvular heart disorders produce blood flow turbulence and often are detected through heart sound heard during cardiac auscultation.

- Primary (mesothelioma, fibrosarcoma)
- Secondary (e.g., carcinoma of the lung or breast, lymphoma)

**Congenital Disorders**

- Complete or partial absence of the pericardium
- Congenital pericardial cysts

*Chronic inflammatory pericarditis can be associated with some agents causing an acute inflammatory response.*
mycobacterial infections, connective tissue diseases (e.g., systemic lupus erythematosus, rheumatoid arthritis), uremia, postcardiac surgery, neoplastic invasion of the pericardium, radiation, trauma, drug toxicity, and contiguous inflammatory processes of the myocardium or lung.42,43

Similar to other inflammatory processes, acute pericarditis is associated with local vasodilation, increased capillary permeability, and accumulation of white blood cells. The capillaries that supply the serous pericardium become permeable, allowing plasma proteins, including fibrinogen, to exit the capillaries and enter the pericardial space. This results in an exudate that varies in composition and amount according to the causative agent. Acute pericarditis frequently is associated with an exudate containing protein and fibrin and heals by resolution or progresses to form scar tissue and adhesions between the layers of the serous pericardium.

The manifestations of acute pericarditis include a triad of chest pain, an auscultatory pericardial friction rub, and electrocardiographic (ECG) changes. The clinical findings may vary according to the causative agent. Nearly all persons with acute pericarditis have chest pain and fever. The pain usually is sharp and abrupt in onset, occurring in the precordial area, and may radiate to the neck, back, abdomen, or side. Pain in the scapular area may result from irritation of the phrenic nerve. The pain typically is pleuritic (aggravated by inspiration and coughing) and positional (decreases with sitting and leaning forward) because of changes in venous return and cardiac filling. These pain characteristics differentiate pericarditis from acute myocardial infarction or pulmonary embolism.

A pericardial friction rub (auscultated through the diaphragm of a stethoscope), often described as “leathery” or “close to the ear,” results from the rubbing and friction between the inflamed pericardial surfaces.43

Diagnosis of acute pericarditis is based on clinical manifestations, ECG, chest radiography, and echocardiography, with laboratory tests being used to confirm the diagnosis. Treatment depends on the cause. When an infection is present, antibiotics specific for the causative agent are prescribed. Aspirin and other non-steroidal anti-inflammatory drugs (NSAIDs) may be given to minimize the inflammatory response and the accompanying undesirable effects.

Recurrence pericarditis can occur in up to 30% of persons with acute pericarditis who responded satisfactorily to treatment.42 A minority of these develop recurrent bouts of pericardial pain, which can sometimes be chronic and debilitating. The process commonly is associated with autoimmune disorders, such as lupus erythematosus, rheumatoid arthritis, scleroderma, and myxedema, but may also occur following viral pericarditis. Treatment includes the use of anti-inflammatory medications such as NSAIDs, corticosteroids, or colchicine. Also develop with neoplasms, cardiac surgery, or trauma. Pericardial effusion exerts its effects through compression of the heart chambers. The normal pericardial space contains about 15 to 50 mL of fluid. Increases in the volume of this fluid, the rapidity with which it accumulates, and the elasticity of the pericardium determine the effect that the effusion has on cardiac function. Small pericardial effusions may produce no symptoms or abnormal clinical findings. Even a large effusion that develops slowly may cause few or no symptoms, provided the pericardium is able to stretch and avoid compressing the heart. However, a sudden accumulation of even 200 mL may raise intracardiac pressure to levels that significantly limit venous return of blood to the heart. Symptoms of cardiac tamponade also may occur with relatively small accumulations of fluid if the pericardium has become thickened by scar tissue or neoplastic infiltrations and loses its elasticity.

The echocardiogram is a rapid, accurate, and widely used noninvasive method of evaluating pericardial effusion. Treatment depends on the extent of the effusion. In small pericardial effusions, diuretics are given to remove the fluid, and NSAIDs, colchicine, or corticosteroids may minimize fluid accumulation. Pericardiocentesis, or removal of fluid from the pericardial sac, often with the aid of echocardiography, is the initial treatment of choice for larger effusions. Aspiration of fluid with laboratory evaluation of the pericardial fluid may be used to identify the causative agent.

Cardiac Tamponade

Pericardial effusion can lead to or may initially present as a condition called cardiac tamponade, in which there is compression of the heart due to the accumulation of fluid or blood in the pericardial sac. This life-threatening condition can be caused by bleeding into the pericardial sac after blunt or penetrating trauma, rupture of the heart following myocardial infarction, complications during percutaneous cardiac procedures or device placement, or retrograde bleeding during aortic dissection.42,43

Cardiac tamponade results in increased intracardiac pressure, progressive limitation of ventricular diastolic filling, and reductions in stroke volume and cardiac output. In other words, the heart cannot fill properly with blood. The severity of the condition depends on the volume of fluid present and the rate at which it accumulates. Rapid accumulation results in an elevated central venous pressure, jugular vein distention, a fall in systolic blood pressure, narrowed pulse pressure, and signs of circulatory shock. The heart sounds may become muffled because of the insulating effects of the pericardial fluid and reduced cardiac function. Persons with slowly developing cardiac tamponade usually appear acutely ill, but not to the extreme seen in those with rapidly developing tamponade.

A significant accumulation of fluid in the pericardium results in increased sympathetic nervous system stimulation, which leads to tachycardia and increased cardiac contractility. A key diagnostic finding in cardiac
tamponade is pulsus paradoxus, or an exaggeration of the normal variation in the systolic blood pressure. Pulsus paradoxus is defined as a 10 mm Hg or more fall in the systolic blood pressure that occurs with inspiration.\(^\text{42,43}\) Normally, the decrease in intrathoracic pressure that occurs during inspiration accelerates venous flow, increasing right atrial and right ventricular filling. This causes the interventricular septum to bulge to the left, producing a slight decrease in left ventricular filling, stroke volume output, and systolic blood pressure. In cardiac tamponade, the left ventricle is compressed from within by movement of the interventricular septum and from without by fluid in the pericardium (Fig. 19-17). This produces a marked decrease in left ventricular filling and left ventricular stroke volume output following inspiration.

Computed tomography (CT) and magnetic resonance imaging (MRI) are useful adjuncts to echocardiography in cardiac tamponade. The ECG often reveals nonspecific T-wave changes and low QRS voltage. Usually only moderate to large effusions can be detected by chest radiography.

Closed pericardiocentesis, in which fluid is removed from the pericardial sac through a needle inserted through the chest wall, may be an emergency lifesaving measure in severe cardiac tamponade. Open pericardiocentesis may be used for recurrent or loculated effusions (i.e., those confined to one or more pockets in the pleural space), during which biopsies can be obtained and pericardial windows created. As with pericardial effusion, laboratory evaluation of the pericardial fluid may be used to identify the causative agent.

**Constrictive Pericarditis**

In constrictive pericarditis, fibrous scar tissue develops between the visceral and parietal layers of the serous pericardium. In time, the scar tissue contracts and interferes with diastolic filling of the heart, at which point cardiac output and cardiac reserve become fixed. It is most commonly associated with inflammation resulting from infections, mediastinal radiation, or cardiac surgical trauma.

The condition is characterized by high venous pressure, low cardiac output, narrow pulse pressure, and fluid retention.\(^\text{44}\) Ascites is a prominent early finding and may be accompanied by pedal edema, dyspnea on exertion, fatigue, and jugular venous distention. The Kussmaul sign is an inspiratory distention of the jugular veins (opposite of normal physiology) caused by the inability of the right atrium, encased in its rigid pericardium, to accommodate the increase in venous return that occurs with inspiration. Exercise intolerance, muscle wasting, and weight loss develop in end-stage constrictive pericarditis. Surgical removal or resection of the pericardium (i.e., pericardiectomy) is the treatment of choice.

---

**SUMMARY CONCEPTS**

- The major threat of pericardial disorders, which include acute and chronic or recurrent pericarditis, pericardial effusion, cardiac tamponade, and constrictive pericarditis, is compression of the heart chambers.
- Acute pericarditis may be infectious in origin or it may be due to systemic diseases. It is characterized by pleuritic chest pain, fever, ECG changes, and pericardial friction rub. Recurrent pericarditis, which is usually associated with autoimmune disorders, often produces few symptoms.
- Pericardial effusion, either acute or chronic, refers to the accumulation of fluid or exudate in the pericardial cavity. It can increase intracardiac pressure, compress the heart, and interfere with venous return to the heart. The amount of fluid
Cardiomyopathies are disorders of the heart muscle. They are usually associated with disorders of myocardial performance, which may be mechanical (e.g., heart failure) or electrical (e.g., life-threatening arrhythmias). The definition and classification of the cardiomyopathies have evolved tremendously with the advance of molecular genetics. The American Heart Association’s classification system divides the cardiomyopathies into two major groups: primary cardiomyopathies, which are confined to the myocardium, and secondary cardiomyopathies, which are associated with other disease conditions.

Primary Cardiomyopathies

The primary cardiomyopathies are classified as genetic, mixed, or acquired, based on their etiology. The genetic cardiomyopathies include hypertrophic cardiomyopathy and arrhythmogenic right ventricular dysplasia. The mixed cardiomyopathies, which include dilated and restrictive cardiomyopathy, are of both genetic and non-genetic origin. Acquired cardiomyopathies include those that have their origin in the inflammatory process (e.g., myocarditis), pregnancy (peripartum cardiomyopathy), and stress (takotsubo cardiomyopathy). In many cases the cause is unknown, and in these cases it is referred to as an idiopathic cardiomyopathy.

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is characterized by unexplained left ventricular hypertrophy with disproportionate thickening of the ventricular septum, abnormal diastolic filling, cardiac arrhythmias, and, in some cases, intermittent left ventricular outflow obstruction (Fig. 19-18). It is one of the most common types of cardiomyopathy, occurring in approximately 1 out of 500 persons in the general population. Hypertrophic cardiomyopathy is the most common cause of sudden cardiac death in young athletes.

Hypertrophic cardiomyopathy is an autosomal dominant disorder caused by mutations in genes encoding proteins of the cardiac sarcomere (i.e., muscle fibers). Histologically, HCM specimens have myocyte hypertrophy with myofibril disarray and increased cardiac fibrosis. More than 400 mutations have been identified in 11 sarcomeric genes. Although HCM is inherited, it may present at any time from early childhood to late adulthood with a broad category of manifestations and a variable clinical course.

Clinically, HCM is characterized by a massively hypertrophied left ventricle with a reduced chamber size and a paradoxical decrease in stroke volume that results from impaired diastolic filling; in about 25% of cases, dynamic obstruction of left ventricular outflow occurs due to disproportionate thickening of the interventricular septum. Hypertrophic cardiomyopathy is frequently associated with the development of left ventricular outflow obstruction.
outflow obstruction that is caused by systolic anterior motion of the mitral valve and midsystolic contact with the ventricular septum. The obstruction is worsened by factors that increase myocardial contraction (e.g., sympathetic stimulation or exertion) or decrease left ventricular filling (e.g., Valsalva maneuver, peripheral vasodilation).

**Clinical Manifestations.** The clinical manifestations of HCM are highly variable and may progress to end-stage heart failure with left ventricular remodeling and systolic dysfunction. The most frequent symptoms of HCM are dyspnea and chest pain in the absence of coronary artery disease. Syncope (fainting) is also common and is typically post-exertional, when diastolic filling diminishes and outflow obstruction increases. Atrial fibrillation can occur as a long-term consequence of elevated left atrial pressures. Ventricular arrhythmias are also common and sudden death may occur, often in athletes after extensive exertion. Risk factors for sudden cardiac death among patients with HCM include a family history of syncope or sudden cardiac death, certain gene mutations, and extreme hypertrophy of the left ventricle.

**Diagnosis and Treatment.** Diagnosis of HCM is frequently established with 2D echocardiography, ECG, and continuous ambulatory monitoring. Cardiac MRI can also be helpful. Genetic testing, through bidirectional deoxyribonucleic acid (DNA) sequence analysis, is important for identifying gene mutations and making diagnoses, although with some limitations. In many patients with HCM, physical examination results are normal. Medical management of HCM is primarily focused on symptom management. The first-line approach to relief of symptoms is pharmacologic therapy designed to block the effects of catecholamines that exacerbate outflow obstruction and to slow heart rate to enhance diastolic filling. In the majority of cases of symptomatic HCM, beta blockers are the initial choice for therapy. Calcium channel blockers, especially verapamil, can also be used in patients who do not respond to beta blockers. Calcium channel blockers can, however, exacerbate left ventricular outflow obstruction and are not recommended for persons with severe outflow obstruction and pronounced symptoms.

Dual-chamber and biventricular pacing may be used to prevent progression of hypertrophy and obstruction. In obstructive HCM that is refractory to drug therapy, septal myotomy–myectomy (surgical excision of part of the outflow myocardial septum) or alcohol ablation of the interventricular septum can be used. An implantable cardioverter–defibrillator should be considered for persons with HCM who have sustained ventricular tachycardia or ventricular fibrillation and are receiving optimal medical therapy.

**Arrhythmogenic Right Ventricular Dysplasia**

Arrhythmogenic right ventricular dysplasia (ARVD) also called arrhythmogenic right ventricular cardiomyopathy (ARVC), is a heart muscle disease that primarily affects the right ventricle, leading to various rhythm disturbances, particularly ventricular tachycardia, and potentially to heart failure. It ranks second, after HCM, as the leading cause of sudden cardiac death in young athletes. The incidence of ARVD varies from about 1 in 2000 to 1 in 5000, affecting men more frequently than women.

Arrhythmogenic right ventricular dysplasia is inherited as an autosomal dominant trait in greater than 50% of cases, although often with incomplete penetrance and variable expression. Although multiple gene mutations have been identified (mapping to chromosomes 1, 2, 3, 14, and 17), the pathogenesis of the disorder remains undefined.

**Clinical Manifestations.** The disorder is characterized by progressive loss of myocytes, with partial or complete replacement of the right ventricular muscle with adipose or fibrofatty tissue. These changes are associated with reentrant ventricular tachyarrhythmias of right ventricular origin that are often precipitated by an exercise-induced discharge of catecholamines. Clinical manifestations include palpitations, syncope, or cardiac arrest, usually in young or middle-aged men. Other symptoms may include abdominal pain and mental confusion.

**Diagnosis and Treatment.** Diagnosis of ARVD is based on clinical, ECG, echocardiographic, and histologic findings. Personal and family history, including first- and second-degree relatives, is important. Treatment for ARVD is aimed at prevention of sudden cardiac death, prevention or delay. Although ARVD cannot be cured, the goal of treatment is to prevent and control the arrhythmias with antiarrhythmic agents. Radiofrequency ablation may be used in cases that are refractory to drug therapy, although it is completely successful in only 30% to 65% of cases, with multiple ablations sometimes needed. An implantable cardioverter–defibrillator is also indicated for drug-refractory cases and for those who have survived a sudden cardiac death episode. Final options for treatment include ventriculotomy and heart transplantation. There are no randomized trials evaluating ARVD treatment modalities at this time.

**Dilated Cardiomyopathy**

Dilated cardiomyopathy (DCM) is a common cause of heart failure and the leading indication for heart transplantation. Up to 35% of cases are reported as familial; however, that proportion may be even higher, but due to incomplete penetrance it is difficult to identify early or latent disease in family members. Most familial cases appear to be transmitted as an autosomal dominant trait, but autosomal recessive, X-linked recessive, and mitochondrial inheritance patterns have been identified. Other causes include infections (i.e., viral, bacterial, fungal, mycobacterial, parasitic), toxins, alcoholism, chemotherapeutic agents, metals, and multiple other disorders. Often no cause is found, in which case it is often referred to as idiopathic DCM.

Dilated cardiomyopathy is characterized by progressive cardiac dilation and contractile (systolic) dysfunction, usually with concurrent hypertrophy.
The heart is enlarged (two to three times its normal weight) and flabby with dilation of all four chambers (Fig. 19-19). Because of wall thinning that accompanies dilation, the ventricular thickness may be less than, equal to, or greater than normal. The histologic abnormalities in DCM are nonspecific. Microscopically, most myocytes are hypertrophied with enlarged nuclei, but many are thinned, stretched, and irregular or atrophied.

Clinical Manifestations. The most common clinical manifestations of DCM are those related to heart failure, such as dyspnea, orthopnea, and reduced exercise capacity. In the end stages, persons with DCM often have ejection fractions of less than 25% (normal ejec-
tion fraction 50% to 65%). As the disease progresses, stasis of blood in the walls of the heart chambers can lead to thrombus formation and systemic emboli. Secondary mitral valve regurgitation and abnormal cardiac rhythms are common. Death is usually due to heart failure or arrhythmias and can occur suddenly.

Treatment. The treatment of DCM is directed toward relieving the symptoms of heart failure, reducing the work of the heart, and preventing atrial and ventricular dysrhythmias. Pharmacologic agents include diuretics to reduce preload, beta blockers to reduce heart rate and myocardial oxygen demand, afterload-reducing agents to decrease left ventricular filling pressures, and angiotensin converting enzyme (ACE) inhibitors to prevent vasoconstriction. Anticoagulant and antiarrhythmic drugs (e.g., amiodarone for atrial fibrillation) may be used. Other treatments may include a biventricular pacemaker, an implantable cardioverter-defibrillator for chronic symptomatic DCM with reduced systolic function, and in cases that are refractory to treatment, cardiac transplantation. The prognosis for patients with DCM who do not undergo cardiac transplantation is poor with the average 5-year survival rate being less than 50%. Removing or avoiding causative agents (if identified); avoiding myocardial depressants, including alcohol; and spacing rest with asymptomatic levels of exercise or activity are also important.

Primary Restrictive Cardiomyopathy

Restrictive cardiomyopathy is a rare form of heart muscle disease in which ventricular filling is restricted because of excessive rigidity (but not necessarily thick-
ening) of the ventricular walls, although the contractile properties or systolic function of the heart remain relatively normal. Restrictive cardiomyopathy can be idiopathic or associated with other conditions that affect the myocardium, principally radiation fibrosis, amyloidosis, sarcoidosis, or metastatic tumors. Genetics may also play a role because familial forms of restrictive cardiomyopathy have been reported.

Symptoms of restrictive cardiomyopathy include dyspnea, PND, orthopnea, peripheral edema, ascites, fatigue, and weakness. The manifestations of restrictive cardiomyopathy resemble those of constrictive pericarditis. In the advanced form of the disease, all the signs of heart failure are present except cardiomegaly.

Myocarditis

Myocarditis, or inflammatory cardiomyopathy, can be defined as an inflammation of the heart. The clinical spectrum of the disease is broad: at one end, the disease is asymptomatic with full recovery, and at the other end it has a precipitous onset of heart failure or arrhythmias, occasionally with sudden cardiac death. An acquired cardiomyopathy, myocarditis is associated with a number of etiologies; however, it is usually caused by a viral infection, most commonly an enterovirus (coxsackievirus group B). In young children adenovirus and parvovirus are the most likely causative agents. Other etiologies include bacterial or fungal infections, hypersensitivity to certain drugs, and autoimmune diseases, such as systemic lupus erythematosus. Myocarditis is a frequent pathologic cardiac finding in persons with acquired immunodeficiency syndrome (AIDS), although it is unclear whether it is due to the human immunodeficiency virus infection itself or to secondary infections.

The pathogenesis of myocarditis is one of cardiac injury, followed by an immunologic response. Myocardial injury due to infectious agents is thought to result from necrosis caused by direct invasion of the offending organism, toxic effects of exotoxins or endotoxins produced by a systemic pathogen, or destruction of cardiac tissue by immunologic mechanisms initiated by the infectious agent. The immunologic response may be directed at foreign antigens of the infectious agent that share molecular characteristics with those of the host cardiac myocytes (i.e., molecular mimicry; see Chapter 16), providing a continuous stimulus for the immune response even after the infectious agent has been cleared from the body.
Clinical Manifestations. The signs and symptoms of myocarditis vary from person to person. Some persons may present with fever, chills, nausea, vomiting, arthralgia, and myalgia, occurring up to 6 weeks before the diagnosis of myocarditis. Other persons may present with heart failure without antecedent symptoms. The onset of heart failure may be gradual or abrupt and fulminant. Emboli may occur because of the procoagulant effect of inflammatory cytokines combined with decreased myocardial contractility. At times, the presentation may mimic ACS, with ST-segment and T-wave changes, positive serum cardiac biomarkers, and regional wall motion abnormalities despite normal coronary arteries. Viral myocarditis in children or young adults is often nonspecific, with symptoms such as fever and poor eating.

Diagnosis and Treatment. The diagnosis of myocarditis can be suggested by clinical manifestations. Methods used in confirming the diagnosis include the ECG, chest radiography, serum cardiac biomarkers (i.e., creatinine phosphokinase, troponin I), and echocardiography. Endomyocardial biopsy findings, obtained through cardiac catheterization, remain the gold standard for establishing the diagnosis of acute myocarditis, despite limited accuracy. Many cases of myocarditis are mild and self-limiting, so first-line treatment remains largely supportive. Initial treatments include supplemental oxygen, bed rest, and antibiotics, if needed. In persons with more severe myocarditis, arrhythmia suppression and hemodynamic support with vasopressors and positive inotropic agents may be needed. Persons with severe fulminant myocarditis may require aggressive short-term support with an intra-aortic balloon pump or left ventricular assist devices. Immunosuppressive therapy continues to be investigated. Although treatment of myocarditis is successful in many persons, some progress to heart failure. For these patients, cardiac transplantation is an important intervention.

Peripartum Cardiomyopathy

Peripartum cardiomyopathy is a dilated cardiomyopathy that occurs in the last month of pregnancy or within 5 months after delivery. It is manifested by signs of systolic dysfunction and heart failure for which there is no identifiable cause or evidence prior to the last month of pregnancy. The incidence is greater in black, multiparous, or older women, and in women with twin fetuses, preeclampsia, or using tocolytic therapy to prevent preterm delivery. Although the etiology of peripartum cardiomyopathy is unknown, several causes have been proposed, including infectious, immunologic, nutritional, drug-induced, and genetic factors. Some women exhibit inflammatory cells in heart biopsies taken during the symptomatic phase of the disorder, suggesting a disordered immune response.

Management of peripartum cardiomyopathy includes standard therapy for heart failure. However, potential teratogenic effects and the excretion of drugs during breast-feeding need to be considered. Prognosis depends on resolution of the heart failure. About half of women with peripartum cardiomyopathy spontaneously recover normal cardiac function; the other half are left with persistent left ventricular dysfunction or progress to develop heart failure.

Stress or “Takotsubo” Cardiomyopathy

First described in Japan in 1991, takotsubo-like left ventricular dysfunction is named after the fishing pot used to trap octopus that has a narrow neck and wide base, a shape similar to that of the affected ventricle. The term transient left ventricular apical ballooning has also been used to describe this syndrome.

An acquired disorder, stress cardiomyopathy has been identified in the clinical setting as a transient, reversible left ventricular dysfunction in response to profound psychological or emotional stress. The syndrome occurs primarily in middle-aged women who present with acute STEMI but who, on cardiac catheterization, have no evidence of CAD. There is, however, impaired myocardial contractility characterized by left ventricular apical ballooning with hypercontractility of the basal left ventricle.

The mechanism for myocardial stunning in stress cardiomyopathy is unclear, although some theories suggest ischemia from coronary artery spasm, microvascular spasm, or direct myocyte injury. When catecholamine levels return to normal, the interventricular gradient resolves and left ventricular function recovers.

Treatment of stress cardiomyopathy is the same as that for heart failure, and most patients with takotsubo cardiomyopathy demonstrate rapid improvement and an excellent prognosis.

Secondary Cardiomyopathies

Secondary cardiomyopathy is a heart muscle disease in the presence of a multisystem disorder. The conditions most commonly associated with secondary cardiomyopathies are identified in Chart 19-2. Some of these disorders produce accumulation of abnormal substances between myocytes (extracellular), whereas others produce accumulation of abnormal substances within myocytes (intracellular).

Almost 100 distinct myocardial diseases can result in the clinical features of DCM. They include cardiomyopathies associated with drugs, diabetes mellitus, muscular dystrophy, autoimmune disorders, and cancer treatment agents (radiation and cancer drugs). Alcoholic cardiomyopathy is the single most common identifiable cause of DCM in the United States and Europe. Doxorubicin (Adriamycin) and other anthracycline drugs used in the treatment of cancer, are potent agents whose usefulness is limited by cumulative dose-dependent cardiac toxicity. Another cancer chemotherapeutic agent with cardiotoxic potential is cyclophosphamide (Cytoxan). Unlike the primary myocyte injury that occurs with doxorubicin, the principal insult with cyclophosphamide appears to be vascular, leading to myocardial hemorrhage.
Heart disease in children encompasses both congenital and acquired disorders. Approximately 1 of every 125 infants born has a congenital heart defect, making this the most common form of structural birth defect. Advances in diagnostic methods and surgical treatment have greatly increased the long-term survival and positive outcomes for children born with congenital heart defects. Although thousands of infants born each year will have a congenital heart disease, other children will develop an acquired heart disease, such as Kawasaki disease. Other acquired disorders that affect children, the cardiomyopathies and rheumatic fever, were discussed earlier in the chapter.

**Fetal and Perinatal Circulation**

The fetal circulation is different anatomically and physiologically from the postnatal circulation. Before birth, oxygenation of blood occurs through the placenta; after birth it occurs through the lungs. The fetus is maintained in a low-oxygen state (PO2 30 to 35 mm Hg; hemoglobin O2 saturation 60% to 70%). To compensate, fetal cardiac output is higher than at any other time in life (400 to 500 mL/Kg/minute) and fetal hemoglobin has a higher affinity for oxygen. Also, the pulmonary vessels in the fetus are markedly constricted because of the fluid-filled lungs and the heightened hypoxic stimulus for vasoconstriction that is present in the fetus.

---

### CHART 19-2 **Conditions Associated with Secondary Cardiomyopathies**

- **Autoimmune Disorders**
  - Systemic lupus erythematosus
  - Rheumatoid arthritis
  - Scleroderma
  - Polyarteritis nodosa

- **Endocrine Disorders**
  - Acromegaly
  - Diabetes mellitus
  - Hypothyroidism and hyperthyroidism
  - Hyperparathyroidism

- **Familial Storage Diseases**
  - Glycogen storage disease
  - Mucopolysaccharidoses
  - Hemochromatosis

- **Infiltrative Disorders**
  - Amyloidosis
  - Sarcoidosis
  - Radiation-induced fibrosis

- **Neuromuscular/Neurologic Disorders**
  - Friedreich ataxia
  - Muscular dystrophy
  - Neurofibromatosis

- **Nutritional Deficiencies**
  - Thiamine (beriberi)
  - Protein (kwashiorkor)

- **Toxins**
  - Alcohol and its metabolites
  - Arsenic
  - Chemotherapeutic agents (anthracyclines [doxorubicin, daunorubicin], cyclophosphamide)
  - Catecholamines
  - Hydrocarbons

---

*Not intended to be inclusive.*
As a result, blood flow through the lungs is less than at any other time in life.

In the fetus, blood enters the circulation through the umbilical vein and returns to the placenta through the two umbilical arteries (Fig. 19-20). A vessel called the ductus venosus allows the majority of blood from the umbilical vein to bypass the hepatic circulation and pass directly into the inferior vena cava. From the inferior vena cava, blood flows into the right atrium, where approximately 40% of the blood volume moves through the foramen ovale into the left atrium. It then passes into the left ventricle and is ejected into the ascending aorta to perfuse the head and upper extremities. In this way, the best-oxygenated blood from the placenta is used to perfuse the brain. At the same time, venous blood from the head and upper extremities returns to the right side of the heart through the superior vena cava, moves into the right ventricle, and is ejected into the pulmonary artery. Because of the very high pulmonary vascular resistance that is present, almost 90% of blood ejected into the pulmonary artery gets diverted through the ductus arteriosus into the descending aorta. This blood perfuses the lower extremities and is returned to the placenta by the umbilical arteries.

At birth, the infant takes its first breath and switches from placental to pulmonary oxygenation of the blood. The most dramatic alterations in the circulation after birth are the elimination of the low-resistance placental vascular bed and the marked pulmonary vasodilation that is produced by initiation of ventilation. Within minutes of birth, pulmonary blood flow increases from 35 mL/kg/minute to 160 to 200 mL/kg/minute.62

The pressure in the pulmonary circulation and the right side of the heart falls as fetal lung fluid is replaced by air and as lung expansion decreases the pressure transmitted to the pulmonary blood vessels. With lung inflation, the alveolar oxygen tension increases, causing reversal of the hypoxemia-induced pulmonary vasoconstriction of the fetal circulation. Cord clamping and removal of the low-resistance placental circulation produce an increase in systemic vascular resistance and a resultant increase in left ventricular pressure. The resultant decrease in right atrial pressure and increase in left atrial pressure produce closure of the foramen ovale flap valve. Reversal of the fetal hypoxemic state also produces constriction of ductal smooth muscle, contributing to closure of the ductus arteriosus. The foramen ovale and the ductus arteriosus normally close within the first day of life, effectively separating the pulmonary and systemic circulations.

After the initial precipitous fall in pulmonary vascular resistance, a more gradual decrease occurs during the first 2 to 9 weeks of life, related to regression of the medial smooth muscle layer in the pulmonary arteries. By the time a healthy, term infant is several weeks old, the pulmonary vascular resistance has fallen to adult levels. Several factors, including alveolar hypoxia, prematurity, lung disease, and congenital heart defects, may affect postnatal pulmonary vascular development. Much of the development of the smooth muscle layer in the pulmonary arterioles occurs during late gestation; as a result, infants born prematurely have less medial smooth muscle; therefore, the muscle layer may regress in a shorter time. The pulmonary vascular smooth muscle in premature infants also may be less responsive to hypoxia. For these reasons, a premature infant may demonstrate a larger decrease in pulmonary vascular resistance resulting in shunting of blood from the aorta through the ductus arteriosus to the pulmonary artery within hours of birth.

Alveolar hypoxia may also delay or prevent the normal decrease in pulmonary vascular resistance that occurs during the first few weeks of life. During this period, the pulmonary arteries remain highly reactive and can constrict in response to hypoxia, acidosis, hyperinflation of the alveoli, and hypothermia.

**Congenital Heart Defects**

The major development of the fetal heart occurs between the 4th and 7th weeks of gestation, and most congenital heart defects arise during this time. The development of the heart can be altered by environmental, genetic, or chromosomal influences. Most congenital heart defects are thought to be multifactorial in origin, resulting from an interaction between a genetic predisposition toward development of a heart defect and environmental influences.

Knowledge about the genetic basis of congenital heart defects has grown dramatically in recent years. This area of research is particularly important as more individuals with congenital heart disease survive into
adulthood and consider having children of their own. Recent evidence suggests that the genetic contribution to congenital heart disease has been underestimated in the past. Some heart defects, such as aortic stenosis, atrial septal defect of the secundum type, pulmonary valve stenosis, tetralogy of Fallot, and certain ventricular septal defects, have a stronger familial predisposition than others. Chromosomal abnormalities are also associated with congenital heart defects, as evidenced by the observation that as many as 30% of children with congenital heart disease have an associated chromosomal abnormality. Heart disease is found in nearly 100% of children with trisomy 18, 50% of those with trisomy 21, and 35% of those with Turner syndrome.

Congenital heart diseases are commonly classified according to their anatomic site (atrial septal or ventricular septal defects), the hemodynamic alterations caused by the anatomic defects (left-to-right or right-to-left shunts), and their effect on pulmonary blood flow and tissue oxygenation (cyanotic or noncyanotic defects).

### Shunting

Shunting of blood refers to the diversion of blood flow from one system to the other—from the arterial to the venous system (i.e., left-to-right shunt) or from the venous to the arterial system (i.e., right-to-left shunt). The shunting of blood in congenital heart defects is determined by the presence of an abnormal opening between the right and left circulations and the degree of resistance to flow through the opening. The shunting of blood can affect both the oxygen content of the blood and the volume of blood being delivered to the vessels in the pulmonary circulation.

The direction of shunting (right-to-left or left-to-right) is largely determined by the vascular resistance of the systemic and pulmonary circulations. Due to the high pulmonary vascular resistance in the neonate, atrial and ventricular septal defects usually do not produce a significant shunt during the 1st weeks of life. As the pulmonary vascular smooth muscle regresses in the neonate, the resistance in the pulmonary circulation falls below that of the systemic circulation, causing a left-to-right shunt in uncomplicated atrial or ventricular septal defects. In more complicated ventricular septal defects, increased resistance to outflow may affect the pattern of shunting. For example, defects that increase resistance to aortic outflow (e.g., aortic valve stenosis, coarctation of the aorta, hypoplastic left heart syndrome) increase left-to-right shunting, whereas defects that obstruct pulmonary outflow (e.g., pulmonary valve stenosis, tetralogy of Fallot) increase right-to-left shunting. Crying, defecating, or even the stress of feeding may increase pulmonary vascular resistance and cause an increase in right-to-left shunting in infants with septal defects.

Cyanosis, a bluish color of the skin most notable in the nail beds and mucous membranes, develops when sufficient deoxygenated blood from the right side of the heart mixes with oxygenated blood in the left side of the heart. Abnormal color becomes obvious when the oxygen saturation falls below 80% in the capillaries (equal to 5 g of deoxygenated hemoglobin). Defects that result in a right-to-left shunting or obstruction of pulmonary blood flow are categorized as cyanotic disorders and those involving left-to-right shunting are usually categorized as acyanotic disorders. Of the congenital defects discussed in this chapter, patent ductus arteriosus, atrial and ventricular septal defects, endocardial cushion defects, pulmonary valve stenosis, and coarctation of the aorta are considered acyanotic; tetralogy of Fallot, transposition of the great vessels, and single-ventricle anatomy are considered cyanotic defects.

A right-to-left shunt results in deoxygenated blood moving from the right side of the heart to the left side and then being ejected into the systemic circulation. With a left-to-right shunt, oxygenated blood intended for ejection into the systemic circulation is recirculated through the right side of the heart and back through the lungs. This increased volume distends the right side of the heart and pulmonary circulation and increases the workload placed on the right ventricle.

### Alterations in Pulmonary Blood Flow

Many of the complications of congenital heart disorders result from a decrease or an increase in pulmonary blood flow. Defects that reduce pulmonary blood flow (e.g., pulmonary stenosis) typically cause symptoms of fatigue, dyspnea, and failure to thrive. In contrast to the arterioles in the systemic circulation, the arterioles in the pulmonary circulation are normally thin-walled vessels that can accommodate the various levels of stroke volume that are ejected from the right heart. The thinning of the pulmonary vessels occurs during the 1st weeks after birth, during which the vessel media thin and pulmonary vascular resistance decreases. In a term infant who has a congenital heart defect that produces markedly increased pulmonary blood flow (e.g., ventricular septal defect), the increased flow stimulates pulmonary vasoconstriction and delays or reduces the normal involutional thinning of the small pulmonary arterioles. In most cases pulmonary vascular resistance is only slightly elevated during early infancy, and the major contribution to pulmonary hypertension is the increased blood flow. However, in some infants with a large right-to-left shunt, the pulmonary vascular resistance never decreases.

Congenital heart defects that persistently increase pulmonary blood flow or pulmonary vascular resistance have the potential of causing pulmonary hypertension and producing irreversible pathologic changes in the pulmonary vasculature. When shunting of systemic blood flow into the pulmonary circulation threatens permanent injury to the pulmonary vessels, a surgical procedure should be done to reduce the flow temporarily or permanently. Pulmonary artery banding consists of placing a constrictive band around the main pulmonary artery, thereby increasing resistance to outflow from the right ventricle. The banding technique is a temporary measure to alleviate symptoms and protect the pulmonary vasculature in anticipation of later surgical repair of the defect.
General Manifestations, Diagnosis, and Treatment

It is increasingly common for congenital heart defects to be diagnosed prenatally. In this case, the infant can be evaluated shortly after birth to confirm the diagnosis and develop a treatment plan. Reliable transabdominal diagnostic images of the fetal heart can be obtained as early as 16 weeks of gestation, and recently, accurate trans-vaginal images have been obtained as early as 11 to 14 weeks of gestation. Among the disorders that can be diagnosed with certainty by fetal echocardiography are AV septal defects, hypoplastic left heart syndrome, aortic valve stenosis, hypertrophic cardiomyopathy, pulmonic valve stenosis, and transposition of the great arteries. Disorders that result in an abnormal four-chamber view, an image typically obtained during routine prenatal ultrasonography, are the most likely to be detected.

In the postnatal period, congenital heart defects may present with numerous signs and symptoms, most commonly a murmur audible on auscultation. Some defects, such as patent ductus arteriosus and small ventricular septal defects, close spontaneously. In other less-severe defects, there may be no obvious signs and symptoms and the disorder may be discovered during a routine health examination. Cyanosis, pulmonary congestion, cardiac failure, and decreased peripheral perfusion are the major concerns in children with more severe defects. Such defects often cause problems immediately after birth or early in infancy. The child may exhibit cyanosis, respiratory difficulty, and fatigability, and is likely to have difficulty with feeding and failure to thrive. Heart failure manifests itself as tachypnea or dyspnea at rest or on exertion. For the infant, this most commonly occurs during feeding. Recurrent respiratory infections and excessive sweating may also be reported. The infant whose peripheral perfusion is markedly decreased may be in a shocklike state.

A generalized cyanosis that persists longer than 3 hours after birth suggests congenital heart disease. An oxygen challenge (administration of 100% oxygen for 5 to 10 minutes) can help to determine whether congenital heart disease is present in a cyanotic newborn. Because infant cyanosis may appear as dusky, it is important to assess the color of the mucous membranes, fingertips, toenails, tongue, and lips. Several programs have instituted routine pulse oximetry screening for all newborns. Pulmonary congestion in the infant causes an increase in respiratory rate, orthopnea, grunting, wheezing, coughing, and crakles. A chest radiograph can quickly differentiate infants who have reduced pulmonary vascular markings (densities) from those who have normal or increased markings.

The treatment plan usually includes supportive therapy (e.g., digoxin, diuretics, and feeding supplementation) designed to help the infant compensate for the limitations in cardiac reserve and to prevent complications. Surgical intervention often is required for severe defects. It may be done in the early weeks of life or, conditions permitting, delayed until the child is older. Children with structural congenital heart disease and those who have had corrective surgery may have a higher-than-expected risk for development of infective endocarditis. Prophylactic antibiotic therapy before dental procedures or other periods of increased risk for bacteremia is suggested for children with certain types of heart defects or surgical procedures.

Children with congenital heart disease also experience a higher than expected incidence of developmental delays. A characteristic pattern of combined disabilities in the areas of visual motor integration, language, motor skills, attention, executive function and behavior has been described in multiple research studies. In an effort to promote early detection of developmental delays and appropriate intervention, the American Heart Association and the American Academy of Pediatrics issued a joint guideline statement in 2012 suggesting systematic surveillance, screening, and evaluation throughout childhood to assess academic, behavioral, psychosocial, and adaptive functioning. Early detection of developmental problems will direct interventions which can prevent or reduce long-term issues known to have a profoundly negative impact on quality of life and ability to achieve optimum potential in adulthood.

Types of Defects

Congenital heart defects can affect almost any of the cardiac structures or central blood vessels (Fig. 19-21). Defects include communication between heart chambers, interrupted development of the heart chambers or valve structures, malposition of heart chambers and great vessels, and altered closure of fetal communication channels. The particular defect reflects the embryo’s stage of development at the time it occurred. It is common for multiple defects to be present in one child and for some congenital heart disorders, such as tetralogy of Fallot, to involve several defects.

Patent Ductus Arteriosus. Patent ductus arteriosus results from persistence of the fetal ductus beyond the prenatal period. In fetal life, the ductus arteriosus is the vital link by which blood from the right side of the heart bypasses the lungs and enters the systemic circulation (Fig. 19-21G). After birth, this passage no longer is needed, and it usually closes during the first 24 to 72 hours of life. The physiologic stimulus and mechanisms associated with permanent closure of the ductus are not entirely known, but the fact that infant hypoxia predisposes to a delayed closure suggests that the increase in arterial oxygen levels that occurs immediately after birth plays a role. Additional factors that contribute to closure are a fall in endogenous levels of prostaglandins and adenosine and the release of vasoactive substances. After constriction, the lumen of the ductus becomes permanently sealed with fibrous tissue within 2 to 3 weeks. Ductal closure may be delayed or prevented in very premature infants, probably as a result of a combination of factors, including decreased medial smooth muscle in the ductus wall, decreased vasoconstriction response to oxygen, and increased circulating levels of prostaglandins,
which have a vasodilating effect. Ductal closure also may be delayed in infants with congenital heart defects that produce a decrease in oxygen tension. Persistent patency of the ductus arteriosus is defined as a duct that remains open beyond 3 months in the full-term infant. The size of the persistent ductus and the difference between the systemic and pulmonary vascular resistance determine its clinical manifestations. Blood typically shunts across the ductus from the higher-pressure left side (systemic circulation) to the lower-pressure right side (pulmonary circulation). After the infant’s pulmonary vascular resistance falls, the patent ductus arteriosus provides for a continuous runoff of aortic blood into the pulmonary artery. With a large patent ductus, the runoff is continuous, resulting in increased pulmonary blood flow, pulmonary congestion, and increased resistance against which the right side of the heart must pump. Increased pulmonary venous return and increased work demands may lead to left ventricular failure.

Spontaneous closure of the ductus seldom occurs after infancy. In the full-term infant or older child, closure can be achieved with either surgical ligation or device occlusion. In children with a small patent ductus, closure is done to prevent infective endocarditis or other complications. In children with a moderate to large patent ductus, closure is accomplished to treat heart failure, prevent the development of pulmonary vascular disease, or both. Drugs that inhibit prostaglandin synthesis (e.g., indomethacin) may be used to induce closure of a patent ductus in preterm newborns. Indomethacin works best if it is used in infants younger than 13 days of age; it is not effective later than 4 to 6 weeks of age.

Although closure of a patent ductus is uniformly recommended when it is present as an isolated lesion, deliberate maintenance of ductal patency can be a lifesaving therapy for children with complex forms of congenital heart disease who have ductal-dependent pulmonary or systemic blood flow, or those with obligatory mixing of the arterial and venous circulations (i.e., transposition...
of the great arteries). Intravenous infusion of prostaglandin E \(_1\) (PGE\(_1\)) has proved extremely effective in maintaining ductal patency or reopening the ductus in newborns. Today, this therapy is routinely administered to newborns with suspected congenital heart defects until they can be transported to a specialized center where a diagnosis can be confirmed.\(^8\)

**Atrial Septal Defects.** In atrial septal defects, an opening in the atrial septum persists as a result of improper septal formation in the atrial septum and septum primum and septum secundum of the foramen ovale (Fig. 19-22). The foramen ovale, which closes shortly after birth, allows blood from the umbilical vein to pass directly into the left heart, bypassing the lungs.

Atrial septal defects may be single or multiple and vary from a small, asymptomatic opening to a large, symptomatic opening. The type of defect is determined by its position and may include an abnormal opening in the septum primum (ostium primum defects), the septum secundum (ostium secundum defects), or a patent foramen ovale. An ostium secundum atrial septal defect in the region of the foramen ovale is the most common defect. The defect may be single or multiple (fenestrated atrial septum). Most atrial septal defects are small and young children with these defects are often asymptomatic, with the defects discovered inadvertently during a routine physical examination at a few years of age.\(^8\)

In the case of an isolated septal defect large enough to allow shunting, the flow of blood usually is from the left side to the right side of the heart because of the more compliant right ventricle and because the pulmonary vascular resistance is lower than the systemic vascular resistance. This produces right ventricular volume overload and increased pulmonary blood flow. In most cases there is a moderate shunt resulting in dilation of the right heart chambers and overperfusion of the pulmonary circulation.

Children with undiagnosed atrial defects are at risk for pulmonary vascular disease, although this is a rare occurrence before 20 years of age. Rarely, infants with a large shunt may develop congestive heart failure and failure to thrive, prompting early intervention to close the defect.\(^8\) Adolescents and young adults may experience atrial flutter or atrial fibrillation and palpitations because of atrial dilatation. Larger symptomatic defects are usually treated surgically or by transcatheter device closure. Smaller defects may be observed for spontaneous closure in the young child.

**Ventricular Septal Defects.** A ventricular septal defect is an opening in the ventricular septum that results from an incomplete separation of the ventricles during early fetal development (see Fig. 19-21B). These defects may be single or multiple and may occur in any position along the ventricular septum. Ventricular septal defects are the most common form of congenital heart defect, accounting for 25% to 30% of congenital heart disorders.\(^8\) A ventricular septal defect may be the only cardiac defect, or it may occur in association with multiple cardiac anomalies.

The ventricular septum originates from two sources: the interventricular groove of the folded tubular heart that gives rise to the muscular part of the septum, and the endocardial cushions that extend to form the membranous portion of the septum. The upper membranous portion of the septum is the last area to close, typically by the 7th week of gestation, and it is here that most defects occur.

Depending on the size of the opening and the pulmonary vascular resistance, the signs and symptoms of a ventricular septal defect may range from an asymptomatic murmur to congestive heart failure.\(^8\) If the defect is small, it allows a small shunt and small increases in pulmonary blood flow. These defects produce few symptoms, and approximately one third close spontaneously. With medium-sized defects, a larger shunt occurs, producing a larger increase in pulmonary blood flow. Most of the children with such defects are asymptomatic and have a low risk for development of pulmonary vascular disease.

In children with large nonrestrictive defects, right and left ventricular pressure is equalized and the degree of shunting is determined by the ratio of pulmonary to systemic vascular resistance. Pulmonary vascular resistance normally falls rapidly after birth, owing to the onset of ventilation and subsequent release of hypoxic pulmonary vasoconstriction. This process is often delayed in infants with large ventricular septal defects. As a result, the pulmonary vascular resistance remains somewhat

![Development of the endocardial cushions, right and left atrioventricular canals, interventricular septum, and septum primum and septum secundum of the foramen ovale. Note that blood from the right atrium flows through the foramen ovale to the left atrium.](image)
higher than normal, and thus the size of the left-to-right shunt may initially be limited. As the pulmonary vascular resistance falls during the first few weeks after birth, the size of the left-to-right shunt increases. Eventually, a large left-to-right shunt develops, and clinical symptoms (e.g., tachypnea; diaphoresis, especially with feeding; and failure to thrive) become apparent. In most cases pulmonary vascular pressure is only slightly elevated during infancy, and the major contributor to pulmonary hypertension is an increase in pulmonary blood flow. However, in some infants with a large septal defect, pulmonary arteriolar thickness never decreases. With continued exposure to high pulmonary blood flow, pulmonary vascular disease develops. In untreated patients, the pulmonary vascular resistance can eventually exceed the systemic resistance. In this case, a reversal of shunt flow occurs and the child demonstrates progressive cyanosis as deoxygenated blood moves from the right to the left side of the heart. These symptoms, coupled with irreversible changes in the pulmonary vasculature, represent an end-stage form of congenital heart disease called Eisenmenger syndrome, a condition that is quite rare today due to advances in diagnosis and treatment.

The treatment of a ventricular septal defect depends on the size of the defect, accompanying hemodynamic derangements, and symptomatology. Children with small or medium-sized defects may be followed without intervention if they remain free from signs of congestive heart failure or pulmonary hypertension. Ventricular defects do not increase in size, and some spontaneously close over time. Prophylactic antibiotic therapy is given during periods of increased risk for bacteremia. The management of infants with large ventricular defects aims to control heart failure and prevent the development of pulmonary vascular disease. Symptomatic infants may require feeding supplements or tube feeding to promote growth and development. In the symptomatic infant in whom complete repair cannot be achieved because of size or other complicating lesions, a palliative procedure may be performed to reduce symptoms. Placement of a synthetic band around the main pulmonary artery (pulmonary artery banding) can reduce pulmonary blood flow until complete repair can be accomplished. Surgical closure of the defect is completed by placement of a synthetic or autologous patch effectively to close the shunt across the ventricular septum. These procedures are typically done electively in the infant or young child and are associated with low morbidity and mortality rates.

Endocardial Cushion Defects. The endocardial cushions form the AV canals, the upper part of the ventricular septum, and the lower part of the atrial septum. The endocardial cushions surround this canal and contribute tissue to the lower part of the atrial septum, the upper part of the ventricular septum, the septal leaflet of the tricuspid valve, and the anterior leaflet of the mitral valve. Any flaw in the development of these tissues results in an endocardial cushion defect. Endocardial cushion defects are responsible for approximately 2% of all congenital heart defects. As many as 30% of children with Down syndrome have endocardial cushion defects.

Because the endocardial cushions contribute to multiple aspects of heart development, several variations of endocardial cushion defects are possible. The defect may be described as partial or complete. The anatomy of the AV valve determines the classification. In partial AV canal defects, the two AV valve rings are complete and separate. The most common type of partial AV canal defect is an ostium primum defect, often associated with a cleft in the mitral valve. In a complete canal defect, there is a common AV valve orifice along with defects in both the atrial and ventricular septal tissue (see Fig. 19-21E). Other cardiac defects may be associated with endocardial cushion defects and most commonly include cardiac malposition defects and tetralogy of Fallot.

Physiologically, endocardial cushion defects result in abnormalities similar to those described for atrial or ventricular septal defects. The direction and magnitude of a shunt in a child with an endocardial cushion defect are determined by the combination of defects and the child’s pulmonary and systemic vascular resistance. The hemodynamic effects of an isolated ostium primum defect are those of the previously described atrial septal defect. These children are largely asymptomatic during childhood. With a complete AV canal defect, pulmonary blood flow is increased after the pulmonary vascular resistance falls because of left-to-right shunting across both the ventricular and atrial septal defects. Children with complete defects often have effort intolerance, easy fatigability, failure to thrive, recurrent infections, and other signs of congestive heart failure, particularly when the shunt is large. Pulmonary hypertension and increased pulmonary vascular resistance result if the lesion is left untreated.

The timing of treatment for endocardial cushion defects is determined by the severity of the defect and symptoms. With an ostium primum defect, surgical repair usually is planned on an elective basis before the child reaches school age. Corrective surgery is required for all complete AV canal defects. Infants with severe symptoms may require a palliative procedure in which the main pulmonary artery is banded to reduce pulmonary blood flow. This typically improves the infant’s ability to grow and develop until a complete repair can be performed.

Pulmonary Stenosis. Obstruction of blood flow from the right ventricle to the pulmonary circulation is termed pulmonary stenosis. The obstruction can occur as an isolated valvular lesion, within the right ventricular chamber, in the pulmonary arteries, or as a combination of stenoses in multiple areas. It is a relatively common defect, estimated to account for approximately 10% of all congenital cardiac disease, and is often associated with other abnormalities.

Pulmonary valvular defect, the most common type of disorder, usually produces some impairment of pulmonary blood flow and increases the workload imposed on the right side of the heart (see Fig. 19-21D). Most children with pulmonic valve stenosis have mild stenosis that does not increase in severity. These children
are largely asymptomatic and are diagnosed by the presence of a systolic murmur. Moderate or greater stenosis has been shown to progress over time, particularly before 12 years of age, so these children require careful follow-up. Critical pulmonary stenosis in the neonate is evidenced by cyanosis due to right-to-left atrial-level shunting and right ventricular hypertension. These infants require prostaglandin E₁, to maintain circulation to the lungs through the ductus arteriosus. Pulmonary valvotomy is the treatment of choice for all valvular defects with pressure gradients from the right ventricle to the pulmonary circulation greater than 30 mm Hg. Transcatheter balloon valvuloplasty has been quite successful in this lesion. Stenosis in the peripheral pulmonary arteries can also be effectively treated with balloon angioplasty, with or without stent placement.

Tetralogy of Fallot. Tetralogy of Fallot is the most common cyanotic congenital heart defect, accounting for approximately 5% to 7% of all congenital heart defects. As the name implies, tetralogy of Fallot consists of four associated defects: (1) a ventricular septal defect involving the membranous septum and the anterior portion of the muscular septum; (2) dextroposition (shifting to the right of the aorta) so that it overrides the right ventricle and is in communication with the septal defect; (3) obstruction or narrowing of the pulmonary outflow channel, including pulmonic valve stenosis, a decrease in the size of the pulmonary trunk, or both; and (4) hypertrophy of the right ventricle because of the increased work required to pump blood through the obstructed pulmonary channels (see Fig. 19-21C). Variations of the defect can include complete atresia of the pulmonary valve or absence of pulmonary valve tissue altogether.

Most children with tetralogy of Fallot display some degree of cyanosis that is caused by a right-to-left shunt across the ventricular septal defect. The degree of cyanosis is determined by the restriction of blood flow into the pulmonary bed. Right ventricular outflow obstruction causes deoxygenated blood from the right ventricle to shunt across the ventricular septal defect and be ejected into the systemic circulation. The degree of obstruction may be dynamic and can increase during periods of stress, causing hypcyanotic attacks (“tet spells”). These spells typically occur in the morning during crying, feeding, or defecating. These activities increase the infant’s oxygen requirements. Crying and defecating may further increase pulmonary vascular resistance, thereby increasing right-to-left shunting and decreasing pulmonary blood flow. With the hypcyanotic spell, the infant becomes acutely cyanotic, hyperpneic, irritable, and diaphoretic. Later in the spell, the infant becomes limp and may lose consciousness. Placing the infant in the knee–chest position increases systemic vascular resistance, which increases pulmonary blood flow and decreases right-to-left shunting. During a hypcyanotic spell, toddlers and older children may spontaneously assume the squatting position, which functions like the knee–chest position to relieve the spell.

Total surgical correction is required for all children with tetralogy of Fallot. Early definitive repair in infancy is currently advocated in most centers experienced in intracardiac surgery in infants.

Transposition of the Great Arteries. In complete transposition of the great arteries, the aorta arises from the right ventricle, and the pulmonary artery arises from the left ventricle (see Fig. 19-21F). The defect is more common in infants whose mothers have diabetes and is two to three times more common in boys. Cyanosis is the most common presenting symptom, resulting from an anomaly that allows the systemic venous return to be circulated through the right heart and ejected into the aorta, and the pulmonary venous return to be recirculated to the lungs through the left ventricle and main pulmonary artery. In infants born with this defect, survival depends on communication between the right and left sides of the heart in the form of a patent ductus arteriosus or septal defect. Ventricular septal defects are present in 50% of infants with transposition of the great arteries at birth and may allow effective mixing of blood. Prostaglandin E₁, should be administered to neonates when this lesion is suspected in an effort to maintain the patency of the ductus arteriosus. Balloon atrial septostomy may be done to increase the blood flow between the two sides of the heart. In this procedure, a balloon-tipped catheter is inserted into the heart through the vena cava and then passed through the foramen ovale into the left atrium. The balloon is then inflated and pulled back through the foramen ovale, enlarging the opening as it goes.

Corrective surgery is essential for long-term survival. An arterial switch procedure, which corrects the relation of the systemic and pulmonary blood flows, is the current procedure of choice, and has survival rates greater than 90%. This procedure is preferably performed in the first 2 to 3 weeks of life, before the postnatal reduction in pulmonary vascular resistance occurs. The coronary arteries are moved to the left-sided great artery and any ventricular septal defects are closed during the same operation. Complications of the arterial switch procedure may include coronary insufficiency, supra-valvar pulmonary stenosis, neo-aortic regurgitation, and rhythm abnormalities.

Coarctation of the Aorta. Coarctation of the aorta consists of a localized narrowing of the aorta. It can occur proximal to (preducal) (see Fig. 19-21H), distal to (postductal), or opposite of (juxtaductal) the entry of the ductus arteriosus. Approximately 98% of coarctations are juxtaductal. The defect is frequently associated with other congenital cardiac lesions, most commonly bicuspid aortic valve, and occurs in approximately 10% of subjects with Turner syndrome, suggesting a genetic linkage (see Chapter 6).

The classic sign of coarctation of the aorta is a disparity in pulsations and blood pressures in the arms and legs. The femoral, popliteal, and dorsalis pedis pulsations are weak or delayed compared with the bounding pulses of the arms and carotid vessels. Normally, the systolic blood pressure in the legs obtained by the cuff method is 10 to 20 mm Hg higher than in the arms.
In coarctation, the pressure in the legs is lower and may be difficult to obtain. Patients with coarctation are often identified during a diagnostic workup for hypertension. Most patients with moderate coarctation remain otherwise asymptomatic owing to collateral vessels that form around the area of narrowing. Left untreated, however, coarctation will result in left ventricular hypertension and hypertrophy and significant systemic hypertension (see Chapter 18). Infants with severe coarctation demonstrate early symptoms of heart failure and may present in critical condition upon ductal closure. Reopening of the duct with prostaglandin E1, if possible, and emergent surgery are needed in this subgroup.88

Children with coarctation causing a blood pressure gradient between the arms and legs of 20 mm Hg or greater should ideally be treated by 2 years of age to reduce the likelihood of persistent hypertension.89 A surgical approach typically involves resection of the narrowed segment of the aorta and end-to-end anastomosis of healthy tissue. This can usually be accomplished without cardiopulmonary bypass, with a mortality rate near zero. Balloon angioplasty with or without stent placement has also been used, although the presence of residual gradients and the reliability of the surgical approach have limited this technique.88

**Functional Single-Ventricle Anatomy.** Several forms of complex congenital heart disease result in only one functional ventricle. Functional single-ventricle anatomy is the most common form of congenital heart disease diagnosed on routine prenatal ultrasonography. There may be a single right or a single left ventricle, or a ventricle of indeterminate morphology.89–92 Hypoplastic left heart syndrome, a term used to describe a group of closely related cardiac anomalies characterized by underdevelopment of the left cardiac chambers, is the most common form of this disorder.92 Several other forms of double-inlet ventricle have been described; however, all forms of this disease result in similar pathologic effects and follow a common pathway of intervention.89–93

All forms of single-ventricle anatomy result in a common mixing chamber of pulmonary and systemic venous return and cause varying degrees of cyanosis (Fig. 19-23). The single ventricle must pump blood to both the pulmonary and systemic circulations, and thus the flow to each circulation is determined by the resistance in each system.89–92 As pulmonary vascular resistance falls, flow to the pulmonary circulation will be preferential and systemic circulation will be compromised. In some defects, such as hypoplastic left heart syndrome, systemic flow depends on a patent ductus arteriosus. Neonates with this lesion typically present with extreme cyanosis and symptoms of heart failure as the ductus begins to close.92

Although functional single-ventricle anatomy cannot be completely repaired, the surgical palliation of these defects has been one of the most innovative interventions for congenital heart disease. The goal of surgical palliation is to redirect systemic venous return directly to the pulmonary arteries and allow the single ventricle to deliver oxygenated blood to the systemic circulation.

This is accomplished in a series of two to three staged surgical palliation interventions during the child’s first years of life. Stage one palliation is designed to ensure unobstructed systemic blood flow and adequate flow to the pulmonary circulation. Stage two, a bidirectional cavopulmonary shunt, redirects systemic venous return from the superior vena cava directly to the pulmonary arteries. Stage three connects flow from the inferior vena cava directly into the pulmonary arteries so that the pulmonary and systemic circulations are effectively separated.93 Cardiac transplantation is also used as an intervention for the most complex forms of single-ventricle congenital heart disease.

Survival rates for children with complex forms of single-ventricle heart disease have improved markedly, but long-term outcomes remain uncertain. Ventricular dysfunction, arrhythmias, and thromboses plague this population of patients. Defining the optimal medical and surgical management strategies for these patients remains an active area of research in pediatric cardiology and cardiac surgery.89–93

**Kawasaki Disease**

Kawasaki disease is an acute vasculitis (i.e., inflammation of the blood vessels) with potential for involvement of the coronary arteries. The disease occurs predominantly in young children; about 80% of patients are younger than 5 years of age.94,95 First described in Japan in 1967 by Dr. Tomisaku Kawasaki, the disease is the leading cause of acquired heart disease in North America and Japan.95,96,67,68 Although most common in
Japan, the disease affects children of many races, occurs worldwide, and is increasing in frequency.

The disease is characterized by a vasculitis that begins in the small vessels (i.e., arterioles, venules, and capillaries) and progresses to involve some of the larger arteries, such as the coronaries. The exact etiology and pathogenesis of the disease remain unknown, but it is thought to be of immunologic origin. Immunologic abnormalities, including increased activation of helper T cells and increased levels of immune mediators and antibodies that destroy endothelial cells, have been detected during the acute phase of the disease. It has been hypothesized that some unknown antigen, possibly a common infectious agent, triggers the immune response in a genetically predisposed child.

**Manifestations and Clinical Course**

The course of the disease is triphasic and includes an acute febrile phase that lasts approximately 7 to 14 days, a subacute phase that follows the acute phase and lasts from days 10 through 24, and a convalescent phase that follows the subacute stage and continues until the signs of the acute-phase inflammatory response have subsided and the signs of the illness have disappeared.

The *acute phase* begins with an abrupt onset of fever, followed by bilateral conjunctivitis, usually without exudates; erythema of the oral and pharyngeal mucosa with "strawberry tongue" and dry, fissured lips; redness and swelling of the hands and feet; rash of various forms; "strawberry tongue" and dry fissured lips; redness and swelling of the hands and feet; rash of various forms; and enlarged cervical lymph nodes. The fever typically is high, reaching 40°C (104°F) or more; has an erratic spiking pattern; is unresponsive to antibiotics; and persists for 5 or more days. The conjunctivitis begins shortly after the onset of fever, persists throughout the febrile course of the disease, and may last as long as 3 to 5 weeks.

The *subacute phase* begins with abatement of the fever and lasts until all signs of the disease have disappeared. During the subacute phase, desquamation (i.e., peeling) of the skin of the fingers and toe tips begins and progresses to involve the entire surface of the palms and soles. Patchy peeling of skin areas other than the hands and feet may occur in some children. The convalescent stage persists from the complete resolution of symptoms until all signs of inflammation have disappeared. This usually takes approximately 8 weeks.

In addition to the major manifestations that occur during the acute stage of the illness, there are several associated, less specific characteristics of the disease, including arthritis, urethritis and pyuria, gastrointestinal manifestations (e.g., diarrhea, abdominal pain), and hepatitis. Arthritis is more common in girls and may occur early in the illness along with the fever and other acute manifestations of the disease or during the 2nd or 3rd week, generally affecting the hands, knees, ankles, or toes. Central nervous system involvement occurs in almost all children and is characterized by pronounced irritability and lability of mood.

Cardiac involvement is the most important manifestation of Kawasaki disease. Coronary artery abnormalities develop in approximately 20% of children, manifested by coronary artery dilation and aneurysm formation as seen on 2D echocardiography. The manifestations of coronary artery involvement include signs and symptoms of myocardial ischemia or, rarely, overt myocardial infarction or rupture of a coronary aneurysm. Pericarditis, myocarditis, endocarditis, heart failure, and arrhythmias also may develop.

**Diagnosis and Treatment**

No specific diagnostic test for Kawasaki disease is available; therefore, the diagnosis is made on clinical grounds following published guidelines. The guidelines specify fever persisting at least 5 days or more without another source in association with at least four principal features, including oral changes that may include erythema or cracking of the lips, strawberry tongue, and erythema of the oral mucosa; bilateral, nonexudative conjunctivitis; rash of various forms (maculopapular, erythema multiforme, or scarlatiniform) with accentuation in the groin region; erythema and swelling of the hands or feet with desquamation of fingers and toes 1 to 3 weeks after onset of illness; and cervical lymphadenopathy, often unilateral, with at least one node that is 1.5 cm in size. Chest radiographs, ECG tests, and 2D echocardiography are used to detect coronary artery involvement and follow its progress. Coronary angiography may be used to determine the extent of coronary artery involvement.

Intravenous gamma globulin and aspirin are considered the best therapies for prevention of coronary artery abnormalities in children with Kawasaki disease. During the acute phase of the illness, aspirin usually is given in larger doses (80 to 100 mg/kg/day divided in four doses) for its anti-inflammatory and antipyretic effects. After the fever is controlled, the aspirin dose is lowered (3 to 5 mg/kg/day, single dose), and the drug is given for 6 to 8 weeks for its anti-platelet-aggregating effects.

Recommendations for cardiac follow-up evaluation (i.e., stress testing and sometimes coronary angiography) are based on the level of coronary artery changes. Anticoagulant therapy may be recommended for children with multiple or large coronary aneurysms. Some restrictions in activities such as competitive sports may be advised for children with significant coronary artery abnormalities.

**SUMMARY CONCEPTS**

- Congenital heart defects arise during fetal development, which occurs during weeks 3 through 8 after conception, and reflect the stage of development at the time the causative event occurred. Several factors contribute to the development of congenital heart defects, including genetic and chromosomal influences, viruses, and environmental agents such as drugs and radiation.
SUMMARY CONCEPTS (continued)

- Congenital heart defects are commonly classified according to anatomic site (e.g., atrial or ventricular septal), hemodynamic alterations (shunting of blood), and their effect on pulmonary blood flow and tissue oxygenation (noncyanotic, cyanotic).

- Hemodynamic alterations may produce shunting of blood from the right to the left or from the left to the right side of the heart, with the direction and degree of shunt depending on the size and position of the defect that connects the two sides of the heart and the difference in resistance between the two sides of the circulation. Left-to-right shunts typically increase the volume of the right side of the heart and pulmonary circulation, and right-to-left shunts transfer deoxygenated blood from the right side of the heart to the left side, diluting the oxygen content of blood that is being ejected into the systemic circulation and causing cyanosis.

- Kawasaki disease is an acute vasculitis of young children that affects the skin, brain, eyes, joints, liver, lymph nodes, and heart. The disease can produce aneurysmal disease of the coronary arteries and is the most common cause of acquired heart disease in young children.

REVIEW EXERCISES

1. A 40-year-old man presents in the emergency department complaining of substernal chest pain that is also felt in his left shoulder. He is short of breath and nauseated. His blood pressure is 148/90 mm Hg and his heart rate is 110 beats/minute. His ECG shows an ST-segment elevation with T-wave inversion. He is given aspirin, morphine, and oxygen. Blood tests reveal elevated CK-MB and troponin I.

   A. What is the probable cause of this man’s symptoms?
   B. Explain the origin of the left arm pain, nausea, and increased heart rate.
   C. What is the significance of the ST-segment changes and elevation in CK-MB and troponin I?
   D. Relate the actions of aspirin, morphine, and oxygen to the treatment of this man’s condition.

2. A 50-year-old woman presents with complaints of paroxysmal nocturnal dyspnea and orthopnea, palpitations, and fatigue. An echocardiogram demonstrates a thickened, immobile mitral valve with anterior and posterior leaflets moving together; slow early diastolic filling of the ventricle; and left atrial enlargement.

   A. What is the probable cause of this woman’s symptoms?
   B. Explain the pathologic significance of the slow early diastolic filling, distended left atrium, and palpitations.
   C. Given the echocardiographic data, what type of cardiac murmur would you expect to find in this woman?
   D. Which circulation (systemic or pulmonary) would you expect to be affected as this woman’s mitral valve disorder progresses?

3. A 4-month-old male infant is brought into the pediatric clinic by his mother. She reports that she noted over the past several weeks that her baby’s lips and mouth and his fingernails and toenails have become a bluish-gray color. She also states that he seems to tire easily and that even nursing seems to wear him out. Lately, he has had several spells where he has suddenly turned blue, has had difficulty breathing, and has been very irritable. During one of these spells he turned limp and seemed to have passed out for a short time. An echocardiogram reveals a thickening of the right ventricular wall with overriding of the aorta, a large subaortic ventricular septal defect, and narrowing of the pulmonary outflow with stenosis of the pulmonary valve.

   A. What is this infant’s probable diagnosis?
   B. Describe the shunting of blood that occurs with this disorder and its relationship to the development of cyanosis.
   C. The mother is instructed to place the infant in the knee–chest position when he has one of the spells in which he becomes blue and irritable. How does this position help to relieve the cyanosis and impaired oxygenation of tissues?
   D. The surgical creation of a shunt between the aorta and pulmonary artery may be performed as a palliative procedure for infants with marked hypoplasia of the pulmonary artery, with corrective surgery performed later in childhood. Explain how this procedure increases blood flow to the lungs.

REFERENCES

Adequate perfusion of body tissues depends on the pumping ability of the heart, a vascular system to transport blood to the tissues of the body and back to the heart, sufficient blood to fill the circulatory system, and tissues that are able to extract and to use oxygen and nutrients from the blood. Heart failure and circulatory shock are different conditions that reflect an impairment of the circulatory system; however both conditions involve many of the same compensatory mechanisms even though they differ in terms of pathogenesis and causes.

Heart Failure

Heart failure is a complex syndrome resulting from functional or structural impairment of ventricular filling or ejection of blood into the circulation.\(^1,2\) It may result from disorders of the pericardium, myocardium, endocardium, cardiac valves, or great vessels, or from metabolic abnormalities. Among the most common causes of heart failure are coronary artery disease, hypertension, dilated cardiomyopathy, and valvular heart disease.\(^1\) Heart failure can occur in any age group but primarily affects the elderly; however, African Americans are disproportionately affected at a younger age.\(^1\) Although morbidity and mortality rates from other cardiovascular diseases have decreased over the past several decades,\(^4\) the incidence of heart failure is increasing at an alarming rate.\(^1\) This change undoubtedly reflects improved treatment methods and increased survival from other forms of heart disease. Mortality rates from heart failure are variable (5% to 75% annually).\(^4\) Once the initial diagnosis of heart failure is made, the survival rate is approximately 50% within 5 years.\(^1\)

Heart failure is associated with either a reduced or preserved left ventricular ejection fraction. Heart failure was traditionally defined as a syndrome with impaired ability of the ventricles to contract and eject blood (systolic failure with a reduced ejection fraction) or impaired ventricular relaxation (diastolic failure with a reduced end-diastolic volume). It is now recognized
Pathophysiology of Heart Failure

In heart failure, the heart does not adequately pump and/or fill with blood, which results in the inability to meet the metabolic needs of the body. The efficiency of the heart as a pump is determined by the volume of blood that it ejects each minute. The volume of blood ejected is dependent upon the ability of the ventricles to relax and fill. The heart has the amazing capacity to adjust its output to meet the varying needs of the body. During sleep, the output declines, and during exercise, it increases markedly. The ability of the heart to increase its output during increased activity is called the cardiac reserve. For example, competitive swimmers and long-distance runners have large cardiac reserves. During exercise, the cardiac output of these athletes rapidly increases to as much as five to six times their resting level. In sharp contrast with healthy athletes, persons with heart failure often use their cardiac reserve at rest. For them, just climbing a flight of stairs or even walking may cause shortness of breath because they exceed their cardiac reserve.

Cardiac Performance and Output

The cardiac cycle consists of diastole and systole. During diastole, normal filling of the ventricles increases the volume of each to about 110 to 120 mL. Then, as the ventricles contract during systole, blood is ejected from the heart, and the volume decreases by about 70 mL, which is called the stroke volume. The fraction of the end-diastolic volume that is ejected is called the ejection fraction (usually about 60% in a healthy person).

Cardiac output, which is the major determinant of cardiac performance, reflects how often the heart beats each minute (heart rate) and how much blood it ejects with each beat (stroke volume). Cardiac output is expressed as the product of the heart rate and stroke volume (i.e., cardiac output = heart rate × stroke volume). The heart rate is regulated by a balance between the activity of the sympathetic nervous system, which produces an increase in heart rate, and the parasympathetic nervous system, which slows it down, whereas the stroke volume is a function of preload, afterload, and myocardial contractility.

Preload and Afterload. The ability of the heart to eject blood that has returned to the ventricles during diastole is determined largely by the loading conditions, or what are called the preload and afterload.

Preload reflects the volume of blood that stretches the ventricle at the end of diastole, just before the onset of systole. It is determined by the venous return to the heart. Also known as the end-diastolic volume, preload increases the length of the myocardial muscle fibers. Within limits, as preload increases, the stroke volume increases in accord with the Frank-Starling mechanism.

Afterload represents the force that the contracting heart muscle must generate to eject blood from the filled ventricles. The main components of afterload are the systemic (peripheral) vascular resistance and ventricular wall tension. When the systemic vascular resistance is elevated, as with arterial hypertension, an increased left intraventricular pressure must be generated to first open the aortic valve and then to eject blood out of the ventricle and into the systemic circulation. This increased pressure equates to an increase in ventricular wall stress or tension.

Myocardial Contractility

Myocardial contractility, also known as inotropy, refers to the contractile performance of the heart, or the ability of the contractile elements (actin and myosin filaments) of the heart muscle to interact and shorten against a load (see Chapter 1, Fig. 1-18). Contractility increases cardiac output independent of preload and afterload. The interaction between the actin and myosin filaments during cardiac muscle contraction (i.e., crossbridge attachment and detachment) requires the use of energy supplied by the breakdown of adenosine triphosphate (ATP) and the presence of calcium ions (Ca²⁺).

As with skeletal muscle, calcium is released from the sarcoplasmic reticulum of cardiac muscle during an action potential (Fig. 20-1). This calcium, in turn, diffuses into the myofibrils and catalyzes the chemical reactions that promote the sliding of the actin and myosin filaments along one another to produce muscle shortening. In addition to the calcium released from the sarcoplasmic reticulum at the time of an action potential, a large quantity of extracellular calcium diffuses into the sarcoplasm through voltage-dependent L-type calcium channels located in the T tubules and myocardial cell membrane. Without the extra calcium that enters through the L-type calcium channels, the strength of the cardiac contraction would be considerably weaker. Opening of the L-type calcium channels is facilitated by the second messenger cyclic adenosine monophosphate (cAMP), the formation of which is coupled to β-adrenergic receptors.

The catecholamines (norepinephrine and epinephrine) exert their inotropic effects by binding to these adrenergic receptors. The L-type calcium channel also contains several other types of receptors. Blockade of L-type calcium channels by drugs that bind to these receptors (i.e., calcium channel-blocking drugs) results in a selective reduction in cardiac contractility.

Another mechanism that can modulate inotropy is the increased activity of the sodium ion (Na⁺)/Ca²⁺ exchange pump and the ATPase-dependent Ca²⁺ pump in the myocardial cell membrane (see Fig. 20-1). These pumps transport calcium out of the cell, thereby preventing the cell from becoming overloaded with calcium. If calcium efflux is inhibited, the rise in intracellular calcium produces an increased inotropy. Digitalis and related
cardiac glycosides are inotropic agents that exert their effects by inhibiting the \( \text{Na}^+ / \text{K}^+ \)-ATPase pump in the myocardial cell membrane, thereby leading to an increase in intracellular calcium handling through the \( \text{Na}^+ / \text{Ca}^{++} \) exchange pump.

**Compensatory Mechanisms**

In heart failure, the cardiac reserve is largely maintained through compensatory mechanisms such as the Frank-Starling mechanism, activation of neurohumoral influences such as the sympathetic nervous system reflexes, the renin-angiotensin-aldosterone mechanism, natriuretic peptides, locally produced vasoactive substances, and myocardial hypertrophy and remodeling.\(^5,10\) (Fig. 20-2). The first two of these adaptations occur rapidly over minutes to hours of myocardial dysfunction and may be adequate to maintain the overall pumping performance of the heart at relatively normal levels. Myocardial hypertrophy and remodeling occur slowly over weeks to months and play an important role in the long-term adaptation to hemodynamic overload. In the failing heart, early decreases in cardiac function may go unnoticed because these compensatory mechanisms maintain the cardiac output. However, these mechanisms contribute not only to the adaptation of the failing heart but also to the pathophysiology of heart failure.\(^11\)

**Length-Tension/Frank-Starling Mechanism**

The Frank-Starling mechanism describes the process whereby the heart increases its stroke volume through an increase in end-diastolic volume or preload (Fig. 20-3). With increased diastolic filling, there is increased stretching of the myocardial fibers, more optimal approximation of the actin and myosin filaments, and a resultant increase in the force of the next contraction (see Chapter 17). As illustrated in Figure 20-3, there is no single Frank-Starling curve.\(^6\) An increase in contractility will increase cardiac output at any end-diastolic volume, causing the curve to move up and to the left, whereas a decrease in contractility will cause the curve to move down and to the right.
In heart failure with a reduced ejection fraction, a decrease in cardiac output and renal blood flow leads to increased sodium and water retention by the kidney with a resultant increase in vascular volume and venous return to the heart, and an increase in ventricular end-diastolic volume. Within limits, as preload and ventricular end-diastolic volume increase, there is a resultant increase in cardiac output. Although this may preserve the resting cardiac output, the resulting chronic elevation of left ventricular end-diastolic pressure is transmitted to the atria and the pulmonary circulation, causing pulmonary congestion.

An increase in cardiac muscle stretch, as occurs with the Frank-Starling mechanism, also produces an increase in ventricular wall tension with a resultant increase in myocardial oxygen consumption. Because increased wall tension increases myocardial oxygen requirements, it can produce ischemia and contribute to further impairment of cardiac function. The use of diuretics in persons with heart failure helps to reduce vascular volume and ventricular filling, thereby unloading the heart and reducing ventricular wall tension.

**Sympathetic Nervous System**

Stimulation of the sympathetic nervous system plays an important role in the compensatory response to decreased cardiac output and in the pathogenesis of
heart failure. Both cardiac sympathetic tone and catecholamine (epinephrine and norepinephrine) levels are elevated during the late stages of most forms of heart failure. By direct stimulation of heart rate and cardiac contractility, regulation of vascular tone, and enhancement of renal sodium and water retention, the sympathetic nervous system initially helps to maintain perfusion of the various body organs.

Although the sympathetic nervous system response is meant to maintain blood pressure and cardiac output, it quickly becomes maladaptive and contributes to the deterioration of heart function. An increase in sympathetic activity can lead to tachycardia, vasoconstriction, and cardiac arrhythmias. Acutely, tachycardia significantly increases the workload of the heart, thus increasing myocardial oxygen demand and leading to cardiac ischemia, myocyte damage, and decreased contractility (inotropy). An increase in systemic vascular resistance causes an increase in cardiac afterload and ventricular wall stress. By promoting arrhythmias, the catecholamines released with sympathetic nervous system stimulation also may contribute to the high rate of sudden death seen with heart failure. Other sympathetic mediated effects include decreased renal perfusion and additional augmentation of the renin-angiotensin-aldosterone system, as well as decreased blood flow to skin, muscle, and abdominal organs.

Renin-Angiotensin-Aldosterone Mechanism

One of the most important effects of lowered cardiac output in heart failure is a reduction in renal blood flow and glomerular filtration rate, which leads to sodium and water retention by way of aldosterone production. With decreased renal blood flow, there is a progressive increase in renin secretion by the kidneys with parallel increases in circulating levels of angiotensin II. The increased concentration of angiotensin II contributes directly to generalized and excessive vasoconstriction, as well as facilitating norepinephrine release and inhibiting reuptake of norepinephrine by the sympathetic nervous system. Angiotensin II also provides a powerful stimulus for aldosterone production by the adrenal cortex (see Chapter 18).

Aldosterone increases tubular reabsorption of sodium, with an accompanying increase in water retention. Because aldosterone is metabolized in the liver, its levels are further increased when heart failure causes liver congestion. Angiotensin II also increases the level of antidiuretic hormone (ADH), which serves as a vasoconstrictor and inhibitor of water excretion (see Chapter 8). In addition to their individual effects on sodium and water balance, angiotensin II and aldosterone are also involved in regulating the inflammatory and reparative processes that follow tissue injury. However, the sustained expression of aldosterone may stimulate fibroblast and collagen deposition, resulting in ventricular hypertrophy as well as fibrosis within the vasculature and myocardium, and thereby contributing to reduced vascular compliance and increased ventricular stiffness.

Natriuretic Peptides

The heart muscle produces and secretes a family of related peptide hormones, called the natriuretic peptides (NPs), which have potent diuretic, natriuretic, vascular smooth muscle, and other neurohumoral actions that affect cardiovascular function. Two of the four known NPs most commonly associated with heart failure are atrial natriuretic peptide and B-type natriuretic peptide. As the name indicates, atrial natriuretic peptide (ANP) is released from atrial cells in response to atrial stretch, pressure, or fluid overload. B-type natriuretic peptide (BNP), so named because it was originally found in extracts of the porcine brain, is primarily secreted by the ventricles as a response to increased ventricular pressure or fluid overload. Although the NPs are not secreted from the same chambers in the heart, they have very similar functions. In response to increased chamber stretch and pressure, they promote rapid and transient natriuresis and diuresis through an increase in the glomerular filtration rate and an inhibition of tubular sodium and water reabsorption. The NPs also facilitate complex interactions with the neurohormonal system, inhibiting the sympathetic nervous system, the renin-angiotensin-aldosterone system, and the antidiuretic hormone (ADH), also known as vasopressin. Circulating levels of both ANP and BNP are elevated in persons with heart failure. The concentrations are well correlated with the extent of ventricular dysfunction, increasing up to 30-fold in persons with advanced heart disease. Assays of BNP are used clinically in the diagnosis of heart failure and to predict the severity of the condition.

Endothelins

The endothelins, released from the endothelial cells throughout the circulation, are potent vasoconstrictors. Like angiotensin II, endothelin can also be synthesized and released by a variety of cell types, such as cardiac myocytes. There are three endothelin (ET) peptides (ET-1, ET-2, and ET-3). In addition to vasoconstrictor actions, the endothelins induce vascular smooth muscle cell proliferation and cardiac myocyte hypertrophy and fibrosis; increase the release of ANP, aldosterone, and catecholamines; and exert antinatriuretic effects on the kidneys. They also have been shown to have a negative inotropic action in patients with heart failure. Plasma ET-1 levels also correlate directly with pulmonary vascular resistance, and it is thought that ET-1 may play a role in mediating pulmonary hypertension in persons with heart failure.

Myocardial Hypertrophy and Remodeling

The development of myocardial hypertrophy constitutes one of the principal mechanisms by which the heart compensates for an increase in workload. Although ventricular hypertrophy improves the work performance of the heart, it is also an important risk factor for subsequent cardiac morbidity and mortality. Inappropriate hypertrophy and remodeling can result in changes in structure (i.e., muscle mass, chamber dilation) and cardiac function (i.e., impaired systolic or diastolic function) that often lead to further pump dysfunction and hemodynamic overload.
Myocardial hypertrophy and remodeling involve a series of complex events at both the molecular and cellular levels. The myocardium is composed of myocytes, or muscle cells, and nonmyocytes. The myocytes are the functional units of cardiac muscle. The nonmyocytes include cardiac macrophages, fibroblasts, vascular smooth muscle, and endothelial cells. These cells, which are present in the interstitial space, remain capable of an increase in cell number and provide support for the myocytes. The nonmyocytes also determine many of the inappropriate changes that occur during myocardial hypertrophy. For example, uncontrolled fibroblast growth is associated with increased synthesis of collagen fibers, myocardial fibrosis, and ventricular wall stiffness.

Recent research has focused on understanding the type of hypertrophy that develops in persons with heart failure. At the cellular level, cardiac muscle cells respond to stimuli from stress placed on the ventricular wall by pressure and volume overload by initiating several different processes that lead to hypertrophy. These include stimuli that produce a symmetric hypertrophy with a proportionate increase in muscle length and width, as occurs in athletes; concentric hypertrophy with an increase in wall thickness, as occurs in hypertension; and eccentric hypertrophy with a disproportionate increase in muscle length, as occurs in dilated cardiomyopathy (Fig. 20-4). When the primary stimulus for hypertrophy is pressure overload, the increase in wall stress leads to parallel replication of myofibrils, thickening of the individual myocytes, and concentric hypertrophy. Concentric hypertrophy may preserve systolic function for a time, but eventually the work performed by the ventricle exceeds the vascular reserve, predisposing to ischemia. With ventricular volume overload, the increase in wall stress leads to replication of myofibrils in series, elongation of the cardiac muscle cells, and eccentric hypertrophy. Eccentric hypertrophy leads to a decrease in ventricular wall thickness or thinning of the wall with an increase in diastolic volume and wall tension.

**Types of Heart Failure**

Heart failure is commonly classified by the ejection fraction (reduced or preserved) or as left-sided or right-sided failure. Heart failure with a reduced ejection fraction (HFrEF) is defined as the inability of the ventricle to eject an adequate cardiac output despite a normal blood pressure with an EF ≤ 40%. Heart failure with a preserved ejection fraction (HFpEF) is characterized by a normal or normal EF (>50%) and abnormal diastolic function. Persons with a reduced or preserved ejection fraction may be symptomatic or asymptomatic. In order to be diagnosed with heart failure, they must also exhibit signs and symptoms, such as shortness of breath, decreased exercise tolerance, and orthopnea (shortness of breath when lying down).

Over the last decade, there has been growing recognition that approximately 50% of adult persons with heart failure have normal or near normal ejection fractions. These people are as a group older, more commonly female, and more frequently have systolic hypertension (associated with large artery stiffness) than those with a reduced ejection fraction. Most people with HFpEF do not complain of symptoms at rest, but rather with physical exercise. When present, the signs and symptoms of heart failure are related to which ventricle is dysfunctional: left or right.

**Reduced versus Preserved Ejection Fraction**

Heart failure can result from pump failure and an impaired ability to eject blood at a rate commensurate with the metabolic needs of the tissues (systolic failure), or it can occur because of resistance to filling of one or both ventricles leading to symptoms of congestion (diastolic failure).

**Reduced Ejection Fraction Heart Failure.** Heart failure with a reduced ejection fraction or systolic heart failure is defined as an EF of less than 40%. It may result from conditions that impair the contractile performance of the heart (e.g., ischemic heart disease and cardiomyopathy), produce a volume overload (e.g., valvular insufficiency and anemia), or generate a pressure overload (e.g., hypertension and valvular stenosis) on the heart.

Along with the decreased EF and cardiac output that occurs with systolic failure, there is a resultant increase in end-systolic and end-diastolic volumes, ventricular dilation and wall tension, and a rise in ventricular end-diastolic pressure. This increased volume, in addition to the normal venous return, leads to an increase in ventricular preload. The rise in preload may represent a compensatory response to maintain stroke volume through the Frank-Starling mechanism despite a reduction in EF. Increased preload, however, can also lead to an excessive accumulation of blood in the atria and the pulmonary venous system, which causes pulmonary congestion.

**FIGURE 20-4.** Different types of myocardial hypertrophy. (A) Normal symmetric hypertrophy with proportionate increases in myocardial wall thickness and length. (B) Concentric hypertrophy with a disproportionate increase in wall thickness. (C) Eccentric hypertrophy with a disproportionate decrease in wall thickness and ventricular dilation.
The cardinal symptoms of systolic failure are dyspnea, fatigue, and peripheral edema. Other symptoms include orthopnea and paroxysmal nocturnal dyspnea, signs of jugular venous distention and cardiac enlargement.\textsuperscript{22}

**Preserved Ejection Fraction Heart Failure.** Although heart failure is commonly associated with impaired systolic function, in approximately half of the cases systolic function is preserved (EF > 50\%) and heart failure results from an inability of the left ventricle to fill sufficiently during diastole.\textsuperscript{23–25} Hypertension remains the leading cause of diastolic dysfunction. Other conditions that cause diastolic dysfunction include those that impede filling of the ventricle (e.g., pericardial effusion, constrictive pericarditis), increase ventricular wall thickness and reduce chamber size (e.g., myocardial hypertrophy, hypertrophic cardiomyopathy), or delay diastolic relaxation of the ventricle (e.g., aging, hypertension).\textsuperscript{23} The prevalence of diastolic failure increases with age and is higher in women than men, and in persons with obesity, hypertension, and diabetes. Aging is often accompanied by a delay in relaxation of the heart during diastole such that diastolic filling begins while the ventricle is still stiff and resistant to stretching. A similar delay in filling occurs in myocardial ischemia, resulting from a lack of energy to break the bonds that form between the actin and myosin filaments and to pump calcium out of the cytosol and back into the sarcoplasmic reticulum.\textsuperscript{23}

With diastolic dysfunction, ventricular relaxation and distensibility are impaired leading to an increase in intraventricular pressure at any given volume. The elevated pressures are transmitted backward from the left ventricle into the left atrium and pulmonary venous system, causing pulmonary congestion and a decrease in lung compliance, which increases the work of breathing and evokes symptoms of dyspnea. Cardiac output is decreased, not because of a reduced ventricular EF as seen with systolic dysfunction but because of a decrease in ventricular filling. Diastolic function is further influenced by the heart rate, which determines how much time is available for ventricular filling. An increase in heart rate shortens the diastolic filling time. Thus, diastolic dysfunction can be aggravated by tachycardia and improved by a reduction in heart rate, which allows the heart to fill over a longer period of time.

**Left-sided versus Right-sided Heart Dysfunction**

The clinical manifestations of heart failure depend upon which heart chamber (i.e., the left or right) is dysfunctional (Fig. 20-5). An important feature of the circulatory system is the fact that the left and right ventricles function as two pumps that are connected in series. To function effectively, the left and right ventricles must maintain equal outputs. Although the initial event that leads to heart failure may be primarily left or right ventricular in origin, heart failure usually progresses over time to involve both ventricles.

**Left Ventricular Dysfunction.** The clinical features of heart failure affecting the left ventricle result from a diminished cardiac output with a resultant decrease in
peripheral blood flow and a progressive accumulation of blood in the pulmonary circulation (see Fig. 20-5). With impairment of left ventricular function, there is a decrease in the ejection of blood into the systemic circulation, an increase in left ventricular and left atrial end-diastolic pressures, and congestion of the pulmonary circulation. When the filtration pressure in the pulmonary capillaries (normally approximately 10 mm Hg) exceeds the capillary osmotic pressure (normally approximately 25 mm Hg), there is a shift of intravascular fluid into the interstitium of the lung and development of pulmonary edema (Fig. 20-6). An episode of pulmonary edema often occurs at night, after the person has been reclining for some time and the gravitational forces have been removed from the circulatory system. It is then that the excess fluid that had been sequestered in the lower extremities during the day is returned to the vascular compartment and redistributed to the pulmonary circulation, causing what is called \textit{paroxysmal nocturnal dyspnea}.

The most common causes of left ventricular dysfunction are hypertension and acute myocardial infarction. Left ventricular heart failure and pulmonary congestion can develop very rapidly in persons with acute myocardial infarction (see Chapter 19). Even when the infarcted area is small, there may be a surrounding area of ischemic tissue. This may result in large areas of ventricular wall hypokinesis or akinesis and rapid onset of pulmonary congestion and edema. Another cause of left heart failure is valvular defects such as stenosis or regurgitation of the aortic or mitral valve. These valvular defects increase the work of the left heart and eventually lead to heart failure if untreated.

**Right Ventricular Dysfunction.** Dysfunction of the right ventricle is often the consequence of disease of the left ventricle; an increase in pulmonary blood volume eventually produces an increased burden on the right side of the heart. Isolated dysfunction of the right ventricle is less common and occurs in persons with intrinsic lung disease or pulmonary hypertension.\textsuperscript{26} It can also occur in persons with pulmonic or tricuspid valvular disease, right ventricular infarction, and cardiomyopathy. Congenital heart defects with right-to-left cardiac shunt can cause isolated right ventricular dysfunction as well (see Chapter 19). When right ventricular dysfunction occurs in response to chronic pulmonary disease, it is referred to as cor pulmonale (see Chapter 23).\textsuperscript{27}

Dysfunction of the right ventricle impairs the ability to move blood from the systemic venous circulation into the pulmonary circulation. Consequently, when the right ventricle fails, there is a reduction in the amount of blood that is delivered to the left side of the heart. This causes an increase in right ventricular end-diastolic, right atrial, and systemic venous pressures. A major consequence is the development of peripheral edema (see Fig. 20-5). Because of the effects of gravity, the edema is most pronounced in the dependent parts of the body—in the lower extremities when the person is in the upright position and in the area over the sacrum when the person is supine. The accumulation of fluid may be evidenced by a gain in weight (edema or effusion). Daily measurement of weight can be used as a means of assessing fluid accumulation in a patient with chronic heart failure.

Failure of the right ventricle also causes congestion of the viscera. As venous distention progresses, blood backs up in the hepatic veins that drain into the inferior vena cava and the liver becomes engorged. This may cause hepatomegaly and pain in the right upper quadrant, and in time, liver function may become significantly impaired. Congestion of the portal circulation also may lead to engorgement of the spleen and the development of ascites. Congestion of the gastrointestinal tract may interfere with digestion and absorption of nutrients, causing anorexia and abdominal discomfort. When severe, the external jugular veins become distended and can be visualized when the person is sitting up or standing.
**Manifestations of Heart Failure**

The manifestations of heart failure depend on the extent and type of cardiac dysfunction that is present and the rapidity with which it develops. A person with previously stable compensated heart failure may develop signs of heart failure for the first time when the condition has advanced to a critical point, such as with a progressive increase in pulmonary hypertension in a person with mitral valve regurgitation. Heart failure also may be precipitated by conditions such as infection, emotional stress, uncontrolled hypertension, or fluid overload. Many persons with serious underlying heart disease, regardless of whether they have previously experienced heart failure, may be relatively asymptomatic as long they carefully adhere to their treatment regimen. A dietary excess of sodium may be a cause of sudden cardiac decompensation.

The signs and symptoms of heart failure reflect the physiologic effects of the impaired pumping ability of the heart, decreased renal blood flow, and activation of sympathetic compensatory mechanisms. They include fluid retention and edema, shortness of breath and other respiratory manifestations, fatigue and limited exercise tolerance, cachexia and malnutrition, and cyanosis.

**Fluid Retention and Edema**

Many of the manifestations of heart failure result from the increased capillary pressures (increased hydrostatic pressures) that develop in the peripheral and pulmonary circulations. The increased capillary pressure reflects an overfilling of the vascular system because of increased sodium and water retention and venous congestion, resulting from impaired cardiac output. Nocturia is a nightly increase in urine output that occurs relatively early in the course of heart failure. It occurs because of the increased cardiac output, renal blood flow, and glomerular filtration rate that follow the increased blood return to the heart when the person is in a supine position. Oliguria, which is a decrease in urine output, is a late sign related to severely reduced cardiac output and resultant renal failure.

Transudation of fluid into the pleural cavity (pleural effusion or hydrothorax) or the peritoneal cavity (ascites) may occur in persons with advanced heart failure. Because the pleural veins drain into both the systemic and pulmonary venous beds, hydrothorax is observed more commonly in persons with hypertension involving both venous systems. Pleural effusion occurs as the excess fluid in the lung interstitial spaces crosses the visceral pleura, which in turn overwhelms the capacity of the pulmonary lymphatic system. Ascites can occur in persons with increased pressure in the hepatic and peroneal veins. It usually reflects right ventricular failure and long-standing elevation of systemic venous pressure.

**Respiratory Manifestations**

Dyspnea due to congestion of the pulmonary circulation is one of the major manifestations of heart failure. Dyspnea related to activity is called exertional dyspnea; however, patients with advanced heart failure may experience dyspnea even at rest. Orthopnea is shortness of breath that occurs when a person is supine. Gravitational forces cause fluid to become sequestered in the lower legs and feet when the person is standing or sitting. When the person assumes the recumbent position, fluid from the legs and dependent parts of the body is mobilized and redistributed to an already distended pulmonary circulation. Paroxysmal nocturnal dyspnea is a sudden attack of dyspnea that occurs during sleep. It disrupts sleep, and the person awakens with a feeling of extreme suffocation that resolves when he or she sits up.

A subtle and often overlooked symptom of heart failure is a chronic dry, nonproductive cough that becomes worse when the person is lying down. Bronchospasm due to congestion of the bronchial mucosa may cause wheezing and difficulty in breathing. This condition is sometimes referred to as cardiac asthma.

Sleep-disordered breathing is a common comorbid condition with heart failure and may contribute to worsening heart failure. Obstructive sleep apnea is one of the most common forms of sleep-disordered breathing. In persons with obstructive sleep apnea, the upper airway collapses, which leads to the complete cessation of airflow (apnea) or partial cessation of air flow (hypopnea) during sleep. Persons with suspected obstructive sleep apnea should be evaluated by a sleep specialist and undergo a sleep study (polysomnography). Those who meet the diagnostic criteria for obstructive sleep apnea (i.e., exhibit more than five apneas/hypopneas per hour of sleep caused by airway obstruction) are treated by applying continuous positive airway pressure (usually 5 to 10 cm H₂O) during sleep. Continuous positive airway pressure (CPAP) is associated with reduced blood pressure and improved cardiac function in patients with heart disease.

Another abnormal respiratory pattern that may occur with heart failure is Cheyne-Stokes respiration, a pattern of periodic breathing characterized by a gradual increase in the depth and sometimes the rate of breathing to a maximum, followed by a decrease, resulting in apnea. Although no longer associated solely with heart failure, it is recognized as an independent risk factor for worsening of heart failure. It has been suggested that Cheyne-Stokes respirations may not be just a marker for increasing severity of heart failure, but may also aggravate it. During sleep, Cheyne-Stokes breathing causes recurrent awakening and thereby reduces slow-wave and rapid eye movement (REM) sleep. The recurrent cycling of hypoventilation/apnea and hyperventilation may also increase sympathetic activity and predispose to arrhythmias.

**Fatigue, Weakness, and Cognitive Impairment**

Fatigue and weakness often accompany diminished output from the left ventricle. Cardiac fatigue is different from general fatigue in that it usually is not present in the morning but appears and progresses as activity increases during the day. In acute or severe
failure of the left ventricle, cardiac output may fall to levels that are insufficient for providing the brain with adequate oxygen, causing cognitive impairment and disturbed behavior. Confusion, impairment of memory, anxiety, restlessness, and insomnia are common in elderly persons with advanced heart failure, particularly in those with cerebral atherosclerosis. These symptoms may confuse the diagnosis of heart failure in the elderly because of other possible causes associated with aging.

Cachexia and Malnutrition

Cardiac cachexia is a condition of malnutrition and tissue wasting that occurs in persons with end-stage heart failure. A number of factors probably contribute to its development, including fatigue and depression that interfere with food intake, and congestion of the liver and gastrointestinal structures that impairs digestion and absorption and produces feelings of fullness. Other factors are circulating toxins and mediators released from poorly perfused tissues that impair appetite and contribute to tissue wasting.

Cyanosis

Cyanosis, or a bluish discoloration of the skin and mucous membranes, is caused by excess desaturated hemoglobin in the blood. It is often a late sign of heart failure, and may be visible especially around the lips and in the peripheral parts of the extremities.
