Cyanosis may be central or peripheral. Central cyanosis develops when impaired pulmonary gas exchange reduces oxygenation of the arterial blood in conditions such as pulmonary edema, left heart failure, or right-to-left cardiac shunting. Peripheral cyanosis develops as a consequence of venous desaturation resulting from extensive extraction of oxygen at the capillary level. It is caused by conditions such as low-output failure that result in delivery of poorly oxygenated blood to the peripheral tissues, or by conditions such as peripheral vasoconstriction that cause excessive removal of oxygen from the blood. Central cyanosis is best monitored by assessing the lips and mucous membranes because these areas are not subject to environmental conditions, such as cold temperatures, that cause peripheral constriction and cyanosis.

Arrhythmias and Sudden Cardiac Death

Both atrial and ventricular arrhythmias can occur in persons with heart failure. Atrial fibrillation is the most common arrhythmia (see Chapter 17). Manifestations associated with atrial fibrillation are related to loss of atrial contraction, tachycardia, irregular heart rate, and symptoms related to a drop in blood pressure. There is also strong evidence that persons with heart failure are at increased risk for sudden cardiac arrest; that is, unwitnessed death or death that occurs within 1 hour of symptom onset. In persons with ventricular dysfunction, sudden death is caused most commonly by ventricular tachycardia or ventricular fibrillation.

Acute Heart Failure Syndromes

The acute heart failure syndromes (AHFS) are defined as “gradual or rapid change in heart failure signs and symptoms resulting in a need for urgent therapy.” These signs and symptoms are primarily the result of severe pulmonary edema due to elevated left ventricular filling pressures, with or without a low cardiac output. The AHFS are among the most common disorders seen in emergency departments. A worsening of chronic heart failure, often complicated by episodes of acute decompensation, is the most common cause of the syndrome.

The AHFS are thought to encompass three different types of conditions: (1) worsening of chronic systolic or diastolic dysfunction that appears to respond to treatment; (2) new-onset acute heart failure that occurs secondary to a precipitating event such as a large myocardial infarction or a sudden increase in blood pressure superimposed on a noncompliant left ventricle; and (3) worsening of end-stage/advanced heart failure that is refractory to treatment, with predominantly left ventricular systolic dysfunction associated with a low-output state. The difference between new-onset AHFS and AHFS caused by chronic heart failure is in the degree of physiologic response, which is more pronounced in the new-onset AHFS and more subtle in chronic heart failure because of the compensatory pathophysiology. For example, with new-onset AHFS, the person will have a strong sympathetic response such as tachycardia with enhanced pulmonary vascular permeability causing rapid and dramatic symptoms of pulmonary edema. Because many compensatory mechanisms operate in persons with chronic heart failure, they tolerate higher pulmonary vascular pressures. Chronic changes in neurohormonal regulation lead to a strong activation of the angiotensin-aldosterone system with a resultant volume overload, and venous congestion in both the systemic and pulmonary circulations.

Acute pulmonary edema is the most dramatic symptom of AHFS. It is a life-threatening condition in which capillary fluid moves into the alveoli. The accumulated fluid in the alveoli and airways causes lung stiffness, makes lung expansion more difficult, and impairs the gas exchange function of the lung. With the decreased ability of the lungs to oxygenate the blood, the hemoglobin leaves the pulmonary circulation without being fully oxygenated, resulting in shortness of breath and cyanosis.

The person with severe pulmonary edema is usually seen sitting and gasping for air. The pulse is rapid, the skin is moist and cool, and the lips and nail beds are cyanotic. As the pulmonary edema worsens and oxygen supply to the brain drops, confusion and stupor appear. Dyspnea and air hunger are accompanied by a productive cough with frothy (resembling beaten egg whites) and often blood-tinged sputum—the effect of air mixing with the serum albumin and red blood cells that have moved into the alveoli. The movement of air through the alveolar fluid produces fine crepitant
sounds called crackles, which can be heard with a stethoscope on chest auscultation. As fluid moves into the larger airways, the crackles become louder and coarser.

**Diagnosis**

Diagnostic methods in heart failure are directed toward establishing the cause of the disorder and determining the extent of the dysfunction. Because heart failure represents the failure of the heart as a pump and can occur in the course of a number of heart diseases or other systemic disorders, the diagnosis of heart failure often is based on signs and symptoms related to the failing heart itself, such as dyspnea and fatigue. Functional classification systems from the New York Heart Association (NYHA) and the American College of Cardiology Foundation/American Heart Association (ACCF/AHA) provide important information about the presence and severity of HF (Table 20-1). The NYHA functional classification system is subjective, meaning the patient describes their level of activity and symptoms. It is widely used in clinical practice and research settings. The ACCF/AHA classification system is more recent and emphasizes the progression of the disease along with risk factors associated with HF, such as hypertension (Stages A and B).

The methods used in the diagnosis of heart failure include history and physical examination, laboratory studies, electrocardiography, chest radiography, and echocardiography. The history should include information related to dyspnea, cough, nocturia, generalized fatigue, exercise intolerance and other signs and symptoms of heart failure. A complete physical examination includes assessment of heart rate and rhythm, heart sounds, blood pressure, jugular veins for venous congestion, lungs for signs of pulmonary congestion, and lower extremities for edema. Pulse oximetry can be used to measure the percentage of hemoglobin oxygen saturation.

Laboratory tests are used in the diagnosis of anemia and electrolyte imbalances and to detect signs of chronic liver congestion. Measurements of BNP are recommended to confirm the diagnosis of heart failure; to evaluate the severity of left ventricular compromise, estimate the prognosis, and evaluate the effectiveness of treatment. BNP may not be as sensitive in persons with heart failure who are obese or have renal failure.

Echocardiography plays a key role in assessing ejection fraction, right and left ventricular wall motion (normal, akinesis, or hypokinesis), wall thickness, ventricular chamber size, valve function, heart defects and pericardial disease. Radionuclide ventriculography and cardiac angiography are recommended if there is reason to suspect coronary artery disease or ischemia as the underlying cause for heart failure. Chest radiographs provide information about the size and shape of the heart and pulmonary vasculature, and also can indicate the relative severity of the failure by revealing if pulmonary edema is predominantly vascular or interstitial or has advanced to the alveolar and bronchial stages. Cardiac magnetic resonance imaging and cardiac computed tomography

are used to document ejection fraction, ventricular pre-load, and regional wall motion.

Invasive hemodynamic monitoring may be used for assessment in acute, life-threatening episodes of heart failure. These monitoring methods include central venous pressure (CVP), pulmonary artery pressure monitoring, measurements of cardiac output, and intra-arterial measurements of blood pressure. Central venous pressure reflects the amount of blood returning to the right side of the heart. Measurements of CVP are best obtained by a catheter inserted into the right atrium through a peripheral vein or by the right atrial port (opening) in a pulmonary artery catheter.

Ventricular volume pressures are obtained indirectly, such as by means of a flow-directed, balloon-tipped pulmonary artery catheter. This catheter is introduced through a peripheral or central vein and then advanced into the right atrium. The balloon is then inflated with air, enabling the catheter to float through the right ventricle into the pulmonary artery until it becomes wedged in a small pulmonary vessel. With the balloon inflated, the catheter monitors pulmonary capillary pressures (i.e., pulmonary capillary wedge pressure or pulmonary artery occlusion pressure), which reflect pressures from the left ventricle. The pulmonary capillary pressures provide a means of assessing the pumping ability of the left ventricle. One type of pulmonary artery catheter is equipped with a thermistor probe to obtain thermodilution measurements of cardiac output. Catheters with oximeters built into their tips that permit continuous monitoring of oxygen saturation (SvO₂) also are available. Intra-arterial blood pressure monitoring provides a means for continuous monitoring of blood pressure. It is used in persons with acute heart failure who need continuous blood pressure monitoring, such as when aggressive intravenous medication therapy or a mechanical assist device is required.

**Treatment**

The goals of treatment for heart failure are determined by the rapidity of onset and severity of the heart failure. Persons with acute heart failure require urgent therapy directed at stabilizing and correcting the cause of the cardiac dysfunction. For persons with chronic heart failure, the goals of treatment are directed toward relieving the symptoms, improving the quality of life, and treating or reducing or eliminating risk factors (hypertension, diabetes, or obesity) with the long-term goal of slowing, halting, or reversing the cardiac dysfunction.\(^1,2\)

Treatment measures for both acute and chronic heart failure include pharmacologic and nonpharmacologic approaches. Mechanical support devices, including the aortic balloon pump (for short-term acute failure) and ventricular assist devices (VADs), can be used to sustain life in persons with severe heart failure. Heart transplant or a VAD remains an option for some people with end-stage heart disease.

It is important to note that current guideline-directed therapies only target HF patients with a reduced ejection fraction. Therapies specific to patients with a preserved ejection fraction or HFpEF have not been established.

**Nonpharmacologic Methods**

Exercise intolerance is typical of persons with chronic heart failure. Consequently, individualized exercise training is important to maximize muscle conditioning. Persons who are not accustomed to exercise and those with more severe heart failure are started at a lower intensity and shorter duration than those who are largely asymptomatic. Sodium and fluid restriction and weight management are important for all persons with heart failure, with the level of sodium and fluid restriction individualized to the severity of sodium intake, and diuretic therapy facilitates the excretion of edema fluid. Counseling, health teaching, and ongoing evaluation programs assist persons with heart failure to self-manage and cope with their treatment regimen.\(^38\)

**Pharmacologic Treatment**

Once heart failure becomes moderate to severe, polypharmacy becomes a management standard. First line therapies for patients with a reduced ejection fraction include β-adrenergic inhibitors, angiotensin-converting enzyme (ACE)/angiotensin receptor inhibitors, and diuretics. But for patients who are intolerant to these drugs or who remain symptomatic despite guideline-directed therapies, additional agents may be used, such as aldosterone antagonists or digoxin.\(^1,2,39\) The choice of pharmacologic agents is determined by problems caused by the disorder (i.e., systolic or diastolic dysfunction), those brought about by activation of compensatory mechanisms (e.g., excess fluid retention, inappropriate activation of sympathetic mechanisms), and the person’s comorbidities.\(^30\) **Diuretics** are among the most frequently prescribed medications for symptoms of volume overload.\(^13\) They promote the excretion of fluid and help to sustain cardiac output and tissue perfusion by reducing preload and allowing the heart to operate at a more optimal part of the Frank-Starling curve. In emergencies, such as acute pulmonary edema, loop diuretics such as furosemide (Lasix) can be administered intravenously. When given intravenously, these medications act quickly to reduce venous return through vasodilation so that right ventricular output and pulmonary vascular resistance are decreased. This response to intravenous administration is extrarenal and precedes the onset of diuresis.

The **ACE inhibitors**, which prevent the conversion of angiotensin I to angiotensin II, have been used effectively in the treatment of chronic heart failure.\(^40\) The renin-angiotensin-aldosterone system is activated early in the course of heart failure and plays an important role in its progression. It results in an increase in angiotensin II, which causes vasoconstriction, unregulated ventricular remodeling, and increased aldosterone production with a subsequent increase in sodium and water retention by
the kidneys. Angiotensin-converting enzyme inhibitors have been shown to limit these harmful complications. The angiotensin II receptor blockers appear to have similar but more limited beneficial effects. They have the advantage of not causing a cough, which is a troublesome side effect of the ACE inhibitors for many persons. Aldosterone receptor antagonists may be used in combination with other agents for persons with heart failure. Hyperkalemia is a potential side effect of aldosterone antagonist that requires additional monitoring.\(^1\) β-Adrenergic receptor blocking drugs are used to decrease left ventricular dysfunction associated with activation of the sympathetic nervous system.\(^6\) Large clinical trials have shown that long-term therapy with β-adrenergic receptor blocking agents reduces morbidity and mortality in persons with chronic heart failure. The mechanism of this benefit remains unclear, but it is likely that chronic elevation of catecholamines and sympathetic nervous system activity causes progressive myocardial damage, leading to a worsening of left ventricular function and a poorer prognosis in persons with heart failure.

**Digitalis** has been a recognized treatment for heart failure for over 200 years. The various forms of digitalis are called cardiac glycosides. They improve cardiac function by increasing the force and strength of ventricular contractions. Digitalis and related cardiac glycosides are inotropic agents that exert their effects by inhibiting the Na\(^+/\)K\(^-\)-ATPase membrane pump, which increases intracellular sodium; this in turn leads to an increase in intracellular calcium through the Na\(^+/\)Ca\(^+\) exchange pump (see Fig. 20-1). The cardiac glycosides also decrease sinoatrial node activity and decrease conduction through the atrioventricular node, thereby slowing the heart rate and increasing diastolic filling time.

**Vasodilator** agents such as isosorbide dinitrate and hydralazine may be added to other standard medications for African-American patients with chronic heart failure.\(^1\) Agents such as nitroglycerin, nitroprusside, and nesiritide (B-type natriuretic peptide) are used in AHFSs to improve left heart performance by decreasing the preload (through vasodilation) or reducing the afterload (through arteriolar dilation), or both.

### Advanced Therapies

Individuals with heart failure are at significant risk of sudden cardiac death from ventricular fibrillation or ventricular tachycardia. Implantation of a cardioverter–defibrillator is indicated in selected patients with heart failure to prevent sudden cardiac death.\(^1,2\) A cardioverter–defibrillator is a programmable implanted device that monitors the cardiac rhythm. It has the capacity to pace the heart and deliver electric shocks to terminate lethal arrhythmias.

Refractory heart failure reflects deterioration in cardiac function that is unresponsive to medical or surgical interventions. Since the early 1960s, significant progress has been made in improving the efficacy of ventricular assist devices (VADs), which are mechanical pumps used to support ventricular function.\(^3\) VADs are used to decrease the workload of the myocardium while maintaining cardiac output and systemic arterial pressure. This decreases the workload on the ventricle and allows it to rest and recover. Most VADs require an invasive open chest procedure for implantation. They may be used in patients who fail or have difficulty being weaned from cardiopulmonary bypass after cardiac surgery, those who develop cardiogenic shock after myocardial infarction, those with end-stage cardiomyopathy, and those who are awaiting cardiac transplantation. Earlier and more aggressive use of VADs as a bridge to transplantation and destination therapy (permanent support) has been shown to increase survival.\(^3,4\) Ventricular assist devices that allow the patient to be mobile and managed at home are sometimes used for long-term or permanent support for treatment of end-stage heart failure, rather than simply as a bridge to transplantation. Ventricular assist devices can be used to support the function of the left ventricle, right ventricle, or both.\(^5,6\)

**Heart transplantation** is the preferred treatment for many persons with end-stage cardiac failure and otherwise good life expectancy.\(^1,2\) Despite the overall success of heart transplantation, donor availability remains a key problem, and thousands are denied transplantation each year. Left ventricular remodeling is a surgical procedure designed to restore the size and shape of the ventricle, and in a subset of patients with severe left ventricular dysfunction this procedure may provide an alternative to cardiac transplantation.\(^3,4\)

### Heart Failure in the Elderly

Heart failure is one of the most common causes of disability in the elderly and is the most frequent hospital discharge diagnosis for the elderly. Among the factors that have contributed to the increased numbers of older people with heart failure are the improved therapies for ischemic and hypertensive heart disease.\(^4\) Thus, persons who would have died from acute myocardial disease 20 years ago are now surviving, but with residual heart damage. Advances in treatment of other diseases have also contributed indirectly to the rising prevalence of heart failure in the older population. In contrast to the etiology in middle-aged persons with heart failure,
Heart Failure and Circulatory Shock

Clinical Manifestations

The manifestations of heart failure in the elderly often are masked by other disease. Nocturia or nocturnal incontinence is an early heart failure symptom but may be caused by other conditions such as prostatic hypertrophy. Lower extremity edema may reflect venous insufficiency. Impaired perfusion of the gastrointestinal tract is a common cause of anorexia and profound loss of lean body mass. Loss of lean body mass may be masked by edema. Exertional dyspnea, orthopnea, and impaired exercise tolerance are cardinal symptoms of heart failure in both younger and older persons with heart failure. However, with increasing age, which is often accompanied by a more sedentary lifestyle, exertional dyspnea becomes less prominent.

Physical signs of heart failure such as elevated jugular venous pressure, hepatic congestion, and pulmonary crackles are less common in the elderly, in part because of the increased incidence of diastolic failure, in which the signs of right ventricular failure are late manifestations and a third heart sound is typically absent. Instead, behavioral changes and altered cognition such as short-term memory loss and impaired problem solving are more common. With exacerbation of heart failure, the elderly may present with acute delirium, dementia, and restlessness. Depression is common in the elderly with heart failure and shares the symptoms of sleep disturbances, cognitive changes, and fatigue.

The elderly also maintain a precarious balance between the managed symptom state and acute symptom exacerbation. During the managed symptom state, they are relatively symptom free while adhering to their treatment regimen. Acute symptom exacerbation, often requiring emergency medical treatment, can be precipitated by seemingly minor conditions such as poor adherence to sodium restriction, infection, or stress. Failure to promptly seek medical care is a common cause of progressive acceleration of symptoms.

Diagnosis and Treatment

The diagnosis of heart failure in the elderly is based on the history, physical examination, chest radiograph, and echocardiographic findings. However, the presenting symptoms of heart failure often are difficult to evaluate and differentiate from changes associated with aging and other co-morbidities. Symptoms of dyspnea on exertion are often interpreted as a sign of “getting older” or attributed to deconditioning from other diseases. Ankle edema is not unusual in the elderly because of decreased skin turgor and the tendency of the elderly to be more sedentary with the legs in a dependent position.

Treatment of heart failure in the elderly involves many of the same methods as in younger persons, with medication dose adaptations to reduce age-related adverse and toxic events. ACE inhibitors may be particularly beneficial to preserve cognitive and functional capacities. Activities are restricted to a level that is commensurate with the cardiac reserve. Seldom is bed rest recommended or advised. Bed rest causes rapid deconditioning of skeletal muscles and increases the risk of complications such as orthostatic hypotension and thromboemboli. Instead, carefully prescribed exercise programs can help to maintain activity tolerance. Even walking around a room usually is preferable to continuous bed rest.

SUMMARY CONCEPTS

- Heart failure occurs when the heart fails to deliver sufficient blood to meet the metabolic needs of body tissues.
- The pathophysiology of heart failure reflects the interplay between a decrease in cardiac output that accompanies heart failure and the compensatory mechanisms that preserve the cardiac reserve. Compensatory mechanisms include the Frank-Starling mechanism, sympathetic nervous system activation, the renin-angiotensin-aldosterone mechanism, natriuretic peptides, endothelins, and myocardial hypertrophy and remodeling. In the failing heart, early decreases in cardiac function may go unnoticed because these compensatory mechanisms maintain the cardiac output.
- Heart failure may be described in terms of ejection fraction (reduced vs preserved). Clinical manifestation depends upon which ventricle is dysfunctional. With a reduced ejection fraction,
SUMMARY CONCEPTS (continued)

there is impaired ejection of blood from the heart during systole; with diastolic dysfunction, there is impaired filling of the heart during diastole. Left ventricular dysfunction is characterized by congestion in the pulmonary circulation and impaired blood flow in the peripheral circulation, and right ventricular dysfunction by congestion in the peripheral circulation.

The manifestations of heart failure include fluid retention and edema, shortness of breath, fatigue and impaired exercise tolerance, impaired gastrointestinal function and malnutrition, and cyanosis. When performance of the right ventricle is impaired, there is dependent edema of the lower parts of the body, engorgement of the liver, and ascites. With failure of the left ventricle, pulmonary congestion with shortness of breath and chronic, nonproductive cough are common.

The acute heart failure syndromes represent a gradual or rapid change in heart failure signs and symptoms, indicating the need for urgent therapy. These symptoms are primarily the result of pulmonary congestion due to elevated right ventricular filling pressures with or without a low cardiac output.

The diagnostic methods in heart failure are directed toward establishing the cause and extent of the syndrome. Treatment is directed toward correcting the cause whenever possible, improving cardiac function, maintaining the fluid volume within a compensatory range, and developing an activity pattern consistent with individual limitations in cardiac reserve. Among the medications used in the treatment of heart failure are diuretics, digitalis, ACE inhibitors and angiotensin receptor blocking agents, β-adrenergic receptor blockers, vasodilators, and aldosterone blockers.

Among the devices used to treat heart failure patients with a reduced ejection fraction are an implantable cardiac defibrillator and ventricular assist devices. Heart transplantation remains the treatment of choice for many persons with end-stage heart failure.

The manifestations of heart failure in the elderly are different and superimposed on other disease conditions; therefore, heart failure often is more difficult to diagnose in the elderly than in younger persons. Because the elderly are more susceptible to adverse and toxic medication reactions, medication doses need to be adapted and more closely monitored.

Circulatory Failure (Shock)

Circulatory shock can be described as an acute failure of the circulatory system to supply the peripheral tissues and organs of the body with an adequate blood supply, resulting in cellular hypoxia. Most often hypotension and hypoperfusion are present, but shock may occur in the presence of normal vital signs. Shock is not a specific disease but a syndrome that can occur in the course of many life-threatening traumatic conditions or disease states. Moreover, no single classification system exists; rather, shock can be classified by the cause, primary pathophysiological derangement, or clinical manifestations. Generally each type of shock has certain distinguishing features; nonetheless, all types of shock reflect an imbalance between oxygen supply and demand. As a result, all shock states share common derangements, such as inadequate peripheral tissue perfusion, alterations in cellular metabolism and function, and impaired organ perfusion, and all share common compensatory mechanisms in response to these derangements.

Pathophysiology of Shock

Circulatory failure results in hypoperfusion of organs and tissues, which in turn results in an insufficient supply of oxygen and nutrients for cellular function and the accumulation of waste products. The cellular injury created by an inadequate delivery of oxygen and substrates also induces the production and release of inflammatory mediators that further compromise perfusion through functional and structural changes within the microvascular circulation. This leads to a vicious cycle in which impaired perfusion is responsible for cellular injury, which causes maldistribution of blood flow, further compromising cellular perfusion, and can culminate in irreversible end-organ damage.

Cellular Responses

Shock ultimately exerts its effect at the cellular level, with failure of the circulation to supply body cells with the oxygen and nutrients needed for production of ATP. Cells require ATP for a number of functions, including operation of the Na+/K+–ATPase membrane pump that moves sodium out of the cell and returns potassium to the inside of the cell. The cell uses two pathways to convert nutrients to ATP (see Chapter 1). The first is the anaerobic (non–oxygen-dependent) glycolytic pathway, located in the cytoplasm, which converts glucose to ATP and pyruvate. The second is the aerobic (oxygen-dependent) pathway, which is located in the mitochondria. When oxygen is available, pyruvate from the anaerobic pathway moves into the mitochondria and enters the aerobic pathway, where it is transformed into ATP and the metabolic by-products carbon dioxide and water. When oxygen is lacking, pyruvate is converted to lactic acid.

As a shock state progresses, cellular metabolism becomes anaerobic because of the decreased availability of oxygen. Excess amounts of lactic acid accumulate in
the cellular and extracellular compartments, and limited amounts of ATP are produced. Without sufficient energy production, normal cell function cannot be maintained. The Na+/K+-ATPase membrane pump function is impaired, resulting in intracellular accumulation of sodium and loss of potassium. The increase in intracellular sodium results in cellular edema and increased cell membrane permeability. Mitochondrial activity becomes severely depressed and lysosomal membranes may rupture, resulting in the release of enzymes that cause further cellular destruction. This is followed by cell death and the release of intracellular contents into the extracellular space. The extent of the cell injury and organ dysfunction is primarily determined by the degree and duration of the shock state.

Compensatory Mechanisms

The clinical manifestations of shock are at least partly due to the body’s compensatory responses to hypoperfusion. The most immediate of the compensatory mechanisms are those of the sympathetic nervous system and the renin-angiotensin mechanism, which maintain cardiac output and blood pressure. Often blood is shunted from the kidneys to other vital organs.

The sympathetic nervous system provides important reflexive mechanisms that are essential to the support of the circulatory system during shock, particularly hypovolemic shock. These reflexes increase heart rate and stimulate constriction of blood vessels throughout the body. There are two types of adrenergic receptors for the sympathetic nervous system: alpha (α) and beta (β). The β receptors which are further divided into subtypes β1 and β2 receptors. Stimulation of the α receptors causes vasoconstriction; stimulation of β1 receptors cause an increase in heart rate and force of myocardial contraction; and of β2 receptors, vasodilation of the skeletal muscle beds and relaxation of the bronchioles. In shock, there is an increase in sympathetic outflow that results in increased epinephrine and norepinephrine release and activation of both α and β receptors (Chapter 34). Thus, increases in heart rate and vasoconstriction occur in most types of shock (cardiac output = stroke × heart rate). The arterioles constrict in most parts of the systemic circulation, thereby increasing the peripheral vascular resistance, and the veins and venous reservoirs constrict, thereby helping to maintain adequate venous return to the heart.

There also is an increase in renin release, leading to an increase in angiotensin II, which augments vasoconstriction and leads to an aldosterone-mediated increase in sodium and water retention by the kidneys. In addition, there is a local release of vasoconstrictors as well as norepinephrine, angiotensin II, vasopressin, and endothelin, which contribute to arterial and venous vasoconstriction.

The compensatory mechanisms that the body recruits cannot be sustained over the long term and become detrimental when the shock state is prolonged. This intense vasoconstriction causes a decrease in tissue perfusion and insufficient supply of oxygen. Cellular metabolism is impaired, vasoactive inflammatory mediators such as histamine are released, production of oxygen free radicals is increased, and excessive lactic acid and hydrogen ions result in intracellular acidity and accompanying metabolic acidosis. Each of these factors promotes cellular dysfunction or death. If circulatory function is reestablished, whether the shock is irreversible or if the patient will survive is determined largely at the cellular level regardless of the type of shock.

Types of Shock

In general, shock states are distinguished by clinical signs and symptoms, history, and physical exam. Circulatory shock can be caused by a decrease in blood volume (hypovolemic shock), an alteration in cardiac function, obstruction of blood flow through the circulatory system (obstructive shock), or excessive vasodilation with maldistribution of blood flow (distributive shock). The main types of shock are summarized in Chart 20-1 and depicted in Figure 20-7.

Hypovolemic Shock

Hypovolemic shock occurs when there is an acute loss of 15% or more of the circulating blood volume. The decrease may be caused by a loss of whole blood, plasma, extracellular fluid or excessive dehydration (Chart 20-1). Hypovolemic shock also can result from an internal hemorrhage or from third-space losses, when extracellular fluid is shifted from the vascular compartment to the interstitial space.

Hypovolemic shock, which has been the most widely studied type of shock, is often used as a prototype in

discussions of the manifestations of shock. Approximately 10% of the total blood volume can be lost or shifted without changing cardiac output or arterial pressure. The average blood donor loses approximately 500 mL or 10% of his or her blood without experiencing adverse effects. However, as increasing amounts of blood (15% to 30% or 750 to 1500 mL) are removed, compensatory mechanisms are triggered.

The most immediate of these compensatory mechanisms are the sympathetic-mediated responses designed to maintain cardiac output and blood pressure (Fig. 20-8). Shortly after the onset of hemorrhage or the loss of fluid volume, tachycardia, increased cardiac contractility, vasoconstriction, and other signs of sympathetic and adrenal medullary activity appear.

The sympathetic vasoconstrictor response also mobilizes blood that has been stored in the venous side of the circulation as a means of increasing venous return to the heart. There is considerable capacity for blood storage in the large veins of the abdomen, and approximately 350 mL of blood that can be mobilized in shock is stored in the liver.

Sympathetic stimulation does not initially cause constriction of the cerebral and coronary vessels, and blood flow to the heart and brain is maintained at essentially normal levels as long as the mean arterial pressure remains above 70 mm Hg. Without (and, at times, despite) compensatory mechanisms to maintain cardiac output and blood pressure, the loss of vascular volume results in a rapid progression from the initial to the progressive, and finally to the irreversible stages of shock (more than 40% volume loss).

Compensatory mechanisms designed to restore blood volume (i.e., draw volume into the intravascular space) include absorption of fluid from the interstitial spaces, conservation of sodium and water by the kidneys, and thirst. Extracellular fluid is distributed between the interstitial spaces and the vascular compartment. When there is a loss of vascular volume, capillary pressures decrease and water is drawn into the vascular compartment from the interstitial spaces. The maintenance of vascular volume is further enhanced by renally mediated humoral mechanisms that conserve fluid. A decrease in renal blood flow and glomerular filtration rate results in activation of the renin-angiotensin-aldosterone mechanism, which produces an increase in sodium reabsorption by
the kidneys. The decrease in blood volume also stimulates centers in the hypothalamus that regulate antidiuretic hormone (ADH) release and thirst. Antidiuretic hormone, also known as vasopressin, constricts the peripheral arteries and veins and greatly increases water retention by the kidneys. Although the mechanism of ADH is more sensitive to changes in serum osmolality, a decrease of 10% to 15% in blood volume serves as a strong stimulus for ADH and thirst.6

During the early or initial stages of hypovolemic shock, vasoconstriction decreases the size of the vascular compartment and increases systemic vascular resistance. This response usually is all that is needed when the injury is slight and blood loss is minimal (e.g., 10% or less). As hypovolemic shock progresses, vasoconstriction of the blood vessels that supply the skin, skeletal muscles, kidneys, and abdominal organs becomes more severe, with a further decrease in blood flow and conversion to anaerobic metabolism resulting in cellular injury.

**Manifestations.** The signs and symptoms of hypovolemic shock depend on its severity and are closely related to low peripheral blood flow and excessive sympathetic stimulation. They include thirst, increased heart rate, cool and clammy skin, decreased arterial blood pressure, oliguria (decreased urine output), and changes in mentation.50,51 Laboratory tests of hemoglobin and hematocrit provide information regarding the severity of blood loss or hemoconcentration due to dehydration. Serum lactate levels and arterial pH provide information about the severity of acidosis due to anaerobic metabolism.52

Early signs of hypovolemic shock include tachycardia, peripheral vasoconstriction, and a slight increase or decrease in blood pressure, as the body tries to maintain cardiac output despite the decrease in stroke volume. Thirst is an early symptom in hypovolemic shock.

In moderate to severe shock arterial blood pressure is decreased. However, controversy exists over the value of blood pressure measurements in the early diagnosis and management of shock. This is because compensatory mechanisms tend to preserve blood pressure until shock is relatively far advanced.51 Furthermore, a normal arterial pressure does not ensure adequate tissue perfusion and oxygenation of vital organs at the cellular level. This does not imply that blood pressure should not be closely monitored in patients at risk for development of shock, but it does indicate the need for other assessment measures.
As shock progresses, the respirations become rapid and deep to compensate for the increased production of acid and decreased availability of oxygen. Decreased intravascular volume results in decreased venous return to the heart and a decreased central venous pressure (CVP). The pulse becomes weak and thready, indicating vasoconstriction and reduced filling of the vascular compartment. When shock becomes severe, the peripheral veins may collapse. Sympathetic stimulation leads to intense vasoconstriction of the skin vessels, which results in cool and mottled skin. In hemorrhagic shock, the loss of red blood cells results in pallor of the skin and mucous membranes.

Urine output decreases very quickly in hypovolemic shock. Compensatory mechanisms decrease renal blood flow as a means of diverting blood flow to the heart and brain. Oliguria of 20 mL/hour or less indicates inadequate renal perfusion. Continuous measurement of urine output is essential for assessing the circulatory and volume status of the person in shock and monitoring the response to fluid replacement.

Restlessness, agitation, and apprehension are common in early shock because of increased sympathetic outflow and increased levels of epinephrine. As the shock progresses and blood flow to the brain decreases, restlessness is replaced by altered arousal and mentation. Loss of consciousness and coma may occur if the person does not receive or respond to treatment.

**Treatment.** The treatment of hypovolemic shock is directed toward correcting or controlling the underlying cause (replacing or shifting volume) and improving tissue perfusion. Ongoing loss of blood must be corrected, such as in surgery. Oxygen is administered to increase oxygen delivery to the tissues. Medications usually are administered intravenously. Frequent measurements of heart rate and cardiac rhythm, blood pressure, and urine output are used to assess the severity of circulatory compromise and to monitor treatment.

Restoration of vascular volume can be accomplished through intravenous administration of fluids, blood, and blood products. The crystalloids (e.g., isotonic saline and Ringer lactate) are readily available and effective, at least temporarily. Colloids or plasma volume expanders (e.g., pentastarch and colloidal albumin) have a high molecular weight, do not necessitate blood typing, and remain in the vascular space for longer periods than crystalloids such as dextrose and saline, but are considerably more expensive. Blood or blood products (packed or frozen red cells) are administered based on hematocrit and hemodynamic findings. Fluids and blood are best administered based on volume indicators such as CVP and urine output.

Vasoactive medications are agents capable of constricting or dilating blood vessels. Considerable controversy exists about the advantages or disadvantages related to the use of these drugs. As a general rule, vasoconstrictor agents are not used as a primary form of therapy in hypovolemic shock, and may be detrimental. Replacing volume is the first priority but vasopressor and inotropic agents may be used as an adjunct to help restore tissue perfusion and normalize cellular metabolism. These agents are given only when volume deficits have been corrected yet hypotension persists.

**Cardiogenic Shock**

Cardiogenic shock occurs when the heart fails to pump blood sufficiently to meet the body’s demands (see Fig. 20-7). Clinically, it is defined as decreased cardiac output, hypotension, hypoperfusion, and indications of tissue hypoxia despite an adequate intravascular volume. Cardiogenic shock most commonly occurs from an acute myocardial infarction, but may also occur from non-ischemic causes including myocardial contusion, acute mitral valve regurgitation due to papillary muscle rupture, sustained arrhythmias, severe dilated cardiomyopathy, and cardiac surgery. Cardiogenic shock can also occur with other types of shock because of inadequate coronary blood flow. Approximately 3% to 6% of the patients with ST elevation MI (STEMI) develop cardiogenic shock despite receiving reperfusion therapy (see Chapter 19). Most patients who die of cardiogenic shock have had extensive damage to the left ventricle because of a recent infarct or reinfarction.

Regardless of cause, in persons with cardiogenic shock there is failure to eject blood from the heart, hypotension, and inadequate cardiac output. Compensatory neurohumoral responses take place, which include activation of the sympathetic and renin-angiotensin systems leading to vasoconstriction, tachycardia, and fluid retention. Increased systemic vascular resistance often contributes to the deterioration of cardiac function by increasing afterload or the resistance to ventricular systole. Preload, the filling pressure, also is increased as blood returning to the heart is added to blood that previously was not pumped forward, resulting in an increase in end-systolic ventricular volume. Increased resistance to ventricular systole (i.e., afterload) combined with decreased myocardial contractility causes an increase in end-systolic ventricular volume and preload, further complicating cardiac status.

**Manifestations.** The signs and symptoms of cardiogenic shock are consistent with those of end-stage heart failure. The lips, nail beds, and skin may become cyanotic because of stagnation of blood flow and increased extraction of oxygen from the hemoglobin as it passes through the capillary bed. Mean arterial and systolic blood pressures decrease due to poor stroke volume, and there is a narrow pulse pressure and near-normal diastolic blood pressure because of arterial vasoconstriction. Urine output decreases because of lower renal perfusion pressures and the increased release of aldosterone. Elevated preload is reflected in a rise in CVP and pulmonary capillary wedge pressure of at least 15 mm Hg. Neurologic changes, such as alterations in cognition or consciousness, may occur because of low cardiac output and poor cerebral perfusion.

**Treatment.** Treatment of cardiogenic shock requires striking a precarious balance between improving cardiac output, reducing the workload and oxygen needs
of the myocardium, and increasing coronary perfor-
sion. Fluid volume must be regulated within a level
that optimizes the filling pressure and stroke volume.
Pulmonary edema and arrhythmias should be corrected
or prevented to increase stroke volume and decrease
the oxygen demands of the heart. Coronary artery perfu-
sion is increased by promoting coronary artery vasodi-
lation, increasing blood pressure, decreasing ventricular
wall tension, and decreasing intracardiac pressures.
Currently there are two therapeutic options for patients
with cardiogenic shock to support the circulatory—
pharmacologic therapy and mechanical support.

The goal of pharmacologic treatment is to increase
cardiac contractility without increasing heart rate.
Dopamine, dobutamine and norepinephrine are the most
commonly used inotropic and vasopressor agents.
Dopamine is often the drug of choice because it acts both
as an inotrope as well as a vasoconstrictor. Dobutamine,
an inotropic agent with arterial vasodilator properties,
can be used in persons with less severe hypotension.
Catecholamines, such as norepinephrine, increase car-
diac contractility but also result in arterial constriction
and tachycardia, which worsens the imbalance between
myocardial oxygen supply and demand. Overall, these
drugs must be used with caution as they have been
associated with dysrhythmias, myocardial injury, and
increased mortality.

Mechanical support using an intra-aortic balloon
pump or extracorporeal membrane oxygenation can help
to increase systemic blood flow and stabilize the
patient. The percutaneous intra-aortic balloon pump,
also referred to as counterpulsation, enhances coronary
and systemic perfusion yet decreases afterload and myo-
cardial oxygen demands.

The primary physiologic result of obstructive shock
is elevated right heart pressure due to right ventricular
dysfunction. Pressures are increased despite impaired
venous return to the heart. Signs of right ventricular
dysfunction occur, including elevation of CVP and jug-
ular venous distention. Treatment modalities focus on
correcting the cause of the disorder, frequently requir-
ing a procedure to remove or correct the obstruction;
for example, surgical interventions such as pulmonary
embolectomy, pericardiocentesis (i.e., removal of fluid
from the pericardial sac) for cardiac tamponade, or the
insertion of a chest tube for correction of a pneumo-
thonorax or hemothorax. In severe or massive pulmonary
embolus, fibrinolytic drugs may be used to break down
the clots causing the obstruction. Once the obstruction
to blood flow is removed then normal blood flow can be
re-established.

**Obstructive Shock**

The term obstructive shock describes circulatory shock
that results from mechanical obstruction of the flow of
blood through the central circulation (great veins, heart,
or lungs; see Fig. 20-7). It is also referred to as extra-
cardiac shock. Obstructive shock may be caused by a
number of conditions, including dissecting aortic aneu-
yrism, cardiac tamponade, pneumothorax, atrial myx-
oma, and evisceration of abdominal contents into the
thoracic cavity because of a ruptured hemidiaphragm.
The most frequent cause of obstructive shock is pulmo-
nary embolism.

**Distributive Shock**

Distributive or vasodilatory shock is characterized by
loss of blood vessel tone, enlargement of the periph-
eral vascular compartment, and displacement of the
vascular volume away from the heart and central cir-
culation. In distributive shock, the capacity of the
vascular compartment expands to the extent that a
normal volume of blood does not fill the circulatory
system (see Fig. 20-7). Therefore, this type of shock
is also referred to as normo-volemic shock. There are
two main causes of the loss of vascular tone: a decrease in the sympathetic control of vasomotor tone, or the release of excessive vasodilator substances. It can also occur as a complication of vessel damage resulting from prolonged and severe hypotension due to hemorrhage, known as irreversible or late-stage hemorrhagic shock. One of the most frequent causes of anaphylactic shock is stings from insects of the order Hymenoptera (Fig. 20-10). Among the most frequent causes of anaphylactic shock are reactions to medications, such as penicillin; foods, such as nuts and shellfish; and insect venoms. The most common cause is stings from insects of the order Hymenoptera (i.e., bees, wasps, and fire ants). Late onset allergy causes life-threatening anaphylaxis in a growing segment of the population (see Chapter 16). Health care workers and others who are exposed to latex are developing latex sensitivities that range from mild urticaria, contact dermatitis, and mild respiratory distress to anaphylactic shock.

Anaphylactic Shock. Anaphylaxis is a clinical syndrome that represents the most severe systemic allergic reaction. Anaphylactic shock results from an immunologically mediated reaction in which vasodilator substances such as histamine are released into the blood. These substances cause vasodilation of arterioles and venules along with a marked increase in capillary permeability. The vascular response in anaphylaxis is often accompanied by life-threatening laryngeal edema and bronchospasm, circulatory collapse, contraction of gastrointestinal and uterine smooth muscle, and urticaria (hives) or angioedema.

Among the most frequent causes of anaphylactic shock are reactions to medications, such as penicillin; foods, such as nuts and shellfish; and insect venoms. The most common cause is stings from insects of the order Hymenoptera (i.e., bees, wasps, and fire ants). Late onset allergy causes life-threatening anaphylaxis in a growing segment of the population (see Chapter 16). Health care workers and others who are exposed to latex are developing latex sensitivities that range from mild urticaria, contact dermatitis, and mild respiratory distress to anaphylactic shock. Children with spina bifida also are at extreme risk for this serious and increasingly common allergy.

The onset and severity of anaphylaxis depend on the sensitivity of the person and the rate and quantity of antigen exposure. Signs and symptoms associated with impending anaphylactic shock include abdominal cramps; apprehension; warm or burning sensation of the skin, itching, and urticaria (i.e., hives); and respiratory distress such as coughing, choking, wheezing, chest tightness, and difficulty in breathing. After blood begins to pool peripherally, there is a precipitous drop in blood pressure and the pulse becomes so weak that it is difficult to detect. Life-threatening airway obstruction may ensue as a result of laryngeal angioedema or bronchial spasm. Early signs appear with a more severe reaction. Anaphylactic shock often develops suddenly; death can occur within minutes unless appropriate medical intervention is promptly instituted.

Treatment includes immediate discontinuation of the inciting agent or action to decrease its absorption (e.g., application of ice to the site of an insect bite); close monitoring of cardiovascular and respiratory function; and maintenance of respiratory gas exchange, cardiac output, and tissue perfusion. Epinephrine, which stimulates alpha and beta receptors, is given in an anaphylactic reaction because it causes systemic vasoconstriction and relaxes the smooth muscle in the bronchioles, thus restoring cardiac and respiratory function. Other treatment measures include the administration of oxygen, antihistamines, drugs, corticosteroids, and bronchodilators. The person should be placed in a supine position because the sitting position can produce a severe decrease in venous return. The prevention of anaphylactic shock is preferable to treatment. Once a person has been sensitized to an antigen, the risk of repeated anaphylactic reactions with subsequent exposure is high. All health care providers should question patients regarding previous drug reactions and inform patients as to the name of the medication they are to receive before it is administered or prescribed. Persons with known hypersensitivities should wear MedicAlert jewelry and carry an identification card to alert medical personnel if they become unconscious or unable to relate this information. Persons who are at risk for anaphylaxis should be provided with emergency medications (e.g., epinephrine autoinjector), instructed to avoid the allergen, and given procedures to follow in case they are inadvertently exposed to the offending antigen.

Sepsis and Septic Shock. Septic shock, which is the most common type of distributive shock, is associated with the systemic immune response to severe infection (Fig. 20-10). The nomenclature related to sepsis and septic shock has been evolving. Sepsis has been defined as a suspected or proven infection plus the clinical manifestations of what has been termed the systemic inflammatory response (e.g., fever, tachycardia, and elevated white blood cell count [leukocytosis]). Severe sepsis is sepsis plus evidence of sepsis-induced organ dysfunction or tissue hypoxia (e.g., hypotension, hypoxemia, oliguria, metabolic acidosis, thrombocytopenia). Septic shock is defined as severe sepsis with hypotension, despite fluid resuscitation.

Severe sepsis accompanied by acute organ dysfunction is a frequently occurring condition in critically ill patients. The growing incidence has been attributed to...
enhanced awareness of the diagnosis, increased number of resistant organisms, growing number of immunocompromised and elderly persons, and greater use of invasive procedures. With early intervention and advances in treatment methods, the mortality rate has decreased; however, the number of deaths has increased because of the increased prevalence.

The pathogenesis of sepsis involves a complex process of cellular activation resulting in release of proinflammatory mediators such as cytokines; recruitment of neutrophils and monocytes; involvement of neuroendocrine reflexes; and activation of complement, coagulation, and fibrinolytic systems. Initiation of the response begins with activation of the innate immune system and release of a number of proinflammatory and anti-inflammatory mediators (Chapter 15). Two of these mediators, tumor necrosis factor (TNF)-α and interleukin-1, are involved in leukocyte adhesion, local inflammation, neutrophil activation, generation of fever, tachycardia, lactic acidosis, ventilation–perfusion abnormalities, and other signs of sepsis. Although activated neutrophils kill microorganisms, they also injure the endothelium (endothelial dysfunction) by releasing mediators that increase vascular permeability. In addition, injured endothelial cells release an excess of nitric oxide, a potent vasodilator that acts as a key mediator of septic shock.

Another important aspect of sepsis that is also related to endothelial dysfunction is an alteration of the procoagulation–anticoagulation balance with an increase in procoagulation factors and a decrease in anticoagulation factors. Lipopolysaccharide on the surface of microorganisms stimulates endothelial cells lining blood vessels to increase their production of tissue factor, thus activating coagulation (see Chapter 12). Fibrinogen is then converted to fibrin, leading to the formation of microvascular thrombi that further amplify tissue injury. In addition, sepsis lowers levels of protein C, protein S, antithrombin III, and tissue factor pathway inhibitor, substances that modulate and inhibit coagulation.

Sepsis and septic shock are typically manifested by hypotension and warm, flushed skin. Whereas other forms of shock (i.e., cardiogenic, hypovolemic, and obstructive) are characterized by a compensatory increase in systemic vascular resistance, septic shock often presents with a decrease in systemic vascular resistance. Hypovolemia is due to arterial and venous dilatation, plus leakage of plasma into the interstitial spaces. Abrupt changes in cognition or behavior are due to reduced cerebral blood flow and may be early indications of septic shock. Regardless of the underlying cause, fever and increased leukocytes are present. An elevated serum lactate or metabolic acidosis indicates anaerobic metabolism due to tissue hypoxia or cellular dysfunction and altered cellular metabolism. Tissue hypoxia produces continued production and activation of inflammatory mediators, resulting in further increases in vascular permeability, impaired vascular regulation, and altered hemostasis. As sepsis continues, organ system failure can occur. Multiple organ dysfunction is the major cause of death in sepsis.

Early recognition of the signs and symptoms of conditions that could lead to sepsis is key to optimizing outcomes and decreasing sepsis-related mortality. The treatment of sepsis and septic shock focuses on control of the causative agent, support of the circulation and the failing organ systems. The administration of antibiotics that are specific for the infectious agent is essential. However, antibiotics do not treat inflammation; thus, the cardiovascular status of the patient must be supported to increase oxygen delivery to the cells and prevent further cellular injury. Swift and aggressive fluid administration is needed to compensate for third spacing, though which type of fluid is optimal remains controversial. Equally aggressive use of vasopressor agents, such as norepinephrine or epinephrine, is needed to counteract the vasodilation caused by inflammatory mediators.
Persons with severe sepsis and hyperglycemia (two consecutive blood glucose readings > 180 mg/dL) should receive insulin therapy following a protocol to maintain their blood glucose levels at a target level of ≤180 mg/dL.67 Ongoing assessment of CVP, mixed venous or arterial oxygen saturation, mean arterial pressure, urinary output, and laboratory measurements of blood chemistries, serum lactate, base deficit, and pH are used to evaluate the progression of sepsis and adequacy of treatment as well as the need for other supportive therapies. This group of interventions lists the sepsis “bundle” that when implemented together produce better outcomes than when implemented individually.67,68

Complications of Shock
As the late Carl Wiggers, a noted circulatory physiologist, once stated, “shock not only stops the machine, but it wrecks the machinery.”72 Many body systems are wrecked by severe shock. Five major complications of severe shock are lung injury, acute kidney failure, gastrointestinal complications, disseminated intravascular coagulation, and multiple organ dysfunction syndrome. These complications of shock are serious and often fatal.

Acute Lung Injury/Acute Respiratory Distress Syndrome
Acute lung injury/acute respiratory distress syndrome (ALI/ARDS) is a potentially lethal form of pulmonary injury that may be either the cause or result of shock (see Chapter 23). Acute lung injury/acute respiratory distress syndrome represents a spectrum of acute respiratory failure with ARDS being the more severe form, associated with greater hypoxemia and mortality. Acute lung injury/acute respiratory distress syndrome is marked by the rapid onset of profound dyspnea that usually occurs after an initiating event, such as trauma, aspiration, or pancreatitis. The respiratory rate and effort of breathing increase. Arterial blood gas analysis establishes the presence of profound hypoxemia that is refractory to supplemental oxygen. The hypoxemia results from impaired matching of ventilation and perfusion and from the greatly reduced diffusion of blood gases across the thickened alveolar membranes.6

The exact cause of ALI/ARDS is unknown. Neutrophils are thought to play a key role in its pathogenesis. A cytokine-mediated activation and accumulation of neutrophils in the pulmonary vasculature and subsequent endothelial and epithelial injury are thought to cause leaking of fluid and plasma proteins into the interstitium and alveolar spaces.73 The fluid leakage causes atelectasis, impairs gas exchange, and makes the lung stiff (poor compliance) and more difficult to inflate. Abnormalities in the production, composition, and function of surfactant may contribute to alveolar collapse and gas exchange abnormalities. Inappropriate vasodilation and vasoconstriction worsen the ventilation and perfusion mismatch.

Interventions for ALI/ARDS focus on increasing the oxygen concentration in the inspired air and supporting ventilation mechanically to optimize gas exchange while avoiding oxygen toxicity and preventing further lung injury. Despite the delivery of high levels of oxygen using high-pressure mechanical ventilatory support and positive end-expiratory pressure, many persons with ALI/ARDS remain hypoxic, often with a fatal outcome.74

Acute Kidney Injury
Acute kidney injury (AKI), formerly known as acute renal failure, often occurs in the context of sepsis and multiple organ failure.73 The renal tubules are particularly vulnerable to ischemia, and AKI is an important factor in mortality due to severe shock. Most cases of AKI are due to impaired renal perfusion in response to decreased intravascular volume.75 The degree of renal damage is related to the severity (or stage) and duration of shock. The renal dysfunction most frequently seen with progressive to severe shock states is acute tubular necrosis. Acute tubular necrosis usually is reversible, although return to normal renal function may require weeks or months (see Chapter 25). Continuous monitoring of urinary output during shock provides a means of assessing renal blood flow. Frequent monitoring of serum creatinine and blood urea nitrogen levels also provides valuable information regarding renal status.

Gastrointestinal Complications
The gastrointestinal tract is particularly vulnerable to ischemia because of the changes in distribution of blood flow to its mucosal surface. In shock, there is widespread constriction of blood vessels that supply the gastrointestinal tract, causing a redistribution of blood flow and a severe decrease in mucosal perfusion. Proton pump inhibitors or histamine 2–receptor antagonists may be given prophylactically to prevent gastrointestinal ulcerations and bleeding in persons with shock who have risk factors for bleeding.67

Disseminated Intravascular Coagulation
Disseminated intravascular coagulation (DIC) is characterized by widespread activation of the coagulation system with resultant formation of fibrin clots and thrombotic occlusion of small and mid-sized vessels (see Chapter 12). The systemic formation of fibrin results from increased generation of thrombin, the simultaneous suppression of physiologic anticoagulation mechanisms, and the delayed removal of fibrin as a consequence of impaired fibrinolysis. Clinically overt DIC is reported to occur in as many as 30% to 50% of persons with Gram negative sepsis.76 As with other systemic inflammatory responses, the derangement of coagulation and fibrinolysis is thought to be mediated by inflammatory mediators and cytokines.

The contribution of DIC to morbidity and mortality in sepsis depends on the underlying clinical condition and the intensity of the coagulation disorder. Depletion of the platelets and coagulation factors increases the risk of bleeding. Deposition of fibrin in the vasculature of organs contributes to ischemic damage and organ failure.
In a number of clinical trials, the occurrence of DIC appeared to be associated with an unfavorable outcome and was an independent predictor of mortality. The mortality rates for persons admitted to the intensive care unit who developed DIC were 45% to 78%. However, it remains uncertain whether DIC was a predictor of unfavorable outcome or merely a marker of the seriousness of the underlying condition causing the DIC.

The management of sepsis-induced DIC focuses on treatment of the underlying disorder and measures to interrupt the coagulation process. Anticoagulation therapy and administration of platelets and plasma may be used. Clinical trials have shown modest to marked reductions in mortality based on the dose of antithrombin III used.

Multiple Organ Dysfunction Syndrome

Multiple organ dysfunction syndrome (MODS) represents the presence of altered organ function in an acutely ill patient such that homeostasis cannot be maintained without intervention. As the name implies, MODS commonly affects multiple organ systems, including the kidneys, lungs, liver, brain, and heart. Multiple organ dysfunction syndrome is a particularly life-threatening complication of shock, especially septic shock. It has been reported as the most frequent cause of death in the noncoronary intensive care unit. Mortality rates vary from 30% to 100%, depending on the number of organs involved. A high mortality rate is associated with failure of the brain, liver, kidneys, and lungs. The pathogenesis of MODS is not clearly understood, and current management therefore is primarily supportive. Major risk factors for the development of MODS are severe trauma, sepsis, prolonged periods of hypotension, hepatic dysfunction, infarcted bowel, advanced age, and alcohol abuse. Interventions for multiple organ failure are focused on support of the affected organs.

Summary Concepts

- Circulatory shock is a life-threatening condition in which body tissues are deprived of oxygen and cellular nutrients or are unable to use these materials in their metabolic processes. The clinical presentation varies and is dependent upon the length of time tissue perfusion has been compromised.
- The manifestations of circulatory shock reflect both the impaired perfusion of body tissues and the body’s attempt to maintain tissue perfusion through conservation of water by the kidney, translocation of fluid from the extracellular to the intravascular compartment, and activation of sympathetic nervous system mechanisms that increase heart rate and divert blood from less essential to more essential body tissues.
- Circulatory shock can result from insufficient volume within the vascular compartment (i.e., hypovolemic shock), failure of the heart as a pump (cardiogenic shock), obstruction of blood flow or venous return to the heart (i.e., obstructive shock), or a maldistribution of blood due to expanded vascular space as a result of excessive vasodilation (i.e., distributive shock).
- Hypovolemic shock, which serves as a prototype for circulatory shock, is characterized as low peripheral blood flow and excessive compensatory sympathetic stimulation. Decreased intravascular volume produces thirst, changes in skin temperature, decreased blood pressure, increased heart rate, decreased venous pressure, decreased urine output, and changes in the sensorium. The intense vasoconstriction that serves to maintain blood flow to the heart and brain causes a decrease in tissue perfusion, impaired cellular metabolism, excessive production of lactic acid, and, eventually, cell death. Whether the shock is irreversible or the patient will survive is determined largely by changes that occur at the cellular level.
- Cardiogenic shock occurs when the heart suddenly fails to pump blood sufficiently to meet the body’s demands. It most commonly occurs from an acute myocardial infarction, but may occur with other types of shock because of inadequate coronary blood flow.
- Obstructive shock results from mechanical obstruction of the flow of blood through the central circulation (great veins, heart, or lungs) that can be caused by a number of conditions, including dissecting aortic aneurysm, cardiac tamponade, pneumothorax, atrial myxoma, and evisceration of abdominal contents into the thoracic cavity because of a ruptured hemidiaphragm.
- There are three types of distributive shock that share the same basic circulatory pattern: neurogenic shock, anaphylactic shock, and septic shock. Septic shock, which is the most common of the three types, is a complex process that is associated with impaired tissue perfusion and an imbalance in the inflammatory response. Sepsis and septic shock have a high mortality rate.
- The complications of shock result from the continued deprivation of blood flow to vital organs or systems. Acute lung injury/acute
SUMMARY CONCEPTS (continued)
respiratory distress syndrome (ALI/ARDS) is characterized by changes in the permeability of the alveolar–capillary membrane with development of interstitial edema and severe hypoxemia that is refractory to oxygen therapy. The renal tubules are particularly vulnerable to ischemia, and acute kidney injury is an important complication of shock. Gastrointestinal ischemia may lead to gastrointestinal bleeding and increased vascular permeability to intestinal bacteria, which can cause further sepsis and shock. Disseminated intravascular coagulation (DIC) is characterized by formation of small clots in the circulation. Multiple organ dysfunction syndrome (MODS), perhaps the most ominous complication of shock, rapidly depletes the body’s ability to compensate and ultimately recover from the shock state.

REVIEW EXERCISES

1. A 75-year-old woman with long-standing hypertension and angina due to coronary heart disease presents with ankle edema, nocturia, increased shortness of breath with activity, and a chronic nonproductive cough. Her blood pressure is 170/80 and her heart rate 92. Electrocardiography and chest radiography indicate the presence of left ventricular hypertrophy.

A. Relate the presence of uncontrolled hypertension and coronary artery disease to the development of heart failure in this woman.

B. Explain the significance of left ventricular hypertrophy in terms of both a compensatory mechanism and a pathologic mechanism in the progression of heart failure.

C. Use Figure 20-2 to explain this woman’s symptoms, including shortness of breath and nonproductive cough.

2. A 26-year-old man is admitted to the emergency department after an automobile injury with excessive blood loss. He is alert and anxious, his skin is cool and moist, his heart rate is 135, and his blood pressure is 100/85. He is receiving intravenous fluids, which were started at the scene of the accident by an emergency medical technician. He has been typed and cross-matched for blood transfusions and a urinary catheter has been inserted to monitor his urinary output. His urinary output has been less than 10 mL since admission and his blood pressure has dropped to 85/70. Efforts to control his bleeding have been unsuccessful and he is being prepared for emergency surgery.

A. Use information regarding the compensatory mechanisms in circulatory shock to explain this man’s presenting symptoms, including urinary output.

B. Use Figure 20-8 to hypothesize about this man’s blood loss and maintenance of blood pressure.

C. The treatment of hypovolemic shock is usually directed at maintaining the circulatory volume through fluid resuscitation rather than maintaining the blood pressure through the use of vasoactive medications. Explain.

The primary function of the respiratory system is gas exchange, with oxygen from the air being transferred to the blood and carbon dioxide from the blood being eliminated into the atmosphere. In addition to gas exchange, the lungs serve as a host defense by providing a barrier between the external environment and the inside of the body. And finally, the lungs are metabolic organs that synthesize and break down different substances.

The content in this chapter focuses on the structure and function of the respiratory system as it relates to the exchange of gases. The function of the red cell in the transport of oxygen is discussed in Chapter 13.

Cough Reflex

Dyspnea
blood vessels, lymph nodes, nerve fibers, thymus gland, and esophagus. Each lung is suspended in its own pleural cavity and connected to the mediastinum by vascular and bronchial structures. The upper part of the lung, which lies against the top of the thoracic cavity, is called the apex, and the lower part, which lies against the diaphragm, is called the base.

**Conducting Airways**

The conducting airways consist of the nasal passages, mouth and pharynx, larynx, trachea, bronchi, and bronchioles (see Fig. 21-1). The air we breathe is warmed and moistened as it moves through these structures. Heat is transferred to the air from the blood flowing through the walls of the respiratory passages, and water from the mucous membranes is used to moisten the air. Except for the vocal cords, which are covered with stratified epithelium, the walls of the conducting airways, including the larynx, trachea, and bronchioles, are lined by pseudostratified columnar epithelium, containing a mosaic of mucus-secreting glands, ciliated cells with hairlike projections, and serous glands that secrete a watery fluid containing antibacterial enzymes. In addition, some less common cell types are interspersed in different parts of the airway.

The mucus produced by the epithelial cells in the conducting airways forms a layer called the mucociliary blanket that protects the respiratory tract by entrapping dust, bacteria, and other foreign particles that enter the airways. The cilia, which constantly are in motion, propel the mucociliary blanket with its entrapped particles in an escalator-like fashion toward the oropharynx, from which it is expectorated or swallowed. The function of the cilia in clearing the lower airways and alveoli is optimal at normal oxygen levels and is impaired in situations of low and high oxygen levels. It is also impaired by drying conditions, such as breathing heated but unhumidified indoor air during the winter months. Cigarette smoking slows down or paralyzes the motility of the cilia. This slowing allows the residue from tobacco smoke, dust, and other particles to accumulate in the lungs, decreasing the efficiency of this pulmonary defense system. As discussed in Chapter 23, these changes are thought to contribute to the development of chronic bronchitis and emphysema.

The air in the conducting airways is kept moist by water contained in the mucous layer of the upper airways and tracheobronchial tree. The capacity of the air to contain water vapor without condensation increases as the temperature rises. Thus, the air in the alveoli, which is maintained at body temperature, usually contains considerably more water vapor than the atmospheric-temperature air that we breathe. The difference between the water vapor contained in the air we breathe and that found in the alveoli is drawn from the moist surface of the mucous membranes that line the conducting airways and is a source of insensible water loss (see Chapter 8). Under normal conditions, approximately 1 pint of water is used each day to humidify the air we breathe. During fever, the water vapor in the lungs increases, causing more water to be lost through the respiratory tract. In addition, fever usually is accompanied by an increase in respiratory rate so that more air passes through the airways, withdrawing moisture from its mucosal surface. As a result, respiratory secretions thicken, preventing free movement of the cilia and impairing the protective function of the mucociliary defense system. This is particularly true in persons whose water intake is inadequate.

**Nasopharyngeal Airways**

The nose is the preferred route for the entrance of air into the respiratory tract during normal breathing. As air passes through the nasal passages, it is filtered, warmed, and humidified. The outer nasal passages are
lined with coarse hairs, which filter and trap dust and other large particles from the air. The upper portion of the nasal cavity, which is lined with a mucous membrane that contains a rich network of small blood vessels, supplies both warmth and moisture to the air we breathe.

The mouth serves as an alternative airway when the nasal passages are plugged or when there is a need for the exchange of large amounts of air, as occurs during exercise. The oropharynx, which extends posteriorly from the soft palate to the epiglottis, is the only opening between the nose, mouth, and lungs. Both swallowed food on its way to the esophagus and air on its way to the larynx pass through it. Obstruction of the oropharynx leads to immediate cessation of ventilation.

Neural control of the tongue and pharyngeal muscles may be impaired in coma and certain types of neurologic disease. In these conditions, the tongue falls back into the pharynx and obstructs the airway, particularly if the person is lying on his or her back. Swelling of the pharyngeal structures caused by injury, infection, or severe allergic reaction also predisposes a person to airway obstruction, as does the presence of a foreign body.

**Laryngotracheal Airways**

The larynx, or voice box, connects the oropharynx with the trachea. The walls of the larynx are supported by rigid cartilaginous structures that prevent collapse during inspiration. The functions of the larynx can be divided into two categories: those associated with speech and those associated with protecting the lungs from substances other than air. The larynx is located in a strategic position between the upper airways and the lungs, and sometimes is referred to as the “watchdog of the lungs.”

The cavity of the larynx is divided into two pairs of two-by-two folds of mucous membrane stretching from front to back with an opening in the middle (Fig. 21-2).

The upper pair of folds, called the vestibular folds or false vocal cords, have a protective function. The lower pair of folds, which have cordlike margins, are termed the vocal folds or vocal cords because their vibrations are required for making vocal sounds. The true vocal cords and the elongated opening between them make up the glottis. A complex set of muscles and ligaments control the opening and closing of the glottis. Speech involves the intermittent release of expired air and opening and closing of the glottis. The epiglottis, which is located above the vocal folds, is a large, leaf-shaped piece of cartilage that is covered with epithelium. During swallowing, the free edges of the epiglottis move downward to cover the larynx, thus routing liquids and foods into the esophagus.

In addition to opening and closing the glottis for speech, the vocal folds of the larynx can perform a sphincter function in closing off the airways. When confronted with substances other than air, the laryngeal muscles contract and close off the airway. At the same time, the cough reflex helps in removing the foreign substance from the airway. If the muscles that control the swallowing mechanism are partially or totally paralyzed, food and fluids can enter the airways instead of the esophagus when a person attempts to swallow. These substances are not easily removed, and when they are pulled into the lungs, they can cause a serious inflammatory condition called aspiration pneumonia.

**Tracheobronchial Airways**

The tracheobronchial airways, which consist of the trachea, bronchi, and bronchioles, can be viewed as a system of branching tubes (Fig. 21-3A). They are similar to a tree whose branches become smaller and more numerous as they divide. There are approximately 23 levels of branching, beginning with the conducting airways and ending with the respiratory airways, where gas exchange takes place (Fig. 21-3B).

The trachea, or windpipe, can be viewed as a continuous tube that connects the larynx and the major bronchi of the lungs. The wall of the trachea consists of four distinct layers: a mucosa layer of ciliated pseudostratified epithelium, a submucosal layer of dense connective tissue, a cartilaginous layer, and an outer layer of connective tissue that binds the trachea to the adjacent structures. A unique feature of the trachea is the presence of a series of horseshoe- or C-shaped rings of hyaline cartilage that prevent it from collapsing when the pressure in the thorax becomes negative (Fig. 21-4). The open part of the C-shaped ring, which abuts the esophagus, is connected by smooth muscle. Since this portion of the trachea is not rigid, the esophagus can expand anteriorly as swallowed food passes through it.

The trachea divides into two branches, forming the right and left main or primary bronchi, as it moves into the thorax (Fig. 21-5A). Between the main bronchi is a keel-like ridge called the carina (Fig. 21-5B). The mucosa of the carina is highly sensitive, producing violent coughing, when a foreign object (e.g., suction catheter) makes contact with it. Initially, the bronchi have

![Figure 21-2. Epiglottis and vocal cords viewed from above with (A) glottis closed and (B) glottis open.](image-url)
the same basic structure as the trachea. Each primary bronchus, accompanied by the pulmonary arteries, veins, and lymph vessels, enters the lung through a slit called the hilus.

On entering the lungs, each primary bronchus divides into secondary or lobular bronchi that supply each of the lobes of the lung—three in the right lung and two in the left. The right middle lobe bronchus, which is particularly subject to obstruction, is relatively small in diameter and length and sometimes bends sharply near its bifurcation, making it particularly subject to obstruction. The secondary bronchi, in turn, divide to form the segmental bronchi that supply the bronchopulmonary segments of the lung. These segments are identified according to their location in the lung (e.g., the apical segment of the right upper lobe) and are the smallest named units in the lung. Lung lesions such as atelectasis and pneumonia often are localized to a particular bronchopulmonary segment.

Initially, the walls of the bronchial airways have the same general structure as the trachea. At the point where the bronchi enter the the lungs to become the intrapulmonary bronchi, the structure changes (Fig. 21-6). The cartilage rings are replaced by cartilage plates of irregular shape that encircle the entire circumference of the airway. A second change that is observed in the wall of
the intrapulmonary bronchus is the addition of a circumferential ring of smooth muscle.

The segmental bronchi continue to branch, forming smaller bronchi, until they become the terminal bronchioles, the smallest of the conducting airways. As these bronchi branch and become smaller, their wall structure changes. The cartilage gradually decreases and there is an increase in smooth muscle and elastic tissue with respect to the thickness of the wall. By the time the bronchioles are reached, there is no cartilage present and their walls are composed mainly of smooth muscle and elastic fibers. Bronchospasm, or contraction of these muscles, causes narrowing of the bronchioles and impairs air flow. The elastic fibers, which radiate from the outer surface of the bronchial wall and connect with elastic fibers arising from other parts of the bronchial tree, exert tension on the bronchial walls; by pulling uniformly in all directions, they help maintain airway patency.

Lungs and Respiratory Airways

The lungs are the functional structures of the respiratory system. In addition to their gas exchange function, they inactivate vasoactive substances such as bradykinin,
convert angiotensin I to angiotensin II, and serve as a reservoir for blood storage. Heparin-producing cells are particularly abundant in the capillaries of the lung, where small clots may be trapped.

**Pleura**

The lungs are encased in a thin double-layered closed sac, called the pleura (see Fig. 21-1). The outer parietal layer of the pleural sac lines the pulmonary cavities and adheres to the thoracic wall, the mediastinum, and the diaphragm. The inner visceral pleura closely covers the lung and is adherent to all its surfaces. It is continuous with the parietal pleura at the hilus of the lung, where the major bronchus and pulmonary vessels enter and leave the lung. A thin film of serous fluid separates the two layers, allowing them to glide over each other, yet hold together so there is no separation between the lungs and the chest wall. The pleural cavity, or space between the two pleural layers, is also a potential space in which serous fluid or inflammatory exudate can accumulate. The term pleural effusion is used to describe an abnormal collection of fluid in the pleural cavity.

**Respiratory Lobules**

The gas exchange function of the lung takes place in the respiratory lobules of the lungs. Each lobule, which is the smallest functional unit of the lung, is supplied by a terminal bronchiolo, alveoli, and pulmonary blood vessels (Fig. 21-7). Blood enters the lobules through a pulmonary artery and exits through a pulmonary vein. Lymphatic structures surround the lobule and aid in the removal of plasma proteins and other particles from the interstitial spaces.

The alveoli, which consist of alveolar ducts and sacs, are the terminal air spaces of the respiratory tract and the actual sites of gas exchange between the air and the blood. The alveolar ducts are elongated airways that have almost no walls at their peripheral boundary. The alveolar sacs are cup-shaped, thin-walled structures that are separated from each other by thin alveolar septa. A single network of capillaries occupies most of the septa, so blood is exposed to air on both sides. There are approximately 300 million alveoli in the adult lung, with a total surface area of approximately 50 to 100 m². Unlike the bronchioles, which are tubes with their own separate walls, the alveoli are interconnecting spaces that have no separate walls. As a result of this arrangement, there is a continual mixing of air in the alveolar structures. Small holes in the walls of adjacent alveoli, the minute pores of Kohn, contribute to the mixing of air.

The alveolar epithelium is composed of two types of cells: type I and type II alveolar cells (Fig. 21-8). Type I alveolar cells are extremely thin squamous cells with a thin cytoplasm and flattened nucleus that occupy about 95% of the surface area of the alveoli. Type I alveolar cells are not capable of regeneration. Type II alveolar cells, which are found interspersed between the type I alveolar cells, are secretory cells that produce the surface-active agent called surfactant. In addition to secreting surfactant, type II alveolar cells are the progenitor cells for type I cells. Following lung injury, they proliferate and restore both type I and type II alveolar cells. The alveoli also contain brush cells and macrophages. The brush cells, which are few in number, are thought to act as receptors that monitor the air quality of the lungs.

The surfactant molecules produced by the type II alveolar cells reduce the surface tension at the air-epithelium interface, and they modulate the immune functions of the lung. Recent research has identified four types of surfactant, each with a different molecular structure: surfactant proteins A, B, C, and D. Surfactants B and C serve to reduce the surface tension at the air-epithelium interface and increase lung compliance and ease of lung inflation. Surfactant B is particularly important to the generation of the surface-reducing film that makes lung expansion possible (to be discussed). Surfactants A and D do not reduce surface tension, but contribute to innate immune defenses that protect against pathogens that have entered the lung. They bind pathogens, damage microbial membranes, regulate microbial phagocytosis, and activate or deactivate the inflammatory response (see Chapter 16).

The alveolar macrophages, which are present in both the connective tissue of the septum and in the air spaces of the alveolus, are responsible for the removal of offending substances from the alveoli (see Fig. 21-8). In the air spaces, they scavenge the surface to remove inhaled particulate matter, such as dust and pollen. Some macrophages move up the bronchial tree in the mucus and are disposed of by swallowing or coughing when they reach the pharynx. Others enter the septal connective tissue where, filled with phagocytosed materials, they remain for life. Thus, at autopsy, the lungs
of urban dwellers, as well as smokers, usually show many alveolar macrophages filled with carbon and other polluting particles from the environment. The alveolar macrophages also phagocytose insoluble infectious agents such as *Mycobacterium tuberculosis*. The activated macrophages then aggregate to form a fibrin-encapsulated granuloma, called a *tubercle*, which serves to contain the infection (see Chapter 23).

### Pulmonary and Bronchial Circulations

The lungs are provided with a dual blood supply: the pulmonary and bronchial circulations. The pulmonary circulation arises from the pulmonary artery and provides for the gas exchange function of the lungs (see Fig. 21-7). Deoxygenated blood leaves the right heart through the pulmonary artery, which divides into a left pulmonary artery that enters the left lung and a right pulmonary artery that enters the right lung. Return of oxygenated blood to the heart occurs by way of the pulmonary veins, which empty into the left atrium. It is important to note that this is the only part of the circulation in which arteries carry deoxygenated blood and veins carry oxygenated blood.

The pulmonary circulation serves several important functions in addition to gas exchange. It removes thromboemboli (blood clots) from the circulation, functions as a metabolic organ, and serves as a blood reservoir for the left side of the heart. Small pulmonary vessels trap thromboemboli, and endothelial cells lining the vessels release fibrolytic substances that help dissolve them. Vasoactive hormones are metabolized in the pulmonary circulation. Angiotensin I is activated and converted to angiotensin II by the angiotensin-converting enzyme (ACE) located on the surface of the pulmonary capillary endothelial cells. Pulmonary endothelial cells also inactivate bradykinin, serotonin, and some of the prostaglandins. As a blood reservoir, the pulmonary circulation contains approximately 500 mL of the total blood volume. During a hemorrhagic event, some of this blood can be mobilized to improve cardiac output.

The bronchial circulation provides the blood supply for the conducting airways and the supporting structures of the lung. It also has a secondary function of warming and humidifying incoming air as it moves through the conducting airways. The bronchial arteries arise from the thoracic aorta and enter the lungs with the major bronchi, dividing and subdividing along with the bronchi as they move out into the lung, supplying them and other lung structures with oxygen. The blood from the capillaries in the bronchial circulation drains into the bronchial veins, with the blood from the larger bronchial veins emptying into the vena cava and blood from the smaller bronchial veins draining into the pulmonary veins. Because the bronchial circulation does not participate in gas exchange, this blood is deoxygenated. As a result, it dilutes the oxygenated blood returning to the left side of the heart by way of the pulmonary veins.

The bronchial blood vessels are the only ones that can undergo angiogenesis (formation of new vessels) and develop collateral circulation when vessels in the pulmonary circulation are obstructed, as in pulmonary embolism. The development of new blood vessels helps to keep lung tissue alive until the pulmonary circulation can be restored.
Innervation

The lung is innervated by both the sympathetic and parasympathetic divisions of the autonomic nervous system. The parasympathetic fibers, which are derived from vagal nerves, and the sympathetic fibers, which originate in the upper thoracic and cervical ganglia, form the pulmonary plexuses that enter the lung in the region of the hilus. Fibers from the plexus follow the major bronchi and blood vessels into the lung to innervate bronchial smooth muscle cells, blood vessels, and epithelial cells (including the goblet and submucosal glands). There is no voluntary motor innervation of the lung, nor are there any pain fibers. Pain fibers are found only in the pleura.

The parasympathetic (cholinergic) fibers are excitatory neurons that respond to acetylcholine. Stimulation of the parasympathetic nervous system is responsible for airway constriction, blood vessel dilation, and increased glandular secretion. The sympathetic nervous system, which responds to the catecholamines norepinephrine and epinephrine, produces bronchodilation, blood vessel constriction, and inhibition of glandular secretion.

Exchange of Gases Between the Atmosphere and the Lungs

The exchange of gases between the atmosphere and the lungs occurs along a pressure gradient, moving from an area of higher pressure to one of lower pressure.

Basic Properties of Gases

The air we breathe is made up of a mixture of gases, mainly nitrogen and oxygen. These gases exert a combined pressure called the atmospheric pressure. The pressure at sea level is defined as 1 atmosphere, which is equal to 760 millimeters of mercury (mm Hg) or 14.7 pounds per square inch (PSI). Respiratory pressures—the pressures within the alveoli and other respiratory structures—are always expressed relative to atmospheric pressure, which is assigned a value of 0 mm Hg. This means that a respiratory pressure of +15 mm Hg is 15 mm Hg above atmospheric pressure, and a respiratory pressure of −15 mm Hg is 15 mm Hg less than atmospheric pressure. Respiratory pressures often are expressed in centimeters of water (cm H_2O) because of the small pressures involved (1 mm Hg = 1.35 cm H_2O pressure).

The pressure exerted by a single gas in a mixture is called the partial pressure. The capital letter “P” followed by the chemical symbol of the gas (e.g., PO_2) is used to denote its partial pressure. The law of partial pressures states that the total pressure of a mixture of gases, as in the atmosphere, is equal to the sum of the partial pressures of the different gases in the mixture. If the concentration of oxygen at 760 mm Hg (1 atmosphere) is 21%, its partial pressure is 160 mm Hg (760 × 0.21).

Water vapor is different from other types of gases; its partial pressure is affected by temperature but not atmospheric pressure. The relative humidity refers to the percentage of moisture in the air compared with the amount that the air can hold without causing condensation (100% saturation). Warm air holds more moisture than cold air. This is the reason that precipitation in the form of rain or snow commonly occurs when the relative humidity is high and there is a sudden drop in atmospheric temperature. The air in the alveoli, which remains 100% saturated at normal body temperature,
has a water vapor pressure of 47 mm Hg, which must be included in the sum of the total pressure of the gases.

**Pulmonary Ventilation**

Ventilation refers to the exchange of gases within the respiratory system. There are two types of ventilation: pulmonary and alveolar. **Pulmonary ventilation** refers to the total exchange of gases between the atmosphere and the lungs, and **alveolar ventilation** to the transfer of gases within the gas exchange portion of the lungs.

Pulmonary ventilation relies on a system of open airways and a change in pressure that is created as the respiratory muscles change the size of the chest cage. The degree to which the lungs inflate and deflate depends on the movement of the chest cage and pressures created by respiratory muscles, the resistance that the air encounters as it moves through the airways, and the compliance or ease with which the lungs can be inflated.

**Respiratory Pressures**

The pressure inside the airways and alveoli of the lungs is called the intrapulmonary pressure or alveolar pressure. The gases in the lungs are in communication with atmospheric air pressure (Fig. 21-9). When the glottis is open and air is not moving into or out of the lungs, as occurs just before inspiration or expiration, the intrapulmonary pressure is zero or equal to atmospheric pressure.

The pressure in the pleural cavity is called the intra-pleural pressure. The intra-pleural pressure is always negative in relation to alveolar pressure in the normally inflated lung. The lungs are elastic structures that would collapse and expel all their air were it not for the negative intrapleural pressure (normally about −4 mm Hg between breaths) that holds them against the chest wall. During inspiration, expansion of the chest cage pulls outward on the lungs to increase the negative pressure so air can move into the lungs; and during expiration, the pressures are reversed causing air to move out of the lung. Although the intrapleural pressure of the inflated lung is always negative in relation to alveolar pressure, it may become positive in relation to atmospheric pressure (e.g., as during forced expiration and coughing).

The **intrathoracic pressure** is the pressure in the thoracic cavity. It is essentially equal to intrapleural pressure and is the pressure to which the lungs, heart, and great vessels are exposed. Forced expiration against a closed glottis (Valsalva maneuver) compresses the air in the thoracic cavity and produces marked increases in both the intrathoracic and intrapleural pressures.

**Chest Cage and Respiratory Muscles**

The **chest cage** is a closed compartment bounded on the top by the neck muscles and at the bottom by the diaphragm. The outer walls of the chest cage are formed by 12 pairs of ribs, the sternum, the thoracic vertebrae, and the intercostal muscles that lie between the ribs. The lungs and major airways share the inner chest cavity with the heart, great vessels, and esophagus. Mechanically, ventilation or the act of breathing depends on the fact that the chest cavity is a closed compartment whose only opening to the exterior is the trachea.

Air moves between the atmosphere and the lungs because of a pressure difference or gradient. According to the laws of physics, the pressure of a gas varies inversely with the volume of its container, with the pressure of the same quantity of gas in a smaller container being greater than that in a larger container. The movement of gases is always from the container with the greater pressure to the one with the lesser pressure. The chest cavity can be likened to a volume container in which the pressure becomes more negative during inspiration as the chest cavity expands, and becomes more positive during expiration as the chest cage contracts. Because of the change in size and pressure of the chest cage, air moves into the lungs during inspiration and out of the lungs during expiration (Fig. 21-10).

The diaphragm is the principal muscle of inspiration. When the diaphragm contracts, the abdominal contents are forced downward and the chest expands from top to bottom (see Fig. 21-10). During normal levels of inspiration, the diaphragm moves approximately 1 cm, but this can be increased to 10 cm on forced inspiration. The diaphragm is innervated by the phrenic nerve roots, which arise from the cervical level of the spinal cord, mainly from C4 but also from C3 and C5. Persons with spinal cord injury above this level require mechanical ventilation. Paralysis of one side of the diaphragm causes the chest to move up on that side rather than down during inspiration because of the negative pressure in the chest. This is called **paradoxical movement**.

The external intercostal muscles, which aid in inspiration, connect to the adjacent ribs and slope downward and forward (Fig. 21-11). When they contract, they raise the ribs and rotate them slightly so that the sternum is pushed forward, enlarging the chest from side
to side and from front to back. The external intercostal muscles receive their innervation from nerves that exit the central nervous system (CNS) at the thoracic level of the spinal cord. Paralysis of these muscles usually does not have a serious effect on respiration because of the effectiveness of the diaphragm.

The accessory muscles of inspiration include the scalene muscles and the sternocleidomastoid muscles. The scalene muscles elevate the first two ribs, and the sternocleidomastoid muscles raise the sternum to increase the size of the chest cavity. These muscles contribute little to quiet breathing but contract vigorously during exercise. For the accessory muscles to assist in ventilation, they must be stabilized in some way. Persons with bronchial asthma often brace their arms against a firm object during an attack as a means of stabilizing their shoulders so that the attached accessory muscles can exert their full effect on ventilation. The head commonly is bent backward so that the scalene and sternocleidomastoid muscles can elevate the ribs more effectively. Other muscles that play a minor role in inspiration are the alae nasi, which produce ringing of the nostrils during obstructed breathing.

Expiration is largely passive. It occurs as the elastic components of the chest wall and lung structures that were stretched during inspiration recoil, causing air to leave the lungs as the intrathoracic pressure increases. When needed, the abdominal and the internal intercostal muscles can be used to increase expiratory effort (see Fig. 21-11B). The increase in intra-abdominal pressure that accompanies the forceful contraction of the abdominal muscles pushes the diaphragm upward and results in an increase in intrathoracic pressure. The internal intercostals pull the ribs downward and inward, assisting in exhalation.

**Lung Compliance**

Lung compliance refers to the ease with which the lungs can be inflated. Compliance can be appreciated by comparing the ease of blowing up a balloon that has been previously inflated with a new balloon that is stiff and noncompliant. Specifically, lung compliance is a measure of the change in lung volume that occurs with a change in intrapulmonary pressure.

Lung compliance is determined by the elastic properties of the lung and alveolar surface tension. It also depends on the compliance of the thoracic or chest cage. It is diminished in conditions that reduce the natural elastic properties of the lung, increase the surface tension in the alveoli, or impair the flexibility of the chest cage.

**Elastic Properties.** The elastic properties of the lung involve at least three basic components: distensibility, stiffness, and elastic recoil. **Distensibility** is the ease with which the lungs can be inflated. **Stiffness** is defined as the resistance to stretch or inflation. Lung tissue is made up of elastin and collagen fibers. The elastin fibers are easily stretched and increase the ease of lung inflation, whereas...
the collagen fibers resist stretching and make lung inflation more difficult. In lung diseases such as interstitial lung disease and pulmonary fibrosis, the lungs become stiff and noncompliant as the collagen fibers are replaced with the collagen fibers of scar tissue. Pulmonary congestion and edema produce a reversible decrease in pulmonary compliance by increasing the water content of the lung.

Elastic recoil describes the ability of the elastic components of the stretched or inflated lung to return to their original position after having been stretched. Overstretching lung tissues, as occurs with emphysema, causes the elastic components of the lung to lose their recoil, making the lung more compliant and easier to inflate but more difficult to deflate because of its inability to recoil.

Surface Tension. An important factor in lung compliance is the surface tension in the alveoli. The alveoli are lined with a thin film of liquid, and it is at the interface between this liquid film and the alveolar air that surface tension develops. This can be explained by the fact that the forces that hold the liquid molecules together are stronger than those that hold the air molecules together. In the alveoli, excess surface tension causes the liquid film to contract, making lung inflation more difficult.

The relationship between the pressure within a sphere such as an alveolus and the tension in the wall can be described using the law of Laplace (pressure = 2 × surface tension/radius). If the surface tension were equal throughout the lungs, the alveoli with the smallest radii would have the greatest pressure, and this would cause them to empty into the larger alveoli (Fig. 21-12A). The reason this does not occur is because of the surface tension-lowering molecules, called surfactant, that line the inner surface of the alveoli.

Pulmonary surfactants, particularly surfactant B, exert several important effects on lung inflation. They decrease alveolar surface tension, thereby increasing lung compliance and ease of inflation. Without this, lung inflation would be extremely difficult. In addition, surfactant helps to keep the alveoli dry and prevents the development of pulmonary edema. This is because water is pulled out of the pulmonary capillaries into the alveoli when increased surface tension causes the alveoli to recoil.

Surfactants also stabilize alveolar inflation by changing their density in relation to alveolar size, with the surfactant molecules becoming more tightly compressed in the small alveoli with their higher surface tension and less compressed in the larger alveoli with their lower surface tension (Fig. 21-12B). At low lung volumes, the molecules become tightly packed, and at higher lung volumes they spread out to cover the alveolar surface. In surgical patients and bed-ridden persons, shallow and quiet breathing often impairs the spreading of surfactant. Encouraging these persons to cough and deep breathe enhances the spreading of surfactant, allowing for a more even distribution of ventilation and prevention of atelectasis (incomplete expansion of a portion of the lung).

The type II alveolar cells that produce surfactant do not begin to mature until the 26th to 27th week.
of gestation; consequently, many premature infants have difficulty producing sufficient amounts of surfactant. This can lead to alveolar collapse and severe respiratory distress. This condition, called infant respiratory distress syndrome, is the single most common cause of respiratory disease in premature infants. Recombinant forms of surfactant are now available for use in treatment of the disorder (see Chapter 22). The synthesis of surfactant can also be impaired in the adult. This usually occurs as the result of severe injury or infection and can contribute to the development of a condition called the acute respiratory distress syndrome (see Chapter 24).

**Airway Resistance**

During breathing, the flow or volume of air that moves into and out of the lungs is directly related to the pressure difference between the lungs and the atmosphere and inversely related to the resistance that the air encounters as it moves through the conducting airways.

**Airway radius.** The primary determinant of airway resistance to airflow is the radius of the conducting airway. Normally, the radius is large enough so that a gradient of less than 1 cm H₂O pressure is needed for sufficient airflow during quiet breathing. The site of most of the resistance occurs in the larger bronchioles and bronchi near the trachea, with the smallest airways contributing very little to the total airway resistance. The low resistance of the smaller bronchioles can be explained in terms of their large number and their parallel arrangements. Many airway diseases, such as emphysema and chronic bronchitis, begin in the small airways. Early detection of these diseases is often difficult because a considerable amount of damage must be present before the usual diagnostic measurements of airway resistance can detect them.

**Lung Volume.** Airway resistance is also affected by lung volume, being less during inspiration than during expiration. This is because elastic-type fibers connect the outside of the airways to the surrounding lung tissues. As a result, these airways are pulled open as the lungs expand during inspiration, and they become narrower as the lungs deflate during expiration (Fig. 21-13). This is one of the reasons persons with conditions that increase airway resistance, such as bronchial asthma, usually have less difficulty during inspiration than during expiration.

**Neural and Local Control of Airway Diameter.** Constriction of bronchial smooth muscle, which controls airway diameter, also contributes to airway resistance. The smooth muscles in the airways are under autonomic nervous system control. Stimulation of the parasympathetic nervous system produces bronchial constriction as well as increased mucus secretion, whereas sympathetic stimulation has the opposite effect. Parasympathetic nerves can be stimulated by reflexes that originate in the lungs, most of which begin with irritation of the epithelial cells by cigarette smoke, dust, noxious gases, or bronchial infections. Inflammatory mediators such as the leukotrienes, histamine, and prostaglandins released by resident mast cells and airway epithelial cells can also cause bronchial constriction.

Many of the drugs used in the treatment of bronchial asthma and other respiratory conditions that produce bronchial constriction act at the level of the autonomic nervous system or inflammatory mediators to relieve airway obstruction. For example, β-adrenergic stimulants are often used to achieve short-term relief of asthma symptoms. Anti-inflammatory agents, such as the corticosteroids or leukotriene antagonists, are used to achieve long-term relief (see Chapter 3, Fig. 3-4).

**Laminar and Turbulent Airflow.** Depending on the velocity and pattern of flow, airflow can be laminar or turbulent. Laminar, or streamlined, airflow occurs at low flow rates in which the air stream is parallel to the sides of the airway. With laminar flow, the air at the periphery must overcome the resistance to flow; and as a result, the air in the center of the airway moves faster. In the bronchial tree with its many branches, laminar airflow probably occurs only in the very small airways, where the velocity of flow is low. Because the small airways contribute little resistance to airflow, they constitute a silent zone in terms of respiratory sounds.

Turbulent airflow is disorganized flow in which the molecules of the gas move laterally, collide with one
another, and change their velocities. Whether turbulence develops depends on the radius of the airways, the interaction of the gas molecules, and the velocity of airflow. It is most likely to occur when the radius of the airways is large and the velocity of airflow is high. Turbulent flow occurs regularly in the trachea. Turbulence of airflow accounts for the respiratory sounds that are heard during chest auscultation (i.e., listening to chest sounds using a stethoscope).

**Airway Compression During Forced Expiration.** Airway resistance does not change considerably during normal quiet breathing, but is significantly increased during forced expiration, such as occurs during vigorous exercise. The marked changes that occur during forced expiration are the result of airway compression. Airflow through the collapsible airways in the lungs depends on the distending airway (intrapulmonary) pressures that hold the airways open and the external (intrathoracic) pressures that surround and compress the airways. The difference between these two pressures (airway minus intrathoracic pressure) is called the *transpulmonary pressure*. For airflow to occur, the distending pressure inside the airways must be greater than the compressing pressure outside the airways.

During forced expiration, the transpulmonary pressure is decreased because of a disproportionate increase in the intrathoracic pressure compared with airway pressure. The resistance that air encounters as it moves out of the lungs causes a further drop in airway pressure. If this drop in airway pressure is sufficiently great, the surrounding intrathoracic pressure will compress the collapsible airways that lack cartilaginous support, causing airflow to be interrupted and air to be trapped in the terminal airways (Fig. 21-14).

Although this type of airway compression usually is seen only during forced expiration in persons with normal respiratory function, it may occur during normal breathing in persons with lung diseases. For example, in conditions that increase airway resistance, such as asthma or chronic obstructive lung disease, the pressure drop along the smaller airways is magnified, and an increase in intra-airway pressure is needed to maintain airway patency. Measures such as pursed-lip breathing increase airway pressure and improve expiratory flow rates in persons with obstructive lung diseases (discussed in Chapter 23). This is also the rationale for using end-expiratory pressure in persons who are being mechanically ventilated. Infants who are having trouble breathing often grunt to increase their expiratory airway pressures and keep their airways open.

**Lung Volumes and Pulmonary Function Studies**

Lung volumes, or the amount of air exchanged during ventilation, can be subdivided into three components: (1) the tidal volume, (2) the inspiratory reserve volume, and (3) the expiratory reserve volume. The tidal volume (TV), usually about 500 mL, is the amount of air that moves into and out of the lungs during a normal breath (Fig. 21-15). The inspiratory reserve volume (IRV) is the maximum amount of air that can be inspired in excess of the normal TV, and the expiratory reserve volume (ERV) is the maximum amount of air that can be exhaled in excess of the normal TV. Approximately 1200 mL of air remains in the lungs after forced expiration; this air is the *residual volume* (RV). The RV increases with age because there is more trapping of air in the lungs at the end of expiration.
The previously described lung volumes and capacities are anatomic and static measurements, determined by spirometry and recorded without relation to time. The spirometer also is used to measure dynamic lung volumes (i.e., ventilation with respect to time); these tests often are used in assessing pulmonary function (Table 21-2). The maximum voluntary ventilation measures the volume of air that a person can move into and out of the lungs during maximum effort lasting for a specific period of time. This measurement usually is converted to liters per minute. Two other useful tests are the forced vital capacity and the forced expiratory volume. The forced vital capacity (FVC) involves full inspiration to total lung capacity followed by forceful maximal expiration. Obstruction of airways produces an FVC that is lower than that observed with more slowly performed vital capacity measurements. The forced expiratory volume (FEV) is the expiratory volume achieved in a given time period. The FEV is the forced expiratory volume that can be exhaled in 1 second. The FEV frequently is expressed as a percentage of the FVC. The FEV and FVC are used in the diagnosis of obstructive lung disorders.

### Table 21-1 Lung Volumes and Capacities

<table>
<thead>
<tr>
<th>Volume</th>
<th>Symbol</th>
<th>Measurement</th>
</tr>
</thead>
<tbody>
<tr>
<td>Tidal volume (about 500 mL at rest)</td>
<td>TV</td>
<td>Amount of air that moves into and out of the lungs with each breath</td>

Ef ciency and Work of Breathing

The ef ciency of breathing is determined by matching the TV and respiratory rate in a manner that provides an optimal minute volume while minimizing the work of breathing. Persons with stiff and noncompliant lungs usually nd it easier to keep their TV low and breathe at a more rapid rate, whereas those with increased airway resistance usually nd it less dif cult to inflate their lungs and increase their TV, while breathing at a slower rate.

Efficiency and Work of Breathing

The ef ciency of breathing is determined by matching the TV and respiratory rate in a manner that provides an optimal minute volume while minimizing the work of breathing. The minute volume, or total ventilation, is the amount of air that is exchanged in 1 minute (TV multiplied by the respiratory rate). It is determined by the metabolic needs of the body, which during normal activity are about 6000 mL (500 mL TV × respiratory rate of 12 breaths/min).

The work of breathing is determined by the amount of effort required to move air through the conducting airways and by the ease of lung expansion. Because expansion of the lungs is dif cult for persons with stiff and noncompliant lungs, they usually nd it easier to breathe if they keep their TV low and breathe at a more rapid rate (e.g., 300 mL × 20 breaths/min = 6000 mL/min) to achieve their minute volume and meet their oxygen needs. In contrast, persons with obstructive airway disease usually nd it less dif cult to inflate their lungs but expend more energy in moving air through the airways. As a result, these persons tend to take deeper breaths and breathe at a slower rate (e.g., 600 mL × 10 breaths/min = 6000 mL) to achieve their oxygen needs.

*By convention, all the lung volumes and rates of flow are expressed in terms of body temperature and pressure and saturated with water vapor (BTPS), which allows for a comparison of the pulmonary function data from laboratories with different ambient temperatures and altitudes.*
Exchange of Gases Within the Lungs

The primary functions of the lungs are oxygenation of the blood and removal of carbon dioxide. Pulmonary gas exchange is conventionally divided into three processes: (1) ventilation or the flow of gases into and out of the alveoli of the lungs, (2) perfusion or flow of blood in the adjacent pulmonary capillaries, and (3) diffusion or transfer of gases between the alveoli and the pulmonary capillaries.

Alveolar Ventilation

The ultimate importance of the alveolar ventilation is to continually renew the air in the gas exchange areas of the lungs where the air is in close proximity to the blood. These areas include the alveoli, alveolar sacs, alveolar ducts, and respiratory bronchioles. It is affected by body position and lung volume as well as by disease conditions that affect the heart and respiratory system.

Distribution of Alveolar Ventilation

The distribution of ventilation between the base (bottom) and apex (top) of the lung varies with body position and reflects the effects of gravity on intrapleural pressure and lung compliance. Compliance reflects the change in volume that occurs with a change in intrapleural pressure. It is lower in fully expanded alveoli, which have difficulty accommodating more air, and greater in alveoli that are less inflated and can more easily expand to accommodate more air. In the seated or standing position, gravity exerts a downward pull on the lung, causing intrapleural pressure at the apex of the lung to become more negative. As a result, the alveoli at the apex of the lung are more fully expanded and less compliant than those at the base of the lung. The same holds true for lung expansion in the dependent portions of the lung in the supine or lateral position. In the supine position, ventilation in the lowermost (posterior) parts of the lung exceeds that in the uppermost (anterior) parts. In the lateral position (i.e., lying on the side), the alveoli in the dependent lung is better ventilated.

The distribution of ventilation also is affected by lung volumes. During full inspiration (high lung volumes) in the seated or standing position, the airways are pulled open and air moves into the more compliant portions of the lower lung. At low lung volumes, the opposite occurs. At functional residual capacity, the intrapleural pressure at the base of the lung exceeds airway pressure, compressing the airways so that ventilation is greatly reduced. In contrast, the airways in the apex of the lung remain open, and the alveoli in this area of the lung are well ventilated.

Even at low lung volumes, some air remains in the alveoli of the lower portion of the lungs, preventing their collapse. According to the law of Laplace (discussed previously), the pressure needed to overcome the tension in the wall of a sphere or an elastic tube is inversely related to its radius; therefore, the small airways close first, trapping some air in the alveoli. This trapping of air may be increased in older persons and persons with chronic lung disease owing to a loss in the elastic recoil properties of the lungs. In these persons, airway closure occurs at the end of normal instead of low lung volumes, trapping larger amounts of air that cannot participate in gas exchange.

Dead Air Space

Dead space refers to the air that must be moved with each breath but does not participate in gas exchange. The movement of air through dead space contributes to the work of breathing but not to gas exchange. Some of the air that enters the respiratory tract during breathing fails to reach the alveoli. This volume (about 150 to 200 mL), which remains in the conducting airways of the nose, pharynx, trachea, bronchi, and bronchioles and does not participate in gas exchange, is referred to as anatomic dead space. A second type of dead space, physiological dead space, consists of the total amount of air that does not participate in gas exchange. It includes the anatomic dead space plus the dead space in alveoli that are perfused, but not ventilated. Physiologic dead space tends to be the same as anatomic dead space in persons with normal respiratory function, but can be considerably larger in the presence of lung disease.

Perfusion

The term perfusion is used to describe the flow of blood through the gas exchange portion of the lung. Deoxygenated blood enters the lung through the pulmonary artery, which has its origin in the right side of the heart and enters the lung at the hilus, along with the primary bronchus. The pulmonary arteries branch in a manner similar to that of the airways. The small pulmonary arteries accompany the bronchus as they move down the lobules and branch to supply the capillary network that surrounds the alveoli (see Fig. 21-7). The oxygenated capillary blood is collected in the small pulmonary veins of the lobules, and then it moves to the larger veins to be collected in the four large pulmonary veins that empty into the left atrium.

The pulmonary blood vessels are thinner, more compliant, and offer less resistance to flow than those in the systemic circulation, and the pressures in the pulmonary system are much lower (e.g., 22/8 mm Hg versus 120/70 mm Hg). The low pressure and low resistance of the pulmonary circulation accommodate the delivery of varying amounts of blood from the systemic circulation without producing signs and symptoms of congestion. The volume in the pulmonary circulation is approximately 500 mL, with approximately 100 mL of this volume located in the pulmonary capillary bed. When the input of blood from the right heart and output of blood to the left heart are equal, pulmonary blood flow remains constant. Small differences between input and output can result in large changes in pulmonary volume if the differences continue for many heartbeats.
The movement of blood through the pulmonary capillary bed requires that the mean pulmonary arterial pressure be greater than the mean pulmonary venous pressure.

**Distribution of Pulmonary Blood Flow**

As with ventilation, the distribution of pulmonary blood flow is affected by body position and gravity. In the upright position, the distance of the upper apices of the lung above the level of the heart may exceed the perfusion capabilities of the mean pulmonary arterial pressure (approximately 12 mm Hg); therefore, blood flow in the upper part of the lungs is less than that in the base. In the supine position, the lungs and the heart are at the same level, and blood flow to the apices and base of the lungs becomes more uniform. In this position, however, blood flow to the posterior or dependent portions (e.g., bottom of the lung when lying on the side) exceeds flow in the anterior or nondependent portions of the lungs.

The alveolar concentration of oxygen also affects pulmonary blood flow. When the concentration of oxygen in air of the alveoli decreases below normal blood, the adjacent blood vessels constrict in an effort to distribute blood where it will be most effectively oxygenated. When alveolar oxygen levels drop below 60 mm Hg, marked vasoconstriction occurs, and at very low oxygen levels, the local flow may be almost abolished. In regional hypoxia, as occurs with a localized airway obstruction (e.g., atelectasis), vasoconstriction is localized to a specific region of the lung. Generalized hypoxia, such as occurs at high altitudes causes vasoconstriction throughout all of the vessels of the lung.

**Shunt**

Shunt refers to blood that moves from the right to the left side of the circulation without being oxygenated. As with dead air space, there are two types of shunts: anatomic and physiologic. In an anatomic shunt, blood moves from the venous to the arterial side of the circulation without moving through the lungs. Anatomic shunting of blood is most commonly due to congenital heart defects (see Chapter 19). In a physiologic shunt, there is mismatching of ventilation and perfusion within the lung, resulting in insufficient ventilation to provide the oxygen needed to oxygenate the blood flowing through the alveolar capillaries. Physiologic shunting of blood usually results from destructive lung disease that impairs ventilation or from heart failure that interferes with movement of blood through sections of the lungs.

**Mismatching of Ventilation and Perfusion**

The gas exchange properties of the lung depend on matching ventilation and perfusion, ensuring that equal amounts of air and blood are entering the respiratory portion of the lungs. Both dead air space and shunt produce a mismatching of ventilation and perfusion, as depicted in Figure 21-16. With shunt (depicted on the

![Figure 21-16](image)

left), there is perfusion without ventilation, resulting in a low ventilation-perfusion ratio. It occurs in conditions such as atelectasis in which there is airway obstruction (see Chapter 23). With dead air space (depicted on the right), there is ventilation without perfusion, resulting in a high ventilation-perfusion ratio. It occurs with conditions such as pulmonary embolism, which impairs blood flow to a part of the lung. The arterial blood leaving the pulmonary circulation reflects mixing of blood from normally ventilated and perfused areas of the lung as well as areas that are not perfused (dead air space) or ventilated (shunt). Many of the conditions that cause mismatching of ventilation and perfusion involve both dead air space and shunt. In chronic obstructive lung disease, for example, there may be impaired ventilation in one area of the lung and impaired perfusion in another area.

**Diffusion**

Diffusion takes place in the respiratory portions of the lung and refers to the movement of gases across the alveolar–capillary membrane. Diffusion of gases in the lung is affected by (1) difference in the pressure of the gas on either side of the membrane, (2) the surface area that is available for diffusion, (3) the thickness of the alveolar–capillary membrane through which the gas must pass, and (4) the diffusion characteristics of the gas. Administration of high concentrations of oxygen increases the difference in partial pressure between the two sides of the membrane and increases the diffusion of the gas. Diseases that destroy lung tissue and the surface area for diffusion and those that increase the thickness of the alveolar–capillary membrane adversely influence the diffusing capacity of the lungs.
For example, the removal of one lung reduces the diffusing capacity by one half. The thickness of the alveolar-capillary membrane and the distance for diffusion are increased in persons with pulmonary edema or pneumonia. The characteristics of the gas and its molecular weight and solubility determine how rapidly the gas diffuses through the respiratory membranes. Carbon dioxide, for example, diffuses 20 times more rapidly than oxygen because of its greater solubility in the respiratory membranes.

**SUMMARY CONCEPTS**

- The primary function of the lungs, which is gas exchange, requires matching of ventilation and perfusion so that equal amounts of air and blood enter the respiratory portion of the lungs.
- Dead air space refers to areas of the lungs that are ventilated but not perfused. The anatomic dead air space represents the volume of air that moves through the conducting airways, but does not participate in air exchange. The physiologic dead space is the total volume of dead air space, including the anatomic dead space and dead space associated with ventilated but unperfused alveoli.
- Shunt refers to blood that moves from the left to the right side of the circulation without being oxygenated. In an anatomic shunt, blood moves directly from the venous to the arterial side of the circulation without moving through the lungs. In a physiologic shunt, there is an absence of ventilation in a perfused portion of the lung.
- Diffusion or movement of gases across the alveolar-capillary membranes of the lung is influenced by the: (1) difference in the partial pressures of the gas on either side of the membrane; (2) surface area available for diffusion; (3) diffusion characteristics of the gas; and (4) thickness of the alveolar-capillary membrane.

**Oxygen and Carbon Dioxide Transport**

Although the lungs are responsible for the exchange of gases with the external environment, it is the blood that transports these gases between the lungs and body tissues. The blood carries oxygen and carbon dioxide in the physically dissolved state and in combination with hemoglobin. Carbon dioxide also is converted to bicarbonate and transported in that form.

Dissolved oxygen and carbon dioxide exert a partial pressure that is designated in the same manner as the partial pressure in the gas state. In the clinical setting, blood gas measurements are used to determine the partial pressure of oxygen (\(P_O_2\)) and carbon dioxide (\(P_CO_2\)) in the blood. Arterial blood commonly is used for measuring blood gases. Venous blood is not used because venous levels reflect the metabolic demands of the tissues rather than the gas exchange function of the lungs. The \(P_O_2\) of arterial blood normally is above 80 mm Hg, and the \(P_CO_2\) is in the range of 35 to 45 mm Hg. Normally, the arterial blood gases are the same or nearly the same as the partial pressure of the gases in the alveoli. The arterial \(P_O_2\) often is written \(PaO_2\), and the alveolar \(P_O_2\) as \(PAO_2\), with the same types of designations being used for \(P_CO_2\). This text uses \(P_O_2\) and \(P_CO_2\) to designate both arterial and alveolar levels of the gases.

**Oxygen Transport**

Oxygen is transported both in the dissolved state and in chemical combination with hemoglobin. Hemoglobin carries about 97% of oxygen in the blood and is the main transporter of oxygen. The remaining 3% of the oxygen is carried in plasma in the dissolved state. Only the dissolved form of oxygen (i.e., \(P_O_2\)) passes through the cell membranes and makes itself available for use in tissue metabolism. The oxygen content of the blood (measured as mL of \(O_2\) per deciliter [dL] or 100 mL of blood) includes both the oxygen carried by hemoglobin and in the dissolved state.

**Hemoglobin Transport**

Hemoglobin is a highly efficient carrier of oxygen. Hemoglobin with bound oxygen is called oxyhemoglobin, and when oxygen is removed, it is called deoxygenated or reduced hemoglobin. Each gram of hemoglobin carries approximately 1.34 mL of oxygen when it is fully saturated. This means that a person with a hemoglobin level of 14 g/dL carries 18.8 mL of oxygen per dL (i.e., \(1.34 \times 14\) g/dL hemoglobin) of blood.

In the lungs, oxygen moves across the alveolar-capillary membrane, through the plasma, and into the red blood cell, where it forms a loose and reversible bond with the hemoglobin molecule. In normal lungs, this process is rapid, so that even with a fast heart rate, the hemoglobin is almost completely saturated with oxygen during the short time it spends in the pulmonary capillaries. As the oxygen moves out of the capillaries in response to the needs of the tissues, the hemoglobin saturation, which usually is approximately 95% to 97% as the blood leaves the left side of the heart, drops to approximately 75% as the mixed venous blood returns to the right side of the heart.

The efficiency of the hemoglobin transport system depends on the ability of the hemoglobin molecule to bind oxygen in the lungs and release it as it is needed in the tissues. Oxygen that remains bound to hemoglobin cannot participate in tissue metabolism.
The term affinity refers to hemoglobin's ability to bind oxygen. Hemoglobin binds oxygen more readily when its affinity is increased and releases it more readily when its affinity is decreased.

The hemoglobin molecule is composed of four polypeptide chains with an iron-containing heme group (see Chapter 14, Fig. 14-2). Because oxygen binds to the iron atom, each hemoglobin molecule can bind four molecules of oxygen when it is fully saturated. Oxygen binds cooperatively with the heme groups on the hemoglobin molecule. After the first molecule of oxygen binds to a heme group, the hemoglobin molecule undergoes a change in shape. As a result, the second and third molecules of oxygen bind more readily, and binding of the fourth molecule is even easier. In a like manner, the unloading of the first molecule of oxygen enhances the unloading of the next molecule and so on. Thus, the affinity of hemoglobin for oxygen changes with hemoglobin saturation.

Hemoglobin's affinity for oxygen is also influenced by pH, carbon dioxide concentration, and body temperature. It binds oxygen more readily under conditions of increased pH (alkalosis), decreased carbon dioxide concentration, and decreased body temperature and it releases it more readily under conditions of decreased pH (acidosis), increased carbon dioxide concentration, and fever. For example, increased tissue metabolism generates carbon dioxide and metabolic acids and thereby decreases the affinity of hemoglobin for oxygen. Heat also is a by-product of tissue metabolism, explaining the effect of fever on oxygen binding.

Red blood cells contain a metabolic intermediate called 2,3-diphosphoglycerate (2,3-DPG) that also affects the affinity of hemoglobin for oxygen. An increase in 2,3-DPG enhances unloading of oxygen from hemoglobin at the tissue level. Conditions that increase 2,3-DPG include exercise, hypoxia that occurs at high altitude, and chronic lung disease.

**Plasma Transport**

The partial pressure (PO₂) of oxygen represents the level of dissolved oxygen in plasma. The amount of dissolved oxygen that is carried in the plasma depends on its partial pressure and its solubility in the plasma. The PO₂ of the arterial blood normally ranges from 85 to 100 mm Hg when breathing room air at 1 atmosphere (760 mm Hg). The solubility of oxygen in plasma is fixed and very small. For every 1 mm Hg of PO₂ present, 0.03 mL of oxygen becomes dissolved in 1 dL of plasma. This means that at a normal arterial PO₂ of 95 mm Hg, about 0.29 mL of oxygen is dissolved in every dL of plasma. Therefore, the amount of oxygen transported in the dissolved state is very small, only about 3% of the total, as compared with the 97% transported by the hemoglobin.

Although the amount of oxygen carried in plasma under normal conditions is small, it can become a lifesaving mode of transport in cases of carbon monoxide poisoning, when most of the hemoglobin sites are occupied by carbon monoxide and are unavailable for transport of oxygen. Carbon monoxide, which combines

---

**FIGURE 21-17. Oxygen-hemoglobin dissociation curve.** (A) Left boxed area represents the steep portion of the curve where oxygen is released from hemoglobin (Hb) to the tissues, and the top boxed area on the plateau of the curve where oxygen is loaded onto hemoglobin in the lung. P₅₀ is the partial pressure of oxygen required to saturate 50% of hemoglobin with oxygen. (B) The effect of body temperature, arterial PCO₂, and pH on hemoglobin affinity for oxygen as indicated by a shift in the curve and position of the P₅₀. A shift of the curve to the right due to an increase in temperature or PCO₂ or a decrease in pH favors release of oxygen to the tissues. A decrease in temperature or PCO₂ or an increase in pH shifts the curve to the left. (C) Effect of anemia on the oxygen-carrying capacity of blood. The hemoglobin can be completely saturated, but the oxygen content of the blood is reduced. (Adapted from Rhoades RA, Tanner GA. Medical Physiology. Boston, MA: Little, Brown; 1996.)

*(text continues on page 533)*
Understanding Oxygen Transport

All body tissues rely on oxygen \((O_2)\) that is transported in the blood to meet their metabolic needs. Oxygen is carried in two forms: dissolved and bound to hemoglobin. About 98% of \(O_2\) is carried by hemoglobin and the remaining 2% is carried in the dissolved state. Dissolved oxygen is the only form that diffuses across cell membranes and produces a partial pressure (\(PO_2\)), which, in turn, drives diffusion. The transport of \(O_2\) involves (1) transfer from the alveoli to the pulmonary capillaries in the lung, (2) hemoglobin binding and transport, and (3) the dissociation from hemoglobin in the tissue capillaries.

1. **Alveoli-to-Capillary Transfer.** In the lung, \(O_2\) moves from the alveoli to the pulmonary capillaries as a dissolved gas. Its movement occurs along a concentration gradient, moving from the alveoli, where the \(PO_2\) is about 100 mm Hg, to the venous end of the pulmonary capillaries with their lesser \(O_2\) concentration and lower \(PO_2\). The dissolved \(O_2\) moves rapidly between the alveoli and the pulmonary capillaries, such that the \(PO_2\) at the arterial end of the capillary is almost if not the same as that in the alveoli.

2. **Hemoglobin Binding and Transport.** Oxygen, which is relatively insoluble in plasma, relies on hemoglobin for transport in the blood. Once oxygen has diffused into the pulmonary capillary, it moves rapidly into the red blood cells and reversibly binds to hemoglobin to form HbO\(_2\). The hemoglobin molecule contains four heme units, each capable of attaching an oxygen molecule. Hemoglobin is 100% saturated when all four units are occupied and is usually about 97% saturated in the systemic arterial blood. The capacity of the blood to carry \(O_2\) is dependent both on hemoglobin levels and the ability of the lungs to oxygenate the hemoglobin.
Oxygen Dissociation in the Tissues. The dissociation or release of O\textsubscript{2} from hemoglobin occurs in the tissue capillaries where the PO\textsubscript{2} is less than that of the arterial blood. As oxygen dissociates from hemoglobin, it dissolves in the plasma and then moves into the tissues where the PO\textsubscript{2} is less than that in the capillaries. The affinity of hemoglobin for O\textsubscript{2} is influenced by the carbon dioxide (PCO\textsubscript{2}) content of the blood and its pH, temperature, and 2,3-diphosphoglycerate (2,3-DPG), a by-product of glycolysis in red blood cells. Under conditions of high metabolic demand, in which the PCO\textsubscript{2} is increased and the pH is decreased, the binding affinity of hemoglobin is decreased, and during decreased metabolic demand, when the PCO\textsubscript{2} is decreased and the pH is increased, the affinity is increased.

Oxygen–Hemoglobin Dissociation Curve

The relationship between the oxygen carried in combination with hemoglobin and the PO\textsubscript{2} of the blood is described by the oxygen–hemoglobin dissociation curve, depicted in Figure 21-17. The x axis of the graph depicts the PO\textsubscript{2} or dissolved oxygen. It reflects the partial pressure of oxygen in the lungs (i.e., the PO\textsubscript{2} ranges from 95 to 100 mm Hg when breathing room air, but can rise to 200 mm Hg or higher when oxygen-enriched air is breathed). The y axis on the left depicts hemoglobin saturation or the amount of oxygen that is carried by hemoglobin. The right y axis depicts oxygen content or total amount of oxygen (i.e., mL O\textsubscript{2}/dL) that is being carried in the blood.

The S-shaped oxygen dissociation curve reflects the effect that oxygen saturation has on the conformation of the hemoglobin molecule and its affinity for oxygen. Its flat upper-right portion represents the binding of oxygen to hemoglobin in the lungs (see Fig. 21-17A). Notice that this plateau occurs at approximately 100 mm Hg PO\textsubscript{2}, at which point the hemoglobin is approximately 98% saturated. Increasing the alveolar PO\textsubscript{2} above this level does not increase hemoglobin saturation. Even at high altitudes, when the partial pressure of oxygen is considerably decreased, the hemoglobin remains relatively well saturated. At 60 mm Hg PO\textsubscript{2}, for example, the hemoglobin is still approximately 89% saturated.

The steeper lower-left portion of the dissociation curve—between 60 and 40 mm Hg PO\textsubscript{2}—represents the removal of oxygen from hemoglobin as it moves through the tissue capillaries. This portion of the curve reflects the fact that there is considerable transfer of oxygen from hemoglobin to the tissues with only a small drop in PO\textsubscript{2}, thereby ensuring a gradient for oxygen to move into body cells. The tissues normally remove approximately 5 mL of oxygen per dL of blood, and the hemoglobin of mixed venous blood is approximately 75% saturated as it returns to the right side of the heart. In this portion of the dissociation curve (saturation <75%), the rate
at which oxygen is released from hemoglobin is determined largely by tissue uptake. During strenuous exercise, for example, the muscle cells may remove as much as 15 mL of oxygen per dL of blood from hemoglobin.

Hemoglobin can be regarded as a buffer system that regulates the delivery of oxygen to the tissues. In order to function as a buffer system, the affinity of hemoglobin for oxygen must change with the metabolic needs of the tissues. This change is represented by a shift to the right or left in the dissociation curve (Fig. 21-17B). A shift to the right indicates that the affinity of hemoglobin for oxygen is increased and the PO\textsubscript{2} that is available to the tissues at any given level of hemoglobin saturation is increased. It usually is caused by conditions that produce an increase in tissue metabolism, such as fever or acidosis, or by an increase in PCO\textsubscript{2}. High altitude and conditions such as pulmonary insufficiency, heart failure, and severe anemia also cause the oxygen dissociation curve to shift to the right. A shift to the left indicates that the affinity of hemoglobin for oxygen is decreased and the PO\textsubscript{2} that is available to the tissues at any given level of hemoglobin saturation is decreased. It occurs in situations associated with a decrease in tissue metabolism, such as alkalosis, decreased body temperature, and decreased PCO\textsubscript{2} levels. The degree of shift can be determined by the P\textsubscript{50}, or the partial pressure of oxygen that is needed to achieve a 50% saturation of hemoglobin. Returning to Figure 22-17B, the dissociation curve on the left has a P\textsubscript{50} of approximately 20 mm Hg; the normal curve, a P\textsubscript{50} of 26; and the curve on the right, a P\textsubscript{50} of 39 mm Hg.

The oxygen content (measured in mL/dL) of blood represents the total amount of oxygen that is carried in the blood, including the dissolved oxygen and that carried by the hemoglobin. It is the oxygen content rather than the PO\textsubscript{2} or hemoglobin saturation that determines the amount of oxygen that is carried in the blood and delivered to the tissues. Thus, an anemic person may have a normal PO\textsubscript{2} and hemoglobin saturation level but decreased oxygen content because of the decreased amount of hemoglobin that is available for binding of oxygen (Fig. 21-17C).

**Carbon Dioxide Transport**

Carbon dioxide is transported in the blood in three forms: dissolved in plasma (10%), attached to hemoglobin (30%), and as bicarbonate (60%). Acid–base balance is influenced by the amount of dissolved carbon dioxide and the bicarbonate level in the blood (see Chapter 8, Understanding Carbon Dioxide Transport).

As carbon dioxide is formed during metabolism, it diffuses out of cells into the tissue spaces and then into the capillaries. The amount of dissolved carbon dioxide that can be carried in plasma is determined by the partial pressure of the gas and its solubility coefficient (0.3 mL/dL blood/mm Hg PCO\textsubscript{2}). Carbon dioxide is 20 times more soluble in plasma than oxygen. Thus, the dissolved state plays a greater role in transport of carbon dioxide compared with oxygen.

Most of the carbon dioxide diffuses into the red blood cells, where either forms carbonic acid or combines with hemoglobin. *Carbonic acid* (H\textsubscript{2}CO\textsubscript{3}) is formed when carbon dioxide combines with water (CO\textsubscript{2} + H\textsubscript{2}O = H\textsuperscript{+} + HCO\textsubscript{3}\textsuperscript{-}). The process is catalyzed by an enzyme called *carbonic anhydrase*, which is present in large quantities in red blood cells. Carbonic anhydrase increases the rate of the reaction between carbon dioxide and water approximately 5000-fold. Carbonic acid readily ionizes to form bicarbonate (HCO\textsubscript{3}\textsuperscript{-}) and hydrogen (H\textsuperscript{+}) ions. The hydrogen ions combine with hemoglobin, which is a powerful acid–base buffer, and the bicarbonate ion diffuses into plasma in exchange for a chloride (Cl\textsuperscript{-}) ion. This exchange is made possible by a special bicarbonate-chloride carrier protein in the red blood cell membrane. As a result of the bicarbonate-chloride shift, the chloride and water content of the red blood cell is greater in venous blood than in arterial blood.

In addition to the carbonic anhydrase-mediated reaction with water, carbon dioxide reacts directly with hemoglobin to form carbaminohemoglobin. The combination of carbon dioxide with hemoglobin is a reversible reaction that involves a loose bond, which allows transport of carbon dioxide from tissues to the lungs, where it is released into the alveoli for exchange with the external environment. The release of oxygen from hemoglobin in the tissues enhances the binding of carbon dioxide to hemoglobin; in the lungs, the combining of oxygen with hemoglobin displaces carbon dioxide.

**Summary Concepts**

- Although the lungs are responsible for the exchange of gases with the environment, it is the blood that transports oxygen from the lungs to the tissues and returns carbon dioxide to the lungs. Most of the oxygen (97% to 99%) in the blood is carried in chemical combination with hemoglobin in red blood cells, with the remaining 1% to 3% being carried in the plasma as a dissolved gas.

- The oxygen dissociation curve is S shaped with a plateau area, above which an increase in dissolved oxygen (PO\textsubscript{2}) has minimal or no effect on hemoglobin saturation. This insures adequate hemoglobin saturation over a wide range of dissolved oxygen values.

- The oxygen content or amount of oxygen that is carried in the blood is equal to amount of oxygen that is carried bound to hemoglobin plus the dissolved form. Since each gram of hemoglobin carries approximately 1.34 mL oxygen, it is the hemoglobin content of the blood rather than the hemoglobin saturation that determines the amount of oxygen that the blood can carry.
Control of Breathing

Unlike the heart, which has inherent rhythmic properties and can beat independently of the nervous system, the muscles that control respiration require continuous input from the nervous system. Movement of the diaphragm, intercostal muscles, sternocleidomastoid, and other accessory muscles that control ventilation is integrated by neurons located in the pons and medulla. These neurons are collectively referred to as the respiratory center (Fig. 21-18).

Respiratory Center

The respiratory center consists of two dense, bilateral aggregates of respiratory neurons involved in initiating inspiration and expiration and incorporating afferent impulses into motor responses of the respiratory muscles. The first, or dorsal, group of neurons is concerned primarily with inspiration. These neurons control the activity of the phrenic nerves that innervate the diaphragm and drive the second, or ventral, group of respiratory neurons. They are thought to integrate sensory input from the lungs and airways into the ventilatory response. The second group of neurons, which contains inspiratory and expiratory neurons, controls the spinal motor neurons of the intercostal and abdominal muscles.

The pacemaker properties of the respiratory center in the medulla result from the cycling of two groups of neurons: the pneumotaxic center in the upper pons and the apneustic center in the lower pons (see Fig. 21-18). The apneustic center has an excitatory effect on inspiration, tending to prolong inspiration. The pneumotaxic center switches inspiration off, assisting in the control of the respiratory rate and inspiratory volume. Brain injury, which damages the connections between the pneumotaxic and apneustic centers, results in an irregular breathing pattern that consists of prolonged inspiratory gasps interrupted by expiratory efforts.

Axons from the neurons in the respiratory center cross in the midline and descend in the ventrolateral columns of the spinal cord. The tracts that control expiration and inspiration are spatially separated in the cord, as are the tracts that transmit specialized reflexes (i.e., coughing and hiccupping) and voluntary control of ventilation. Only at the level of the spinal cord are the respiratory impulses integrated to produce a reflex response.

Carbon dioxide is transported in the blood: (1) as the dissolved gas (10%), (2) attached to hemoglobin (30%), and (3) as bicarbonate (60%). The reversible action of carbon dioxide with water to form bicarbonate is catalyzed by the enzyme carbonic anhydrase within red cells and is the major pathway for generation of bicarbonate.

**FIGURE 21-18.** Schematic representation of activity in the respiratory center. Impulses traveling over afferent neurons (dashed lines) communicate with central neurons, which activate efferent neurons that supply the muscles of respiration. Respiratory movements can be altered by a variety of stimuli.
Regulation of Breathing

The control of breathing has both automatic and voluntary components. Automatic regulation involves afferent input from two types of sensors or receptors: chemoreceptors and lung and chest wall receptors.

Chemoreceptors

Chemoreceptors monitor blood levels of oxygen, carbon dioxide, and pH and adjust ventilation to meet the changing metabolic needs of the body. Input from these sensors is transmitted to the respiratory center, and ventilation is adjusted to maintain the arterial blood gases within a normal range. There are two types of chemoreceptors: central chemoreceptors, located in the brain stem, and peripheral chemoreceptors, located in the carotid arteries and aorta.

Central chemoreceptors are located near the respiratory center in the medulla and are bathed in cerebrospinal fluid (CSF). They are exquisitely sensitive to changes in the PCO$_2$ of the blood perfusing them. Although the central chemoreceptors monitor carbon dioxide levels, the actual stimulus for these receptors is provided by hydrogen ions in the CSF. The CSF is separated from the blood by the blood–brain barrier, which permits free diffusion of carbon dioxide but not hydrogen ions. For this reason, changes in the pH of the blood have considerably less effect in stimulating ventilation than carbon dioxide, which stimulates the central chemoreceptors indirectly by changing the hydrogen ion concentration of the CSF. This occurs as carbon dioxide crosses the blood–brain barrier and rapidly combines with water to form carbonic acid, which then dissociates into bicarbonate and hydrogen ions, with the hydrogen ions producing a direct stimulating effect on respiration. The central chemoreceptors are extremely sensitive to short-term changes in blood PCO$_2$ levels. An increase in the PCO$_2$ of the blood produces an increase in ventilation that reaches its peak within a minute or so and then declines if the PCO$_2$ level remains elevated. Thus, persons with chronically elevated blood PCO$_2$ levels no longer respond to this stimulus for increased ventilation, but rely on the stimulus provided by a decrease in arterial PO$_2$ levels that is sensed by the peripheral chemoreceptors.

The peripheral chemoreceptors, which are located in the bifurcation of the common carotid arteries and in the arch of the aorta, monitor arterial PO$_2$ levels. Although the peripheral chemoreceptors also monitor changes in PCO$_2$ and pH, they play a much more important role in monitoring PO$_2$ levels. These receptors exert little control over ventilation until the PO$_2$ has dropped below 60 mm Hg. Hypoxia is the main stimulus for ventilation in persons with chronically elevated levels of carbon dioxide. If these patients are given oxygen therapy at a level sufficient to increase the PO$_2$ above that needed to stimulate the peripheral chemoreceptors, their ventilation may be seriously depressed.

Lung and Chest Wall Receptors

Lung receptors monitor the status of breathing in terms of airway resistance and lung expansion. There are three types of lung receptors: stretch, irritant, and juxtacapillary receptors. Receptors in the joints, tendons, and muscles of the chest wall structures may also play a role in breathing, particularly when quiet breathing is called for or when breathing efforts are opposed by increased airway resistance or reduced lung compliance.

Stretch receptors are located in the smooth muscle layers of the conducting airways. They respond to changes in pressure in the walls of the airways. When the lungs are inflated, these receptors inhibit inspiration and promote expiration. They are important in establishing breathing patterns and minimizing the work of breathing by adjusting respiratory rate and TV to accommodate changes in lung compliance and airway resistance.

The irritant receptors are located between the airway epithelial cells. They are stimulated by noxious gases, cigarette smoke, inhaled dust, and cold air. Stimulation of the irritant receptors leads to airway constriction and a pattern of rapid, shallow breathing. This pattern of breathing probably protects respiratory tissues from the damaging effects of toxic inhalants. It also is thought that the mechanical stimulation of these receptors may ensure more uniform lung expansion by initiating periodic sighing and yawning. It is possible that these receptors are involved in the bronchoconstriction response that occurs in some persons with bronchial asthma.

The juxtacapillary or J receptors are located in the alveolar wall, close to the pulmonary capillaries. It is thought that these receptors sense lung congestion. These receptors may be responsible for the rapid, shallow breathing that occurs with pulmonary edema, pulmonary embolism, and pneumonia.

Voluntary Regulation of Ventilation

Voluntary regulation of ventilation integrates breathing with voluntary acts such as speaking, blowing, and singing. These acts, which are initiated by the motor and premotor cortex, cause a temporary suspension of automatic breathing. The automatic and voluntary components of respiration are regulated by afferent impulses that are transmitted to the respiratory center from a number of sources. Afferent input from higher brain centers is evidenced by the fact that a person can consciously alter the depth and rate of respiration. Fever, pain, and emotion exert their influence through lower brain centers. Vagal afferents from sensory receptors in the lungs and airways are integrated in the dorsal area of the respiratory center.

Cough Reflex

Coughing is a neurally mediated reflex that protects the lungs from the accumulation of secretions and from entry of irritating and destructive substances. It is one of the primary defense mechanisms of the respiratory tract. The cough reflex is initiated by receptors located in the tracheobronchial wall, receptors that are extremely sensitive to irritating substances and the presence of excess secretions. Afferent impulses from these receptors are transmitted through the vagus to the medullary center, which integrates the cough response.
Dyspnea

Dyspnea is the perceived shortness of breath or difficulty breathing. It may occur at rest or with exertion, be continuous or intermittent, or have a pattern of acute or chronic occurrences. Dyspnea may occur in otherwise healthy persons, as during exercise or exposure to low ambient levels of oxygen. It is a common complaint of persons with primary lung diseases such as pneumonia, asthma, and emphysema; heart disease that is characterized by pulmonary congestion; and neuromuscular disorders such as myasthenia gravis and muscular dystrophy that affect the respiratory muscles.

The physiological mechanisms underlying the sensation of dyspnea remain elusive. Dyspnea is not a single phenomenon. There are at least three varieties of breathing difficulty—air hunger, labored breathing, and chest tightness. The sensation of air hunger is thought to be mediated by transmission of excessive chemoreceptor stimulation of the medullary respiratory center to sensory centers in the forebrain. Labored breathing, a sensation of working hard to breathe, is a common complaint of persons with weakened respiratory muscles. It is thought to be mediated by excessive input from stretch receptors in the chest muscles or chest wall. The sensation of chest tightness, an early symptom of an asthmatic attack, appears to be related to input from lung receptors that monitor bronchial constriction. In contrast, the dyspnea that accompanies pulmonary congestion due to heart failure appears to be related to input from lung receptors that monitor vascular distention (i.e., the previously described J receptors). More than one mechanism may be responsible for the dyspnea seen in a particular disease state. For example, severe flow limitations in chronic pulmonary disease can produce stimuli that give rise to the sensation of increased breathing difficulty, and the presence of hypoxia and/or hypercapnia may produce the sensation of air hunger.

Like other subjective symptoms, such as fatigue and pain, dyspnea is difficult to quantify because it relies on a person’s perception of the problem. Like pain, dyspnea is also a multidimensional sensation, involving the sensation of both sensory intensity (i.e., work of breathing) and unpleasantness (i.e., air hunger or chest tightness). A commonly used method for assessing dyspnea is a retrospective determination of the level of daily activity at which dyspnea is experienced. The visual analog scale may be used to assess breathing difficulty that occurs with a given activity, such as walking a certain distance. The visual analog scale consists of a line (often 10 cm in length) with descriptors such as “easy to breathe” on one end and “very difficult to breathe” on the other.

The treatment of dyspnea depends on the cause. For example, persons with impaired respiratory function may require oxygen therapy, and those with pulmonary edema may require measures to improve heart function. Methods to decrease anxiety, breathing retraining, and energy conservation measures may be used to decrease the subjective sensation of dyspnea.

SUMMARY CONCEPTS

- Pulmonary ventilation or the act of breathing involves movement of the diaphragm, intercostal muscles, and other respiratory muscles. These muscles are controlled by neurons of respiratory centers in the pons and medulla with input from higher brain centers and peripheral receptors.

- Control of breathing has both automatic and voluntary components. The automatic regulation of ventilation is controlled by two types of receptors: chemoreceptors, which monitor blood levels of carbon dioxide, oxygen, and pH; and lung receptors, which monitor the status of breathing in terms of airway resistance and lung expansion. Voluntary respiratory control is needed for integrating breathing and actions such as speaking, blowing, and singing. These acts, which are initiated by the motor and premotor cortex, cause temporary suspension of automatic breathing.
SUMMARY CONCEPTS (continued)

- The cough reflex protects the lungs from the accumulation of secretions and from the entry of irritating and destructive substances; it is one of the primary defense mechanisms of the respiratory tract.
- Dyspnea is a subjective sensation of difficulty in breathing that is seen in cardiac, pulmonary, and neuromuscular disorders. It can present as air hunger brought about by inadequate ventilation, labored or difficult breathing due to weakened respiratory muscles, or chest tightness that occurs with bronchoconstriction.

REVIEW EXERCISES

1. Relate the efficiency and work of breathing to changes in the tidal volume and respiratory rate observed in persons with:
   A. Decreased lung compliance in fibrotic lung disease
   B. Increased airway resistance in emphysema.

2. Use the solubility coefficient for oxygen and the oxygen-hemoglobin dissociation curve depicted in Figure 22-17 to answer the following questions:
   A. What is the hemoglobin saturation at a high altitude in which the barometric pressure is 500 mm Hg (consider oxygen to represent 21% of the total gases)?
   B. It is usually recommended that the hemoglobin saturation of persons with chronic lung disease be maintained at about 89% when they are receiving supplemental low-flow oxygen. What would their PO\textsubscript{2} be at this level of hemoglobin saturation, and what is the rationale for keeping the PO\textsubscript{2} at this level?
   C. Why are measures of hemoglobin saturation not necessarily a good measure of the oxygen-carrying capacity of blood?
   D. What is the oxygen content of a person with carbon monoxide poisoning who is receiving 100% oxygen at 3 atmospheres pressure in a hyperbaric chamber? Consider that most of the person’s hemoglobin is saturated with carbon dioxide.

3. Describe the receptor/s (peripheral and central), afferent pathways, central integration, and efferent neural pathways that:
   A. Determine the tidal volume and respiratory rate of the minute volume
   B. Participate in the cough reflex
   C. Contribute to the breathlessness that accompanies intensive exercise and the dyspnea that accompanies lung disease.

Respiratory Tract Infections, Neoplasms, and Childhood Disorders

Respiratory illnesses represent one of the more common reasons for visits to the physician, admission to the hospital, and forced inactivity among all age groups. The common cold, although not usually serious, results in missed work and school days. Pneumonia and influenza are ranked as the eighth leading cause of death in the United States. Tuberculosis remains one of the deadliest diseases in the world. In addition to microbial pathogens, cigarette smoking contributes significantly to disorders of the respiratory tract, including lung cancer. The content in this chapter is divided into three sections: respiratory tract infections, cancer of the lung, and respiratory disorders in children.

Respiratory Tract Infections

Respiratory tract infections can involve the upper respiratory tract (i.e., nose, oropharynx, and larynx), the lower respiratory tract (i.e., lower airways and lungs), or both. The discussion in this section of the chapter focuses on the common cold, rhinosinusitis, influenza, pneumonia, tuberculosis, and fungal infections of the lung. For the most part, the signs and symptoms of respiratory tract infections depend on the function of the structure involved, the severity of the infectious process, and the person’s general health status and age. Acute respiratory infections in children are discussed in the last section of the chapter.

Viruses are the most frequent cause of respiratory tract infections. They can cause infections ranging from a self-limited cold to life-threatening pneumonia. Moreover, viral infections can damage the bronchial epithelium, obstruct airways, and lead to secondary bacterial infections. Each viral species has its own pattern of respiratory tract involvement. The rhinoviruses grow best at 33°C and remain strictly confined to the
upper respiratory tract. The influenza virus can infect both the upper and lower respiratory tracts. Bacteria can infect the nose and sinuses, and both bacteria and fungi can produce infections of the lung, many of which cause significant morbidity and mortality.

The Common Cold

The common cold is a viral infection of the upper respiratory tract. It occurs more frequently than any other respiratory tract infection. Most adults have two to three colds per year, whereas the average school child may have up to 12 per year. The condition usually begins with a sore and scratchy throat followed by profuse and watery rhinorrhea, nasal congestion, sneezing, and coughing. Other cold symptoms include malaise, fatigue, headache, hoarseness, sinus congestion, and myalgia. Fever is a common sign in children but is an infrequent finding in adults. The disease process is self-limited, usually lasting up to 10 days.

Initially thought to be caused by either a single “cold virus” or group, the common cold is now recognized to be associated with many different viruses. The most common are the rhinoviruses, parainfluenza viruses, respiratory syncytial virus, coronavirus, and adenoviruses. Of these, the rhinoviruses are the most common cause of colds in persons between 5 and 40 years of age. In children younger than 3 years of age, infections from the respiratory syncytial virus and parainfluenza viruses are most common.

The “cold viruses” are rapidly spread from person to person. Children are the main source of infection often acquiring a new strain of the virus from another child in school or day care. The fingers are the greatest source of spread, and the nasal mucosa and conjunctival surface of the eyes are the most common portals for entry of the virus. The most highly contagious period is during the first 3 days after the onset of symptoms, and the incubation period is approximately 5 days. Cold viruses have been found to survive for more than 5 hours on the skin and hard surfaces, such as plastic countertops. Aerosol spread of colds through coughing and sneezing is much less important than the spread by fingers picking up the virus from contaminated surfaces and carrying it to the nasal membranes and eyes. This suggests that careful attention to hand washing is one of the most important preventive measures for avoiding the common cold.

Because the common cold is an acute and self-limited illness in persons who are otherwise healthy, symptomatic treatment with rest and antipyretic drugs is usually all that is needed. Antibiotics are ineffective against viral infections and are not recommended. Over-the-counter (OTC) remedies are available for treating the symptoms of a common cold. Antihistamines are popular OTC drugs because of their action in drying nasal secretions. Although they do not work as a monotherapy, a first-generation antihistamine in combination with a decongestant may be slightly beneficial in relieving general symptoms, nasal congestion, and cough. However, there is no evidence that they shorten the duration of the cold. They are not recommended for use in children. Decongestant drugs (i.e., sympathomimetic agents) are available in OTC nasal sprays, drops, and oral cold medications. These drugs constrict the blood vessels in the nasal mucosa and reduce nasal swelling. Rebound nasal swelling can occur with indiscriminate or chronic use of nasal drops and sprays. Oral preparations containing decongestants may cause systemic vasoconstriction and elevation of blood pressure when given in doses large enough to relieve nasal congestion, and they should be avoided in persons with hypertension, heart disease, hyperthyroidism, diabetes mellitus, or other health problems.

Rhinosinusitis

The term rhinitis refers to an inflammation of the nasal passages and sinusitis to an inflammation of the paranasal sinuses. Although it has not been universally accepted, the suggestion has been made that the term rhinosinusitis is a more accurate term for what is commonly referred to as sinusitis, because the mucosa of the nasal cavities and paranasal sinuses are lined with a continuous mucous membrane layer and sinusitis rarely occurs in the absence of infectious or allergic rhinitis.

The paranasal sinuses are air-filled extensions of the respiratory part of the nasal cavities into the frontal, ethmoid, sphenoid, and maxilla bones (Fig. 22-1A). The sinuses, which are named for the bones in which they are found, are connected by narrow openings or ostia with the superior, middle, and inferior nasal turbinates of the nasal cavity. The anterior ethmoid, frontal, and maxillary sinuses all drain into the nasal cavity through a relatively convoluted and narrow passage called the ostiomeatal complex (see Fig. 22-1B). The sphenoidal sinuses drain from a separate complex between the sphenoid and the superior turbinate (see Fig. 22-1C).

The most common causes of rhinosinusitis are conditions that obstruct the narrow ostia that drain the sinuses. Most commonly, rhinosinusitis develops when a viral upper respiratory tract infection or allergic rhinitis obstructs the ostiomeatal complex and impairs the mucociliary clearance mechanism. Nasal polyps also can obstruct the sinus openings and facilitate sinus infection. Infections associated with nasal polyps can be self-perpetuating because constant irritation from the infection can facilitate polyp growth. Barotrauma caused by changes in barometric pressure, as occurs in airline pilots and flight attendants, may lead to impaired sinus ventilation and clearance of secretions. Swimming, diving, and abuse of nasal decongestants are other causes of sinus irritation and impaired drainage. Maxillary sinusitis may result from dental infection, and teeth that are tender should be carefully examined for signs of an abscess.

Clinical Features

Rhinosinusitis can be classified as acute, subacute, or chronic. Acute viral rhinosinusitis may last from 5 to 7 days and acute bacterial rhinosinusitis up to 4 weeks. Subacute rhinosinusitis lasts from 4 weeks to less than 12 weeks, whereas chronic rhinosinusitis lasts beyond 12 weeks.
Acute rhinosinusitis may be of viral, bacterial, or viral–bacterial etiology. In most cases, bacterial infection is preceded by a viral upper respiratory infection, which in turn leads to inflammation and obstruction of the ostiomeatal complex. Rhinovirus is the most common viral pathogen. *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Moraxella catarrhalis* make up the majority of community-acquired bacterial pathogens.

In contrast to acute infections, the pathogens found in chronic rhinosinusitis are usually a mixture of aerobic and anaerobic bacteria, including *Staphylococcus aureus*, coagulase-negative *Staphylococcus*, and anaerobic gram-negative bacilli. Although the mechanisms that contribute to the chronicity of the disorder are uncertain, mucociliary dysfunction, mucostasis, hypoxia, and release of microbial products are thought to play a role. Allergies may also play an important role in the pathogenesis of chronic rhinosinusitis. In immunocompromised persons, such as those with human immunodeficiency virus (HIV) infection, the sinuses may become infected with gram-negative species and opportunistic fungi. In persons in this group, particularly those with leukopenia, the disease may have a fulminating and even fatal course.

**Manifestations.** The symptoms of acute viral rhinosinusitis often are similar to those of the common cold and allergic rhinitis (discussed in Chapter 16). They include facial pain, headache, purulent nasal discharge, decreased sense of smell, and fever. A history of a preceding common cold and the presence of purulent nasal drainage, pain on bending, unilateral maxillary pain, and pain in the teeth are common findings with involvement of the maxillary sinuses. The symptoms of acute viral rhinosinusitis usually resolve within 5 to 7 days without medical treatment. Acute bacterial rhinosinusitis is suggested by symptoms that worsen after 5 to 7 days or persist beyond 10 days, or symptoms that are out of proportion to those usually associated with a viral upper respiratory tract infection. Persons who are immunocompromised, such as those with leukemia, aplastic anemia, bone marrow transplant, or HIV infection, may present with fever of unknown origin, rhinorrhea, or facial edema. Often, other signs of inflammation such as purulent drainage are absent.

In persons with chronic rhinosinusitis, the only symptoms may be nasal obstruction, a sense of fullness in the ears, postnasal drip, hoarseness, chronic cough, and loss of taste and smell. Sinus pain often is absent; instead, the person may complain of a headache that is dull and constant. Persons with chronic rhinosinusitis may have superimposed bouts of acute rhinosinusitis. The mucosal changes that occur during acute and subacute forms of rhinosinusitis are usually reversible; whereas, those that occur during chronic rhinosinusitis may be irreversible.

**Diagnosis.** The diagnosis of rhinosinusitis usually is based on symptom history and a physical examination that includes inspection of the nose and throat. Headache due to sinusitis needs to be differentiated from other types of headache. Sinusitis headache usually is exaggerated by bending forward, coughing, or sneezing. Physical examination findings in acute bacterial sinusitis include turbinate edema, nasal crusts, purulent drainage, and failure of transillumination of the maxillary sinuses. Transillumination is done in a completely darkened room by placing a flashlight against the skin overlying the infraorbital rim, directing the light inferiorly, having the
person open his or her mouth, and observing the hard palate for light transmission. Sinus radiographs and computed tomography (CT) scans may be used. CT scans usually are reserved for diagnosis of chronic rhinosinusitis or to exclude complications.\(^7\)\(^8\) Magnetic resonance imaging (MRI) is expensive and usually reserved for cases of suspected neoplasms or fungal sinusitis.

**Treatment.** Treatment of rhinosinusitis depends on the cause and includes appropriate use of antibiotics, intranasal corticosteroids, mucolytic agents, and symptom relief measures.\(^7\)\(^8\) Antibiotics are usually reserved for persons with severe or persistent symptoms and specific findings of bacterial infection. The treatment of acute rhinosinusitis includes measures to promote adequate drainage by reducing nasal congestion. The topical \(\alpha\)-adrenergic decongestants may be used on a short-term (3 days) basis in older children and adults for this purpose. The use of antihistamines is controversial, particularly for acute rhinosinusitis, because they can dry up secretions and thereby decrease drainage. Mucolytic agents such as guaifenesin may be used to thin secretions. Intranasal corticosteroids reduce inflammation and edema of the nasal mucosa, nasal turbinate, and sinus ostia. They may be used as an initial treatment in persons with acute rhinosinusitis and in those with both allergies and rhinosinusitis.\(^7\)\(^8\) Nonpharmacologic measures include saline nasal sprays and steam inhalation. Surgical intervention directed at correcting obstruction of the ostiomeatal openings may be indicated in persons with chronic rhinosinusitis that is resistant to other forms of therapy. Indications for surgical intervention include obstructive nasal polyps and obstructive nasal deformities.

**Complications.** Because of the sinuses’ proximity to the brain and orbital wall, sinusitis can lead to intracranial and orbital wall complications. Intracranial complications are seen most commonly with infection of the frontal and ethmoid sinuses because of their proximity to the dura and drainage of the veins from the frontal sinus into the dural sinus. Orbital complications can range from edema of the eyelids to orbital cellulitis and subperiosteal abscess formation. Facial swelling over the involved sinus, abnormal extraocular movements, protrusion of the eyeball, periorbital edema, or changes in mental status may indicate intracranial complications and require immediate medical attention.

**Influenza**

Influenza is one of the most important causes of acute upper respiratory tract infection in humans. Until the advent of acquired immunodeficiency syndrome (AIDS), influenza was the last uncontrolled, potentially fatal pandemic. In the United States, epidemics of influenza typically occur during the winter months, accounting for over 35,000 deaths annually.\(^13\) Rates of infection are highest among children, but rates of serious illness and death are highest among persons who are 65 years of age or older.

**Etiology**

Influenza is caused by viruses belonging to the Orthomyxoviridae family, whose members are characterized by a segmented, single-stranded ribonucleic acid (RNA) genome.\(^13\)\(^15\) There are three distinct types of influenza viruses, designated A, B, and C. Influenza A and B cause epidemics. Influenza C does not cause epidemics, but is responsible for mild upper respiratory infections in children and adults.

Influenza A viruses are further categorized into subtypes based on two glycoproteins studding their lipid envelope: hemagglutinin (H) and neuraminidase (N) (Fig. 22-2). Hemagglutinin, for which there are 16 different variants (H1 thru H16), allows the virus to anchor to the surface of epithelial cells in the respiratory tract; and neuraminidase, of which there are 9 variants (N1 thru N9), allows for digestion of host secretion and, later, release of viral particles from host cells.\(^13\) For example, an influenza virus circulating worldwide in 2013 was identified as H3N2. Immunity to the surface H and N antigens reduces the likelihood and severity of infection with the influenza virus.

Epidemics and pandemics result from the ability of the influenza virus to develop new subtypes against which the population is not protected.\(^13\)\(^15\) The genetic diversity of influenza A is fostered by its segmented genomic structure and ability to infect and replicate in humans and many avian and animal species, including swine. Epidemics of influenza A occur when minor changes in the amino acids of the H and N glycoproteins, called antigenic drift, generate a new subtype to which the population is only partially protected by cross-reacting antibodies. Pandemics occur when a process called an antigenic shift causes both the H and N antigens to be replaced through recombination of the RNA segments with those of animal viruses, making all individuals susceptible to the new influenza virus.

As with many viral respiratory tract infections, influenza is more contagious than bacterial respiratory tract infections. In contrast to the rhinoviruses, transmission occurs by inhalation of droplet nuclei rather than touching contaminated objects. Adults are usually considered infectious from the day before symptom onset to 5 to 10 days after the first symptoms appear.\(^15\) Children can be infectious for greater than 10 days, and young children can shed virus for up to 6 days before their illness onset. Severely immunocompromised persons can shed virus for weeks or months.

**Pathogenesis**

The Influenza viruses can cause three types of infections: an uncomplicated upper respiratory infection (rhinitis), viral pneumonia, and a respiratory viral infection followed by a bacterial infection. Influenza initially establishes upper airway infection. In doing this, the virus first targets and kills mucus-secreting, ciliated, and other epithelial cells, leaving gaping holes between the underlying basal cells and allowing extracellular fluid to escape. This is the reason for the rhinorrhea or “runny nose” that is characteristic of this phase of the infection.
If the virus spreads to the lower respiratory tract, the infection can cause severe shedding of bronchial and alveolar cells. In addition to compromising the natural defenses of the respiratory tract, influenza infection promotes bacterial adhesion to epithelial cells.

**Manifestations**

In the early stages, the symptoms of influenza often are indistinguishable from other viral infections. There is an abrupt onset of fever and chills; malaise; muscle aching; headache; profuse, watery nasal discharge; nonproductive cough; and sore throat.\(^{15-17}\) One distinguishing feature of an influenza viral infection is the rapid onset, sometimes in as little as minutes, of profound malaise. The symptoms of uncomplicated rhinotracheitis usually peak by days 3 to 5 and disappear by days 7 to 10. Weakness, cough, and malaise may persist for weeks after clinical resolution of influenza. Young children with influenza viral infection can have initial symptoms mimicking bacterial sepsis with high fevers and febrile convulsions.

Viral pneumonia occurs as a complication of influenza, most frequently in the elderly or in persons with cardiopulmonary disease, but has been reported in pregnant women and in healthy, immunocompetent people.\(^{18}\) It typically develops within 1 day after onset of influenza and is characterized by rapid progression of fever, tachypnea, tachycardia, cyanosis, and hypotension. The clinical course of influenza pneumonia progresses rapidly. It can cause hypoxemia and death within a few days of onset. Survivors often develop diffuse pulmonary fibrosis.

Secondary complications typically include sinusitis, otitis media, bronchitis, and bacterial pneumonia.\(^{15}\) Persons who develop secondary bacterial pneumonia usually report that they were beginning to feel better when they experienced a return of fever, shaking chills, pleuritic chest pain, and productive cough. The most common causes of secondary bacterial pneumonia are *S. pneumoniae, S. aureus, H. influenzae,* and *M. catarrhalis.*

This form of pneumonia commonly produces less cyanosis and tachypnea and is usually milder than primary influenza pneumonia. Influenza-related deaths can result from pneumonia as well as exacerbations of cardiopulmonary conditions and other disease. Reye syndrome (fatty liver with encephalitis) is a rare complication of influenza, particularly in young children who have been given aspirin as an antipyretic agent.\(^{15}\)

**Diagnosis and Treatment**

Diagnosis is based on symptoms such as sudden onset of fever, cough, weakness, and myalgias. The probability of influenza varies with the prevalence of the disease in
the community and with the vaccination status of the person. Nationally, influenza-like illnesses usually hit a peak between January and March.

The appropriate treatment of people with influenza depends on accurate and timely diagnosis. The early diagnosis can reduce the inappropriate use of antibiotics and provide the opportunity for use of an antiviral drug.\textsuperscript{15–17} Rapid diagnostic tests, which are available for use in outpatient settings, allow health care providers to diagnose influenza more accurately, consider treatment options more carefully, and monitor the influenza type and its prevalence in their community.\textsuperscript{18}

The goals of treatment for influenza are designed to limit the infection to the upper respiratory tract. The symptomatic approach for treatment of uncomplicated influenza rhinotracheitis focuses on rest, keeping warm, and drinking large amounts of liquids. Analgesics and cough medications can also be used. Rest decreases the oxygen requirements of the body and reduces the respiratory rate and the chance of spreading the virus from the upper to lower respiratory tract. Keeping warm helps maintain the respiratory epithelium at a core body temperature of 37°C (98.6°F) or higher if fever is present, thereby inhibiting viral replication, which is optimal at 35°C (96°F). Drinking large amounts of fluids ensures that the function of the epithelial lining of the respiratory tract is not further compromised by dehydration. Antiviral medications may be indicated in some persons. Antibacterial antibiotics should be reserved for bacterial complications. The use of aspirin to treat fever should be avoided in children because of the risk of Reye syndrome.

Two antiviral drugs are available for treatment of influenza: Zanamivir (Relenza) and oseltamivir (Tamiflu) are inhibitors of neuraminidase, the glycoprotein necessary for viral replication and release. These drugs, which have been approved for treatment of acute uncomplicated influenza infection, are effective against both influenza A and B viruses. Zanamivir is administered intranasally and oseltamivir is administered orally. Zanamivir can cause bronchospasm and is not recommended for persons with asthma or chronic obstructive lung disease. To be effective, the antiviral drugs should be initiated within 36 hours after onset of symptoms.\textsuperscript{15,16}

Influenza Immunization

Because influenza is so highly contagious, prevention relies primarily on vaccination. Currently, a trivalent inactivated influenza vaccine (TIIV) and a live attenuated influenza vaccine (LAIV3) are available.\textsuperscript{19} A quadrivalent live attenuated influenza vaccine (LAIV4), which contains an additional B-type strain of the virus, is expected to replace the trivalent formulation. A quadrivalent inactivated influenza vaccine will also be available, in addition to the trivalent vaccine.\textsuperscript{19}

The formulation of the vaccines must be changed yearly in response to antigenic changes in the influenza virus. The Centers for Disease Control and Prevention (CDC) Advisory Committee on Immunization Practices (ACIP) annually updates its recommendations for the composition of the vaccine. The effectiveness of the influenza vaccine in preventing and reducing the severity of influenza infection depends primarily on the age and immunocompetence of the recipient and the match between the virus strains included in the vaccine and those that circulate during the influenza season. The influenza vaccines are contraindicated in persons with anaphylactic hypersensitivity to eggs or to other components of the vaccine, persons with a history of Guillain-Barré syndrome, and persons with acute febrile illness.\textsuperscript{19}

The TIIV, which is administered by injection, has become the mainstay for prevention of influenza. It has proved to be inexpensive and effective in reducing illness caused by influenza. Immunization may be used for any person 6 months of age or older, including those with high-risk conditions. It is recommended for all persons older than 50 years of age, persons with chronic health problems or who have immunodeficiencies (such as HIV infection), residents of nursing homes and other chronic-care facilities, women who are pregnant during the influenza season, health care providers, and household contacts or caregivers of persons who put them at higher risk for severe complications of influenza.\textsuperscript{19}

The LAIVs, which are administered nasally, are cold-adapted viruses that replicate efficiently in the 25°C temperatures of the nasopharynx, inducing protective immunity against viruses included in the vaccine, but replicate inefficiently at the 38°C to 39°C temperature of the lower airways. Live attenuated influenza vaccine is an option for vaccination of healthy, nonpregnant persons, 2 to 49 years who do not have a medical condition that predisposes them to medical complications from influenza.\textsuperscript{19}

Pneumonias

The term pneumonia describes inflammation of the parenchymal structures of the lung, such as the alveoli and bronchioles. Although antibiotics have significantly reduced the mortality rate from pneumonias, these diseases remain a leading cause of morbidity and mortality worldwide, particularly among the elderly and those with debilitating diseases. Etiologic agents include both infectious and noninfectious agents.

Classification

Pneumonias can be commonly classified according to the type of agent (typical or atypical) causing the infection, and distribution of the infection (lobar pneumonia or bronchopneumonia). Because of the overlap in symptomatology and changing spectrum of infectious organisms involved, pneumonias are increasingly being classified as community-acquired and hospital-acquired (nosocomial) pneumonias, depending on the setting in which they occur. Persons with compromised immune function constitute a special concern in both categories.

Typical pneumonias result from infection by bacteria that multiply extracellularly in the alveoli and cause inflammation and exudation of fluid into the air-filled alveolar spaces (Fig. 22-3A). Atypical pneumonias are caused by viral and mycoplasma infections that invade...
the alveolar septum and the interstitium of the lung (Fig. 22-3B). They produce less striking symptoms and physical findings than bacterial pneumonia; there is a lack of alveolar infiltration and purulent sputum, leukocytosis, and lobar consolidation on the radiograph. Acute bacterial pneumonias can be classified as lobar pneumonia or bronchopneumonia, based on their anatomic pattern of distribution. \(^{14}\) In general, lobar pneumonia refers to consolidation of a part or all of a lung lobe, and bronchopneumonia signifies a patchy consolidation involving more than one lobe (Fig. 22-4).

**Community-Acquired Pneumonia.** The term community-acquired pneumonia is used to describe infections from organisms found in the community rather than in the hospital or nursing home. It is defined as an infection that begins outside the hospital or is diagnosed within 48 hours after admission to the hospital in a person who has not resided in a long-term care facility for 14 days or more before admission. \(^{20,23}\) Community-acquired pneumonia may be further categorized according to risk of mortality and need for hospitalization based on age, presence of coexisting disease, and severity of illness, using physical examination, laboratory, and radiologic findings.

Community-acquired pneumonia may be either bacterial or viral. \(^{14,20,23}\) The most common cause of infection in all categories is *S. pneumoniae*. Other common pathogens include *H. influenzae*, *S. aureus*, and gram-negative bacilli. Less common agents are *Mycoplasma pneumoniae*, *Chlamydia* species, and viruses, sometimes called *atypical agents*. Common viral causes of community-acquired pneumonia include the influenza virus, respiratory syncytial virus, adenovirus, and parainfluenza virus.

The methods used in the diagnosis of community-acquired pneumonia depend on age, coexisting health problems, and the severity of illness. In persons younger than 65 years of age and without coexisting disease, the diagnosis usually is based on history and physical examination, chest radiographs, and knowledge of the microorganisms currently causing infections in the community. Sputum specimens may be obtained for staining procedures and culture. Blood cultures may be done for persons requiring hospitalization.

Treatment involves the use of appropriate antibiotic therapy. Empiric antibiotic therapy, based on knowledge regarding an antibiotic’s spectrum of action and ability to penetrate bronchopulmonary secretions, is often used for persons with community-acquired pneumonia who do not require hospitalization. Hospitalization and more intensive care may be required depending on the person’s age, preexisting health status, and severity of the infection.

**Hospital-Acquired Pneumonia.** Hospital-acquired, or nosocomial, pneumonia is defined as a lower respiratory tract infection that was not present or incubating on admission to the hospital. Usually, infections occurring 48 hours or more after admission are considered hospital acquired. \(^{14,24,25}\) Persons requiring intubation and mechanical ventilation are particularly at risk, as are those with compromised immune function, chronic lung disease, and airway instrumentation, such as endotracheal intubation or tracheotomy. Ventilator-associated pneumonia is pneumonia that develops in mechanically ventilated patients more than 48 hours after intubation.
Most hospital-acquired infections are bacterial. The organisms differ from those responsible for community-acquired pneumonias, and reflect those present in the hospital environment. Gram-negative rods (Enterobacteriaceae and Pseudomonas species) and S. aureus are the most common isolates. Many of these organisms have acquired antibiotic resistance and are thus difficult to treat.

**Pneumonia in Immunocompromised Persons.** Pneumonia in immunocompromised persons remains a major source of morbidity and mortality. Although almost all types of microorganisms can cause pulmonary infection in immunocompromised persons, certain types of immunologic defects tend to favor certain types of infections. Defects in humoral immunity predispose to bacterial infections against which antibodies play an important role, whereas defects in cellular immunity predispose to infections caused by viruses, fungi, mycobacteria, and protozoa. Neutropenia and impaired granulocyte function, as occur in persons with leukemia or bone marrow depression as well as persons undergoing chemotherapy, predispose to infections caused by S. aureus, Aspergillus, gram-negative bacilli, and Candida. The time course of infection often provides a hint to the type of agent involved. A fulminating pneumonia usually is caused by bacterial infection, whereas an insidious onset usually is indicative of a viral, fungal, protozoal, or mycobacterial infection.

**Acute Bacterial (Typical) Pneumonia**

Bacterial pneumonias remain an important cause of mortality among the elderly and debilitated. The lungs below the main bronchi is normally sterile despite frequent entry of microorganisms into the air passages by inhalation during ventilation or aspiration of nasopharyngeal secretions. Most people unknowingly aspirate small amounts of organisms that have colonized their upper airways, particularly during sleep. These organisms do not normally cause infection because of the small number that are aspirated and because the respiratory tract’s defense mechanisms prevent them from entering the distal air passages (Table 22-1). Loss of the cough reflex, damage to the ciliated endothelium that lines the respiratory tract, or impaired immune defenses predispose to colonization and infection of the lower respiratory system. Bacterial adherence also plays a role in colonization of the lower airways. The epithelial cells of critically and chronically ill persons are more receptive to binding microorganisms that cause pneumonia. Other clinical risk factors favoring colonization of the tracheobronchial tree include antibiotic therapy that alters the normal bacterial flora, diabetes, smoking, chronic bronchitis, and viral infection.

Bacterial pneumonias are commonly classified according to etiologic agent. This is because the clinical and morphologic features, and thus the therapeutic implications, often vary with the causative agent. The discussion in this section focuses on two types of bacterial pneumonia: pneumococcal pneumonia and Legionnaires’ disease.

**Pneumococcal Pneumonia.** *S. pneumoniae (pneumococcus)* causes pyogenic (pus-forming) infections, primarily of the lungs, ears, sinuses, and meninges. It is one of the most common bacterial pathogens and the most common cause of bacterial pneumonia.

*S. pneumoniae* is an aerobic, gram-positive diplococcus. There are over 80 antigenically distinct serotypes of pneumococci; antibody to one serotype does not protect against infection with another. The virulence of *S. pneumoniae* is a function of its polysaccharide capsule, which prevents or delays digestion by phagocytes. The polysaccharide is an antigen that primarily elicits a B-cell response with antibody production. In the absence of antibody, clearance of the pneumococci from the body relies on the reticuloendothelial system, with the macrophages in the spleen playing a major role in elimination of the organism. This, along with the spleen’s role in antibody generation, increases the risk for pneumococcal bacteremia in persons who are anatomically or functionally asplenic, such as children with sickle cell disease.

The initial step in the pathogenesis of pneumococcal infection is the attachment and colonization of the organism to the mucus and cells of the nasopharynx. Colonization does not equate with signs of infection.

Perfectly healthy people can be colonized and carry the organism without evidence of infection. The spread of particular strains of pneumococci, particularly antibiotic-resistant strains, is largely by healthy, colonized individuals.

The signs and symptoms of pneumococcal pneumonia vary widely, depending on the age and health status of the infected person. In previously healthy persons, the onset usually is sudden and is characterized by malaise; severe, shaking chills; and fever. The temperature may go as high as 106°F (41°C). During the initial or congestive stage, coughing brings up watery sputum and breath sounds are limited, with fine crackles. As the disease progresses, the character of the sputum changes; it may be blood tinged or rust colored to purulent. Pleuritic pain, a sharp pain that is more severe with respiratory movements, is common. With antibiotic therapy, fever usually subsides in approximately 48 to 72 hours, and recovery is uneventful. Elderly persons are less likely to experience marked elevations in temperature; in these persons, the only sign of pneumonia may be a loss of appetite and deterioration in mental status.

Treatment includes the use of antibiotics that are effective against *S. pneumoniae*. In the past, *S. pneumoniae* was uniformly susceptible to penicillin. However, penicillin-resistant and multidrug-resistant strains have been emerging in the United States and other countries.

The prevalence and intrinsic virulence of the pneumococci and their resistance to antimicrobial therapy has emphasized the need for vaccination. Two vaccine formulations are currently available: the pneumococcal conjugate vaccine (PCV13) and the pneumococcal polysaccharide vaccine (PPSV23). The PCV13 protects against 13 types of pneumococcal bacteria. It is recommended for use in infants and young children and for all adults 50 years of age and older who have conditions that weaken the immune system such as HIV infection, organ transplantation, leukemia, lymphoma, and severe kidney disease. The PPSV23 vaccine consists of the 23 most common capsular serotypes that cause the most common invasive pneumococcal disease. It is recommended for all adults 65 years of age and older and for those 2 years of age and older who are at high risk for the disease. It is also recommended for adults who smoke or have asthma.

**Legionnaires’ Disease.** Legionnaires’ disease is a form of bronchopneumonia caused by a gram-negative rod, *Legionella pneumophila*. Transmission from person to person has not been documented; instead, the infection typically occurs when water that contains the pathogen is aerosolized into appropriately sized droplets and is inhaled or aspirated by a susceptible host. Although healthy persons can contract the infection, the risk is greater among persons with chronic diseases and those with impaired cell-mediated immunity.

*Legionella* pneumonia may present subacutely for days or a week, but more typically presents acutely with malaise, weakness, lethargy, fever, and dry cough. Other manifestations include disturbances of central nervous system function, gastrointestinal tract involvement, arthralgias, and elevation in body temperature, sometimes to more than 40°C (104°F). The presence of pneumonia along with diarrhea, hyponatremia, and confusion is characteristic of *Legionella* pneumonia. The disease causes consolidation of lung tissues and impairs gas exchange. Another characteristic of the disease is a lack of a normal pulse-temperature relationship in which a fever is not accompanied by an appropriate rise in heart rate. For example, a temperature of 102°F is normally accompanied by a heart rate of 110 beats/min; in *Legionella* pneumonia it is often less than 100 beats/min.

Diagnosis is based on clinical manifestations, radiologic studies, and specialized laboratory tests to detect the presence of the organism. Urine antigen tests and sputum fluorescent antibody tests allow for rapid detection of *L. pneumophila* serotype 1, but are less sensitive than culture for identifying other serotypes. Treatment consists of administration of antibiotics that are known to be effective against *L. pneumophila*. Delay in instituting antibiotic therapy significantly increases mortality rates; therefore, antibiotics known to be effective against *L. pneumophila* should be included in the treatment regimen for severe community-acquired pneumonia.

**Primary Atypical Pneumonia**

The atypical pneumonias are characterized by patchy involvement of the lung, largely confined to the alveolar septum and pulmonary interstitium. The term *atypical* denotes a lack of lung consolidation, production of moderate amounts of sputum, moderate elevation of white blood cell count, and lack of alveolar exudate. These pneumonias are caused by a variety of agents, the most common being *Mycoplasma pneumoniae*. Mycoplasma infections are particularly common among children and young adults. Other etiologic agents include viruses (e.g., influenza virus, respiratory syncytial virus, adenoviruses, rhinoviruses, rubella [measles] and varicella [chickenpox] viruses) and *Chlamydia pneumoniae*. In some cases, the cause is unknown.

The agents that cause atypical pneumonias damage the respiratory tract epithelium and impair respiratory tract defenses, thereby predisposing to secondary bacterial infections. The sporadic form of atypical pneumonia is usually mild with a low mortality rate. It may, however, assume epidemic proportions with intensified severity and greater mortality, as occurred in the influenza pandemic of 1918.

The clinical course among persons with mycoplasmal and viral pneumonias varies widely from a mild infection that masquerades as a chest cold to a more serious and even fatal outcome. The symptoms may remain confined to fever, headache, and muscle aches and pains. Cough, when present, is characteristically dry, hacking, and nonproductive. The diagnosis is usually made based on history, physical findings, and chest radiographs.
Tuberculosis

Pulmonary tuberculosis remains one of the deadliest diseases in the world. It is estimated that, if better methods to control infection are not developed, by the year 2020 nearly 1 billion people worldwide will be newly infected with tuberculosis, over 150 million will become clinically ill, and 36 million will die of the disease. With the introduction of antibiotics in the 1950s, the United States and other Western countries enjoyed a long period of decline in the number of infections. However, since the mid-1980s the rate of infection has increased, particularly among HIV-infected people. In the United States, the biggest increase in new cases was from 1985 to 1993, after which the number of reported cases has again declined. In part, this decline reflects the impact of resources committed to assist state and local control efforts, wider screening and prevention programs, and increased support for prevention programs among HIV-infected persons.

Tuberculosis is more common among foreign-born persons from countries with a high incidence of tuberculosis and among residents of high-risk congregate settings such as correctional facilities, drug treatment facilities, and homeless shelters. Outbreaks of a drug-resistant form of tuberculosis have emerged, complicating the selection of drugs and affecting the duration of treatment.

Etiology

Tuberculosis is an airborne infection caused by the *M. tuberculosis* mycobacterium. The mycobacteria are slender, rod-shaped, aerobic bacilli that do not form spores (Fig. 22-5). They are similar to other bacteria except for a waxy cell wall that is responsible for many of the bacteria’s characteristics including its slow growth, antigenicity, and resistance to detergents, disinfectants, and antibiotics. It also renders the bacteria resistant to common laboratory stains. Once stained, the dye cannot be discolored with acid solution, hence the name acid-fast bacilli. Although *M. tuberculosis* can infect practically any organ of the body, the lungs are most frequently involved.

Tuberculosis is an airborne infection spread by minute, invisible particles, called *droplet nuclei*, that are harbored in the respiratory secretions of persons with active tuberculosis. Coughing, sneezing, and talking all create respiratory droplets; these droplets evaporate, leaving the organisms (droplet nuclei), which remain suspended in the air and are circulated by air currents. Thus, living in crowded and confined conditions increases the risk for spread of the disease.

Pathogenesis

The pathogenesis of tuberculosis in a previously unexposed, immunocompetent person is centered on the development of a cell-mediated immune response that confers resistance to the organism and development of tissue hypersensitivity to the tubercular antigens. The destructive features of the disease result from a cell-mediated hypersensitivity response (see Chapter 16) rather than the destructive capabilities of the tubercle bacillus.

Macrophages are the primary cell infected with *M. tuberculosis*. Inhaled droplet nuclei pass down the bronchial tree without settling on the epithelium and are deposited in the alveoli. Soon after entering the lung, the bacilli are phagocytosed by alveolar macrophages, but resist destruction. Although the macrophages that first ingest *M. tuberculosis* cannot kill the organisms, they initiate a cell-mediated immune response that eventually contains the infection. As the tubercle bacilli multiply, the infected macrophages degrade them and present their antigens to helper (CD4+) T lymphocytes. The sensitized helper T cells, in turn, stimulate the macrophages to increase their concentration of lytic enzymes. This boosts their ability to kill the bacilli; however, when released, these lytic enzymes also damage lung tissue. The development of a population of activated cytotoxic (CD8+) T cells and macrophages capable of ingesting and destroying the bacilli constitutes the cell-mediated immune response, a process that takes about 3 to 6 weeks to become effective.

In immunocompetent persons, the cell-mediated immune response results in the development of a gray-white, circumscribed granulomatous lesion, called a *Ghon focus*, that contains the tubercle bacilli, modulated macrophages, and other immune cells. It is usually located in the subpleural area of the upper segments of the lower lobes or in the lower segments of the upper lobe. When the number of organisms is high, the hypersensitivity reaction causes the central portion of the Ghon focus to undergo necrosis, producing a soft, whitish core of dead cells referred to as a caseous (cheeselike) necrosis. During this same period, tubercle bacilli, free or inside macrophages, drain along the lymph channels to the tracheobronchial lymph nodes of the affected lung and there evoke the formation of caseous granulomas. The combination of the primary lung lesion and lymph...
node granulomas is called a Ghon complex (Fig. 22-6). The Ghon complex eventually heals, undergoing shrinkage, fibrous scarring, and calcification, the last of these being visible radiographically. However, small numbers of organisms may remain viable for years. Later, if immune mechanisms decline or fail, latent tuberculosis infection has the potential to develop into secondary tuberculosis.

**Primary Tuberculosis**

Primary tuberculosis is a form of the disease that develops in previously unexposed, and therefore unsensitized, persons. It is typically initiated as a result of inhaling droplet nuclei that contain the tubercle bacillus (Fig. 22-7). Most people with primary tuberculosis are asymptomatic and go on to develop latent tuberculosis infection in which T lymphocytes and macrophages surround the organism in granulomas that limit their spread. Individuals with latent tuberculosis do not have active disease and cannot transmit the organism to others.

In approximately 5% of newly infected people, the immune response is inadequate; these people go on to develop progressive primary tuberculosis with continued destruction of pulmonary tissue and spread to multiple sites within the lung. This usually occurs in young children, whose immune systems are immature, or in adults with HIV infection or other immunodeficiency disorders. Sometimes the onset of symptoms is abrupt, with high fever, pleuritis, and lymphadenitis. As the disease spreads, the organism gains access to the sputum, allowing the person to infect others.

In rare instances, tuberculosis may erode into a blood vessel, giving rise to hematogenic dissemination. Miliary tuberculosis describes minute lesions, resembling millet seeds, resulting from this type of dissemination that can involve almost any organ, particularly the brain, meninges, liver, kidney, and bone marrow.

**Secondary Tuberculosis**

Secondary tuberculosis represents either reinfection from inhaled droplet nuclei or reactivation of a previously healed primary lesion (see Fig. 22-7). It often occurs in situations of impaired body defense mechanisms. The partial immunity that follows primary tuberculosis normally affords protection against reinfection and helps localize the disease should reactivation occur. After the development of hypersensitivity, the infection becomes quiescent in the majority of patients. Cavities are formed as a result of the immune response walling off the infection. These cavities may coalesce to a size of up to 10 to 15 cm in diameter (Fig. 22-8). In vulnerable patients such as the very young or immunocompromised adults, the primary infection can progress into...
and employees in congregate settings (e.g., corrections facilities, homeless shelters, long-term care facilities), and health care workers with high-risk patients. The tuberculin test cannot distinguish between active and latent infection, and has several other limitations. Because the hypersensitivity response to the test depends on cell-mediated immunity, false-negative test results can occur in immunocompromised persons; that is, a negative tuberculin test result can mean that the person has a true lack of exposure to tuberculosis or is anergic (unable to mount a normal immune response to the test). False-positive results can also occur; for example, in persons who have nontuberculous mycobacterial infection or who have received the Bacillus Calmette-Guérin (BCG) vaccine for tuberculosis prevention. Although the BCG vaccine is not used in the United States for tuberculosis prevention, many immigrants will have received it.

Recently, two interferon gamma release assays have come on the market. These tests are in vitro assays of CD4+ T-cell-interferon gamma release in response to stimulation by specific M. tuberculosis antigens. Since the antigens are absent from all BCG strains and most nontuberculous mycobacteria, the test is superior to the tuberculin skin test. Genotyping can be done to identify different strains of M. tuberculosis in persons who have been diagnosed with active tuberculosis. It can be used to evaluate second episodes of tuberculosis to determine whether the second episode was due to relapse or reinfection. Genotyping also permits the evaluation of isolates with different patterns of drug susceptibility. In addition, it is useful in investigating outbreaks of infection and determining sites and patterns of M. tuberculosis transmission in communities.

**Treatment**

The goals of therapy are to treat infected individuals by eliminating the tubercle bacilli while preventing the spread of infection and development of drug-resistant forms of the disease. The tubercle bacillus is an aerobic organism that multiplies slowly and remains relatively dormant in oxygen-poor caseous material. However, it undergoes a high rate of mutation and tends to acquire resistance to any one drug. For this reason, multidrug regimens are used for treating persons with active tuberculosis, and treatment typically continues for 6 months or longer. Treatment duration is prolonged due to the slow-growing nature of the tuberculosis bacteria that impairs the effectiveness of antibiotics that target actively replicating organisms.

The basic principles of tuberculosis treatment are: (1) to administer multiple drugs to which the organisms are susceptible, (2) to add at least two new drugs when treatment failure is suspected, (3) to provide the safest and most effective therapy in the shortest period of time, and (4) to ensure adherence to therapy. Adherence to treatment can be improved by providing detailed education about the disease and its treatment in addition to a case manager who supervises all aspects of an individual’s care. Direct observed therapy (DOT), which
requires that a health care worker physically observe the person’s ingestion of the medications, also improves adherence to the program.16

The primary drugs used are isoniazid (INH), ethambutol, pyrazinamide, and rifampin. In addition to persons with active tuberculosis, persons who have had contact with cases of active tuberculosis and who are at risk for development of an active form of the disease are treated.35–38 Prophylactic treatment is also used for persons who have latent tuberculosis infection but do not have active disease. These persons are considered to harbor a small number of microorganisms and usually are treated with INH.34

Persons with drug-resistant M. tuberculosis infection require careful supervision and more extensive drug regimens.16–38 Drug susceptibility tests are used to guide treatment. Tuberculosis in persons with concomitant HIV infection requires management by experts in both tuberculosis and HIV.

**Fungal Infections**

Although most fungal infections are asymptomatic, they can be severe or even fatal in persons who have experienced a heavy exposure, have underlying immune deficiencies, or develop progressive disease that is not recognized or treated. The host’s cell-mediated immune response is paramount in controlling such infections; thus, immunocompromised persons, particularly those with HIV infection, are particularly prone to development of severe or fatal infection.

Pathologic fungi generally induce a delayed cell-mediated hypersensitivity response to their chemical constituents (see Chapter 15). Cellular immunity is mediated by antigen-specific T lymphocytes and cytokine-activated macrophages that assume fungicidal properties. The primary pulmonary lesions consist of aggregates of macrophages stuffed with organisms, with similar lesions developing in the lymph nodes that drain the area. These lesions develop into granulomas complete with giant cells and may develop central necrosis and calcification resembling that of primary tuberculosis.

**Types of Infections**

Fungi are classified as yeasts and molds. Yeasts are round and grow by budding. Molds form tubular structures called hyphae and grow by branching and forming spores (see Chapter 14). Some fungi are dimorphic, meaning that they grow as yeasts at body temperatures and as molds at room temperatures.

A simple classification of mycoses (diseases caused by fungi) divides them into superficial, cutaneous, subcutaneous, or deep (systemic) mycoses. The superficial, cutaneous, or subcutaneous mycoses cause disease of the skin, hair, and nails. Deep fungal infections may produce pulmonary and systemic infections and are sometimes fatal. They are caused by virulent fungi that live freely, typically in soil or decaying organic matter and frequently in specific geographic regions. The most common of these are the dimorphic fungi, *Histoplasma capsulatum*, *Coccidioides immitis*, and *Blastomyces dermatitidis*.39,40 These fungi form infectious spores, which enter the body through the respiratory system. Most people who become infected with these fungi develop only minor symptoms or none at all—only a small minority develop serious disease.

Each of the dimorphic fungi has a typical geographic distribution. *H. capsulatum*, which is the etiologic agent in histoplasmosis, is endemic along the major river valleys of the central and eastern United States (i.e., Ohio, Missouri, Mississippi river valleys), eastern Canada, Mexico, Central and South America, Africa, and southeast Asia.40,41 The organism grows in areas that have been enriched with bird excreta: old chicken houses, pigeon lofts, barns, and trees where birds roost. The infection is acquired by inhaling the fungal spores that are released when the dirt or dust from the infected areas is disturbed. *C. immitis*, which causes coccidioidomycosis, is most prevalent in the southwestern United States, principally in California, Arizona, and Texas; Mexico; and Central and South America.40,42 Because of its prevalence in the San Joaquin Valley, the disease is sometimes referred to as San Joaquin fever or valley fever. *C. immitis* lives in soil, and events that disturb soil, such as dust storms and digging during construction, have been associated with increased incidence of the disease. *B. capsulatum*, the agent causing blastomycosis, is most commonly found in the south-central and northwestern United States and Canada.40,43

**Clinical Features**

Depending on the host’s resistance and immunocompetence, the diseases usually take one of three forms: (1) an acute primary disease, (2) a chronic (cavitary) pulmonary disease, or (3) a disseminated infection. The lesions of fungal infections consist of epithelioid cell granulomatous containing aggregates of macrophages with engulfed microorganisms. Similar nodules develop in the regional lymph nodes. There is a striking similarity to the primary lesions of tuberculosis. The clinical manifestations often consist of a mild, self-limited flu-like syndrome.

In the vulnerable host, chronic cavitary lesions develop, with a predilection for the upper lobe of the lung, resembling the secondary form of tuberculosis. The most common manifestations are productive cough, fever, night sweats, and weight loss. Disseminated disease most often develops as an acute and fulminating infection in the very old or the very young or in persons with compromised immune function. Although the macrophages of the reticuloendothelial system can remove the fungi from the bloodstream, they are unable to destroy them. Characteristically, this form of the disease presents with a high fever, generalized lymph node enlargement, hepatosplenomegaly, muscle wasting, anemia, leukopenia, and thrombocytopenia. There may be hoarseness, ulcerations of the mouth and tongue, nausea, vomiting, diarrhea, and abdominal pain. Often, meningitis becomes a dominant feature of the disease. Persons with blastomycosis may experience cutaneous infections
that induce pseudoepitheliomatous hyperplasia, which may be mistaken for squamous cell carcinoma.

Skin tests similar to the tuberculin test can be used to detect exposure to Histoplasma and Coccidioides. There is no reliable skin test for Blastomyces. The diagnosis of acute infection is usually made by direct visualization of the organism in tissue sections or sputum culture. Serologic tests that detect antibodies against the specific fungi are available, but lack sensitivity and specificity. Treatment depends on the severity of infection. General symptomatic therapy is given as needed for disease that is limited to the chest with no evidence of progression. The oral or intravenous antifungal drugs are used in the treatment of persons with progressive disease.

## Summary Concepts

- **Viruses** are the most frequent cause of respiratory tract infections, including the common cold and infection with the influenza virus. The common cold occurs more frequently than any other respiratory infection. The fingers are the usual source of transmission, and the most common portals of entry are the nasal mucosa and the conjunctiva of the eye. The influenza virus causes three syndromes: an uncomplicated rhinotracheitis, a respiratory viral infection followed by a bacterial infection, and viral pneumonia. The contagiousness of influenza results from the ability of the virus to mutate and form subtypes against which the population is unprotected.

- **Pneumonias** are respiratory disorders involving inflammation of the lung structures, such as the alveoli and bronchioles. They are caused by infectious agents such as bacteria and viruses. They are commonly classified according to the type of organism causing the infection (typical or atypical), location of the infection (lobar pneumonia or bronchopneumonia), and setting in which it occurs (community or hospital acquired).

- **Tuberculosis** is a chronic respiratory infection caused by the bacterium M. tuberculosis. The destructiveness of the disease results from the cell-mediated hypersensitivity response that the bacillus evokes rather than its inherent destructive capabilities. The treatment of tuberculosis, which focuses on eliminating the tuberculosis bacilli from infected persons and eliminating its spread, requires multiple medications and has been complicated by outbreaks of drug-resistant forms of the disease.

- Infections caused by the fungi H. capsulatum (histoplasmosis), C. immitis (coccidioidomycosis), and B. dermatitidis (blastomycosis) produce pulmonary manifestations that resemble tuberculosis. These infections are common but seldom serious unless they produce progressive destruction of lung tissue or the infection disseminates to organs and tissues outside the lungs.

## Cancer of the Lung

Cancer of the lung is currently the leading cause of cancer-related death in the United States and worldwide.\(^ {13,14,44-48} \) The incidence and rates of death from the disease rose dramatically in the 20th century, correlating with an increase in cigarette smoking. This epidemic of lung cancer deaths is now receding in countries where tobacco control has reduced smoking, but it is rapidly rising in others. Because lung cancer often is far advanced before it is discovered, the prognosis is generally poor. The overall 5-year survival rate is 16%, a dismal statistic that has changed little in the past 50 years.

Carcinogenic chemicals in tobacco smoke trigger genetic changes that convert normal bronchial cells to cancer cells. Other influences may act in concert with smoking or may by themselves be responsible for some lung cancers. For example, there is increased incidence of lung cancer in asbestos workers and workers exposed to dusts containing arsenic, chromium, nickel, and vinyl chloride.\(^ {14} \) Lung cancer is also a disease of aging, with 60% of cases diagnosed in persons older than 65 years of age.\(^ {44} \)

### Types of Lung Cancer

Four histologic types account for most primary lung cancers: adenocarcinoma (males 37%, females 47%), squamous cell lung carcinoma (males 32%, females 25%), large cell carcinoma (males 18%, females 10%), and small cell carcinoma (males 14%, females 18%).\(^ {14} \) For therapeutic purposes such as staging and treatment, lung cancers are further identified as non–small cell lung cancer (NSCLC) and small cell lung cancer (SCLC).\(^ {13,14} \) One of the key reasons for this classification is that SCLC has usually metastasized by the time of diagnosis and hence is not typically amenable to surgery. It is usually best treated with chemotherapy, with or without radiation.

### Non–Small Cell Lung Cancers

The NSCLCs include squamous cell carcinomas, adenocarcinomas, and large cell carcinomas.\(^ {13,14} \) Squamous cell carcinoma is most commonly found in men and is closely correlated with a smoking history. Squamous cell

552 UNIT 6 Respiratory Function

- Infections caused by the fungi H. capsulatum (histoplasmosis), C. immitis (coccidioidomycosis), and B. dermatitidis (blastomycosis) produce pulmonary manifestations that resemble tuberculosis. These infections are common but seldom serious unless they produce progressive destruction of lung tissue or the infection disseminates to organs and tissues outside the lungs.

- **Cancer of the Lung**

Cancer of the lung is currently the leading cause of cancer-related death in the United States and worldwide.\(^ {13,14,44-48} \) The incidence and rates of death from the disease rose dramatically in the 20th century, correlating with an increase in cigarette smoking. This epidemic of lung cancer deaths is now receding in countries where tobacco control has reduced smoking, but it is rapidly rising in others. Because lung cancer often is far advanced before it is discovered, the prognosis is generally poor. The overall 5-year survival rate is 16%, a dismal statistic that has changed little in the past 50 years.

Carcinogenic chemicals in tobacco smoke trigger genetic changes that convert normal bronchial cells to cancer cells. Other influences may act in concert with smoking or may by themselves be responsible for some lung cancers. For example, there is increased incidence of lung cancer in asbestos workers and workers exposed to dusts containing arsenic, chromium, nickel, and vinyl chloride.\(^ {14} \) Lung cancer is also a disease of aging, with 60% of cases diagnosed in persons older than 65 years of age.\(^ {44} \)

### Types of Lung Cancer

Four histologic types account for most primary lung cancers: adenocarcinoma (males 37%, females 47%), squamous cell lung carcinoma (males 32%, females 25%), large cell carcinoma (males 18%, females 10%), and small cell carcinoma (males 14%, females 18%).\(^ {14} \) For therapeutic purposes such as staging and treatment, lung cancers are further identified as non–small cell lung cancer (NSCLC) and small cell lung cancer (SCLC).\(^ {13,14} \) One of the key reasons for this classification is that SCLC has usually metastasized by the time of diagnosis and hence is not typically amenable to surgery. It is usually best treated with chemotherapy, with or without radiation.

### Non–Small Cell Lung Cancers

The NSCLCs include squamous cell carcinomas, adenocarcinomas, and large cell carcinomas.\(^ {13,14} \) Squamous cell carcinoma is most commonly found in men and is closely correlated with a smoking history. Squamous cell
carcinoma tends to originate in the central bronchi as an intraluminal growth and is thus more amenable to early detection through cytologic examination of the sputum than other forms of lung cancer.\(^\text{13}\) It tends to spread centrally into major bronchi and adjacent intrapulmonary lymph nodes (Fig 22-9). Central cavitation of the tumor is frequent.

Currently, \textit{adenocarcinoma} is the most common subtype of lung cancer in North America.\(^\text{13,14}\) Its association with cigarette smoking is weaker than for squamous cell carcinoma. It is the most common type of lung cancer in women and nonsmokers. Adenocarcinoma is a malignant epithelial cell tumor with glandular differentiation or mucin production by the tumor cells. These tumors tend to be located more peripherally than squamous cell carcinomas and are often associated with pleural fibrosis and scarring (Fig 22-10). In general, adenocarcinomas have a poorer stage-for-stage prognosis than squamous cell carcinomas.

\textit{Large cell carcinomas} have large, polygonal cells. They constitute a group of neoplasms that are highly anaplastic and difficult to categorize as squamous cell carcinoma or adenocarcinoma. They tend to occur in the periphery of the lung, invading subsegmental bronchi and larger airways. They have a poor prognosis because of their tendency to spread to distant sites early in their course.\(^\text{13,14}\)

**Small Cell Lung Cancer**

Small cell lung cancer is characterized by a distinctive cell type—small round to oval cells that are approximately the size of a lymphocyte.\(^\text{13,14,49,50}\) The cells grow in clusters that exhibit neither glandular nor squamous organization. The tumors are thought to arise from the neuroendocrine cells of the bronchial epithelium, and some of the tumor cells may be able to secrete hormonally active products. This cell type is associated with several types of paraneoplastic syndrome (signs and symptoms caused by secretions of or immune response to tumor cells), including the syndrome of inappropriate antidiuretic hormone secretion (SIADH; see Chapter 8). This type of cancer has the strongest association with cigarette smoking and is rarely observed in someone who has not smoked.

Small cell lung cancer is highly malignant, tends to infiltrate widely, disseminate early, and is rarely resectable. About 70\% of the cancers have detectable metastases at the time of diagnosis; the rest are assumed to have micrometastases. Brain metastases are particularly common with SCLC and may provide the first evidence of the tumor. Response rates for treatment with chemotherapy (cisplatin and etoposide) are excellent, with 50\% to 60\% complete response in persons with limited disease and 15\% to 20\% complete response in those with extensive disease.\(^\text{47}\) However, remissions tend to be short-lived with a mean duration of 6 to 8 months. Once the disease has recurred, the mean survival length is 3 to 4 months. Overall the 2-year survival is 20\% to 40\% in limited-stage disease and less than 5\% in extensive disease.

**Clinical Features**

Lung cancers are aggressive, locally invasive, and widely metastasizing tumors. Squamous cell and adenocarcinomas usually begin as small mucosal lesions that may follow one of several patterns of growth. They may form intraluminal masses that invade the bronchial mucosa and infiltrate the peribronchial connective tissue, or they may form large, bulky masses that extend into the adjacent lung tissue. Some large tumors undergo
central necrosis and acquire local areas of hemorrhage, and some invade the pleural cavity and chest wall and spread to adjacent intrathoracic structures. All types of lung cancer, especially small cell lung carcinoma, have the capacity to synthesize bioactive products and produce paraneoplastic syndromes.

**Manifestations**

The manifestations of lung cancer are extremely variable, depending on the location of the tumor, the presence of distant metastasis, and the occurrence of paraneoplastic syndromes. Often the malignancy develops insidiously, giving little or no warning of its presence.  

The manifestations of lung cancer can be divided into three categories based on: (1) those due to involvement of the lung and adjacent structures; (2) the effects of local spread and metastasis; and (3) nonmetastatic paraneoplastic manifestations. As with other cancers, lung cancer also causes nonspecific symptoms such as anorexia and weight loss. Because its symptoms are similar to those associated with smoking and chronic bronchitis, they often are disregarded. Metastases already exist in many patients presenting with evidence of lung cancer. The most common sites of these metastases are the brain, bone, and liver. Many of the manifestations of lung cancer result from local irritation and obstruction of the airways and from invasion of the mediastinum and pleural space. The earliest symptoms usually are chronic cough, shortness of breath, and wheezing because of airway irritation and obstruction.  

Hemoptysis (i.e., blood in the sputum) occurs when the lesion erodes into blood vessels. Pain receptors in the chest are limited to the parietal pleura, mediastinum, larger blood vessels, and parietal intercostal afferent vagal fibers. Dull, intermittent, poorly localized retrosternal pain is common in tumors that involve the mediastinum. Pain becomes persistent, localized, and more severe when the disease invades the pleura. Brain metastasis, which occurs in 10% of NSCLC (most commonly with adenocarcinoma) and 20% to 30% of SCLC, may present with headache, nausea, vomiting, seizures, dizziness, and altered mental status.  

Tumors that invade the mediastinum may cause hoarseness because of the involvement of the recurrent laryngeal nerve and cause difficulty in swallowing because of compression of the esophagus. An uncommon complication called the superior vena cava syndrome occurs in some persons with mediastinal involvement. Interruption of blood flow in this vessel usually results from compression by the tumor or involved lymph nodes. The disorder can interfere with venous drainage from the head, neck, and chest wall. The outcome is determined by the speed with which the disorder develops and the adequacy of the collateral circulation. Tumors adjacent to the visceral pleura often insidiously produce pleural effusion. This effusion can compress the lung and cause atelectasis and dyspnea. It is less likely to cause fever, pleural friction rub, or pain than pleural effusion resulting from other causes. Paraneoplastic syndromes are incompletely understood patterns of organ dysfunction related to immune-mediated or secretory effects neoplasia (see Chapter 7). They include hypercalcemia from secretion of parathyroid-like peptide, Cushing syndrome from ACTH secretion, SIADH, neuromuscular syndromes (e.g., Eaton-Lambert syndrome), and hematologic disorders (e.g., migratory thrombophlebitis, nonbacterial endocarditis, disseminated intravascular coagulation). Neurologic or muscular symptoms can develop 6 months to 4 years before the lung tumor is detected. One of the more common of these problems is weakness and wasting of the proximal muscles of the pelvic and shoulder girdles, with decreased deep tendon reflexes but without sensory changes. Hypercalcemia is most often seen in persons with squamous cell carcinoma, hematologic syndromes in persons with adenocarcinomas, and the remaining syndromes in persons with small cell neoplasms. Manifestations of the paraneoplastic syndrome may precede the onset of other signs of lung cancer and may lead to discovery of an occult tumor.

**Diagnosis and Treatment**

The diagnosis of lung cancer is based on a careful history and physical examination and on other tests such as chest radiography, bronchoscopy, cytologic studies (Papanicolaou [Pap] test) of the sputum or bronchial washings, percutaneous needle biopsy of lung tissue, and scalene lymph node biopsy. Computed tomographic scans, MRI studies, and ultrasonography are used to locate lesions and evaluate the extent of the disease. Positron emission tomography (PET) is a noninvasive alternative for identifying metastatic lesions in the mediastinum or distant sites. Persons with SCLC should also have a CT scan or MRI of the brain for detection of metastasis. Annual screening of some high-risk groups with low-dose computed tomography (LDCT) has been proposed as a method for reducing the lung cancer mortality rate by detecting the disease at an earlier stage.  

Like other cancers, lung cancer is classified according to extent of disease. Non-small cell lung cancers are usually classified according to cell type (i.e., squamous cell carcinoma, adenocarcinoma, and large cell carcinoma) and staged according to the 2009 revised Tumor, Node, Metastasis (TNM) staging system. Initial clinical staging involves a CT scan of the chest that includes the adrenal gland to determine tumor size, invasion, and local and regional lymph node involvement. Small cell lung cancers are not staged using the TNM system because micrometastases are assumed to be present at the time of diagnosis. Instead, they are usually classified as limited disease, when the tumor is limited to the unilateral hemithorax, or extensive disease, when it extends beyond these boundaries.  

Treatment methods for NSCLC include surgery, radiation therapy, and systemic chemotherapy. These treatments may be used singly or in combination. Surgery is used for the removal of small, localized NSCLC tumors. It can involve a lobectomy, pneumonectomy, or segmental resection of the lung. Radiation therapy can be used as a definitive or main treatment modality, as part of a combined treatment plan, or for palliation of symptoms.
Cancer of the lung is a leading cause of death worldwide, with cigarette smoking being implicated in the majority of cases. Environmental hazards, such as exposure to asbestos, increase the risk for development of lung cancer. Because the disease develops insidiously, it often is far advanced before it is diagnosed, a fact that explains the poor 5-year survival rate.

For purposes of staging and treatment, lung cancer is divided into nonsmall cell and small cell carcinoma. The main reason for this is that almost all small cell lung cancers have metastasized at the time of diagnosis and are not amenable to surgical resection.

The manifestations of lung cancer can be attributed to the involvement of the lung and adjacent structures, the effects of local spread and metastasis, and paraneoplastic syndromes involving endocrine, neurologic, and hematologic disorders. As with other cancers, lung cancer causes nonspecific symptoms such as anorexia and weight loss. Treatment methods for lung cancer include surgery, irradiation, and chemotherapy.

**SUMMARY CONCEPTS**

- Cancer of the lung is a leading cause of death worldwide, with cigarette smoking being implicated in the majority of cases. Environmental hazards, such as exposure to asbestos, increase the risk for development of lung cancer. Because the disease develops insidiously, it often is far advanced before it is diagnosed, a fact that explains the poor 5-year survival rate.

- For purposes of staging and treatment, lung cancer is divided into nonsmall cell and small cell carcinoma. The main reason for this is that almost all small cell lung cancers have metastasized at the time of diagnosis and are not amenable to surgical resection.

- The manifestations of lung cancer can be attributed to the involvement of the lung and adjacent structures, the effects of local spread and metastasis, and paraneoplastic syndromes involving endocrine, neurologic, and hematologic disorders. As with other cancers, lung cancer causes nonspecific symptoms such as anorexia and weight loss. Treatment methods for lung cancer include surgery, irradiation, and chemotherapy.

**Respiratory Disorders in Children**

Acute respiratory diseases are the most common cause of illness in infancy and childhood. This section focuses on (1) lung development, with an emphasis on the developmental basis for lung disorders in children; (2) respiratory disorders in the neonate; and (3) respiratory infections in children. A discussion of bronchial asthma in children and cystic fibrosis is included in Chapter 23.

**Lung Development**

Although other body systems are physiologically ready for extrauterine life as early as 25 weeks of gestation, the lungs take much longer to mature. Immaturity of the respiratory system is a major cause of morbidity and mortality in infants born prematurely. Even in infants born at term, the lungs are not fully mature, and additional growth and maturation continue well into childhood.

Lung development may be divided into four characteristic stages: the embryonic, pseudoglandular, canalicular, saccular, and alveolar stages. It is generally accepted that weeks 0 to 6 of gestation comprise the embryonic stage; weeks 6 to 16, the pseudoglandular stage; weeks 16 to 26, the canalicular stage; weeks 24 to birth, the terminal sac (saccular) stage; and 32 weeks to 8 years, the alveolar stage. The first three stages are devoted to development of the conducting airways and the last two stages to development of the gas exchange portion of the lung. By the 25th to 28th weeks, sufficient terminal sacs are present to permit survival. Before this time, the premature lungs are incapable of adequate gas exchange. Development of the pulmonary circulation occurs in parallel with lung development. The vessels increase in length and diameter. By the 20th week of gestation, the full number of pre-acinar vessels is present in each segment. During the terminal saccular stage of development, the saccular epithelium becomes very thin and the pulmonary capillaries begin to bulge into these sacs to form the alveoli of the lung.

By 28 weeks, the terminal sacs are lined with squamous epithelial cells or type I alveolar cells, across which gas exchange takes place. Scattered among the squamous epithelial cells are rounded secretory epithelial cells—type II alveolar cells. Type II alveolar cells begin to develop at approximately 24 weeks. These cells produce surfactant, a substance capable of lowering the surface tension of the air–alveoli interface (see Chapter 21). By the 26th to 30th weeks, sufficient amounts of surfactant are available to prevent alveolar collapse when breathing begins.

Although transformation of the lungs from glandlike structures to highly vascular, alveoli-like organs occurs during the late fetal period, mature alveoli do not form for some time after birth. The growth of the lung during infancy and early childhood involves an increase in the number rather than the size of the alveoli. Only about one sixth of the adult number of alveoli is present in the lungs of a full-term infant. By the 8th year of life, the adult complement of alveoli is present.

**Ventilation in the Neonate**

Effective ventilation requires coordinated interaction between the muscles of the upper airways, including those of the pharynx and larynx, the diaphragm, and the...
intercostal muscles of the chest wall. In the infant, the diaphragm inserts more horizontally than in the adult. As a result, contraction of the diaphragm tends to draw the lower ribs inward, especially if the infant is placed in the horizontal position. The intercostal muscles, which normally lift the ribs during inspiration, are not fully developed in the infant. Instead, they function largely to stabilize the chest. Under circumstances such as crying, the intercostal muscles of the neonate function together with the diaphragm to splint the chest wall and prevent its collapse.

The chest wall of the neonate is highly compliant. A striking characteristic of neonatal breathing is the paradoxical inward movement of the upper chest during inspiration, especially during active sleep. Normally, the infant’s lungs also are compliant, which is advantageous to the infant with its compliant chest cage because it takes only small changes in inspiratory pressure to inflate a compliant lung. However, with respiratory disorders that decrease lung compliance, the diaphragm must generate more negative pressure; as a result, the compliant chest wall structures are sucked inward. Inspiratory retractions are abnormal inward movements of the chest wall during inspiration; they may occur intercostally (between the ribs), in the substernal or epigastric area, and in the supraclavicular spaces (Fig. 22-11).

**Airway Resistance**

Normal lung inflation requires uninterrupted movement of air through the extrathoracic airways (i.e., nose, pharynx, larynx, and upper trachea) and intrathoracic airways (i.e., bronchi and bronchioles). The neonate (0 to 4 weeks of age) breathes predominantly through the nose and does not adapt well to mouth breathing. Any obstruction of the nose or nasopharynx may increase upper airway resistance and increase the work of breathing.

The airways of the infant and small child are much smaller than those of the adult. Because the resistance to airflow is inversely related to the fourth power of the radius \( r^4 \), relatively small amounts of mucus secretion, edema, or airway constriction can produce marked changes in airway resistance and airflow. Nasal flaring (enlargement of the nares) is a method that infants use to take in more air. This method of breathing increases the size of the nares and decreases the resistance of the small airways.

Normally, the extrathoracic airways (i.e., those extending from the nose to the thoracic inlet) in the infant narrow during inspiration and widen during expiration, and the intrathoracic airways (i.e., those located within the thorax) widen during inspiration and narrow during expiration. This occurs because the pressure inside the extrathoracic airways reflects the intrapleural pressures that are generated during breathing, whereas the pressure outside the airways is similar to atmospheric pressure. Thus, during inspiration, the pressure inside becomes more negative, causing the airways to narrow, and during expiration it becomes more positive, causing them to widen. In contrast to the extrathoracic airways, the pressure outside the intrathoracic airways is equal to the intrapleural pressure. These airways widen during inspiration as the surrounding intrapleural pressure becomes more negative and pulls them open, and they narrow during expiration as the surrounding pressure becomes more positive. These changes are exaggerated in conditions that cause airway obstruction, particularly in infants with their softer and more compliant airways.

**Lung Volumes and Gas Exchange**

The functional residual capacity, which is the air left in the lungs at the end of normal expiration, plays an important role in the infant’s gas exchange. In the infant, the functional residual capacity occurs at a higher lung volume than in the older child or adult. This higher end-expiratory volume results from a more rapid respiratory rate, which leaves less time for expiration. However, the increased residual volume is important to the neonate for several reasons: (1) it holds the airways open throughout all phases of respiration, (2) it favors the reabsorption of intrapulmonary fluids, and (3) it maintains more uniform lung expansion and enhances gas exchange. During active sleep, the tone of the upper airway muscles is reduced, so that the time spent in expiration is shorter and the intercostal activity that stabilizes the chest wall is less. This results in a lower end-expiratory volume and less optimal gas exchange during active sleep.

**Control of Ventilation**

Fetal arterial oxygen pressures \( (PO_2) \) normally range from 25 to 30 mm Hg, and carbon dioxide pressures \( (PCO_2) \) range from 45 to 50 mm Hg, independent of any respiratory movements. Any decrease in oxygen levels induces quiet sleep in the fetus with subsequent cessation of breathing movements, both of which lead to a decrease in oxygen consumption. At birth, switching to oxygen derived from the aerated lung causes an immediate increase in arterial \( PO_2 \) to approximately 50 mm Hg; within a few hours, it increases to approximately 70 mm Hg. These levels, which greatly exceed fetal levels, cause the chemoreceptors that sense arterial \( PO_2 \) levels to become silent for several days. Although the

---

infant’s arterial PO\textsubscript{2} may fluctuate during this critical
time, the chemoreceptors do not respond appropriately. It is not until several days after birth that the chemoreceptors “reset” their PO\textsubscript{2} threshold; only then do they become the major controller of breathing. However, the response seems to be biphasic, with an initial hyperventilation followed by a decreased respiratory rate and even apnea. In normal infants, especially those born prematurely, breathing patterns and respiratory reflexes depend on the arousal state.\textsuperscript{54} Periodic breathing and apnea are characteristic of premature infants and reflect patterns of fetal breathing. The fact that they occur with sleep and disappear during wakefulness underscores the importance of arousal.

**Alterations in Breathing Patterns**

Most respiratory disorders in the infant or small child produce a decrease in lung compliance or an increase in airway resistance manifested by changes in breathing patterns, rib cage distortion (retractions), audible respiratory sounds, and use of accessory muscles.\textsuperscript{55}

Children with restrictive lung disorders, such as pulmonary edema or respiratory distress syndrome, breathe at faster rates, and their respiratory excursions are shallow. *Grunting* is an audible noise emitted during expiration. An expiratory grunt is common as the child tries to raise the end-expiratory pressure to maintain airway patency and prolong the period of oxygen and carbon dioxide exchange across the alveolar–capillary membrane.

Increased airway resistance can occur in either the extrathoracic or intrathoracic airways. When the obstruction is in the extrathoracic airways, inspiration is more prolonged than expiration. *Nasal flaring* helps reduce the nasal resistance and maintain airway patency. It can be a sign of increased work of breathing and is a significant finding in an infant. *Inspiratory retractions* are often observed with airway obstruction in infants and small children (see Fig. 22-11). In conditions such as croup, the pressures distal to the point of obstruction must become more negative to overcome the resistance; this causes collapse of the distal airways, and the increased turbulence of air moving through the obstructed airways produces an audible crowing sound called *stridor* during inspiration.

When the obstruction is in the intrathoracic airways, as occurs with bronchiolitis and bronchial asthma, expiration is prolonged and the child makes use of the accessory expiratory muscles (abdominals). Rib cage retractions may also be present. Intrapleural pressure becomes more positive during expiration because of air trapping; this causes collapse of intrathoracic airways and produces an audible wheezing or whistling sound during expiration.

**Respiratory Disorders in the Neonate**

The neonatal period is one of transition from placental dependency to air breathing. This transition requires functioning of the surfactant system, conditioning of the respiratory muscles, and establishment of parallel pulmonary and systemic circulations. Respiratory disorders develop in infants who are born prematurely or who have other problems that impair this transition. Among the respiratory disorders of the neonate are respiratory distress syndrome, bronchopulmonary dysplasia, and persistent fetal circulation (i.e., delayed closure of the ductus arteriosus and foramen ovale; see Chapter 19).

**Respiratory Distress Syndrome**

Respiratory distress syndrome (RDS), also known as *hyaline membrane disease*, is one of the most common causes of respiratory disease in premature infants.\textsuperscript{55,56} In these infants, pulmonary immaturity, together with surfactant deficiency, leads to alveolar collapse (Fig. 22-12). The type II alveolar cells that produce surfactant do not begin to mature until approximately the 25th to 28th weeks of gestation; consequently, many premature infants are born with poorly functioning type II alveolar cells and have difficulty producing sufficient amounts of surfactant. The incidence of RDS is higher among preterm male infants,

![FIGURE 22-12. Pathogenesis of respiratory distress syndrome (RDS) in the infant.](image-url)
white infants, infants of diabetic mothers, and those subjected to asphyxia, cold stress, precipitous deliveries, and delivery by cesarean section (when performed before the 38th week of gestation).

Surfactant synthesis is influenced by several hormones, including insulin and cortisol. Insulin tends to inhibit surfactant production; this explains why infants of insulin-dependent diabetic mothers are at increased risk for development of RDS. Cortisol can accelerate maturation of type II cells and formation of surfactant. The reason that premature infants born by cesarean section presumably are at greater risk for development of RDS is that they are not subjected to the stress of vaginal delivery, which is thought to increase the infants' cortisol levels. These observations have led to administration of corticosteroid drugs before delivery to mothers with infants at high risk for development of RDS.

Surfactant reduces the surface tension in the alveoli, thereby equalizing the retractive forces in the large and small alveoli and reducing the amount of pressure needed to inflate and hold the alveoli open. Without surfactant, the large alveoli remain inflated, whereas the small alveoli become difficult to inflate. At birth, the first breath requires high inspiratory pressures to expand the lungs. With normal levels of surfactant, the lungs retain up to 40% of the residual volume after the first breath, and subsequent breaths require far lower inspiratory pressures. With a surfactant deficiency, the lungs collapse between breaths, making the infant work as hard with each successive breath as with the first breath. The airless portions of the lungs become stiff and noncompliant. A hyaline membrane forms inside the alveoli as protein- and fibrin-rich fluids are pulled into the alveolar spaces. The fibrin–hyaline membrane constitutes a barrier to gas exchange, leading to hypoxemia and carbon dioxide retention, a condition that further impairs surfactant production.

Infants with RDS present with multiple signs of respiratory distress, usually within the first 24 hours of birth. Central cyanosis is a prominent sign. Breathing becomes more difficult, and retractions occur as the infant’s soft chest wall is pulled in as the diaphragm descends. Grunting sounds accompany expiration. As the tidal volume drops because of atelectasis, the respiratory rate increases (usually to 60 to 120 breaths per minute) in an effort to maintain normal minute ventilation. Fatigue may develop rapidly because of the increased work of breathing. The stiff lungs of infants with RDS also increase the resistance to blood flow in the pulmonary circulation. As a result, a hemodynamically significant patent ductus arteriosus may develop in infants with RDS (see Chapter 19).

The basic principles of treatment for infants with suspected RDS focus on the provision of supportive care, including gentle handling and minimal disturbance. An incubator or radiant warmer is used to prevent hypothermia and increased oxygen consumption. Continuous cardiorespiratory monitoring is needed. Monitoring of blood glucose and prevention of hypoglycemia are also recommended. Oxygen levels can be assessed through an arterial (umbilical) line or by a transcutaneous oxygen sensor. Treatment includes administration of supplemental oxygen, continuous positive airway pressure through nasal prongs, and often, assisted mechanical ventilation.

Exogenous surfactant therapy is used to prevent and treat RDS. The surfactants are suspended in saline and administered into the airways, usually through an endotracheal tube. The treatment often is initiated soon after birth in infants who are at high risk for RDS.

**Bronchopulmonary Dysplasia**

Bronchopulmonary dysplasia (BPD) is a chronic lung disease that occurs in infants, usually preterm infants treated with mechanical ventilation or prolonged oxygen supplementation. Bronchopulmonary dysplasia is primarily a disease of infants weighing less than 1000 g born at less than 28 weeks' gestation, many of whom have little or no lung disease at birth but develop progressive respiratory failure over the first few weeks of life. Although the disorder is most often associated with preterm birth, it can occur in term infants who require aggressive ventilator therapy for severe, acute lung disease.

Morphologic features of BPD include alveolar hypoplasia, variable alveolar wall fibrosis, and minimal airway disease. The histopathology of BPD indicates interference with normal lung maturation, which may prevent subsequent lung growth and development. This pathogenesis is thought to be multifactorial and affect both the lungs and the heart. Mechanical ventilation and oxygen produce lung injury through their effect on alveolar and vascular development. Oxygen induces injury by producing free radicals that cannot be metabolized by the immature antioxidant systems of the preterm infant. Several clinical features, including immaturity, acquired infections, and malnutrition, may contribute to the development of BPD.

Bronchopulmonary dysplasia is characterized by chronic respiratory distress, persistent hypoxemia when breathing room air, reduced lung compliance, increased airway resistance, and severe expiratory flow limitation. There is a mismatching of ventilation and perfusion with development of hypoxemia and hypercapnia. Acute lung injury also impairs growth, structure, and function of the developing pulmonary circulation after premature birth. Pulmonary vascular resistance may be increased and pulmonary hypertension and cor pulmonale (i.e., right heart failure associated with lung disease) may develop. The infant with BPD often demonstrates tachycardia, rapid and shallow breathing, chest retractions, cough, and poor weight gain. Clubbing of the fingers occurs in children with severe disease. Hepatomegaly and periorbital edema may develop in infants with right heart failure.

The treatment of BPD includes nutritional support, maintenance of adequate oxygenation, and prompt treatment of infections. Severe BPD requires mechanical ventilation and administration of supplemental oxygen. Weaning from ventilation is accomplished gradually, and some infants may require ventilation at home. Rapid lung growth occurs during the first year of life, and lung function usually improves. Adequate nutrition is essential for recovery of infants with BPD. There has been an
interest in the protective effect of polyunsaturated fatty acids, vitamin A, and other nutrients such as inositol (a sulfur-containing amino acid) and selenium in preventing lung injury in high-risk premature infants.57

Most adolescents and young adults who had severe BPD during infancy have some degree of pulmonary dysfunction, consisting of airway obstruction, airway hyperreactivity, or hyperinflation.

**Respiratory Infections in Children**

In children, respiratory tract infections are common, and although they are troublesome, they usually are not serious. Frequent infections occur because the immune systems of infants and small children have not been exposed to many common pathogens; consequently, they tend to contract infections with each new exposure. Although most of these infections are not serious, they can impair airflow because of the small size of the child’s airways. For example, an infection that causes only sore throat and hoarseness in an adult may result in serious airway obstruction in a small child.

**Upper Airway Infections**

In infants and children, obstruction of the upper airways because of infection tends to exert its greatest effect during the inspiratory phase of respiration. Movement of air through an obstructed upper airway, particularly the vocal cords in the larynx, causes stridor. Impairment of the expiratory phase of respiration also can occur, causing wheezing. With mild to moderate obstruction, inspiratory stridor is more prominent than expiratory wheezing because the airways tend to dilate with expiration. When the swelling and obstruction become severe, the airways no longer can dilate during expiration, and both stridor and wheezing occur.

Cartilaginous support of the trachea and the larynx is poorly developed in infants and small children. These structures are soft and tend to collapse when the airway is obstructed and the child cries, causing the inspiratory pressures to become more negative. When this happens, the stridor and inspiratory effort are increased. The phenomenon of airway collapse in the small child is analogous to what happens when a thick beverage, such as a milkshake, is pulled through a soft paper or plastic straw. The straw collapses when the negative pressure produced by the sucking effort exceeds the flow of liquid through the straw.

Common upper airway infections in infants and small children include croup (laryngotracheobronchitis) and epiglottitis.60-61 Croup is the more common and usually is benign and self-limited. Epiglottitis is a rapidly progressive and life-threatening condition. The site of involvement is illustrated in Figure 22-13, and the characteristics of both infections are compared in Table 22-2.

**Croup.** Croup is characterized by inspiratory stridor, hoarseness, and a barking cough. The British use the term croup to describe the cry of the crow or raven, and this is undoubtedly how the term originated.

Croup is usually caused by viruses.60-65 The parainfluenza virus (types 1 to 3) accounts for approximately 75% all cases, with the remaining 25% being caused by adenoviruses, respiratory syncytial virus, and influenza A and B.63 Viral croup usually is seen in children 3 months to 5 years of age. The condition may affect the entire laryngotracheal tree, but because the subglottic area is the narrowest part of the respiratory tree in this age group, the obstruction usually is greatest in this area.

Although the respiratory manifestations of croup may appear suddenly, they usually are preceded by upper respiratory infections that cause rhinorrhea (i.e., runny nose), coryza (i.e., common cold), hoarseness, and a low-grade fever. In most children, the manifestation of croup advances only to stridor and slight dyspnea before they begin to recover. The symptoms usually subside when the child is exposed to moist air. For example, letting the bathroom shower run and then taking the child into the bathroom often brings prompt and dramatic relief of symptoms. Exposure to cold air also seems to relieve the airway spasm; often, the severe symptoms are relieved simply because the child is exposed to cold air on the way to the hospital emergency department. Viral croup does not respond to antibiotics; expectorants, bronchodilating agents, and antihistamines are not helpful. The child should be disturbed as little as possible and carefully monitored for signs of respiratory distress.

Airway obstruction may progress in some children. As the obstruction increases, the stridor becomes continuous and is associated with nasal flaring with substernal and intercostal retractions. Agitation and crying aggravate the signs and symptoms, and the child prefers to sit up or be held upright. In the cyanotic, pale, or obstructed child, any manipulation of the pharynx, including use of a tongue depressor, can cause cardiorespiratory arrest and should be done only in a medical setting that has the facilities for emergency airway management. Other treatments may be required when a humidifier or mist tent is ineffective. One method is to administer a racemic
Acute epiglottitis is a dramatic, potentially fatal condition characterized by inflammatory edema of the supraglottic area, including the epiglottis and pharyngeal structures. It is thought that it may have an allergic origin. Spasmodic croup characteristically occurs at night and tends to recur with respiratory tract infections. The episode usually lasts several hours and may recur several nights in a row.

Most children with spasmodic croup can be effectively managed at home. An environment of high humidity (i.e., cold-water room humidifier or taking the child into a bathroom with a warm, running shower) lessens irritation and prevents drying of secretions.

Epiglottitis typically presents with an acute onset of sore throat and fever. The child appears pale, toxic, and lethargic and assumes a distinctive position—sitting up with the mouth open and the chin thrust forward. Symptoms rapidly progress to difficult swallowing, a muffled voice, drooling, and extreme anxiety. Moderate to severe respiratory distress is evident. There is inspiratory and sometimes expiratory stridor, flaring of the nares, and inspiratory retractions of the suprasternal notch and supraclavicular and intercostal spaces. Within a matter of hours, epiglottitis may progress to complete obstruction of the airway and death unless adequate treatment is instituted. Epiglottitis is a medical emergency and immediate establishment of an artificial airway is necessary. Examination of the throat with a tongue blade or other instrument may cause airway spasm and cardiopulmonary arrest and should be done only by medical personnel experienced in intubation of small children. It also is unwise to attempt any procedure, such as drawing blood, which would heighten the child’s anxiety because this also could precipitate airway spasm and cause death. Recovery from epiglottitis is usually rapid and uneventful after an adequate airway has been established and appropriate antibiotic therapy initiated.

### Lower Airway Infections

Lower airway infections produce air trapping with prolonged expiration. Wheezing results from bronchospasm, mucosal inflammation, and edema. The child presents with increased expiratory effort, increased respiratory rate, and wheezing. If the infection is severe, there also are marked intercostal retractions and signs of impending respiratory failure. Acute bronchiolitis is a viral infection of the lower airways, most commonly caused by the respiratory syncytial virus. Other viruses, such as parainfluenza-3, and other agents such as Streptococcus pyogenes, S. pneumoniae, and S. aureus now represent the most common causes of pediatric epiglottitis.

Establishment of an artificial airway may become necessary in severe airway obstruction.
virus and some adenoviruses, as well as mycoplasmas, also are causative. The infection produces inflammatory obstruction of the small airways and necrosis of the cells lining the lower airways. It usually occurs during the first 2 years of life, with a peak incidence between 3 and 6 months of age. The source of infection usually is a family member with a minor respiratory illness. Older children and adults tolerate bronchiolar edema much better than infants and do not manifest the clinical picture of bronchiolitis. Because the resistance to airflow in a tube is inversely related to the fourth power of the radius, even minor swelling of bronchioles in an infant can produce profound changes in airflow.

Most affected infants in whom bronchiolitis develops have a history of a mild upper respiratory tract infection. These symptoms usually last several days and may be accompanied by fever and diminished appetite. There is then a gradual development of respiratory distress, characterized by a wheezy cough, dyspnea, and irritability. The infant usually is able to take in sufficient air but has trouble exhaling it. Air becomes trapped in the lung distal to the site of obstruction and interferes with gas exchange. Hypoxemia and, in severe cases, hypercapnia may develop. Airway obstruction may produce air trapping and hyperinflation of the lungs or collapse of the alveoli. Infants with acute bronchiolitis have a typical appearance, marked by breathlessness with rapid respirations, a distressing cough, and retractions of the lower ribs and sternum. Crying and feeding exaggerate these signs. Wheezing and crackles may or may not be present, depending on the degree of airway obstruction. In infants with severe airway obstruction, wheezing decreases as the airflow diminishes. Usually, the most critical phase of the disease is the first 48 to 72 hours. Cyanosis, pallor, listlessness, and sudden diminution in or absence of breath sounds indicate impending respiratory failure. The characteristics of bronchiolitis are described in Table 22-2.

Infants with respiratory distress usually are hospitalized. Treatment is largely supportive. Hypoxic children should receive humidified oxygen. Elevation of the head facilitates respiratory movements and avoids airway compression. Handling is kept at a minimum to avoid tiring. Because the infection is viral, antibiotics are not effective and are given only for a secondary bacterial infection. The use of bronchodilators (i.e., epinephrine) and corticosteroids remains controversial.

Dehydration may occur as the result of increased insensible water losses because of the rapid respiratory rate and feeding difficulties, and measures to ensure adequate hydration are needed. Recovery usually begins after the first 48 to 72 hours and usually is rapid and complete. Adequate hand washing is essential to prevent the nosocomial spread of respiratory syncytial virus.

**Signs of Impending Respiratory Failure**

Respiratory problems of infants and small children often originate suddenly, and respiratory failure can develop rapidly from obstructive disorders such as epiglottitis or lung infection such as bronchiolitis. Children with impending respiratory failure due to airway or lung disease have rapid breathing; exaggerated use of the accessory muscles; retraction, which are more pronounced in the child than in the adult because of higher chest compliance; nasal flaring; and grunt- ing during expiration. The signs and symptoms of impending respiratory failure are listed in Chart 22-1.

**SUMMARY CONCEPTS**

- Although other body systems are physiologically ready for extrauterine life as early as 25 weeks of gestation, the lungs take much longer to mature. Type II alveolar cells, which produce surfactant, a substance capable of lowering the surface tension at the air–alveoli interface, begin to develop at approximately 24 weeks, and by the 26th to 30th weeks produce sufficient amounts of surfactant to prevent alveolar collapse.
- Respiratory distress syndrome is one of the most common causes of respiratory disease in premature infants. In these infants, pulmonary immaturity, together with surfactant deficiency, lead to alveolar collapse.
- Normally, both an infant’s chest wall and lungs are compliant, allowing for small changes in inspiratory pressure to inflate the lung. In respiratory disorders that decrease lung compliance, the diaphragm must generate more negative pressure; as a result, the compliant chest wall structures are sucked inward, producing abnormal inward movements of the chest wall during inspiration called retractions.

(continued)
SUMMARY CONCEPTS (continued)

- Children with restrictive lung disorders, such as pulmonary edema or respiratory distress syndrome, breathe at faster rates, and their respiratory excursions are shallow. Grunting is an audible noise emitted during expiration. An expiratory grunt is common as the child tries to raise the end-expiratory pressure to maintain airway patency and prolong the period of oxygen and carbon dioxide exchange across the alveolar–capillary membrane.

- Because of the small size of the airway of infants and children, respiratory tract infections in these groups often are more serious. Infections that may cause only a sore throat and hoarseness in the adult may produce serious obstruction in the child. Among the respiratory tract infections that affect small children are croup, bronchiolitis, and epiglottitis, a life-threatening supraglottic infection that may cause airway obstruction and asphyxia.

REVIEW EXERCISES

1. It is flu season, and although you had a flu shot last year, you have not had one this year. Imagine yourself experiencing an abrupt onset of fever, chills, malaise, muscle aching, and nasal stuffiness. Your family practitioner tells you that you have a viral upper respiratory infection. Last year you had a flu shot. You cannot remember if you had the flu shot last year. You are concerned that you have been vaccinated and the flu shot did not work.

A. Which of these symptoms would lead you to believe you are coming down with the flu?

B. Because you hate to miss classes, you decide to go to the student health center to get an antibiotic. After being seen by a health professional, you are told that antibiotics are ineffective against the flu virus, and you are instructed not to attend classes but instead to go home, take acetaminophen for your fever, go to bed and stay warm, and drink a lot of fluids. Explain the rationale for each of these recommendations.

C. Explain why last year’s flu shot did not protect you during this year’s flu season.

D. There is concern about the possibility of an influenza pandemic such as the one that occurred during the 1917–1918 season. What is the rationale for this concern?

2. Bacterial (e.g., *S. pneumoniae*) pneumonia is commonly manifested by a cough productive of sputum, whereas with atypical (e.g., *M. pneumoniae*) pneumonia, the cough is usually nonproductive or absent.

A. Explain.

3. A 4-month-old infant is admitted to the pediatric intensive care unit with a diagnosis of bronchiolitis. The infant is tachypneic, with wheezing, nasal flaring, and retractions of the lower sternum and intercostal spaces during inspiration.

A. What is the usual pathogen in bronchiolitis? Would this infection be treated with an antibiotic?

B. Explain the physiologic mechanism involved in the retraction of the lower sternum and intercostal spaces during inspiration.

C. What would be the signs of impending respiratory failure in this infant?

The major function of the lungs is to oxygenate the blood and remove carbon dioxide as a means of supporting the metabolic functions of the body's tissues. Many types of disease are capable of disrupting the normal gas exchange function of the lungs. In some cases the disruption is temporary and in other cases it is marked and disabling. This chapter focuses on disorders that disrupt ventilation and pulmonary gas exchange. It is divided into six sections: the physiologic effects of altered ventilation and gas exchange, disorders of lung inflation, obstructive airway disorders, chronic interstitial lung disorders, disorders of the pulmonary circulation, and acute respiratory disorders.

**Physiologic Effects of Ventilation and Diffusion Disorders**

Disorders of lung inflation
- Disorders of the Pleura
  - Pleuritis
  - Pleural Effusion

  - Hypercapnic/ Hypoxemic Respiratory Failure
  - Clinical Features

**Disorders of Ventilation and Gas Exchange**

The primary function of the respiratory system is gas exchange between the atmospheric air in the alveoli and the blood in the pulmonary circulation. In the process, oxygen ($O_2$) from air in the alveoli diffuses into the blood in the pulmonary capillaries and carbon dioxide ($CO_2$) moves from the blood in pulmonary capillaries into the alveoli (discussed in Chapter 21). This section provides a brief overview of two abnormal states (hypoxemia and hypercapnia) that develop as the result of impaired ventilation and gas exchange that occur with many of the disorders discussed in the chapter.

Respiration can be divided into three parts: ventilation, perfusion, and diffusion. **Ventilation** involves the movement of air into the lungs. However, not all inspired air reaches the alveoli where gas exchange takes place. Of each 500 mL of air, which is the typical volume of air that is inhaled by the average-sized adult, about 150 mL remains behind in the airways, with the remainder (350 mL) moving into the alveoli. This is called **alveolar ventilation** and represents the portion of ventilation that participates in gas exchange. The actual movement or **diffusion** of $O_2$ and $CO_2$ takes place in the lung driven by
the partial pressure (P) of the gases. Thus, oxygen moves from the alveoli, where the partial pressure of oxygen (PO₂) averages 104 mm Hg when breathing room air, to the blood in the pulmonary capillaries, where the average PO₂ is only 40 mm Hg.³ Carbon dioxide moves in the opposite direction, from the blood in the pulmonary capillaries, where the partial pressure of carbon dioxide (PCO₂) is 45 mm Hg, to the alveolar air, where the PCO₂ is 40 mm Hg.³ These values vary with tissue metabolism and the oxygen content of the inspired air.

Perfusion involves the movement of blood through the pulmonary circulation, including the pulmonary capillaries, where gas exchange takes place. Adequate oxygenation of the blood and removal of CO₂ depend on perfusion or movement of blood through the pulmonary blood vessels and appropriate contact between ventilated alveoli and perfused capillaries of the pulmonary circulation (ventilation and perfusion matching).

Hypoxemia

Hypoxemia refers to a reduction in the PO₂ of the arterial blood. It can result from an inadequate amount of O₂ in the air, disease of the respiratory system, dysfunction of the neurologic system, or alterations in circulatory function. The mechanisms whereby respiratory disorders lead to a significant reduction in PO₂ are hypventilation, impaired diffusion of gases, inadequate circulation of blood through the pulmonary capillaries, and mismatching of ventilation and perfusion² (see Chapter 21). Often, more than one mechanism contributes to hypoxemia in persons with respiratory or cardiac disease.

Hypoxemia produces its effects through tissue hypoxia and the compensatory mechanisms that the body uses to adapt to the lowered oxygen level. Body tissues vary considerably in their vulnerability to hypoxia; those with the greatest need are the brain and heart. If the PO₂ in these organs falls below a critical level, aerobic metabolism ceases and anaerobic metabolism takes over, with formation and release of lactic acid. This results in increased serum lactate levels and a metabolic acidosis (see Chapter 8).

Mild hypoxemia or reduction in the PO₂ of arterial blood produces few manifestations. Recruitment of sympathetic nervous system compensatory mechanisms produces an increase in heart rate, peripheral vasoconstriction, and a mild increase in blood pressure.³ This is because hemoglobin saturation is still approximately 90% when the PO₂ is only 60 mm Hg (see Chapter 21, Fig. 21-22). More pronounced hypoxemia may produce personality changes, restlessness, uncoordinated muscle movements, euphoria, impaired judgment, delirium, and, eventually, stupor and coma.

Cyanosis refers to the bluish discoloration of the skin and mucous membranes resulting from an excessive concentration of reduced or deoxygenated hemoglobin in the small blood vessels. It usually is most pronounced in the lips, nail beds, ears, and cheeks. The degree of cyanosis is modified by the amount of cutaneous pigment, skin thickness, and the state of the cutaneous capillaries. Cyanosis is more difficult to distinguish in persons with dark skin and in areas of the body with increased skin thickness. Although cyanosis may be evident in persons with respiratory failure, it often is a late sign. A deoxygenated hemoglobin concentration of approximately 5 g/dL of deoxygenated hemoglobin is required in the circulating blood for cyanosis to occur.¹ The absolute quantity of reduced hemoglobin, rather than the relative quantity, is important in producing cyanosis. Persons with anemia are less likely to exhibit cyanosis because they have less hemoglobin to transport oxygen even though their cardiac output and lung function are normal. A person with a high hemoglobin level because of polycythemia may be cyanotic in the absence of hypoxia.

Cyanosis can be divided into two types: central and peripheral. Central cyanosis is evident in the tongue and lips. It is caused by an increased amount of deoxygenated hemoglobin in the arterial blood. Peripheral cyanosis occurs in the extremities and on the tip of the nose or ears. It is caused by slowing of blood flow to an area of the body, with increased extraction of oxygen from the blood. It results from vasoconstriction and diminished peripheral blood flow, as occurs with cold exposure, shock, heart failure, or peripheral vascular disease.

The manifestations of chronic hypoxemia may be insidious in onset and attributed to other causes, particularly in persons with chronic lung disease. The body compensates for chronic hypoxemia with increased ventilation, pulmonary vessel vasoconstriction, and increased production of red blood cells. Pulmonary vasoconstriction occurs as a local response to alveolar hypoxia; it increases pulmonary arterial pressure and improves the matching of ventilation and perfusion. Increased production of red blood cells results from the release of erythropoietin from the kidneys in response to hypoxia (see Chapter 13). Other adaptive mechanisms include a shift to the right in the oxygen dissociation curve, which increases O₂ release to the tissues (see Chapter 21).

Diagnosis of hypoxemia is based on clinical observation and diagnostic tests that measure PO₂ levels. The analysis of arterial blood gases provides a direct measure of the O₂ content of the blood and is the best indicator of the ability of the lungs to oxygenate the blood. Mixed venous oxygen saturation (SvO₂; i.e., oxygen saturation of hemoglobin in venous blood) reflects the body’s extraction at the tissue levels. Venous blood samples can be obtained either through a pulmonary artery catheter or central line.

Noninvasive measurements of arterial O₂ saturation of hemoglobin can be obtained using pulse oximetry.⁴,⁵ Reusable clip probes (finger, nasal, ear) and single-use adhesive probes (finger and forehead) are available.⁵ Advantages of the reusable clip probe include the rapidity with which measurements can be obtained and cost-effectiveness. The adhesive probes allow for more secure placement and ability to monitor sites other than those used by the clip probes.

Pulse oximetry uses light-emitting diodes and combines plethysmography (i.e., changes in light absorbance and vasodilation) with spectrophotometry.⁴,⁵ Spectrophotometry uses a red-wavelength light that passes through oxygenated hemoglobin and is absorbed by
deoxygenated hemoglobin, and an infrared-wavelength light that is absorbed by oxygenated hemoglobin and passes through deoxygenated hemoglobin. The pulse oximeter cannot distinguish between oxygen–carrying hemoglobin and carbon monoxide–carrying hemoglobin. In addition, the pulse oximeter cannot detect elevated levels of methemoglobin. Although pulse oximetry is not as accurate as arterial blood gas measurements, it provides the means for noninvasive and continuous monitoring of O₂ saturation, which is a useful indicator of respiratory and circulatory status.

Treatment of hypoxemia is directed toward correcting the cause of the disorder and increasing the gradient for diffusion through the administration of supplemental oxygen. Oxygen may be delivered by nasal cannula or mask or administered directly into an endotracheal or tracheostomy tube in persons who are mechanically ventilated.³ A high-flow administration system is one in which the flow rate and reserve capacity are sufficient to provide all the inspired air. A low-flow administration system delivers less than the total inspired air. The concentration of O₂ being administered (usually determined by the flow rate) is based on the PO₂ of arterial blood. A high flow rate must be carefully monitored in persons with chronic lung disease because increases in alveolar oxygen concentration above the person’s baseline may suppress the hypoxia-induced ventilatory drive. Although oxygen is necessary and vital to life, there also is the danger of oxygen toxicity with concentrations above 60%. Continuous breathing of oxygen at high concentrations can lead to diffuse parenchymal lung injury due to oxygen free radicals. Persons with healthy lungs begin to experience respiratory symptoms such as cough, sore throat, substernal distress, nasal congestion, and painful inspiration after breathing pure oxygen for 24 hours.⁴

### Hypercapnia

Hypercapnia refers to an increase in the carbon dioxide content of the arterial blood.³⁶ The PCO₂ is proportional to carbon dioxide production and inversely related to alveolar ventilation. The diagnosis of hypercapnia is based on physiologic manifestations and arterial blood gas levels.

Hypercapnia can occur in a number of disorders that cause hypoventilation or mismatching of ventilation and perfusion.³⁶ The diffusing capacity of carbon dioxide is 20 times that of oxygen; therefore, hypercapnia without hypoxemia is usually observed only in situations when supplemental oxygen is provided. In cases of ventilation–perfusion mismatching, hypercapnia is usually accompanied by a decrease in arterial PO₂ levels. Conditions that increase carbon dioxide production, such as an increase in metabolic rate or a high-carbohydrate diet, can contribute to the degree of hypercapnia that occurs in persons with impaired respiratory function. Changes in the metabolic rate resulting from an increase in activity, fever, or disease can have profound effects on carbon dioxide production. Alveolar ventilation usually rises proportionally with these changes, and hypercapnia occurs only when this increase is inappropriate or a compensatory rise in alveolar ventilation is inadequate.

Hypercapnia affects a number of body functions, including acid–base balance, as well as kidney, nervous system, and cardiovascular function. Elevated levels of CO₂ produce respiratory acidosis (see Chapter 8). The body normally compensates for an increase in PCO₂ by increasing renal bicarbonate (HCO₃⁻) retention, which results in an increase in serum HCO₃⁻ and pH levels. As long as the pH is within normal range, the main complications of hypercapnia are those resulting from the accompanying hypoxia. Because the body adapts to chronic increases in blood levels of carbon dioxide, persons with chronic hypercapnia may not have symptoms until the PCO₂ becomes markedly elevated, causing respiratory depression and altered mental status.

The treatment of hypercapnia is directed at decreasing the work of breathing and improving the ventilation–perfusion balance. The use of intermittent rest therapy, such as nocturnal negative-pressure ventilation, in persons with chronic obstructive pulmonary disease or chest wall disease may be effective in increasing the strength and endurance of the respiratory muscles and improving the PCO₂. Respiratory muscle retraining aimed at improving the respiratory muscles, their endurance, or both has been used to improve exercise tolerance and diminish the likelihood of respiratory fatigue. Mechanical ventilation may become necessary in situations of acute hypercapnia.

### SUMMARY CONCEPTS

- The primary functions of the respiratory system are to remove appropriate amounts of carbon dioxide from the blood entering the pulmonary circulation and provide adequate amount of oxygen to blood leaving the pulmonary circulation. This is accomplished through the process of ventilation, in which air moves into and out of the lungs, and diffusion, in which gases move between the alveoli and the pulmonary capillaries. Although both affect gas exchange, oxygenation of the blood largely depends on diffusion, while removal of carbon dioxide depends on ventilation.
- **Hypoxemia** refers to a decrease in blood oxygen levels that results in a decrease in tissue oxygenation. Hypoxemia can occur as the result of hypoventilation, diffusion impairment, shunt, and ventilation–perfusion abnormalities. Acute hypoxemia is manifested by increased respiratory effort (increased respiratory and heart rates), cyanosis, and impaired sensory and neurologic function. The body compensates for chronic hypoxemia by increased ventilation, pulmonary vasoconstriction, and increased production of red blood cells.

(continued)
Air entering through the airways inflates the lung, and the negative pressure in the pleural cavity keeps the lung from collapsing. Disorders of lung inflation are caused by conditions that obstruct the airways, cause lung compression, or produce lung collapse. There can be compression of the lung by an accumulation of fluid in the intrapleural space; complete collapse of an entire lung, as in pneumothorax; or collapse of a segment of the lung due to airway obstruction, as in atelectasis.

Disorders of the Pleura

The pleura is a thin, double-layered serous membrane that encases the lungs. The outer parietal layer lines the thoracic wall and superior aspect of the diaphragm. It continues around the heart and between the lungs, forming the lateral walls of the mediastinum. The inner visceral layer covers the lung and is adherent to all its surfaces. The pleural cavity or space between the two layers contains a thin film of serous fluid that lubricates the pleural surfaces and allows the parietal and visceral pleurae to slide smoothly over each other during breathing movements. The pressure in the pleural cavity, which is negative in relation to atmospheric pressure, holds the lungs against the chest wall and keeps them from collapsing. Disorders of the pleura include pleuritis, pleural effusion, and pneumothorax.

Pleuritis

Pleuritis (also called pleurisy) refers to inflammation of the parietal pleura that typically results in characteristic pleural pain. Since the visceral pleura does not contain pain receptors, pleural pain results from somatic pain fibers that innervate the parietal pleura. The pain is usually unilateral and abrupt in onset, and is usually made worse by chest movements such as deep breathing and coughing that exaggerate pressure changes in the pleural cavity and increase movement of the inflamed or injured pleural surfaces. Because deep breathing is painful, tidal volumes usually are kept small, and breathing becomes more rapid to maintain the minute ventilation. Reflex splinting of the chest muscles may occur, causing a lesser respiratory expansion on the affected side.

There are numerous causes of pleuritis and pleuritic pain. The setting in which it occurs provides useful diagnostic information. In young, healthy individuals, it is commonly caused by viral infections or pneumonia. The presence of pleural effusion or air in the pleural cavity requires further diagnostic information.

It is important to differentiate pleural pain from pain produced by other conditions, such as musculoskeletal strain of the chest muscles, bronchial irritation, and myocardial disease. Musculoskeletal pain may occur as the result of frequent, forceful coughing. This type of pain usually is bilateral and located in the inferior portions of the rib cage, where the abdominal muscles insert into the anterior rib cage. It is made worse by movements associated with contraction of the abdominal muscles. The pain associated with irritation of the bronchi usually is substernal and dull in character rather than sharp. It is made worse with coughing but is not affected by deep breathing. Myocardial pain, which is discussed in Chapter 19, usually is located in the substernal area and is not affected by respiratory movements.

Treatment of pleuritis consists of treating the underlying disease and inflammation. Analgesics and non-steroidal anti-inflammatory drugs (NSAIDs; e.g., indomethacin) may be used for pleuritic pain. Although these agents reduce inflammation, they may not entirely relieve the discomfort associated with deep breathing and coughing.

Pleural Effusion

Pleural effusion refers to an abnormal collection of fluid in the pleural cavity. Like fluid developing in other transcellular spaces in the body, pleural effusion occurs when the rate of fluid formation exceeds the rate of its removal (see Chapter 8). Normally, fluid enters the pleural space from capillaries in the parietal pleura and is removed by their lymphatics. Fluid can also enter from the interstitial spaces of the lung through the visceral pleura or from small holes in the diaphragm. The lymphatics have the capacity to reabsorb about 20 times the fluid that is formed. Accordingly, fluid may accumulate when there is excess fluid formation (from the interstitium of the lung, the parietal pleura, or the peritoneal cavity) or when there is decreased removal by the lymphatics.

The fluid that accumulates in a pleural effusion may be a transudate or exudate, purulent (containing pus), chyle, or sanguineous (bloody). The accumulation of a serous transudate (clear fluid) in the pleural cavity is referred to as hydrothorax. The condition may be unilateral or bilateral. The most common cause of hydrothorax is congestive heart failure. Other causes are renal failure, nephrosis, liver failure, and malignancy. An exudate is a pleural fluid that has a specific gravity greater than 1.020 and often contains inflammatory cells.

Transudative and exudative pleural effusions are distinguished by measuring the lactate dehydrogenase (LDH) and protein levels in the pleural fluid. Lactate dehydrogenase is an enzyme that is released from inflamed and injured pleural tissue. Exudative pleural effusions are characterized by the presence of proteins and/or elevated LDH levels in the pleural fluid, whereas...
transudates have none of these features. Because measurements of LDH are easily obtained from a sample of pleural fluid, it is a useful marker for diagnosis of exudative pleural disorders. Conditions that produce exudative pleural effusions are bacterial pneumonia, viral infection, pulmonary infarction, and malignancies. Empyema refers to an infection in the pleural cavity that results in exudate containing glucose, proteins, leukocytes, and debris from dead cells and tissue. The infection may be caused by invasion from an adjacent bacterial pneumonia or a subdiaphragmatic infection, by rupture of a lung abscess into the pleural space, or by trauma.

Chylothorax is the effusion of lymph in the thoracic cavity. Chyle, a milky fluid containing chylomicrons, is found in the lymph fluid drained by lacteals in the villi of the small intestine. The thoracic duct transports chyle to the central circulation. Chylothorax results from trauma, inflammation, or malignant infiltration obstructing chyle transport from the thoracic duct to the central circulation. It is the most common cause of pleural effusion in the fetus and neonate, resulting from congenital malformation of the thoracic duct or lymph channels. Chylothorax can also occur as a complication of intrathoracic surgical procedures and use of the great veins for total parenteral nutrition and hemodynamic monitoring.

Hemothorax is the presence of blood in the pleural cavity. Bleeding may arise from chest injury, a complication of chest surgery, malignancies, or rupture of a great vessel such as an aortic aneurysm. It is usually diagnosed by the presence of blood in the pleural fluid. Hemothorax usually requires drainage, and if the bleeding continues, surgery to control the bleeding may be required.

The manifestations of pleural effusion vary with the cause. Fluid in the pleural cavity acts as a space-occupying mass, causing a decrease in lung expansion on the affected side that is proportional to the amount of fluid collected. Characteristic signs of pleural effusion are dullness to percussion and diminished breath sounds. Hypoxemia may occur because of decreased surface area for diffusion and usually is corrected with supplemental oxygen. Dyspnea, the most common symptom, occurs when fluid in the pleural cavity compresses the lung, resulting in increased effort or rate of breathing. Pleuritic pain usually occurs only when inflammation is present, although constant discomfort may be felt with large effusions.

Diagnosis of pleural effusion is based on chest radiographs, chest ultrasonography, and computed tomography (CT). Thoracentesis (aspiration of fluid from the pleural space) can be used to obtain a sample of pleural fluid for diagnosis. The treatment of pleural effusion is directed at the cause of the disorder. With large effusions, thoracentesis may be used to remove fluid from the intrapleural space and allow for reexpansion of the lung. A palliative method used for treatment of pleural effusions caused by a malignancy is the injection of a sclerosing agent into the pleural cavity. This method of treatment causes obliteration of the pleural space and prevents the reaccumulation of fluid. Chest tube drainage may be necessary in cases of continued effusion.

Pneumothorax

Pneumothorax refers to the presence of air in the pleural space. Pneumothorax causes partial or complete collapse of the affected lung. Pneumothorax can occur without an obvious cause or injury (i.e., spontaneous pneumothorax) or as a result of direct injury to the chest or major airways (i.e., traumatic pneumothorax). Tension pneumothorax describes a life-threatening condition in which increased pressure within the pleural cavity impairs both respiratory and cardiac function.

Spontaneous Pneumothorax. Spontaneous pneumothorax is hypothesized to occur due to the rupture of an air-filled bleb, or blister, on the surface of the lung. Rupture of these blebs allows atmospheric air from the airways to enter the pleural cavity (Fig. 23-1). Because alveolar pressure normally is greater than pleural pressure, air flows from the alveoli into the pleural space, causing the involved portion of the lung to collapse and air continues to flow into the pleural space until a pressure gradient no longer exists or the decline in lung size causes the leak to seal. Spontaneous pneumothoraces can be divided into primary and secondary pneumothoraces. Primary pneumothorax occurs in otherwise healthy persons, whereas secondary pneumothorax occurs in persons with underlying lung disease.

In primary spontaneous pneumothorax, the blebs usually are located at the top of the lungs. The condition is seen in persons who are tall and thin. It has been suggested that the difference in pleural pressure from the top to the bottom of the lung is greater in tall persons and that this difference in pressure may contribute to the development of blebs. Smoking is another factor that has been associated with primary spontaneous pneumothorax. Inflammation of the small airways related

![FIGURE 23-1. Mechanism for development of spontaneous pneumothorax, in which an air-filled bleb on the surface of the lung ruptures, allowing atmospheric air from the airways to enter the pleural space.](image)
to smoking is thought to contribute to the condition, and cessation of smoking may reduce the chance of recurrence.

Secondary spontaneous pneumothoraces usually are more serious because they occur in persons with lung disease. They are associated with many different types of lung conditions that cause trapping of gases and destruction of lung tissue, including asthma, tuberculosis, cystic fibrosis, sarcoidosis, bronchogenic carcinoma, and metastatic pleural diseases. The most common cause of secondary spontaneous pneumothorax is emphysema. Secondary spontaneous pneumothorax may be life-threatening because of the underlying lung injury and poor compensatory reserves.

**Traumatic Pneumothorax.** Traumatic pneumothorax may be caused by penetrating or nonpenetrating chest injuries, most commonly fractured or dislocated ribs that penetrate the pleura. Hemothorax may accompany these injuries.8,13 Pneumothorax also may accompany fracture of the trachea or major bronchus or rupture of the esophagus. Persons with pneumothorax due to chest trauma frequently have other complications and may require chest surgery. Medical procedures such as transthoracic needle aspirations, central line insertion, intubation, and positive-pressure ventilation occasionally may cause pneumothorax. Traumatic pneumothorax also can occur as a complication of cardiopulmonary resuscitation.

**Tension Pneumothorax.** Tension pneumothorax occurs when the intrapleural pressure exceeds atmospheric pressure.8,13 It is a life-threatening condition and occurs when injury to the chest or respiratory structures allows air to enter but not leave the pleural space (Fig. 23-2). This results in a rapid increase in pressure within the chest that causes compression of the unaffected lung, a shift in the mediastinum to the opposite side of the chest, and compression of the vena cava, which results in a decrease in venous return to the heart and reduced cardiac output. Although tension pneumothorax can develop in persons with spontaneous pneumothoraces, it is seen most often in persons with traumatic pneumothoraces. It also may result as a complication of mechanical ventilation. A simple pneumothorax can progress to a tension pneumothorax when positive-pressure mechanical ventilation is employed.

**Clinical Features.** The manifestations of pneumothorax depend on its size and the integrity of the underlying lung. In spontaneous pneumothorax, manifestations of the disorder include development of ipsilateral chest pain.7,8,13,14 There is an almost-immediate increase in respiratory rate, often accompanied by dysnea that occurs as a result of the activation of receptors that monitor lung volume. Asymmetry of the chest may occur because of the air trapped in the pleural cavity on the affected side. This asymmetry may be evidenced during inspiration as a lag in the movement of the affected side, with inspiration delayed until the unaffected lung reaches the same level of pressure as the lung with the air trapped in the pleural space. Percussion of the chest produces a more hyperresonant sound, and breath sounds are decreased or absent over the area of the pneumothorax.

With tension pneumothorax, the trachea deviates toward the opposite side of the chest along with the structures in the mediastinal space (see Fig. 23-2). The position of the trachea can be used as a means of assessing for a mediastinal shift. Because of the increase in intrathoracic pressure, stroke volume or the amount of blood that the heart ejects with each beat is reduced to such an extent that cardiac output is decreased despite an increase in heart rate. There may be distention of the neck veins, subcutaneous emphysema (i.e., presence of air in the subcutaneous tissues of the chest and neck), and clinical signs of shock due to impaired cardiac function.

Hypoxemia usually develops immediately after a large pneumothorax, followed by vasoconstriction of the blood vessels in the affected lung, causing the blood flow to shift to the unaffected lung. In persons with primary spontaneous pneumothorax, this mechanism usually returns oxygen saturation to normal within 24 hours. Hypoxemia usually is more serious
in persons with underlying lung disease in whom secondary spontaneous pneumothorax develops or in persons with underlying heart disease who are unable to compensate with an increase in heart rate and stroke volumes. Regardless of etiology, the hypoxemia caused by the partial or total loss of lung function can be life-threatening. Without immediate intervention, the increased thoracic pressure will further impair both cardiac and pulmonary function, resulting in severe hypoxemia and hypotension.

Diagnosis of pneumothorax can be confirmed by chest radiograph, CT scan, or ultrasonography. Pulse oximetry and blood gas analysis may be done to determine the effect on blood oxygen levels. Treatment of pneumothorax varies with the cause and extent of the disorder. In small spontaneous pneumothoraces, the air usually reabsorbs spontaneously, and only observation and follow-up chest radiographs are required. Supplemental oxygen may be used to correct the hypoxemia until the air is reabsorbed. In larger pneumothoraces, the air is removed by needle aspiration or a closed drainage system used with or without suction. This type of drainage system uses a one-way valve to allow air to exit the pleural space and prevent it from reentering the chest.

Emergency treatment of tension pneumothorax involves the prompt insertion of a large-bore needle or chest tube into the affected side of the chest along with one-way valve drainage or continuous chest suction to aid in lung reexpansion. Sucking chest wounds, which allow air to pass in and out of the chest cavity, should be treated by promptly covering the area with an airtight covering. Chest tubes are inserted as soon as possible.

**Atelectasis**

*Atelectasis* refers to an incomplete expansion of a lung or portion of a lung. It can be caused by airway obstruction, lung compression such as occurs in pneumothorax or pleural effusion, or increased recoil of the lung due to loss of pulmonary surfactant (see Chapter 21). The disorder may be present at birth (i.e., primary atelectasis) or develop during the neonatal period or later in life (i.e., acquired or secondary atelectasis).

Primary atelectasis of the newborn implies that the lung has never been inflated. It is seen most frequently in premature and high-risk infants. A secondary form of atelectasis can occur in infants who established respiration and subsequently experienced impairment of lung expansion. Among the causes of secondary atelectasis in the newborn is the respiratory distress syndrome associated with lack of surfactant and airway obstruction due to aspiration of amniotic fluid or blood.

Acquired atelectasis occurs mainly in adults. It most commonly results from airway obstruction, for example, by a mucus plug in the airway or by external compression of the airway from fluid, a tumor mass, exudate, or other matter in the pleural cavity or area surrounding the airway (Fig. 23-3). Portions of alveoli, a small segment of lung, or an entire lung lobe may be involved. Complete obstruction of an airway is followed by the absorption of air from the dependent alveoli and collapse of that portion of the lung. Breathing high concentrations of oxygen increases the rate at which gases are absorbed from the alveoli and predisposes to atelectasis. The danger of obstructive atelectasis increases after surgery. Anesthesia, pain, administration of narcotics, and immobility tend to promote retention of viscid bronchial secretions and airway obstruction. The encouragement of coughing and deep breathing, frequent change of position, adequate hydration, and early ambulation decrease the risk for atelectasis.

The clinical manifestations of atelectasis include tachypnea, tachycardia, dyspnea, cyanosis, signs of hypoxemia, diminished chest expansion, absence of breath sounds, and intercostal retractions. Both chest expansion and breath sounds are decreased on the affected side. There may be intercostal retraction (pulling in of the intercostal spaces) over the involved area during inspiration. Signs of respiratory distress are proportional to the extent of lung collapse. If the collapsed area is large, the mediastinum and trachea shift to the affected side. In compression atelectasis, the mediastinum shifts away from the affected lung.

The diagnosis of atelectasis is based on signs and symptoms. Chest radiographs are used to confirm the diagnosis. Computed tomography scans may be used to show the exact location of the obstruction. Treatment depends on the cause and extent of lung involvement. It is directed at reducing the airway obstruction or lung compression and at reinfation of the collapsed area of the lung. Ambulation, deep breathing, and body positions that favor increased lung expansion are used when appropriate. Administration of oxygen may be needed to correct the hypoxemia. Bronchoscopy may be used as both a diagnostic and treatment method.
SUMMARY CONCEPTS

- Disorders of the pleura include pleuritis, pleural effusion, and pneumothorax. Pleuritis, or inflammation of the pleura, characteristically causes unilateral pain that is abrupt in onset and exaggerated by respiratory movements. Pleural effusion refers to the abnormal accumulation of fluid in the pleural cavity. The fluid may be a transudate (i.e., hydrothorax), exudate (i.e., empyema), chyle (i.e., chylothorax), or blood (hemorthorax).

- Pneumothorax refers to an accumulation of air in the pleural cavity that causes partial or complete collapse of the lung. Pneumothorax can result from rupture of an air-filled bleb on the lung surface or from penetrating or nonpenetrating injuries. A tension pneumothorax is a life-threatening event in which air accumulates in the thorax, collapsing the lung on the injured side and progressively shifting the mediastinum to the opposite side of the thorax, producing severe cardiac and respiratory impairment.

- Atelectasis refers to an incomplete expansion of the lung. Primary atelectasis occurs most often in premature and high-risk infants. Acquired atelectasis occurs mainly in adults and is caused most commonly by a mucus plug in the airway or by external compression by fluid, tumor mass, exudate, or other matter in the area surrounding the airway.

Obstructive Airway Disorders

Obstructive airway disorders are caused by conditions that limit expiratory airflow. Bronchial asthma represents an acute and reversible form of airway disease caused by narrowing of the airways due to bronchoconstriction, inflammation, and increased airway secretions. Chronic obstructive disorders include a variety of airway diseases, such as bronchial asthma, chronic obstructive pulmonary disease, bronchiectasis, and cystic fibrosis.

Physiology of Airway Disease

Air moves through the upper airways (i.e., trachea and major bronchi) into the lower or pulmonary airways (i.e., bronchi and alveoli), which are located in the lung. In the pulmonary airways, the cartilaginous layer that provides support for the trachea and major bronchi gradually disappears and is replaced with crisscrossing strips of smooth muscle (see Chapter 21).

The contraction and relaxation of the smooth muscle layer, which is innervated by the autonomic nervous system, controls the diameter of the bronchial airways and consequent resistance to airflow. Parasympathetic stimulation through the vagus nerve and cholinergic receptors produces bronchoconstriction, whereas sympathetic stimulation, through β-adrenergic receptors, produces bronchodilation. At rest, a slight vagal-mediated bronchoconstrictor tone predominates. When there is need for increased airflow, as during exercise, the bronchodilator effects of the sympathetic nervous system are stimulated and the bronchoconstrictor effects of the parasympathetic nervous system are inhibited. Bronchial smooth muscle also responds to inflammatory mediators, such as histamine, that act directly on bronchial smooth muscle cells to produce bronchoconstriction.

Bronchial Asthma

Bronchial asthma is a common obstructive airway disease that affects adults and children and occurs in all populations and locations throughout the world. It has been estimated that 25.7 million people in the United States suffer from asthma, 7.0 million of them children under 18 years of age. The disease continues to be costly, both in terms of emergency room visits and lost work days. Close to 2.1 million emergency room visits were attributed to asthma in 2009, and in 2008 it accounted for an estimated 14.2 million lost work days for adults.

Asthma is a chronic inflammatory disease of the airways involving recurring symptoms of airflow obstruction and bronchial hyper-responsiveness. Airway obstruction is characterized by episodic wheezing, difficulty breathing, feeling of chest tightness, and a cough that often is worse at night and in the early morning. These episodes, which usually are reversible either spontaneously or with treatment, also cause an associated increase in bronchial responsiveness to a variety of stimuli.

Etiology and Pathogenesis

Asthma is commonly categorized into two types: extrinsic or allergic, due to a type I hypersensitivity reaction, and intrinsic or non-atopic, that occurs without an allergic component. In either type, episodes of bronchospasm can be triggered by diverse nonimmune mechanisms, including respiratory tract infections, exercise, ingestion of aspirin, emotional upset, and exposure to bronchial irritants such as cigarette smoke.

Asthma may also be classified according to the agents or events that trigger an attack. These include seasonal, exercise-induced, drug-induced (e.g., aspirin), and occupational asthma.

The common denominator underlying all forms of asthma is an exaggerated hypersensitivity response to a variety of stimuli. After exposure to an inciting factor (allergens, drugs, cold, or exercise), inflammatory mediators released by activated macrophages, eosinophils, mast cells, and basophils induce bronchoconstriction, increased
vascular permeability, and mucus production.\textsuperscript{15,16} In some persons, persistent changes in airway structures occur, including injury to epithelial cells, smooth muscle hypertrophy, and blood vessel proliferation.

Recent research has focused on the role of T lymphocytes in the pathogenesis of bronchial asthma. It is now known that there are two subsets of T-helper cells (T\textsubscript{H}1 and T\textsubscript{H}2) that develop from the same precursor CD4\textsuperscript{+} T lymphocyte (see Chapter 15).\textsuperscript{15} T\textsubscript{H}1 cells differentiate in response to microbes and stimulate the differentiation of B cells into immunoglobulin (Ig) M and IgG-producing plasma cells. T\textsubscript{H}2 cells, on the other hand, respond to allergens by stimulating B cells to differentiate into IgE-producing plasma cells that bind to mucosal mast cells. Subsequent IgE-mediated reactions to inhaled allergens elicit an asthmatic attack (see Chapter 16, Fig. 16-1). In persons with allergic asthma, T-cell differentiation appears to be skewed toward T\textsubscript{H}2 cells. Although the molecular basis for this preferential differentiation is unclear, it seems likely that both genetic and environmental factors play a role.

**Atopic Asthma.** Atopic asthma is typically initiated by a type I hypersensitivity reaction induced by exposure to an extrinsic antigen or allergen.\textsuperscript{15,16} It usually has its onset in childhood or adolescence and is seen in persons with a family history of atopic allergy (see Chapter 16). Persons with atopic asthma often have other allergic disorders, such as hay fever, urticaria, and eczema. Attacks are related to exposure to specific allergens. Among air-borne allergens implicated in perennial (year-round) asthma are house dust mite allergens, cockroach allergens, animal danders, and \textit{Alternaria} (a fungus).

The mechanisms of response to allergens in atopic asthma can be described in terms of the early-phase and the late-phase responses\textsuperscript{15,16} (Fig. 23-4). The symptoms of the \textit{early-phase response} (also called the \textit{acute-phase response}), which usually develop within 10 to 20 minutes of exposure to the allergen, are caused by the release of chemical mediators from presensitized IgE-coated mast cells. In the case of air-borne antigens, the reaction occurs when antigen binds to previously sensitized mast cells on the mucosal surface of the airways (Fig. 23-5A). Mediator release results in the infiltration of inflammatory cells, opening of the mucosal intercellular junctions, and increased access of antigen to the more prevalent submucosal mast cells. In addition, there is bronchospasm caused by stimulation of parasympathetic receptors, mucosal edema caused by increased vascular permeability, and increased mucus secretions. The acute response usually can be inhibited or reversed by bronchodilators, such as \(\beta\)-agonists, but not by the anti-inflammatory actions of corticosteroids.

The \textit{late-phase response}, which develops 4 to 8 hours after exposure to an asthmatic trigger, involves inflammation and increased airway responsiveness that

![FIGURE 23-4. Mechanisms of early- and late-phase IgE-mediated bronchospasm.](image-url)
prolong the asthma attack and set into motion a vicious cycle of exacerbations. Typically, the response reaches a maximum within a few hours and may persist for 12 to 24 hours or longer. An initial trigger in the late-phase response causes the release of inflammatory mediators from mast cells, macrophages, and epithelial cells. These substances induce the migration and activation of other inflammatory cells (e.g., basophils, eosinophils, neutrophils), which then produce epithelial injury and edema, changes in mucociliary function, reduced clearance of respiratory tract secretions, and increased airway responsiveness (see Fig. 23-5B). Chronic inflammation can lead to airway remodeling, in which case airflow limitations may be only partially reversible.

Nonatopic Asthma. Intrinsic or nonatopic asthma triggers include respiratory tract infections, exercise, hyperventilation, cold air, drugs and chemicals, hormonal changes and emotional upsets, air-borne pollutants, and gastroesophageal reflux. Respiratory tract infections, especially those caused by viruses, may produce their effects by causing epithelial damage and stimulating the production of IgE antibodies directed toward the viral antigens. In addition to precipitating an asthmatic attack, viral respiratory infections increase airway responsiveness to other asthma triggers. This hyperresponsiveness may persist for weeks beyond the original infection.

Exercise-induced asthma occurs in a number of persons with bronchial asthma. Although the cause of exercise-induced asthma is unclear, hyperventilation and corresponding changes in airway physiology may play a role. It has been suggested that the increased ventilatory rate required to meet higher oxygen demands during exercise challenges the ability of the airways to condition the inhaled air to the correct moist and heat levels before the air reaches the alveoli. Vigorous exercise results in the inhalation of increased volumes of relatively cold and dry air and loss of body heat from the respiratory mucosa, which in turn induces mast cells and epithelial cells to release proinflammatory mediators such as histamine and leukotrienes. The response commonly is exaggerated when the person exercises in a cold environment. Wearing a mask over the nose and mouth often minimizes the attack or prevents it. In addition to inflammatory cytokines, airway cooling stimulates cholinergic receptors in the airways, with a resultant increase in airway resistance. A warm-up period alleviates the symptoms for some persons.

Inhaled irritants, such as tobacco smoke and strong odors, are thought to induce bronchospasm by way of irritant receptors and a vagal reflex. Exposure to parental smoking has been reported to increase asthma severity in children. Occupational asthma is caused by sensitizing agents or irritants encountered in the workplace. Occupational asthma from sensitizers usually presents with a latent period of exposure, followed by the onset of disease. Irritant or nonimmunologic asthma results from high levels of exposure to irritant gases such as sulfur dioxide, nitrogen dioxide, and ozone, which may induce inflammatory exacerbations of airway

FIGURE 23-5. Pathogenesis of bronchial asthma. (A) The early-phase response triggered by an IgE-mediated release of mediators from sensitized mast cells. The release of chemical mediators results in increased mucus production, opening of mucosal intercellular junctions with exposure of submucosal mast cells to antigen, and bronchospasm. (B) The late-phase response involves epithelial cell injury with decreased mucociliary function and accumulation of mucus; release of inflammatory mediators with recruitment of neutrophils, eosinophils, and basophils; increased vascular permeability and edema; and increased airway responsiveness and bronchospasm.
manifestations of chemicals that can provoke an asthmatic attack are the sulfites used in food processing and as preservatives added to beer, wine, and fresh vegetables. There is a small group of persons in whom aspirin and other NSAIDs evoke the clinical triad of nasal polyps, chronic rhinosinusitis, and bronchial asthma.15,16,27 The mechanism of the hypersensitivity reaction is complex and not fully understood, but most evidence points toward an abnormality in arachidonic acid (AA) metabolism in which aspirin inhibits the bronchodilating cyclooxygenase pathway without affecting the lipoxygenase pathway, thereby shifting the balance toward the bronchoconstrictor leukotrienes (see Chapter 3, Fig. 3-4). Avoidance of aspirin and all NSAIDs is a necessary part of the treatment program.

Both emotional factors and changes in hormone levels are thought to contribute to an increase in asthma symptoms. Emotional factors produce bronchospasm by way of vagal pathways. They can act as a bronchospastic trigger, or they can increase airway responsiveness to other triggers through noninflammatory mechanisms. Reproductive hormones may play a role in asthma in women. Up to 40% of women with asthma report a premenstrual increase in asthma symptoms.28 Female reproductive hormones have a regulatory role on β2-adrenergic function, and it has been suggested that abnormal regulation may be a possible mechanism for premenstrual asthma.

Symptoms of gastroesophageal reflux are common in both adults and children with asthma, suggesting that reflux of gastric secretions may act as a bronchospastic trigger. Reflux during sleep can contribute to nocturnal asthma.19

manifestations

Persons with asthma exhibit a wide range of signs and symptoms ranging from episodes of wheezing and feelings of chest tightness to acute immobilizing attacks. The attacks differ from person to person, and between attacks, many persons are symptom free. Attacks may occur spontaneously or in response to various triggers, respiratory infections, emotional stress, or weather changes. Asthma is often worse at night. Studies of nocturnal asthma suggest that there is a circadian and sleep-related variation in hormones and respiratory function.29 The greatest decrease in respiratory function occurs at about 4:00 AM, at which time cortisol levels are low, melatonin levels high, and eosinophil activity increased.30

During an asthmatic attack, the airways narrow because of bronchospasm, edema of the bronchial mucosa, and mucus plugging. Expiration becomes prolonged because of progressive airway obstruction.19–22 The amount of air that can be forcibly expired in 1 second (forced expiratory volume in 1 second [FEV1.0]) and the peak expiratory flow rate (PEF), measured in liters per second, are decreased.

During a prolonged attack, air becomes trapped behind the occluded and narrowed airways, causing hyperinflation of the lungs. This produces an increase in the residual volume (RV) along with a decrease in the inspiratory reserve capacity (tidal volume + inspiratory reserve volume [IRV]) and forced vital capacity (FVC), such that the person breathes close to his or her functional residual capacity (residual volume + expiratory reserve volume; see Chapter 21, Fig. 21-17). As a result, more energy is needed to overcome the tension already present in the lungs, and the accessory muscles (e.g., sternocleidomastoid muscles) are required to maintain ventilation and gas exchange. This increased work of breathing further increases oxygen demands and causes dyspnea and fatigue. Because air is trapped in the alveoli and inspiration is occurring at higher residual lung volumes, the cough becomes less effective. As the condition progresses, the effectiveness of alveolar ventilation declines, and mismatching of ventilation and perfusion occurs, causing hypoxemia and hypercapnia. Pulmonary vascular resistance may increase as a result of the hypoxemia and hyperinflation, leading to a rise in pulmonary arterial pressure and increased work demands on the right heart.

The physical signs of bronchial asthma vary with the severity of the attack. A mild attack may produce a feeling of chest tightness, a slight increase in respiratory rate with prolonged expiration, and mild wheezing. A cough may accompany the wheezing. More severe attacks are accompanied by use of the accessory muscles, distant breath sounds due to air trapping, and loud wheezing. As the condition progresses, fatigue develops, the skin becomes moist, and anxiety and apprehension ensue. Sensations of shortness of breath may be severe, and often the person is able to speak only one or two words before taking a breath. At the point at which airflow is markedly decreased, breath sounds become inaudible, wheezing diminishes, and the cough becomes ineffective despite being repetitive and hacking.19 This point often marks the onset of respiratory failure. A common error on physical examination is the absence of wheezing which signifies severe bronchospasm and represents the lack of air movement. With appropriate treatment, wheezing can be unmasked as air movement improves.

Diagnosis and Treatment

The diagnosis of asthma is based on a careful history and physical examination, laboratory findings, and pulmonary function studies (see Chapter 21).19–22 Spirometry provides a means for measuring FVC, FEV1.0, PEF, tidal volume, expiratory reserve volume, and inspiratory reserve volume. The FEV1.0/FVC ratio can then be calculated. The level of airway responsiveness can be measured by inhalation challenge tests using methacholine (a cholinergic agonist), histamine, or exposure to a nonpharmacologic agent such as cold air. The Expert Panel of the National Asthma Education and Prevention Program (NAEPP) has developed classification systems intended for use in identifying persons at high risk for development of life-threatening asthma attacks and directing asthma treatment19 (Table 23-1).

Small, inexpensive, portable meters that measure PEF are available. Although not intended for use in the
diagnosis of asthma, they can be used in clinics and physicians’ offices and by persons in their home to provide frequent measures of flow rates. Day–night (circadian) variations in asthma symptoms and PEF variability can be used to indicate the severity of bronchial hyperresponsiveness. The person’s best performance is established from readings taken over several weeks. This often is referred to as the individual’s personal best and is used as a reference to indicate changes in respiratory function. A PEF below 40% of the predicted or personal best during an acute asthmatic attack indicates a severe exacerbation and the need for immediate intervention, and a PEF below 25% of the predicted or personal best indicates a life-threatening attack.\(^\text{19}\)

Successful management of bronchial asthma requires control of factors contributing to asthma severity and pharmacologic treatment. Control measures are aimed at prevention of exposure to allergens and irritants. They include education of the person and family regarding known triggers; therefore, a careful history is needed to identify all contributory factors. Annual influenza vaccination is recommended for persons with persistent asthma. A program of desensitization may be undertaken in persons with persistent asthma who react to allergens, such as house dust mites, that cannot be avoided. This involves the injection of selected antigens (based on skin tests) to stimulate the production of IgG antibodies that block the IgE response. A course of allergen immunotherapy is typically of 3 to 5 years’ duration.\(^\text{19}\)

Traditionally, drugs used to treat asthma were categorized according to their predominant mechanism of action—relaxation of bronchial smooth muscle (bronchodilator) and suppression of airway inflammation (anti-inflammatory drugs). A more recent classification divides asthma medications into two general categories according to their roles in the overall management of asthma symptoms (quick-relief or long-term maintenance medications).\(^\text{19}\)

### Quick-relief Medications

The quick-relief medications include the short-acting \(\beta_2\)-agonists, anticholinergic agents, and systemic corticosteroids.\(^\text{19,21,31}\) The short-acting \(\beta_2\)-agonists relax bronchial smooth muscle and provide prompt relief of symptoms, usually within 30 minutes. They are administered by inhalation (i.e., metered-dose inhaler [MDI] or nebulizer).

The anticholinergic agents block cholinergic receptors and reduce intrinsic vagal tone that causes bronchoconstriction. These medications, which are administered by inhalation, produce bronchodilation by direct action on the large airways but do not change the composition or viscosity of the bronchial mucus. It is thought that they may provide some additive benefit for treatment of asthma exacerbations when administered with inhaled \(\beta_2\)-agonists.

A short course of systemic corticosteroids, administered orally or parenterally, may be used for treating the inflammatory reaction associated with the late-phase response. Although their onset of action is slow (>4 hours), systemic corticosteroids may be used in the treatment of moderate to severe exacerbations because of their action in preventing the progression of the exacerbation, speeding recovery, and preventing early relapses.

### Long-term Medications

The long-term medications are taken on a daily basis to achieve and maintain control of persistent asthma symptoms. They include inhaled corticosteroids, long-acting bronchodilators, cromolyn and nedocromil, leukotriene receptor antagonists, and theophylline.\(^\text{19,21,31}\) The corticosteroids are considered the most effective anti-inflammatory agents for use in

long-term treatment of asthma. Inhaled corticosteroids administered by MDI usually are preferred because of minimal systemic absorption and reduced disruption in hypothalamic-pituitary-adrenal function.

The long-acting β2-agonists, available for administration by the inhaled or oral routes, act by relaxing bronchial smooth muscle. They are used as an adjunct to anti-inflammatory medications for providing long-term control of symptoms, especially nocturnal symptoms, and for preventing exercise-induced bronchospasm. The long-acting β2-agonists have durations of action of at least 12 hours and should not be used to treat acute symptoms or exacerbations.19

The leukotriene receptor antagonists (montelukast and zafirlukast) block the action of the leukotrienes, which are arachidonic acid derivatives synthesized by a number of inflammatory cells in the airways, including eosinophils, mast cells, macrophages, and basophils.15,31 Several of the leukotrienes exert many of the effects known to occur in asthma, including bronchoconstriction, increased bronchial reactivity, mucosal edema, and mucus hypersecretion. A particular advantage of the leukotriene receptor antagonists is that they are taken orally.

Theophylline, a phosphodiesterase inhibitor, is a bronchodilator that acts by relaxing bronchial smooth muscle. The sustained-release form of the drug is used as an adjuvant therapy, particularly to relieve nighttime symptoms.19 It may be used as an alternative, but not preferred, medication in long-term preventative therapy when there are issues concerning adherence with regimens using inhaled medications or when cost is a factor. Because elimination of the drug varies widely among persons, blood levels are required to ensure that a therapeutic but not toxic dose is achieved.17

The anti-IgE monoclonal antibody omalizumab is the first biologic immunoregulatory agent available to treat asthma.29 It binds to the portion of the IgE that recognizes its receptor on the surface of mast cells and basophils. Omalizumab, which is indicated for treatment of moderate and severe persistent asthma, is administered subcutaneously every 2 to 4 weeks, depending on the dose. The drug has been approved for adults and children 12 years of age and older.

Severe Asthma

Severe (or refractory) asthma represents a subgroup (probably <10%) of persons with asthma who have high medication requirements to maintain good symptom control, or who continue to have persistent symptoms despite high medication use.32,33 The condition has been described as persistent asthma that required continuous high-dose inhaled or oral corticosteroids for more than 50% of the previous year and the need for additional daily treatment with controller medications, exhibited evidence of disease exacerbations or instability, and required hospitalizations or emergency room visits.19,21,32,33 Persons with severe asthma are at increased risk for a fatal or near-fatal asthmatic attack. Underestimating the severity of the attack may be a contributing factor.34 Deterioration often occurs rapidly during an acute attack, and underestimation of its severity may lead to a life-threatening delay in seeking medical attention.

Little is known about the causes of severe asthma. Among the proposed risk factors are genetic predisposition, continued allergen or tobacco exposure, infection, intercurrent sinusitis or gastroesophageal reflux disease, and lack of compliance or adherence with treatment measures.33 Because bronchial asthma likely involves multiple genes, mutations in genes regulating cytokines (e.g., IL-4), growth factors, or receptors for medications used in treatment of asthma (β2-adrenergic agonist or glucocorticoid) could be involved. Environmental factors include both allergen and tobacco exposure, with the strongest reaction occurring in response to house dust mite antigens, cockroach allergen, and Alternaria exposure.

Bronchial Asthma in Children

Asthma is a common chronic illness in children. In the United States, asthma is the most common cause of childhood emergency department visits, hospitalizations, and missed school days.35–38 Although childhood asthma may have its onset at any age, up to 80% of children who develop asthma are symptomatic before 5 years of age.39 Asthma is more prevalent among black than white children.36–39 Worldwide, childhood asthma appears to be increasing in prevalence.35 It is particularly common in children living in suburban areas, as compared to rural areas of developing countries.

As with adults, asthma in children commonly is associated with an IgE-related reaction. It has been suggested that IgE directed against respiratory viruses in particular may be important in the pathogenesis of wheezing illnesses in infants (i.e., bronchiolitis), which often precede the onset of asthma.37,38 Previous severe infections with the respiratory syncytial virus (RSV) are a risk factor in the development of asthma. Other contributing factors include exposure to environmental allergens such as pet dander, dust mite antigens, and cockroach allergens. Exposure to environmental tobacco smoke also contributes to asthma in children.36–39

The signs and symptoms of asthma in infants and small children vary with the stage and severity of an attack. Because airway patency decreases at night, many children have acute signs of asthma at this time. Often, previously well infants and children develop what may seem to be a cold with rhinorrhea, rapidly followed by irritability, nonproductive cough, wheezing, tachypnea, dyspnea with prolonged expiration, and use of accessory muscles of respiration. Cyanosis, hyperinflation of the chest, and tachycardia indicate increasing severity of the attack. Wheezing may be absent in children with extreme respiratory distress. The symptoms may progress rapidly and require a trip to the emergency department or hospitalization.

As with adults and older children, the Expert Panel of the NAEPP recommends a stepwise approach to diagnosing and managing childhood asthma.19 Treatment involves not only pharmacologic agents but also
Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease (COPD) denotes a group of respiratory disorders characterized by chronic and recurrent obstruction of airflow in the pulmonary airways.\textsuperscript{15,16,40,41} The airflow obstruction is usually progressive, may be accompanied by airway hyperreactivity, and may be partially reversible. COPD remains a leading cause of morbidity and mortality worldwide. It is the fourth leading cause of death in the United States, and is projected to become the third leading cause of death worldwide.\textsuperscript{41}

The most common cause of COPD is smoking, as evidenced by the fact that 85% to 90% of persons with COPD have a history of smoking.\textsuperscript{15,16} Other predisposing factors include exposure to occupational dusts and chemicals, airway infections, and asthma or airway hyperresponsiveness.\textsuperscript{41} Unfortunately, clinical findings are almost always absent during the early stages of COPD. By the time symptoms appear or are recognized, the disease is usually far advanced. For smokers with early signs of airway disease, there is hope that early recognition, combined with appropriate treatment and smoking cessation, may prevent or delay the usually relentless progression of the disease.

The term chronic obstructive pulmonary disease encompasses two types of obstructive airway disease: emphysema, with enlargement of air spaces and destruction of lung tissue, and chronic obstructive bronchitis, with increased mucus production, obstruction of small airways, and a chronic productive cough.\textsuperscript{15,16} Persons with COPD often have overlapping features of both emphysema and chronic bronchitis.

The mechanisms involved in the pathogenesis of COPD usually are multiple and include inflammation and fibrosis of the bronchial wall, hypertrophy of the submucosal glands and hypersecretion of mucus, and loss of elastic fibers and alveolar tissue (Fig. 23-6). Inflammation and fibrosis of the bronchial wall, along with excess mucus secretion and destruction of elastic fibers, cause mismatching of ventilation and perfusion. Destruction of alveolar tissue decreases the surface area for gas exchange, and loss of elastic fibers, which normally provide traction and hold the airways open, impairs the expiratory flow rate, increases air trapping, and predisposes to airway collapse.

Emphysema

Emphysema is characterized by a loss of lung elasticity and abnormal enlargement of the air spaces distal to the terminal bronchioles, with destruction of the alveolar walls and capillary beds\textsuperscript{16} (Fig. 23-7). Enlargement of the air spaces leads to hyperinflation of the lungs and produces an increase in total lung capacity (TLC). Two of the recognized causes of emphysema are smoking, which incites lung injury, and an inherited deficiency of α\textsubscript{1}-antitrypsin, an antiprotease enzyme that protects the lung from injury. Genetic factors other than an inherited α\textsubscript{1}-antitrypsin deficiency also may play a role in smokers who develop COPD at an early age.\textsuperscript{41}
Emphysema is thought to result from the breakdown of elastin and other alveolar wall components by enzymes, called proteases, which digest proteins. The proteases—particularly elastase, which is an enzyme that digests elastin—are released from polymorphonuclear leukocytes (i.e., neutrophils), alveolar macrophages, and other inflammatory cells. Normally, the lung is protected by antiprotease enzymes, including α₁-antitrypsin. Cigarette smoke and other irritants stimulate the movement of inflammatory cells into the lungs, resulting in increased release of elastase and other proteases. In smokers in whom COPD develops, antiprotease production and release may be inadequate to neutralize the excess protease production such that the process ofelastic tissue destruction goes unchecked (Fig. 23-8).

A hereditary deficiency in α₁-antitrypsin accounts for approximately 1% of all cases of COPD and is more common in young persons with emphysema. The type and amount of α₁-antitrypsin that a person has are determined by a pair of codominant genes referred to as protein inhibitor (PI) genes. Homozygotes who carry two defective PI genes have only about 15% to 20% of the normal plasma concentration of α₁-antitrypsin. Smoking and repeated respiratory tract infections, which also decrease α₁-antitrypsin levels, contribute to the risk for emphysema in persons with α₁-antitrypsin deficiency. Laboratory methods are available for measuring α₁-antitrypsin levels. Human α₁-antitrypsin is

available for replacement therapy in persons with a hereditary deficiency of the enzyme.

There are two commonly recognized types of emphysema: centriacinar or centrilobular, and panacinar (Fig. 23-9). The centriacinar type affects the bronchioles in the central part of the respiratory lobule, with initial preservation of the alveolar ducts and sacs. It is the most common type of emphysema and is seen predominantly in male smokers. The panacinar type produces initial involvement of the peripheral alveoli and later extends to involve the more central bronchioles. This type of emphysema is more common in persons with α₁-antitrypsin deficiency. It also is found in smokers in association with centriacinar emphysema.

**Chronic Bronchitis**

Chronic bronchitis represents airway obstruction of the major and small airways. The condition is seen most commonly in middle-aged men and is associated with chronic irritation from smoking and recurrent infections. A clinical diagnosis of chronic bronchitis requires a history of a chronic productive cough that has persisted for at least 3 consecutive months in at least 2 consecutive years. Typically, the cough has been present for many years, with a gradual increase in acute exacerbations that produce frankly purulent sputum.

The earliest feature of chronic bronchitis is hypersecretion of mucus in the large airways, associated with hypertrophy of the submucosal glands in the trachea and bronchi. Although mucus hypersecretion in the large airways is the cause of sputum overproduction, the accompanying changes in the small airways (small bronchi and bronchioles) are now thought to be important in the airway obstruction that develops. Histologically, these changes include a marked increase in goblet cells and excess mucus production with plugging of the airway lumen, inflammatory infiltration, and fibrosis of the bronchiolar wall. It is thought that both the submucosal hypertrophy in the large airways and the increase in goblet cells in the smaller airways are a protective reaction against tobacco smoke and other pollutants. Viral and bacterial infections are common in persons with chronic bronchitis and are thought to be a result rather than a cause of the disease. While infections are not responsible for initiating the disease process, they are probably important in maintaining it and may be critical in producing acute exacerbations.

**Manifestations**

The clinical manifestations of COPD usually have an insidious onset and persons characteristically seek medical attention in the fifth or sixth decade of life, with manifestations of excessive cough, sputum production, and shortness of breath. The productive cough usually occurs in the morning and the dyspnea becomes more severe as the disease progresses. Frequent exacerbations of infection and respiratory insufficiency are common, causing absence from work and eventual disability. The late stages of COPD are characterized by recurrent respiratory infections and chronic respiratory failure. Death usually occurs during an exacerbation of illness associated with infection and respiratory failure.

The mnemonics “pink puffer” and “blue bloater” have been used to differentiate the clinical manifestations of emphysema and chronic obstructive bronchitis. Persons with predominant emphysema are classically referred to as pink puffers, a reference to the lack of cyanosis, the use of accessory muscles, and pursed-lip (“puffer”) breathing. With loss of lung elasticity and hyperinflation of the lungs, the airways often collapse during expiration because pressure in surrounding lung tissues exceeds airway pressure. Air becomes trapped in the alveoli and lungs, producing an increase in the anteroposterior dimensions of the chest, the so-called barrel chest that is typical of persons with emphysema. Such persons have a dramatic decrease in breath sounds throughout the chest. Because the diaphragm may be functioning near its maximum ability, the person is vulnerable to diaphragmatic fatigue and acute respiratory failure. Persons with a clinical syndrome of chronic bronchitis are classically
labeled blue bloaters, a reference to cyanosis and fluid retention associated with right-sided heart failure. In practice, differentiation between the two types of COPD is often difficult. This is because persons with COPD often have some degree of both emphysema and chronic bronchitis.

The manifestations of COPD are associated with episodes of moderate to severe respiratory impairment due to obstruction of airflow, which is greater on expiration than inspiration, resulting in increased work of breathing but decreased effectiveness. The development of exertional dyspnea, often described as increased effort to breathe, heaviness, air hunger, or gasping, can be insidious. Activities involving significant arm work, particularly above the shoulders, are usually difficult for persons with COPD. The breathing becomes increasingly more labored, even at rest; the expiratory phase of respiration is prolonged; and expiratory wheezes and crackles can be heard on auscultation. Persons with severe airflow obstruction may also exhibit use of the accessory muscles, often sitting in the characteristic “tripod” position in which the arms are braced to facilitate use of the sternocleidomastoid, scalene, and intercostal muscles. Pursed-lip breathing enhances airflow because it increases the resistance to the outflow of air and helps to prevent airway collapse by increasing airway pressure. Eventually, persons with COPD are unable to maintain normal blood gases by increasing their breathing effort. Hypoxemia, hypercapnia, and cyanosis develop, reflecting an imbalance between ventilation and perfusion.

Exacerbations, which are characterized by increased cough, sputum, dyspnea, and fatigue, are increasingly frequent as the disease progresses. They are often difficult to distinguish from other causes of respiratory deterioration, such as pneumonia, congestive heart failure, pulmonary emboli, and pneumothorax with radiologic or laboratory tests. Persons with frequent exacerbations exhibit a faster decline in lung function and have a lower quality of life, an increased need for hospitalization, and a higher mortality rate.

Severe hypoxemia, in which arterial PO$_2$ levels fall below 55 mm Hg, causes reflex vasoconstriction of the pulmonary vessels and further impairment of gas exchange in the lung. It is more common in persons with the chronic bronchitis form of COPD. Hypoxemia also stimulates red blood cell production, causing polycythemia. The increase in pulmonary vasoconstriction and subsequent elevation in pulmonary artery pressure further increase the work of the right ventricle. As a result, persons with COPD may develop right-sided heart failure with peripheral edema (i.e., cor pulmonale). However, signs of overt right-sided heart failure are seen less frequently since the advent of supplemental oxygen therapy (to be discussed).

**Diagnosis and Treatment**

The diagnosis of COPD is based on a careful history and physical examination, pulmonary function studies, chest radiographs, and laboratory tests. Airway obstruction prolongs the expiratory phase of respiration and
affords the potential for impaired gas exchange because of mismatching of ventilation and perfusion. The FVC is the amount of air that can be forcibly exhaled after maximal inspiration. In patients with chronic lung disease, the FVC is decreased, the FEV$_{1.0}$ is decreased, and the ratio of FEV$_{1.0}$ to FVC is decreased. Lung volume measurements reveal a marked increase in RV, an increase in TLC, and elevation of the RV-to-TLC ratio. These and other measurements of expiratory flow are determined by spirometry and are used in the diagnosis and severity of COPD (see Chapter 21, Fig. 21-15). Other diagnostic measures become important as the disease advances. Measures of exercise tolerance, nutritional status, hemoglobin saturation, and arterial blood gases can be used to assess the overall impact of COPD on health status and to direct treatment.

The treatment of COPD depends on the stage of the disease and often requires an interdisciplinary approach. Smoking cessation is the only measure that slows the progression of the disease. Maintaining and improving physical and psychosocial functioning is an important part of the treatment program. A long-term pulmonary rehabilitation program can significantly reduce hospitalizations and increase a person’s ability to manage and cope with his or her impairment in a positive way. This program includes breathing exercises that focus on restoring the function of the diaphragm, reducing the work of breathing, and improving gas exchange. Physical conditioning with appropriate exercise training increases maximal oxygen consumption and reduces ventilatory effort and heart rate for a given workload. Work simplification and energy conservation strategies may be needed when impairment is severe.

Respiratory tract infections can prove life-threatening to persons with severe COPD. A person with COPD should avoid exposure to others with known respiratory tract infections and should avoid attending large gatherings during periods of the year when influenza or respiratory tract infections are prevalent. Immunization for influenza and pneumococcal infections decreases the likelihood of their occurrence. Although antibiotics are used to treat acute exacerbations of COPD due to bacterial infection, there is no evidence that the prophylactic use of antibiotics prevents acute exacerbations.

The pharmacologic treatment of COPD includes the use of bronchodilators, including inhaled adrenergic and anticholinergic agents. Inhaled β$_2$-agonists have been the mainstay of treatment of COPD for many years. It has been suggested that long-acting inhaled β$_2$-agonists may be even more effective than the short-acting forms of the drug. The anticholinergic drugs, which are administered by inhalation, produce bronchodilation by blocking parasympathetic cholinergic receptors that produce contraction of bronchial smooth muscle. They also reduce the volume of sputum without altering its viscosity. Because these drugs have a slower onset and longer duration of action, they are typically used on a regular basis rather than as needed. Inhalers that combine an anticholinergic drug with a β$_2$-adrenergic agonist are available. Oral theophylline may be used in treatment of persons who fail to respond to inhaled bronchodilators. The long-acting theophylline preparations may be used to reduce overnight declines in respiratory function. When theophylline is prescribed, blood levels are used as a guide in arriving at an effective dose schedule.

Although inhaled corticosteroids are often used in treatment of COPD, there is controversy regarding their usefulness. There is evidence that inflammation in COPD is not suppressed by inhaled or oral corticosteroids. Because corticosteroids are useful in relieving asthma symptoms, they may benefit persons with asthma concomitant with COPD. Inhaled corticosteroids also may be beneficial in treating acute exacerbations of COPD, minimizing the undesirable effects that often accompany systemic use.

Oxygen therapy is prescribed for selected persons with significant hypoxemia (arterial PO$_2$ < 55 mm Hg). Administration of continuous low-flow (1 to 2 L/min) oxygen to maintain arterial PO$_2$ levels between 55 and 65 mm Hg decreases dyspnea and pulmonary hypertension and improves neuropsychological function and activity tolerance. The overall goal of oxygen therapy is to maintain a hemoglobin oxygen saturation of at least 90%. Portable oxygen administration units, which allow mobility and the performance of activities of daily living, are often used in severe COPD. Because the ventilatory drive associated with hypoxic stimulation of the peripheral chemoreceptors does not occur until the arterial PO$_2$ has been reduced to about 60 mm Hg or less, increasing the arterial PO$_2$ above 60 mm Hg tends to depress the hypoxic stimulus for ventilation and often leads to hypoventilation and carbon dioxide retention.

**Bronchiectasis**

Bronchiectasis is characterized by a permanent dilation of bronchi caused by destruction of the bronchial muscle wall and elastic supporting tissue. It is not a primary disease but occurs secondary to a number of abnormalities that profoundly obstruct the airways or produce persistent infection, including atelectasis, obstruction of the smaller airways, diffuse bronchitis, and cystic fibrosis. In the past, bronchiectasis often followed a necrotizing bacterial pneumonia that frequently complicated measles, pertussis (whooping cough), or influenza. Tuberculosis was also commonly associated with bronchiectasis. Thus, with the advent of antibiotics that more effectively treat respiratory infections such as tuberculosis, and with immunization against pertussis and measles, there has been a marked decrease in the prevalence of bronchiectasis.

**Etiology and Pathogenesis**

Two processes are critical to the pathogenesis of bronchiectasis: obstruction and chronic persistent infection. Regardless of which may come first, both cause damage to the bronchial walls, leading to weakening and dilation. On gross examination, bronchial dilation is classified as saccular, cylindrical, or varicose. Saccular bronchiectasis involves the proximal third to
fourth generation of bronchi (see Chapter 21, Fig. 21-4). These bronchi become severely dilated and end blindly in dilated sacs, with collapse and fibrosis of more distal lung tissue. Cylindrical bronchiectasis involves uniform and moderate dilation of the sixth to eighth generations of airways. It is a milder form of disease than saccular bronchiectasis and leads to fewer symptoms. Varicose bronchiectasis involves the second through eighth branchings of bronchi and results in bronchi that resemble varicose veins. Bronchiolar obliteration is not as severe and symptoms are variable.

**Manifestations**

Bronchiectasis is usually manifested by a chronic productive cough, often with several hundred milliliters of foul-smelling, purulent sputum a day. Hemoptysis is common. Dyspnea and wheezing occur in about 75% of patients. Weight loss, anemia, and other systemic manifestations are common. Clubbing of the fingers is infrequent in mild cases, but common in severe disease. Obstructive pulmonary dysfunction with hypoxemia is seen in moderate to severe cases. However, due to improved treatment with better antibiotics and physical therapy, outcome and life expectancy have improved considerably.

**Diagnosis and Treatment**

Diagnosis is based on history and imaging studies. The condition often is evident on chest radiographs. High-resolution CT scanning of the chest allows for definitive diagnosis. Accuracy of diagnosis is important because interventional bronchoscopy or surgery may be palliative or curative in some types of obstructive disease.

Treatment consists of early recognition and management of infections along with regular postural drainage and chest physical therapy. Persons with this disorder benefit from many of the rehabilitation and treatment measures used for chronic bronchitis and emphysema.

**Cystic Fibrosis**

Cystic fibrosis (CF), which is a major cause of severe chronic respiratory disease in children and young adults, is an inherited disorder involving fluid secretion by the exocrine glands in the epithelial lining of the respiratory, gastrointestinal, and reproductive tracts. In addition to chronic respiratory disease, CF is manifested by pancreatic exocrine deficiency and elevation of sodium chloride in the sweat. Nasal polyps, sinus infections, pancreatitis, and cholelithiasis also are common. Excessive loss of sodium in the sweat predisposes young children to salt depletion episodes. Most males with CF have congenital bilateral absence of the vas deferens with azoospermia.

Cystic fibrosis is inherited as an autosomal recessive trait. Homozygotes have all or substantially all of the clinical symptoms of the disease, compared with heterozygotes, who are carriers of the disease but have no recognizable symptoms. Cystic fibrosis occurs most frequently in white populations of northern Europe, North America, and Australia/New Zealand. Although it occurs less frequently among African, Hispanic, Middle Eastern, South Asian, and Eastern Asian populations, it may occur in these populations as well.
of Cl\(^{-}\) into airway lumen is impaired. This ultimately leads to a series of secondary events, including increased absorption of Na\(^{+}\) and water from the airways into the blood. This lowers the water content of the mucociliary blanket coating the respiratory epithelium, causing it to become more viscid. The resulting dehydration of the mucous layer leads to defective mucociliary function and accumulation of viscid secretions that obstruct the airways and predispose to recurrent pulmonary infections. Similar transport abnormalities and pathophysiologic events take place in the pancreatic and biliary ducts and in the vas deferens in males.

**Manifestations**

Respiratory manifestations of CF are caused by an accumulation of viscid mucus in the bronchi, impaired mucociliary clearance, and lung infections. Chronic bronchiolitis and bronchiectasis are the initial lung manifestations, but after months and years, structural changes in the bronchial wall lead to bronchiectasis. In addition to airway obstruction, the basic genetic defect that occurs with CF predisposes to chronic infection with a surprisingly limited number of organisms, the most common being *Pseudomonas aeruginosa*, *Burkholderia cepacia*, *Staphylococcus aureus*, and *Haemophilus influenzae*. Soon after birth, initial infection with bacterial pathogens occurs and is associated with an excessive neutrophilic inflammatory response that appears to be independent of the infection itself. There is evidence that the airway secretions in persons with CF provide a favorable environment for harboring these organisms. *Pseudomonas aeruginosa*, in particular, has a propensity to undergo mucoid transformation in this environment. The complex polysaccharide produced by these organisms provides a hypoxic environment and generates a biofilm that protects *Pseudomonas* against antimicrobial agents. Pulmonary inflammation is another cause of decline in respiratory function in persons with CF and may precede the onset of chronic infection.

Exocrine pancreatic function is abnormal in more than 85% of affected children. Steatorrhea, diarrhea, and abdominal pain are common. In the newborn, meconium ileus may cause intestinal obstruction, a fatal condition if left untreated. The degree of pancreatic involvement is highly variable. In some children, the defect is relatively mild, and in others, the involvement is severe and impairs intestinal absorption. In addition to exocrine pancreatic insufficiency, hyperglycemia may occur, especially after 10 years of age, when approximately 8% of persons with CF develop diabetes mellitus.

**Diagnosis and Treatment**

Early diagnosis and treatment are important in delaying the onset and severity of chronic illness in children with CF. Diagnosis is based on the presence of respiratory and gastrointestinal manifestations typical of CF, a history of CF in a sibling, or a positive newborn screening test result. Confirmatory laboratory tests include the sweat test and DNA tests for *CFTR* gene mutations. The sweat test, using pilocarpine iontophoresis
to collect the sweat followed by chemical analysis of its chloride content, remains the standard approach to diagnosis. Newborns with CF have elevated blood levels of immunoreactive trypsinogen, presumably because of secretory obstruction in the pancreas. A variety of newborn screening tests are in place to identify infants with cystic fibrosis, most of which consist of a combination of immunoreactive trypsinogen and limited DNA analysis. These tests can be done on blood spots collected for routine newborn screening tests.

Treatment measures are directed toward early and aggressive measures to slow progression of secondary organ dysfunction and sequelae such as chronic lung infection and pancreatic insufficiency. They include the use of antibiotics to prevent and manage infections, the use of chest physical therapy (chest percussion and postural drainage) and mucolytic agents to prevent airway obstruction, and nutritional therapy including pancreatic enzyme replacement. Routine laboratory evaluations are key to assessing pulmonary function and response to therapeutic interventions. These studies include radiologic examinations, pulmonary function testing, and microbiologic cultures of respiratory secretions.

Appropriate antibiotic therapy directed against bacterial pathogens isolated from the respiratory tract is an essential component in the management of CF lung disease. Antibiotics are initially used to prevent colonization with P. aeruginosa; they are used as maintenance therapy once the airways are colonized with P. aeruginosa and other organisms such as S. aureus; and they are administered as aggressive treatment during acute exacerbations of pulmonary symptoms caused by infections. To avoid adverse effects and to obtain high airway concentrations, the inhalation route is often used as an option for home delivery of these agents, with other routes of delivery being used during periods of progressive symptoms.

The abnormal viscosity of airway secretions is attributed largely to the presence of polymorphonuclear white blood cells and their degradation products. A purified recombinant human deoxyribonuclease (rhDNase), an enzyme that breaks down these products, has been developed. Clinical trials have shown that the drug, which is administered by inhalation, can decrease pulmonary symptoms and reduce the frequency of respiratory exacerbations. Although many persons benefit from the therapy, the drug is costly, and recommendations for its use are evolving.

Up to 90% of patients with CF have complete loss of exocrine pancreatic function and inadequate digestion of fats and proteins. They require supplemental vitamins and minerals and enteric-coated, pH-sensitive pancreatic enzyme supplements. At one time, a low-fat, high-protein, high-calorie diet was recommended. With the advent of improved pancreatic enzyme products, however, normal amounts of fat in the diet are usually tolerated and preferred.

Progress of the disease is variable. Improved medical management has led to longer survival. Today, many people with the disease can expect to live into their 40s and beyond. Lung transplantation is being used as a treatment for persons with end-stage lung disease.

The last 10 years have seen promising results from research into the management of cystic fibrosis using small molecules called cystic fibrosis transmembrane regulator protein (CFTR) modulators designed to increase the time the CFTR channels in the cell surface remain open.

**SUMMARY CONCEPTS**

- Obstructive airway disorders due to bronchial smooth muscle hyperreactivity or changes in bronchial wall structure, injury to the mucosal lining of the airways, or excess respiratory tract secretions are characterized by limitation in movement of atmospheric air into and out of the gas exchange portion of the lung.
- Bronchial asthma is a chronic disorder of the airways that causes reversible episodes of airway obstruction due to bronchial smooth muscle hyperreactivity and airway inflammation. Extrinsic (or atopic) asthma is a type I hypersensitivity reaction triggered by an allergen; whereas intrinsic asthma is triggered by respiratory tract infections, exercise, drugs and chemicals, airborne pollutants, and gastroesophageal reflux.
- An asthmatic episode is characterized by two types of responses—acute and late phase. The acute-phase response results in immediate bronchoconstriction on exposure to an inhaled antigen and usually subsides within 90 minutes. The late-phase response develops 4 to 8 hours after exposure to an asthmatic trigger; and involves inflammation and increased airway responsiveness that prolong the attack and cause a vicious cycle of exacerbations.
- Chronic obstructive pulmonary disease (COPD) encompasses two types of obstructive airway disease: emphysema, with enlargement of air spaces and destruction of lung tissue, and chronic obstructive bronchitis, with increased mucus production, obstruction of small airways, and a chronic productive cough. Persons with COPD often have overlapping features of both emphysema and chronic bronchitis, and both are manifested by eventual mismatching of ventilation and perfusion. As the conditions advance, signs of respiratory distress and impaired gas exchange become evident, with development of hypercapnia and hypoxemia.
- Bronchiectasis is an uncommon form of COPD that is characterized by an abnormal dilation of the large bronchi associated with infection and destruction of the bronchial walls.
SUMMARY CONCEPTS (continued)

- Cystic fibrosis (CF) is an autosomal recessive genetic disorder manifested by chronic lung disease, pancreatic exocrine deficiency, and elevation of sodium chloride in the sweat. The defect causes exocrine gland secretions to become exceedingly viscous, and promotes colonization of the respiratory tract with P. aeruginosa and other organisms such as S. aureus. Accumulation of viscous mucus in the bronchi, impaired mucociliary function, and infection contribute to the development of chronic lung disease and a decreased life expectancy.

Interstitial Lung Diseases

The diffuse interstitial lung diseases, also called diffuse parenchymal lung diseases, are a diverse group of lung disorders that produce similar inflammatory and fibrotic changes in the interstitium or interalveolar septa of the lung. Because the interstitial lung diseases result in a stiff and noncompliant lung, they are commonly classified as restrictive lung disorders.

In contrast to the obstructive lung diseases, which primarily involve the airways of the lung, the interstitial lung disorders exert their effects on the collagen and elastic connective tissue found in the delicate interstitium of the alveolar walls. Many of these diseases also involve the airways, arteries, and veins. The clinical hallmark of these widespread lung changes is diminished lung compliance, which presents as restrictive lung disease. The lungs are stiff and difficult to inflate. More pressure is needed to expand the lungs, which in turn necessitates more effort in breathing. Damage to alveolar epithelium and interstitial vasculature produces impaired gas exchange and hypoxemia. With progression, persons develop respiratory failure, often in association with pulmonary hypertension and cor pulmonale.

The interstitial lung diseases may be acute or insidious in onset; they may be rapidly progressive, slowly progressive, or static in their course. Over 100 distinct entities of interstitial lung diseases have been recognized including hypersensitivity pneumonitis (discussed in Chapter 16); lung diseases caused by medications (e.g., the cancer drug bleomycin and the antiarrhythmic drug amiodarone) and radiation therapy; the occupational lung diseases, including the pneumoconioses that are caused by the inhalation of inorganic dusts such as silica, coal dust, and asbestos; immunologic lung disorders, such as those that accompany rheumatoid arthritis and scleroderma; and granulomatous diseases such as sarcoidosis. Examples of interstitial lung diseases and their causes are listed in Chart 23-1. The discussion in this chapter focuses on idiopathic pulmonary fibrosis and sarcoidosis, two of the most common interstitial lung diseases seen in the clinical setting.

Pathogenesis

Current theory suggests that most interstitial lung diseases, regardless of their cause, have a common pathogenesis. It is thought that these disorders are initiated by some type of injury to the alveolar epithelium, followed by an inflammatory process that involves the alveoli and interstitium of the lung. If the injury is mild and self-limited, resolution with restoration of normal lung structures follows. However, with persistence of the injurious agent, an accumulation of inflammatory and immune cells causes continued damage to lung tissue and replacement of normally functioning lung tissue with fibrous scar tissue. Alveolar macrophages secrete a host of fibrogenic factors, including fibroblast growth factor, transforming growth factor-β (TGF-β), and platelet-derived growth factor, which can attract fibroblasts as well as stimulate their proliferation. Alveolar cells also appear to play a role in the process. Destruction of type I alveolar cells is often accompanied by proliferation of type II alveolar cells (see Chapter 21). These cells secrete chemotactic factors that attract additional macrophages, growth factors, and cytokines such as TGF-β that contribute to fibrotic changes.

Clinical Features

In general, the interstitial lung diseases are characterized by clinical changes consistent with restrictive rather than obstructive changes in the lung. Persons with

*This list is not intended to be inclusive.
Interstitial lung diseases have dyspnea, tachypnea, and eventual cyanosis, without evidence of wheezing or signs of airway obstruction. Usually, there is an insidious onset of breathlessness that initially occurs during exercise and may progress to the point at which the person is totally incapacitated. Typically, the person breathes with a tachypneic pattern of breathing, in which the respiratory rate is increased and the tidal volume is decreased. This pattern of breathing serves to maintain minute volume yet reduces the work of breathing because it takes less work to move air through the airways at an increased rate than it does to stretch a stiff lung to accommodate a larger tidal volume. A nonproductive cough may develop, particularly with continued exposure to the inhaled irritant. Clubbing of the fingers and toes may develop.

Lung volumes, including vital capacity and total lung capacity, are reduced in interstitial lung disease. In contrast to COPD, in which expiratory flow rates are reduced, the FEV₁/ₐ usually is preserved, even though the ratio of FEV₁/ₐ to FVC may increase. Although resting arterial blood gases usually are normal in the course of the disease, arterial PO₂ levels may fall during exercise. In persons with advanced disease, hypoxemia often is present, even at rest. In the late stages of the disease, hypercapnia and respiratory acidosis develop. The impaired diffusion of gases is thought to be caused by alterations in the alveolar–capillary membrane as well as an increase in shunt resulting from unventilated regions of the lung.

The diagnosis of interstitial lung disease requires a careful personal and family history, with particular emphasis on exposure to environmental, occupational, and other injurious agents. Chest radiographs may be used as an initial diagnostic method, and to follow the progress of the disease. A biopsy specimen for histologic study and culture may be obtained by surgical incision, bronchoscopy, or bronchoalveolar lavage, in which fluid is instilled into the alveoli through a bronchoscope and then removed by suction for laboratory study.

The treatment goals for persons with interstitial lung disease focus on identifying and removing the injurious agent, suppressing the inflammatory response (typically with corticosteroids), preventing progression of the disease, and providing supportive therapy for persons with advanced disease. Many of the supportive treatment measures, such as oxygen therapy and measures to prevent infection, are similar to those discussed for persons with COPD.

**Idiopathic Pulmonary Fibrosis**

The most common diagnosis among persons with interstitial lung disease is idiopathic pulmonary fibrosis. The disease is characterized by diffuse interstitial fibrosis, which in severe cases results in severe hypoxemia and cyanosis. As the name implies, the cause of the disorder is unknown. Men are affected more commonly than women and approximately two thirds of persons are older than 60 years of age at the time of presentation.

A number of conditions and risk factors are associated with the disease. Cigarette smoking increases the risk, as do certain occupations such as farming, hairdressing, stonecutting, and metal cutting. Although viruses have not been clearly implicated in the pathogenesis of idiopathic pulmonary fibrosis, several viral proteins and antibodies to viruses are associated with the disease. In addition, some people may have a genetic predisposition to the disease.

The disease is characterized by patchy interstitial fibrosis that causes collapse of alveolar walls and formation of cystic spaces lined by hyperplastic type II alveolar cells or bronchial epithelium. Secondary hypertensive changes due to intimal fibrosis and medial thickening of the pulmonary arteries are often present.

Idiopathic pulmonary fibrosis usually presents insidiously, with gradual onset of a nonproductive cough and progressive dyspnea. Cyanosis, cor pulmonale, and peripheral edema may present late in the disease. Diagnosis is confirmed by surgical biopsy. Unfortunately, the progress of the disease is relentless despite current methods of treatment. The mean survival after diagnosis is 3 to 5 years.

**Sarcoidosis**

Sarcoidosis is a multisystem disorder in which granulomas are found in many tissues and organs, particularly the lung. The disorder predominantly affects adults younger than 40 years of age, although it can occur in older persons. The incidence is highest among North American blacks and northern European whites; and women are affected more frequently than men.

The cause of sarcoidosis remains unclear. It is thought that the disorder may result from exposure of genetically predisposed persons to specific environmental agents. Defective human leukocyte antigen (HLA) genes located in the major histocompatibility complex may be linked to disease susceptibility and prognosis. Multiple lines of evidence suggest that the inciting agent triggers an immune response that depends on host susceptibility.

The immune response is characterized by chronic inflammation, monocyte recruitment, and granuloma formation in which multinucleated giant cells are frequently seen. These granulomas do not show evidence of necrosis or caseation. The inflammation often involves the alveoli (alveolitis). It is composed largely of macrophages and lymphocytes, with the latter thought to be of particular importance in the pathogenesis of the disease.

Sarcoidosis has variable manifestations and an unpredictable course of progression in which any organ system can be affected. The three systems that most commonly manifest symptoms are the lungs, eyes, and skin. Persons with sarcoidosis frequently seek health care either as a result of abnormalities detected on an incidental chest film or because of insidious onset of
respiratory symptoms (shortness of breath, nonproductive cough, chest pain) or constitutional signs and symptoms (e.g., fever, sweating, anorexia, weight loss, fatigue, myalgia). Eye involvement (anterior uveitis) and skin involvement (skin papules and plaques) are particularly common extrathoracic manifestations, but there may be cardiac, neuromuscular, hematologic, hepatic, endocrine, and lymph node findings.

Sarcoidosis is characterized by either progressive chronicity or periods of activity interspersed with remissions, sometimes permanent, that may be spontaneous or induced by corticosteroid therapy. Approximately 65% to 75% of persons recover with minimal clinical and radiographic abnormalities. Other persons have persistent radiographic abnormalities and progression of their respiratory symptoms, with or without additional extrathoracic disease.

The diagnosis of sarcoidosis is based on history and physical examination, tests to exclude other diseases, chest radiography, and biopsy to obtain confirmation of noncaseating granulomas. A thorough ophthalmologic evaluation is recommended for most persons, even those without ocular symptoms.

Treatment is directed at interrupting the granulomatous inflammatory process that is characteristic of the disease and managing the associated complications. When treatment is indicated, corticosteroid drugs are used. These agents produce clearing of the lung, as seen on the chest radiograph, and improve pulmonary function, but it is not known whether they affect the long-term outcome of the disease.

SUMMARY CONCEPTS

- The interstitial lung diseases are a diverse group of lung disorders that produce similar inflammatory and fibrotic changes in the interstitium or alveolar septa of the lung. As a result, the lungs become stiff and difficult to inflate, increasing the work of breathing and causing dyspnea and decreased exercise tolerance due to hypoxemia, without evidence of wheezing or signs of airway obstruction.

- These diseases include drug- and radiation-induced lung disease, environmental and occupational lung diseases caused by inhalation of organic and inorganic dusts, immunologic lung disorders such as those that accompany scleroderma, idiopathic pulmonary fibrosis, and sarcoidosis.

- The restrictive lung disorders reduce the diffusing capacity of the lung, producing various degrees of hypoxemia, dyspnea, tachypnea, and eventual cyanosis.

---

Disorders of the Pulmonary Circulation

As blood moves through the pulmonary capillaries, the oxygen content increases and the carbon dioxide decreases. These processes depend on the matching of ventilation (i.e., gas exchange) and perfusion (i.e., blood flow). This section discusses two major problems of the pulmonary circulation: pulmonary embolism and pulmonary hypertension. Pulmonary edema, another major problem of the pulmonary circulation, is discussed in Chapter 20.

Pulmonary Embolism

Pulmonary embolism develops when a blood-borne substance lodges in a branch of the pulmonary artery and obstructs blood flow. The embolism may consist of a thrombus (Fig. 23-13), air that has accidentally been injected during intravenous infusion, fat that has been mobilized from the bone marrow after a fracture or from a traumatized fat depot, or amniotic fluid that has entered the maternal circulation during childbirth.

Pathogenesis

Although pulmonary emboli can originate from a number of sources, most arise from deep vein thrombosis (DVT) in the large veins of the lower legs, typically originating in the popliteal vein or larger veins above it (see Chapter 18). The presence of thrombosis in the deep veins of the legs or pelvis often is unsuspected until embolism occurs. Among the physiologic factors that contribute to venous thrombosis are venous stasis, venous endothelial injury, and hypercoagulability states. Venous stasis and venous endothelial injury can result from prolonged bed rest (particularly with immobilization of the legs), severe trauma (including burns and fractures), surgery (particularly orthopedic surgery of the knee or hip), childbirth, myocardial infarction and congestive heart failure, and spinal cord injury. Hypercoagulability is related to various factors. Cancer cells can produce thrombin and synthesize procoagulation factors, increasing the risk for thromboembolism. Pregnancy, and hormone replacement therapy are thought to increase the resistance to endogenous anticoagulants and risk of pulmonary embolism. There is also increased risk for pulmonary embolism among users of oral contraceptives, particularly in women who smoke. The thrombophilias (e.g., antithrombin III deficiency, protein C and S deficiencies, factor V Leiden mutation) are a group of inherited disorders affecting coagulation that make an individual prone to the development of venous thromboemboli (see Chapter 12).

The pathophysiologic effects of thromboembolism depend largely on the size of the embolus and degree of pulmonary blood flow obstruction. Obstruction of pulmonary blood flow causes reflex bronchoconstriction in the affected area of the lung, ventilation without perfusion, impaired gas exchange, and loss of alveolar surfactant. Pulmonary hypertension and right heart strain may develop with large emboli or in those with poor cardiac reserve.

Although small areas of infarction may occur, pulmonary infarction is uncommon. This is because the lung is perfused not only by the pulmonary arteries but also by the bronchial arteries and air from the alveoli. If the bronchial circulation is normal and adequate ventilation is maintained, a decrease in pulmonary artery perfusion does not usually cause infarction.

Manifestations

The clinical manifestations of pulmonary embolism depend on the size and location of the obstruction. Small emboli that become lodged in the peripheral branches of the pulmonary artery are clinically silent and may go unrecognized, especially in the elderly and acutely ill. Persons with moderate-sized emboli often present with breathlessness accompanied by pleuritic pain, apprehension, slight fever, and cough productive of blood-streaked sputum. Tachycardia often occurs to compensate for decreased oxygenation, and the breathing pattern is rapid and shallow. Patients with massive emboli usually present with sudden collapse, crushing substernal chest pain, shock, and sometimes loss of consciousness. The pulse is rapid and weak, the blood pressure is low, the neck veins are distended, and the skin is cyanotic and diaphoretic. Massive pulmonary emboli often are fatal.

Diagnosis and Treatment

Diagnosis of pulmonary embolism is based on clinical signs and symptoms, blood gas determinations, D-dimer testing, lung perfusion scans, CT scans of the chest, and, in selected cases, pulmonary angiography. Laboratory studies and radiologic films are useful in ruling out other conditions that might give rise to similar symptoms. Because emboli can cause an increase in pulmonary vascular resistance, the electrocardiogram (ECG) may be used to detect signs of right heart strain. There has been recent interest in combining several noninvasive methods (lower limb compression ultrasonography, D-dimer measurements, and clinical assessment measures) as a means of establishing a diagnosis of pulmonary embolism.

Because most pulmonary emboli originate from DVT, venous studies such as lower limb compression ultrasonography, impedance plethysmography, and contrast venography are often used as initial diagnostic procedures. Of these, lower limb compression ultrasonography has become an important noninvasive means for detecting DVT. D-dimer testing involves the measurement of plasma D-dimer, a degradation product of coagulation factors that have been activated as a result of a thromboembolic event. The ventilation–perfusion scan uses radiolabeled albumin, which is injected intravenously, and a radiolabeled gas, which is inhaled. A scintillation (gamma) camera is used to scan the various lung segments for blood flow and distribution of the radiolabeled gas. Ventilation–perfusion scans are useful only when their results are either normal or indicate a high probability of pulmonary embolism. Helical (spiral) CT angiography requires administration of an intravenous radiocontrast medium. It is sensitive for the detection of emboli in the proximal pulmonary arteries and provides another method of diagnosis. Pulmonary angiography involves the passage of a venous catheter through the right heart and into the pulmonary artery under fluoroscopy. Although it remains the most accurate method of diagnosis, it is an invasive procedure; therefore, its use is reserved for selected cases.

Treatment goals for pulmonary emboli include preventing DVT and the development of thromboemboli, protecting the lungs from exposure to thromboemboli when they occur, and in the case of large and life-threatening pulmonary emboli, sustaining life and restoring pulmonary blood flow. Thrombolytic therapy using streptokinase, urokinase, or recombinant tissue plasminogen activator may be indicated in persons with life-threatening pulmonary emboli. Thrombolytic therapy is followed by anticoagulant therapy (e.g., heparin and then warfarin) to prevent clot recurrence but carries the risk of bleeding complications and is contraindicated in many post-surgical patients. Anticoagulation with unfractionated or low-molecular weight heparin is frequently employed to prevent additional clot burden when signs of right heart strain are absent. Surgical interruption of the vena cava or...
insertion of a filter to prevent emboli from traveling to the lung may be indicated in life-threatening situations or in cases where thrombolytic therapy or anticoagulation is contraindicated.

Venous thromboembolism is often clinically silent until it presents with significant morbidity and mortality. Thus, recognition of risk factors and appropriate preventative treatment are essential. Prophylactic measures include early ambulation for postoperative and postpartum patients and the use of graded compression elastic stockings and intermittent pneumatic compression (IPC) boots for bedridden patients. Intermittent pneumatic compression boots provide intermittent inflation of air-filled sleeves that prevent venous stasis. Some devices produce sequential gradient compression that moves blood upward in the leg. Anticoagulant therapy may be used to decrease the likelihood of deep vein thrombosis, thromboembolism, and fatal pulmonary embolism after major surgical procedures (see Chapter 12). Low-molecular-weight heparin, which can be administered subcutaneously, often is used. Warfarin, an oral anticoagulant drug, may be used for persons with a long-term risk for development of thromboemboli. Newer factor Xa inhibitors are gaining popularity as an alternative to warfarin due to their efficacy and fewer food and drug interactions.

Pulmonary Hypertension

The pulmonary circulation is normally a low-pressure system designed to accommodate varying amounts of blood delivered from the right heart. The main pulmonary artery and major branches are relatively thin-walled, compliant vessels. The distal pulmonary arterioles also are thin walled and have the capacity to dilate, collapse, or constrict depending on the presence of vasoactive substances released from the endothelial cells of the vessel, neurohumoral influences, flow velocity, oxygen tension, and alveolar ventilation.

Pulmonary hypertension is a disorder characterized by an abnormal elevation of pressure within the pulmonary circulation—namely, the pulmonary arterial system. Secondary causes of pulmonary hypertension are less common than those of primary pulmonary hypertension. Secondary causes of pulmonary hypertension are less common than those of primary pulmonary hypertension. Secondary causes of pulmonary hypertension are less common than those of primary pulmonary hypertension. Secondary causes of pulmonary hypertension are less common than those of primary pulmonary hypertension.

Secondary Pulmonary Hypertension

Secondary pulmonary hypertension refers to an increase in pulmonary pressures associated with other disease conditions, usually cardiac or pulmonary. Often more than one disorder, such as COPD, heart failure, and sleep apnea, contributes. Secondary pulmonary hypertension may develop at any age. Mechanisms include: (1) elevation of pulmonary venous pressure, (2) increased pulmonary blood flow, (3) pulmonary vascular obstruction, and (4) hypoxemia.

Elevation of pulmonary venous pressure is common in conditions such as mitral valve disorders or left ventricular diastolic dysfunction. In each of these alterations, the elevated left atrial pressure is transmitted to the pulmonary circulation. Continued increases in left atrial pressure can lead to medial hypertrophy and intimal thickening of the small pulmonary arteries, causing sustained hypertension.

Increased pulmonary blood flow results from increased flow through left-to-right shunts in congenital heart diseases such as atrial or ventricular septal defects and patent ductus arteriosus. If the high-flow state is allowed to continue, morphologic changes occur in the pulmonary vessels, leading to sustained pulmonary hypertension. The pulmonary vascular changes that occur with congenital heart disorders are discussed in Chapter 19.

Obstruction of pulmonary blood flow is commonly due to pulmonary thromboemboli. Persons who are promptly treated for acute pulmonary thromboembolism with anticoagulants rarely develop pulmonary hypertension. However, in some persons chronic obstruction of the pulmonary vascular bed develops because of impaired resolution of the thromboembolism.

Continued exposure of the pulmonary vessels to hypoxemia is a common cause of pulmonary hypertension. Unlike blood vessels in the systemic circulation, most of which dilate in response to hypoxemia and hypercapnia, the pulmonary vessels constrict. The stimuli for constriction are thought to originate in the air spaces near the smaller branches of the pulmonary arteries. In regions of the lung that are poorly ventilated, the response is adaptive in that it diverts blood flow away from the poorly ventilated areas to those areas that are more adequately ventilated. This effect, however, becomes less beneficial as more and more areas of the lung become poorly ventilated. Pulmonary hypertension is a common problem resulting from hypoxemia that develops in persons with advanced COPD or interstitial lung disease. It also may develop at high altitudes in persons with normal lung function. Persons who experience marked hypoxemia during sleep (such as those with sleep apnea) often experience marked elevations in pulmonary arterial pressure.

Secondary pulmonary hypertension is difficult to recognize in its early stages, when the signs and symptoms are primarily those of the underlying disease. Pulmonary hypertension may cause, or contribute to, dyspnea, present initially with exertion and later at rest. Fatigue and syncope on exertion also occur, presumably the result of reduced cardiac output and elevated pulmonary artery pressures.

Diagnosis is based on radiographic findings and echocardiography. Doppler ultrasonography is a reliable noninvasive method for estimating pulmonary artery systolic pressure. Treatment measures are directed toward the underlying disorder. Vasodilator therapy may be indicated.

Primary Pulmonary Arterial Hypertension

Primary pulmonary arterial hypertension (PAH) is persistent elevation in pulmonary artery pressure that occurs in the absence of identified cardiopulmonary or other secondary causes of pulmonary hypertension.
It is a rare and debilitating disorder characterized by abnormal proliferation and contraction of vascular smooth muscle, coagulation abnormalities, and marked intimal fibrosis leading to obliteration or obstruction of the pulmonary arteries and arterioles (Fig. 23-14). The resulting increase in pulmonary artery pressure results in progressive right heart failure, low cardiac output, and death if left untreated.

A familial form of PAH appears to be inherited as an autosomal dominant trait with a variable but low penetrance, with some individuals inheriting the trait without exhibiting the disease. A causal relationship has been established between several appetite-suppressant drugs, including fenfluramine, and the development of PAH. Although the drug has been removed from the world market, many were exposed before that time. Pulmonary arterial hypertension is also associated with human immunodeficiency virus (HIV) infection. The mechanism by which HIV infection produces PAH remains unknown, but treatment of HIV infection does not appear to affect the severity or natural history of the underlying pulmonary hypertension. Other conditions associated with PAH include portal hypertension and persistent pulmonary hypertension in the newborn.

Although the specific mechanisms responsible for the vascular changes that occur in PAH remain unknown, a number of mechanisms have been proposed including diminished levels of nitric oxide and prostacyclin, two potent vasodilators. Nitric oxide is produced locally in the lungs, and prostacyclin is produced by the vascular endothelium. Moreover, increased levels of several growth factors, including endothelin-1, vascular endothelial growth factor, and platelet-derived growth factor, may contribute. Endothelin-1 is a peptide produced by the vascular endothelium that has potent vasoconstrictor and paracrine effects on vascular smooth muscle. Results of studies relating these mechanisms to the structure and function of the pulmonary arterial circulation have already been translated into targeted therapies for PAH.

Symptoms of PAH typically progress from shortness of breath and decreasing exercise tolerance to right heart failure, with marked peripheral edema and functional limitations. Other common symptoms include fatigue, angina, and syncope (fainting) or near-syncope. The diagnosis of primary pulmonary hypertension is based on an elevated pulmonary artery pressure and an absence of disorders that cause secondary pulmonary hypertension.

Treatment for primary pulmonary hypertension consists mainly of measures to improve right heart function as a means of reducing fatigue and peripheral edema. Supplemental oxygen may be used to increase exercise tolerance. The calcium channel blockers (nifedipine, diltiazem) may be effective early in the course of the disease but offer little in advanced stages.

More recent medications for treatment of primary pulmonary arterial hypertension include prostacyclin analogues, endothelin receptor antagonist, and phosphodiesterase type 5 inhibitors. Continuous long-term infusion of prostacyclin (e.g., epoprostenol), a potent pulmonary vasodilator, has been shown to provide symptomatic benefits and improved survival in selected patients. Because of its short half-life (3 to 5 minutes), the drug must be administered by continuous intravenous infusion through an indwelling catheter with an automatic ambulatory pump. Properties of the drug other than its vasodilating effects include inhibition of platelet aggregation and beneficial vascular remodeling effects. Endothelin, which is a potent vasoconstrictor and stimulator of vascular smooth muscle proliferation, is believed to be important in the

pathogenesis of primary pulmonary arterial hypertension. Oral endothelin antagonists (e.g., ambrisentan) have proved to be effective in treating moderate to severe primary pulmonary hypertension and may become the treatment of choice for all stages of the disease.66 Sildenafil (e.g., Revatio), a highly selective phosphodiesterase-5 inhibitor that acts in a manner similar to nitric oxide to produce vasodilation, is approved for use in pulmonary hypertension. Lung transplantation may be an alternative for persons who do not respond to other forms of treatment.

Cor Pulmonale

The term cor pulmonale refers to right heart failure resulting from primary lung disease or pulmonary hypertension. The increased pressures and work result in hypertrophy and eventual failure of the right ventricle. The manifestations of cor pulmonale include the signs and symptoms of the primary lung disease and the signs of right-sided heart failure (see Chapter 20). Signs of right-sided heart failure include venous congestion, peripheral edema, shortness of breath, and a productive cough, which becomes worse during periods of heart failure. Plethora (i.e., redness), cyanosis, and warm, moist skin may result from the compensatory polycythemia and desaturation of arterial blood that accompany chronic lung disease. Drowsiness and altered consciousness may occur as the result of carbon dioxide retention. Management of cor pulmonale focuses on the treatment of the lung disease and heart failure. Low-flow oxygen therapy may be used to reduce the pulmonary hypertension and polycythemia associated with severe hypoxemia caused by chronic lung disease.

Acute Respiratory Disorders

The function of the respiratory system is to add oxygen to the blood and remove carbon dioxide. Disruptions in gas exchange occur with acute lung injury respiratory distress syndrome, and respiratory failure. Although the mechanisms prompting these conditions may vary, both are life-threatening situations with a high risk of morbidity and mortality.

Acute Lung Injury/Acute Respiratory Distress Syndrome

Acute respiratory distress syndrome (ARDS) is a clinical syndrome that is characterized by severe dyspnea of rapid onset, hypoxemia, and pulmonary infiltrates. Acute lung injury (ALI) is a less-severe form of the disorder, but has the potential for evolving into ARDS. The two conditions are differentiated by the extent of hypoxemia as determined by the ratio of the partial pressure of oxygen in the arterial blood (PO₂) to fraction of inspired oxygen (FiO₂).67-70 The incidence of ALI/ARDS is not consistently reported, although it is estimated to occur in approximately 150,000 to 200,000 persons each year in North America. Despite the most sophisticated interventions, the mortality rate varies from 35% to 60% and morbidity is extensive, including physical, cognitive, and emotional sequelae.15,71

Both ARDS and ALI can result from a number of conditions, including aspiration of gastric contents, major trauma (with or without fat emboli), sepsis secondary to pulmonary or nonpulmonary infections, acute pancreatitis, hematologic disorders, metabolic events, and reactions to drugs and toxins (Chart 23-2).

Etiology and Pathogenesis

Although a number of conditions may lead to ALI/ARDS, they all produce similar pathologic lung changes that include diffuse epithelial cell injury with increased permeability of the alveolar–capillary membrane (Fig. 23-15). The increased permeability permits fluid, plasma proteins, and blood cells to move out of the vascular compartment into the interstitium and alveoli of the lung.15,69 Diffuse alveolar cell damage leads to accumulation of fluid, surfactant inactivation, and formation of a hyaline membrane that is fibrous and impervious to gas exchange.
As the disease progresses, the work of breathing becomes greatly increased as the lung stiffens and becomes more difficult to inflate. There is increased intrapulmonary shunting of blood, impaired gas exchange, and hypoxemia despite high supplemental oxygen therapy. Gas exchange is further compromised by alveolar collapse resulting from abnormalities in surfactant production. When injury to the alveolar epithelium is severe, disorganized epithelial repair may lead to fibrosis.

The pathogenesis of ALI/ARDS is unclear, although both local and systemic inflammatory responses occur. It is thought that dysregulated inflammation, accumulation of neutrophils, uncontrolled activation of coagulation pathways, and altered permeability of the endothelial and epithelial barriers all play a role. Initially, a direct or indirect pulmonary insult is believed to promote the accumulation of neutrophils in the microcirculation. These neutrophils activate and migrate in large numbers across the alveolar epithelial surfaces, releasing proteases, cytokines, and reactive oxygen species that lead to increased permeability in the alveolar epithelial cells and damage to type I and type II alveolar cells. This in turn leads to pulmonary edema, hyaline membrane formation, and loss of surfactant that decrease pulmonary compliance and make air exchange difficult.

**Clinical Features**

Clinically, ALI/ARDS is marked by a rapid onset, usually within 12 to 18 hours of the initiating event, of respiratory distress, an increase in respiratory rate, and signs of respiratory failure. Chest radiography shows diffuse bilateral infiltrates of the lung tissue in the absence of cardiac dysfunction (non-cardiogenic pulmonary edema). Marked hypoxemia occurs that is refractory to treatment with supplemental oxygen therapy. Many persons with ARDS have a systemic response that results in multiple organ failure, particularly of the renal, gastrointestinal, cardiovascular, and central nervous systems.

The treatment goals in ARDS are to supply oxygen to vital organs and provide supportive care until the condition causing the pathologic process has been reversed and the lungs have had a chance to heal. Assisted ventilation using high concentrations of oxygen may be required to correct the hypoxemia. Positive end-expiratory pressure breathing, which increases the...
pressure in the airways during expiration, may be used to assist in re-inflating the collapsed areas of the lung and to improve the matching of ventilation and perfusion. Smaller tidal volumes (6 mL/kg) based on ideal body weight have been shown to reduce barotrauma secondary to lower plateau pressures and optimal positive end expiratory pressure (PEEP) therapy prevents damage associated with the collapse and re-inflation of alveoli.

**Acute Respiratory Failure**

Respiratory failure can be viewed as impaired gas exchange due to either pump (heart) or lung failure, or both. It is not a specific disease, but can occur in the course of a number of conditions that impair ventilation, compromise the matching of ventilation and perfusion, or impair gas diffusion. Acute respiratory failure may occur in previously healthy persons as the result of acute disease or trauma involving the respiratory system, or it may develop in the course of a chronic neuromuscular or lung disease.

Respiratory failure is a condition in which the respiratory system fails in one or both of its gas exchange functions—oxygenation of mixed venous blood and removal of carbon dioxide. The function of the respiratory system can be said to consist of two aspects: (1) gas exchange (movement of gases across the alveolar–capillary membrane) and (2) ventilation (movement of gases into and out of the alveoli due to the action of the respiratory muscles, the respiratory center in the central nervous system [CNS], and the pathways that connect the centers in the CNS with the respiratory muscles). Thus, respiratory failure is commonly divided into two types: (1) hypoxemic respiratory failure due to failure of the gas exchange function of the lung and (2) hypercapnic/hypoxemic respiratory failure due to ventilatory failure. The classification should not be viewed as rigid since lung disorders that cause impaired gas exchange can be complicated by ventilatory failure and ventilatory failure can be accompanied by lung disorders that impair gas diffusion. Causes of the two types of respiratory failure are summarized in Chart 23-3.

**Hypoxemic Respiratory Failure**

In persons with hypoxemic respiratory failure, two major pathophysiologic factors contribute to the lowering of arterial PO2: ventilation–perfusion mismatching and impaired diffusion.

**Mismatching of Ventilation and Perfusion.** The mismatching of ventilation and perfusion occurs when areas of the lung are ventilated but not perfused or when areas are perfused but not ventilated. Usually the hypoxemia seen in situations of ventilation–perfusion mismatching is more severe in relation to hypercapnia than that seen in hypoventilation. Severe mismatching of ventilation and perfusion often is seen in persons with advanced COPD. These disorders contribute to the retention of carbon dioxide by reducing the effective alveolar ventilation, even when total ventilation is maintained.

This occurs because a region of the lung is not perfused and gas exchange cannot take place or because an area of the lung is not being ventilated. Maintaining a high ventilation rate effectively prevents hypercapnia but also increases the work of breathing.

The hypoxemia associated with ventilation–perfusion disorders often is exaggerated by conditions such as hypoventilation and decreased cardiac output. For example, sedation can cause hypoventilation in persons with severe COPD, resulting in further impairment of ventilation. Likewise, a decrease in cardiac output because of myocardial infarction can exaggerate the ventilation–perfusion impairment in a person with mild pulmonary edema or COPD.

The beneficial effect of oxygen administration on PO2 levels in ventilation–perfusion disorders depends on the degree of mismatching that is present. Because oxygen administration increases the diffusion gradient in ventilated portions of the lung, it usually is effective in raising arterial PO2 levels. However, high-flow oxygen may decrease the respiratory drive, resulting in a decrease in ventilation and an increase in PCO2.

**Impaired Diffusion.** Impaired diffusion describes a condition in which gas exchange between the alveolar air and pulmonary blood is impeded because of an increase in the distance for diffusion or a decrease in the permeability or surface area of the respiratory membranes to the movement of gases. It most commonly occurs in conditions such as interstitial lung disease, ALI/ARDS, pulmonary edema, and pneumonia.

Conditions that impair diffusion may produce severe hypoxemia but no hypercapnia because of the increase...
in ventilation and greater diffusion rate of carbon dioxide. Hypoxemia resulting from impaired diffusion can be partially or completely corrected by the administration of high concentrations of oxygen. In this case, the high concentration of oxygen serves to overcome the decrease in diffusion by establishing a larger alveolar-to-capillary diffusion gradient.

**Hypercapnic/Hypoxemic Respiratory Failure**

In the hypercapnic form of respiratory failure, patients are unable to maintain a level of alveolar ventilation sufficient to eliminate CO₂ and keep arterial O₂ levels within normal range. Because ventilation is determined by a sequence of events ranging from the generation of impulses in the CNS to movement of air through the conducting airways, there are several stages at which problems can adversely affect the total minute ventilation.

Hypoventilation or ventilatory failure occurs when the volume of “fresh” air moving into and out of the lungs is significantly reduced. It is commonly caused by conditions outside the lungs such as depression of the respiratory center (e.g., drug overdose, brain injury), diseases of the nerves supplying the respiratory muscles (e.g., Guillain-Barré syndrome, spinal cord injury), disorders of the respiratory muscles (e.g., muscular dystrophy), exacerbation of chronic lung disease (e.g., COPD), or thoracic cage disorders (e.g., severe scoliosis or crushed chest).

Hypoventilation has two important effects on arterial blood gases. First, it almost always causes an increase in PCO₂. The rise in PCO₂ is directly related to the level of ventilation; reducing the ventilation by one half causes a doubling of the PCO₂. Thus, the PCO₂ level is a good diagnostic measure for hypoventilation. Second, it may cause hypoxemia, although the hypoxemia that is caused by hypoventilation can be readily abolished by the administration of supplemental oxygen.

**Clinical Features**

Acute respiratory failure is usually manifested by varying degrees of hypoxemia and hypercapnia. There is no absolute definition of the levels of PO₂ and PCO₂ that indicate respiratory failure; however, it is conventionally defined as an arterial PO₂ of less than 60 mm Hg, an arterial PCO₂ of more than 45 mm Hg, or both when prior blood values have been normal. Again, these cut-off values are not rigid, but serve as a general guide in combination with history and physical assessment data.

The signs and symptoms of acute respiratory failure are those of the underlying disease combined with those of hypoxemia and hypercapnia. Hypoxemia is accompanied by increased respiratory drive and increased sympathetic tone. Potential signs include cyanosis, restlessness, confusion, anxiety, delirium, fatigue, tachypnea, hypertension, cardiac arrhythmias, and tremor. The initial cardiovascular effects are tachycardia with increased cardiac output and increased blood pressure. Serious cardiac arrhythmias may be triggered. The pulmonary vasculature constricts in response to low alveolar PO₂. If severe, the pulmonary vasoconstriction may result in acute right ventricular failure with manifestations such as jugular vein distention and dependent edema. Profound acute hypoxemia can cause convulsions, retinal hemorrhages, and permanent brain damage. Hypotension and bradycardia are often preterminal events in persons with hypoxemic respiratory failure, indicating the failure of compensatory mechanisms. Many of the adverse consequences of hypercapnia are the result of respiratory acidosis. Direct effects of acidosis include depression of cardiac contractility, decreased respiratory muscle contractility, and arterial vasodilation (see Chapter 8). Raised levels of PCO₂ greatly increase cerebral blood flow, which may result in headache, increased cerebrospinal fluid pressure, and sometimes papilledema (see Chapter 38, Fig. 38-9). The headache is due to dilation of the cerebral vessels. Additional indicators of hypercapnia are warm and flushed skin and hyperemic conjunctivae. Hypercapnia produces nervous system effects similar to those of an anesthetic—hence the term carbon dioxide narcosis.

There is progressive somnolence, disorientation, and, if the condition is left untreated, coma. Mild to moderate increases in blood pressure are common. Air hunger and rapid breathing occur when alveolar PCO₂ levels rise to approximately 60 to 75 mm Hg; as PCO₂ levels reach 80 to 100 mm Hg, the person becomes lethargic and sometimes semicomatose.

The treatment of respiratory failure focuses on correcting the problem causing impaired gas exchange when possible and on relieving the hypoxemia and hypercapnia. A number of treatment modalities are available, including the establishment of an airway, use of bronchodilating drugs, and antibiotics for respiratory infections. Controlled oxygen therapy and mechanical ventilation are used in treating blood gas abnormalities associated with respiratory failure.

When alveolar ventilation is inadequate to maintain PO₂ or PCO₂ levels because of respiratory or neurologic failure, mechanical ventilation may be lifesaving. Usually a nasotracheal, orotracheal, or tracheotomy tube is inserted into the trachea to provide the airway needed for mechanical ventilation. There has been recent interest in noninvasive forms of mechanical ventilation that use a face mask to deliver positive-pressure ventilation.

**SUMMARY CONCEPTS**

- The hallmark of acute lung injury and acute respiratory distress syndrome is a pronounced inflammatory response that affects the lung and may result in systemic organ failure. The acute inflammatory response results in damage and dysfunction of the alveolar–capillary membrane of the lung. Classically, there is interstitial edema of lung tissue, an increase in surface tension caused by inactivation of surfactant, collapse of alveolar structures, a stiff and noncompliant lung (continued)
SUMMARY CONCEPTS (continued)

596
UNIT 6  Respiratory Function

that is difficult to inflate, and impaired diffusion of the respiratory gases with severe hypoxia that is resistant to oxygen therapy.

- Acute respiratory failure is a condition in which the lungs fail to oxygenate the blood adequately (hypoxemic respiratory failure) or prevent undue retention of carbon dioxide (hypercapnic/hypoxemic respiratory failure). The causes of respiratory failure are many. It may arise acutely in persons with previously healthy lungs, or it may be superimposed on chronic lung disease. Treatment of acute respiratory failure is directed toward treatment of the underlying disease, maintenance of adequate gas exchange and tissue oxygenation, and general supportive care. When alveolar ventilation is inadequate to maintain PO₂ or PCO₂ levels because of impaired respiratory function or neurologic failure, mechanical ventilation may be necessary.

REVIEW EXERCISES

1. A 30-year-old man is brought to the emergency department with a knife wound to the chest. On visual inspection, asymmetry of chest movement during inspiration, displacement of the trachea, and absence of breath sounds on the side of the wound are noted. His neck veins are distended, and his pulse is rapid and weak. A rapid diagnosis of tension pneumothorax is made.

   A. Explain the observed respiratory and cardiovascular function in terms of the impaired lung expansion and the air that has entered the chest as a result of the injury.
   B. What type of emergent treatment is necessary to save this man’s life?

2. A 10-year-old boy who is having an acute asthmatic attack is brought to the emergency department by his parents. The boy is observed to be sitting up and struggling to breathe. His breathing is accompanied by use of the accessory muscles, a weak cough, and audible wheezing sounds. His pulse is rapid and weak and both heart and breath sounds are distant on auscultation. His parents relate that his asthma began to worsen after he developed a “cold,” and now he doesn’t even get relief from his “albuterol” inhaler.

   A. Explain the changes in physiologic function underlying this boy’s signs and symptoms.
   B. What is the most probable reason for the progression of this boy’s asthma in terms of the early- and late-phase responses?
   C. The boy is treated with a systemic corticosteroid and inhaled anticholinergic and β₂-adrenergic agonist and then transferred to the intensive care unit. Explain the action of each of these medications in terms of relieving this boy’s symptoms.

3. A 62-year-old man with an 8-year history of chronic obstructive pulmonary disease (COPD) reports to his health care provider with complaints of increasing shortness of breath, ankle swelling, and a feeling of fullness in his upper abdomen. The expiratory phase of his respirations is prolonged, and expiratory wheezes and crackles are heard on auscultation. His blood pressure is 160/90 mm Hg, his red blood cell count is 6.0 × 10¹²/L (normal is 4.2 to 5.4 × 10¹²/L), his hematocrit is 65% (normal male value is 40% to 50%), his arterial PO₂ is 55 mm Hg, and his O₂ saturation, which is 85% while he is resting, drops to 55% during walking exercise.

   A. Explain the physiologic mechanisms responsible for his edema, hypertension, and elevated red blood cell count.
   B. His arterial PO₂ and O₂ saturation indicate that he is a candidate for continuous low-flow oxygen. Explain the benefits of this treatment in terms of his activity tolerance, blood pressure, and red blood cell count.
   C. Explain why the oxygen flow rate for persons with COPD is normally titrated to maintain the arterial PO₂ between 60 and 65 mm Hg.

4. An 18-year-old woman is admitted to the emergency department with a suspected drug overdose. Her respiratory rate is slow (4 to 6 breaths/min) and shallow. Arterial blood gases reveal a PCO₂ of 80 mm Hg and a PO₂ of 60 mm Hg.

   A. What is the cause of this woman’s high PCO₂ and low PO₂?
   B. Hypoventilation almost always causes an increase in PCO₂. Explain.
   C. Even though her PO₂ increases to 90 mm Hg with institution of oxygen therapy, her PCO₂ remains elevated. Explain.

The kidneys are remarkable organs. Each is smaller than a person’s fist, but in a single day the two organs process approximately 1700 L of blood and combine their waste products into approximately 1.5 L of urine. As part of their function, the kidneys filter physiologically essential substances, such as sodium and potassium, from the blood and selectively reabsorb those substances that are needed to maintain the normal composition of internal body fluids. Substances that are not needed or are in excess of those needed pass into the urine. In addition to regulating the volume and composition of body fluids, the kidneys also perform endocrine functions. They release renin, an enzymatic hormone that participates in the regulation of blood pressure and maintenance of the circulating blood volume; they produce erythropoietin, a hormone that stimulates red blood cell production; and they convert vitamin D to its active form.

**Functional Anatomy of the Kidney**

The kidneys are paired, bean-shaped organs that lie outside the peritoneal cavity in the back of the upper abdomen, one on each side of the vertebral column at the level of the 12th vertebra. Each kidney is about the size of a fist and weighs approximately 150 grams. They are highly vascular and receive blood from the renal arteries, which branch from the aorta. The renal veins carry the blood from the kidneys back to the inferior vena cava.

The kidneys are covered by a layer of connective tissue called the perirenal fascia, which is continuous with the peritoneum. The perirenal space contains fat and connective tissue. The kidneys are posterior to the psoas major muscles and anterior to the diaphragm. They are divided into the left and right kidneys by the inferior vena cava. The right kidney is slightly lower than the left, and the inferior vena cava occupies the right pararenal space.

The kidneys are surrounded by a capsule of renal fascia, which is continuous with the parietal peritoneum. The renal fascia is divided into an anterior and posterior layer, which are separated by a layer of fat. The anterior layer of renal fascia is attached to the diaphragm, and the posterior layer is attached to the posterior abdominal wall.

The kidneys are supplied with blood by the renal arteries, which arise from the aorta. The renal arteries divide into interlobar arteries, which supply the outer part of the kidneys. The interlobar arteries divide into arcuate arteries, which supply the medulla. The arcuate arteries divide into interlobular arteries, which supply the cortex.

The interlobular arteries give rise to a network of capillaries, called the glomerular capillaries, which form the glomeruli. The glomeruli are clusters of capillaries that are arranged in a network and are continuous with the Bowman’s capsules. The Bowman’s capsules are Bowman’s capsules, which are double-walled sacs that enclose the glomeruli.

The Bowman’s capsules contain the nephrons, which are the functional units of the kidneys. Each nephron consists of a renal corpuscle, which contains the glomerulus and Bowman’s capsule, and a tubule, which is continuous with the Bowman’s capsule. The tubule is divided into a proximal convoluted tubule, a straight portion, a loop of Henle, a distal convoluted tubule, and a collecting duct.

The renal corpuscle is supplied with blood by the afferent arteriole, which arises from the interlobular arteries. The efferent arteriole, which arises from the renal corpuscle, supplies blood to the peritubular capillaries, which surround the tubule. The peritubular capillaries drain into the vasa recta, which are arteries that run parallel to the tubule and return blood to the renal veins.

The nephron is responsible for the formation of urine. The glomerulus filters and reabsorbs substances from the blood, and the tubule reabsorbs and secretes substances into the tubule. The filtrate is collected in the collecting ducts and transported to the renal pelvis, which is a cup-shaped structure that collects urine from the renal calyces. The urine then flows through the ureters to the urinary bladder, where it is stored until it is voided.
thoracic to 3rd lumbar vertebrae (Fig. 24-1). The right kidney normally is situated lower than the left, presumably because of the position of the liver. In the adult, each kidney is approximately 10 to 12 cm long, 5 to 6 cm wide, and 2.5 cm deep and weighs approximately 113 to 170 g. The medial border of the kidney is indented by a deep s-shape called the hilus. It is here that blood vessels and nerves enter and leave the kidney. The ureters, which connect the kidneys with the bladder, also enter the kidney at the hilus.

**Gross Structure**

The kidney is composed of up to 18 lobes. Each lobular is in turn composed of nephrons, which are the functional units of the kidney. Two distinct regions can be identified on the bisected kidney—an outer cortex and an inner medulla (Fig. 24-2). The cortex has a reddish-brown granular appearance that is absent from the medulla. The medulla consists of light-colored, cone-shaped masses—the renal pyramids—that are divided by columns of the cortex that extend into the medulla. Each pyramid, topped by a region of cortex, forms a lobe of the kidney. The apices of the pyramids form the papillae (i.e., 8 to 18 per kidney, corresponding to the number of lobes), which are perforated by the openings of the collecting tubules. The renal pelvis is a wide, funnel-shaped structure at the upper end of the ureter. It is made up of the calyces or cuplike structures that drain the upper and lower halves of the kidney.

The kidney is sheathed in a fibrous external capsule and surrounded by a mass of fatty connective tissue, especially at its ends and borders. The adipose tissue protects the kidney from mechanical blows and assists, together with the attached blood vessels and fascia, in holding the kidney in place. Although the kidneys are relatively well protected, they may be bruised by blows to the loin or by compression between the lower ribs and the ileum. Because the kidneys are located outside the peritoneal cavity, injury and rupture do not produce the same threat of peritoneal involvement as that of other organs such as the liver or spleen.

**Renal Blood Supply**

Each kidney is supplied by a single renal artery that arises on either side of the aorta. As the renal artery approaches the kidney, it divides into segmental arteries that enter the hilus of the kidney. In the kidney, each segmental artery branches into several lobular arteries that
supply the upper, middle, and lower parts of the kidney. The lobular arteries further subdivide to form the interlobular arteries at the level of the corticomedullary junction (Fig. 24-3). These arteries give off branches, the arcuate arteries, which arch across the top of the pyramids. Small intralobular arteries radiate from the arcuate arteries to supply the cortex of the kidney. The afferent arterioles that supply the glomeruli arise from the intralobular arteries.

Although nearly all the blood that enters the kidney flows through the cortex, less than 10% passes into the medulla and only about 1% moves into the papillae. Under conditions of decreased perfusion or increased sympathetic nervous system stimulation, blood flow is redistributed away from the cortex toward the medulla. This redistribution of blood flow decreases glomerular filtration while maintaining the urine-concentrating ability of the kidneys, a factor that is important during conditions such as shock.

The Nephron

Each kidney is composed of more than 1 million tiny, closely packed functional units called nephrons, each of which is capable of producing urine (Fig. 24-4A). Each nephron consists of a glomerulus, where blood is filtered, and a system of tubular structures where water, electrolytes, and other substances needed to maintain the
constancy of the internal environment are reabsorbed into the bloodstream while other, unneeded materials are secreted into the tubular filtrate for elimination.

Nephrons can be roughly grouped into two categories. Approximately 85% of the nephrons originate in the superficial part of the cortex and are called cortical nephrons (Fig. 24-4B). They have short, thick loops of Henle that penetrate only a short distance into the medulla. The remaining 15% are called juxtamedullary nephrons. They originate deeper in the cortex and have longer and thinner loops of Henle that penetrate the entire length of the medulla. The juxtamedullary nephrons are largely concerned with urine concentration.

The nephrons are supplied by two capillary systems, the glomerulus and peritubular capillary network (see Fig. 24-4A). The glomerulus is a unique, high-pressure capillary filtration system located between two arterioles—the afferent and the efferent arterioles. The peritubular capillaries originate from the efferent arteriole. They are low-pressure vessels that are adapted for reabsorption rather than filtration. These capillaries surround all portions of the tubules, an arrangement that permits rapid movement of solutes and water between the fluid in the tubular lumen and the blood in the capillaries. In the deepest part of the renal cortex, the efferent arterioles continue as long, thin-walled looping vessels called the vasa recta. The vasa recta accompany the long loops of Henle in the medullary portion of the kidney to assist in the exchange of substances flowing in and out of that portion of the kidney. The peritubular capillaries rejoin to form the venous channels through which blood leaves the kidneys and empties into the inferior vena cava.

The Renal Corpuscle

The renal corpuscle, commonly called the glomerulus, consists of a compact tuft of capillaries, with a central region of mesangial cells and surrounding matrix, encased in a thin double-layered capsule called Bowman capsule. The inner or visceral layer of the capsule envelops the capillaries of the glomerulus and the external or parietal layer forms the outer wall of the capsule. Blood flows into the glomerular capillaries through the afferent arterioles and flows out through the efferent arterioles, which leads to a second capillary network, the peritubular capillaries, that surrounds the renal tubules. Fluid and particles from the blood are filtered through the capillary wall into a fluid-filled space between the visceral and parietal layers of Bowman capsule, called Bowman space. The portion of the blood that is filtered into the capsule space is called the glomerular filtrate (Fig. 24-5A).

The glomerular capillary wall consists of a thin layer of endothelial cells, a glomerular basement membrane, and a surrounding layer of visceral epithelial cells of Bowman capsule (Fig. 24-5B). The endothelium of the glomerular capillary, which interfaces with blood as it moves through the capillary, contains many small perforations, called fenestrations. These fenestrations allow for the free passage of water, and of small particles such as sodium, potassium, and glucose, but prevent the passage of red blood cells, white blood cells, or platelets. In addition to their role as a filtration barrier, the endothelial cells synthesize a number of vasoactive substances such as nitric oxide (a vasodilator) and endothelin-1 (a vasoconstrictor) that control renal blood flow.
The glomerular basement membrane consists of a homogeneous acellular meshwork of collagen fibers, glycoproteins, and mucopolysaccharides (Fig. 24-5C). Because the endothelial and epithelial layers of the glomerular capillary have porous structures, the basement membrane determines the permeability of the capillary membrane. The spaces between the fibers that make up the basement membrane represent the pores of a filter and determine the size-dependent permeability barrier of the glomerulus. The size of the pores in the basement membrane normally prevents red blood cells and plasma proteins from passing into the filtrate. Alterations in the structure and function of the glomerular basement membrane are responsible for the leakage of proteins and blood cells into the filtrate that occurs in many forms of glomerular disease.

The visceral layer of the Bowman capsule is composed of epithelial cells that are highly modified to perform a filtering function. These large cells, called podocytes, have numerous finger-like processes that completely encircle the outer surface of the capillaries (see Fig. 24-5C). The elongated spaces between the interdigitating foot processes, called filtration slits, function as a size-selective filter that prevents proteins and macromolecules that have crossed the basement membrane from entering Bowman space.

Another important component of the glomerulus is the mesangium. In some areas, the capillary endothelium and the basement membrane do not completely surround each capillary tuft. Instead, the mesangial cells, which lie between the tufts, provide support for the glomerulus in these areas (Fig. 24-5B). The mesangial cells produce an intercellular substance similar to that of the basement membrane. This substance covers the endothelial cells where they are not covered by basement membrane. The mesangial cells also exhibit contractile properties and are thought to contribute to the regulation of blood flow through the glomerulus; possess phagocytic properties and remove macromolecular materials that enter the intercapillary spaces; and are capable of proliferation. Although the mesangial area is normally narrow and contains only a small number of cells, mesangial hyperplasia and increased mesangial matrix develop in many forms of glomerular disease.

**Tubular Components of the Nephron**

The nephron tubule is divided into several segments: the proximal tubule, which drains Bowman capsule; a thin looped structure, the loop of Henle; a distal coiled portion, the distal convoluted tubule; and the final segment, the collecting tubule (see Fig. 24-4A). The filtrate passes through each of these segments before reaching the pelvis of the kidney.

The proximal tubule is a highly coiled structure that lies in the cortex of the kidney and dips toward the renal pelvis to become the loop of Henle. The loop consists of a descending and ascending limb. The ascending loop of Henle returns to the region of the renal corpuscle, where it becomes much thicker, and is referred to as the thick ascending limb. Beyond the thick ascending limb of Henle is the distal convoluted tubule, which like the proximal tubule lies in the renal cortex. The distal convoluted tubule is divided into two segments: the diluting segment and the late distal tubule. The late distal tubule fuses with the collecting tubule. The collecting tubule is divided into two segments: the cortical tubule and the medullary collecting tubule.

Throughout its course, the tubule is composed of a single layer of epithelial cells resting on a basement membrane. The structure of the epithelial cells varies with tubular function. The cells of the proximal tubule have a fine, villous structure that increases the surface area for reabsorption; they also are rich in mitochondria, which support active transport processes. The epithelial layer thins in segments of the loop of Henle and has few mitochondria, indicating minimal metabolic activity and reabsorptive function.

**SUMMARY CONCEPTS**

- The kidneys are paired, bean-shaped organs that lie outside the peritoneal cavity in the posterior abdomen, one on either side of the vertebral column. On longitudinal section, a kidney can be divided into an outer cortex and an inner medulla. The cortex and medulla are composed of nephrons, blood vessels, and nerves.

- The nephrons, which are the functional units of the kidney, consist of a renal capsule (glomerulus and Bowman capsule) where blood is filtered, and tubular structures (proximal tubule, loop of Henle, distal tubule, and collecting tubule) where water, electrolytes, and soluble nutrients are reabsorbed into the blood and waste products are secreted from the blood into the tubular fluid.

- The nephrons are supplied by two capillary systems, a glomerulus and peritubular capillary network. The glomerulus is a unique, high-pressure capillary filtration system located between two arterioles—the afferent and the efferent arterioles. The peritubular capillaries, which originate from the efferent arteriole and surround the tubules, are low-pressure vessels adapted for reabsorption rather than filtration.

**Urine Formation**

Urine formation involves the filtration of blood by the glomerulus to form an ultrafiltrate of urine, the selective reabsorption by the renal tubules of substances needed
to maintain the constancy of the internal environment, and the secretion of unneeded and waste materials into the urine filtrate. The urine that is formed represents the sum of the three processes—glomerular filtration, tubular reabsorption, and tubular secretion.

**Glomerular Filtration**

Urine formation begins with the filtration of essentially protein-free plasma through the glomerular capillaries into the Bowman space. The movement of fluid through the glomerular capillaries is determined by the same factors (i.e., capillary filtration pressure, colloidal osmotic pressure, and capillary permeability) that affect fluid movement through other capillaries in the body. The glomerular filtrate has a chemical composition similar to plasma, but contains almost no proteins because large molecules do not readily pass through the openings in the glomerular capillary wall. Approximately 125 mL of filtrate is formed each minute. This is called the glomerular filtration rate (GFR). This rate can vary from a few milliliters per minute to as high as 200 mL/minute.

The location of the glomerulus between two arterioles allows for maintenance of a high-pressure filtration system. The capillary filtration pressure (approximately 60 mm Hg) in the glomerulus is approximately two to three times higher than that of other capillary beds in the body. The filtration pressure and the GFR are regulated by relaxation and constriction of the afferent and efferent arterioles. For example, relaxation of the afferent arteriole increases the filtration pressure and the GFR by increasing glomerular blood flow; whereas relaxation of the efferent arteriole decreases resistance to outflow of blood, decreasing the glomerular pressure and the GFR. The afferent and the efferent arterioles are innervated by the sympathetic nervous system and are sensitive to vasoactive hormones, such as angiotensin II. During periods of strong sympathetic stimulation, such as shock, constriction of the afferent arteriole causes a marked decrease in renal blood flow, and thus glomerular filtration pressure. Consequently, urine output can fall almost to zero.

**Tubular Reabsorption and Secretion**

From Bowman capsule, the glomerular filtrate moves into the tubular segments of the nephron. In its movement through the lumen of the tubular segments, the glomerular filtrate is changed considerably by the tubular transport of water and solutes. Tubular transport can result in reabsorption of substances from the tubular fluid into the peritubular capillaries or secretion of substances into the tubular fluid from the blood in the peritubular capillaries (Fig. 24-6).

The mechanisms of transport across the tubular cell membrane are similar to those of other cell membranes in the body and include active and passive transport mechanisms. Water and urea (a by-product of protein metabolism) are passively absorbed along concentration gradients. Sodium (Na⁺), other electrolytes, as well as urate (a metabolic end-product of purine metabolism), glucose, and amino acids, are reabsorbed using primary or secondary active transport mechanisms to move across the tubular membrane. Some substances, such as excess K⁺ and urate, are secreted into the tubular fluids. Under normal conditions, approximately 1 mL of the 125 mL of glomerular filtrate that is formed each minute is excreted in the urine. The other 124 mL is reabsorbed in the tubules. This means that the average output of urine is approximately 60 mL/hour.

Renal tubular cells have two membrane surfaces through which substances must pass as they are reabsorbed from the tubular fluid. The outside membrane that lies adjacent to the interstitial fluid is called the basolateral membrane, and the side that is in contact with the tubular lumen and tubular filtrate is called the luminal membrane. In most cases, substances move from the tubular filtrate through the luminal membrane into the tubular cell along a concentration gradient, but they require facilitated transport or carrier systems to move across the basolateral membrane into the interstitial fluid, where they are absorbed into the peritubular capillaries.

The bulk of energy used by the kidney is for active sodium transport mechanisms that facilitate sodium reabsorption and cotransport of other electrolytes and substances such as glucose and amino acids. This is called secondary active transport or cotransport (Fig. 24-7). In secondary active transport, two or more substances interact with a specific membrane protein (a carrier protein) and are transported across the membrane. As one of the substances (in this case sodium) diffuses
adenosine triphosphatase (ATPase), but depends on such as glucose does not require energy directly from the blood. Thus, the secondary active transport of a substance or an amino acid against its concentration gradient, used to move another substance (for instance, glucose down its concentration gradient, the energy released is used to move another substance (for instance, glucose across the luminal membrane into the tubular cell and then into the peritubular capillary.

down its concentration gradient, the energy released is used to move another substance (for instance, glucose or an amino acid) against its concentration gradient. Thus, the secondary active transport of a substance such as glucose does not require energy directly from adenosine triphosphatase (ATPase), but depends on the energy-dependent Na+/K+-adenosine triphosphatase (ATPase) pump on the basolateral side of renal tubular cells. This pump maintains a low intracellular sodium concentration that facilitates the downhill movement of sodium across the luminal membrane; it is this downhill diffusion of sodium to the interior of the cell that provides the energy for the simultaneous uphill transport of glucose across the luminal membrane. A few substances, such as hydrogen (H⁺), are secreted into the tubule.

**Proximal Tubule.** Approximately 65% of all reabsorptive and secretory processes that occur in the tubular system take place in the proximal tubule. There is almost complete reabsorption of nutritionally important substances, such as glucose, amino acids, lactate, and water-soluble vitamins (Fig. 24-8). Electrolytes, such as Na⁺, K⁺, Cl⁻, and bicarbonate (HCO₃⁻), are 65% to 80% reabsorbed. As these solutes move into the tubular cells, their concentration in the tubular lumen decreases, providing a concentration gradient for the osmotic reabsorption of water and urea. The proximal tubule is highly permeable to water, and the osmotic movement of water occurs so rapidly that the concentration difference of solutes on either side of the membrane seldom is more than a few milliosmoles.

Many substances, such as glucose, are freely filtered in the glomerulus and reabsorbed by energy-dependent cotransport carrier mechanisms. The maximum amount of substance that these transport systems can reabsorb per unit time is called the *transport maximum*. The transport maximum is related to the number of carrier proteins that are available for transport and usually is sufficient to ensure that all of a filtered substance such as glucose can be reabsorbed rather than being eliminated in the urine. The plasma level at which the substance appears in the urine is called the *renal threshold*. Under some circumstances, the amount of substance filtered in the glomerulus exceeds the transport maximum. For example, when the blood glucose level is elevated in uncontrolled diabetes mellitus, the amount that is filtered in the glomerulus often exceeds the transport maximum (approximately 320 mg/minute), and glucose spills into the urine.

**FIGURE 24-7.** Mechanism for secondary active transport or cotransport of glucose and amino acids in the proximal tubule. The energy-dependent sodium–potassium pump on the basolateral surface of the cell maintains a low intracellular gradient that facilitates the downhill movement of sodium and glucose or amino acids (cotransport) from the tubular lumen into the tubular cell and then into the peritubular capillary.

**FIGURE 24-8.** Sites of tubular water (H₂O), glucose, amino acids, Na⁺ (sodium), Cl⁻ (chloride), HCO₃⁻ (bicarbonate), K⁺ (potassium), Ca²⁺ (calcium), and Mg²⁺ (magnesium) reabsorption; and sites of organic acids and bases, H⁺ (hydrogen), and K⁺ secretion.
In addition to reabsorbing solutes and water, cells in the proximal tubule also secrete organic cations and anions into the urine filtrate (see Figs. 24-6 and 24-8). Many of these organic anions and cations are end products of metabolism (e.g., urate, oxalate) that circulate in the plasma. The proximal tubule also secretes exogenous organic compounds such as penicillin, aspirin, and morphine. Many of these compounds are bound to plasma proteins and not freely filtered in the glomerulus. Therefore, excretion by filtration alone eliminates only a small portion of these potentially toxic substances from the body.

**Loop of Henle.** The loop of Henle plays an important role in controlling the concentration of the urine. It does this by establishing a high concentration of osmotically active particles in the interstitium surrounding the medullary collecting tubules where the antidiuretic hormone exerts its effects.

The loop of Henle is divided into three segments: the thin descending segment, the thin ascending segment, and the thick ascending segment. Taken as a whole, the loop of Henle always reabsorbs more sodium and chloride than water. This is in contrast to the proximal tubule, which reabsorbs sodium and water in equal proportions. The thin descending limb is highly permeable to water and moderately permeable to urea, sodium, and other ions. As the urine filtrate moves down the descending limb, water moves out of the filtrate into the surrounding interstitium. Thus, the osmolality of the filtrate reaches its highest point at the elbow of the loop of Henle. In contrast to the descending limb, the ascending limb of the loop of Henle is impermeable to water. In this segment, solutes move out, but water cannot follow and remains in the filtrate. As a result, the tubular filtrate becomes more and more dilute, often reaching an osmolality of 100 mOsM/kg H₂O as it enters the distal convoluted tubule, compared with the 285 mOsM/kg H₂O in plasma. This allows for elimination of free water from the body. For this reason, the segment of the tubule is often called the diluting segment.

The thick segment of the loop of Henle begins in the ascending limb where the epithelial cells become thickened. As with the thin ascending limb, this segment is impermeable to water. The thick segment contains a Na⁺/K⁺/2Cl⁻ cotransport system (Fig. 24-9). This system involves the cotransport of positively charged Na⁺ and K⁺ accompanied by two negatively charged Cl⁻. The gradient for the operation of this cotransport system is provided by the basolateral membrane sodium–potassium ATPase pump, which maintains a low intracellular sodium concentration. Approximately 20% to 25% of the filtered load of sodium, potassium, and chloride is reabsorbed in the thick loop of Henle. Movement of these ions out of the tubule leads to the development of a transmembrane potential that favors the passive reabsorption of small divalent cations such as calcium and magnesium. The thick ascending loop of Henle is the site of the powerful “loop” diuretics (e.g., furosemide [Lasix]), which exert their action by inhibiting the Na⁺/K⁺/2Cl⁻ cotransporters.

**Distal and Collecting Tubules.** Like the thick ascending loop of Henle, the distal convoluted tubule is relatively impermeable to water, and reabsorption of sodium chloride from this segment further dilutes the tubular fluid. Sodium reabsorption occurs through a Na⁺/Cl⁻ cotransport mechanism. Approximately 5% of filtered sodium chloride is reabsorbed in this section of the tubule. Unlike the thick ascending loop of Henle, neither Ca²⁺ nor Mg²⁺ is passively absorbed in this segment of the tubule. Instead, Ca²⁺ is actively reabsorbed in a process that is largely regulated by parathyroid hormone and possibly by vitamin D. The thiazide diuretics, which are widely used to treat disorders such as hypertension, exert their action by blocking sodium reabsorption in this segment of the renal tubules, while enhancing the active reabsorption of calcium into the blood via the calcium-sodium exchange transport mechanism. For this reason, thiazide diuretics have proved useful in reducing the incidence of calcium kidney stones in persons with hypercalciuria (discussed in Chapter 25).

The late distal tubule and the cortical collecting tubule constitute the site where aldosterone exerts its action on sodium reabsorption and potassium secretion and elimination. Although responsible for only 2% to 5% of sodium chloride reabsorption, this site is largely responsible for determining the final sodium concentration of the urine. The late distal tubule with the cortical collecting tubule also is the major site for regulation of potassium excretion by the kidney. When the body is confronted with a potassium excess, as occurs with a diet high in potassium content, the amount of potassium secreted into the urine filtrate at this site may exceed the amount filtered in the glomerulus.
The mechanism for sodium reabsorption and potassium secretion in this section of the nephron is distinct from other tubular segments. This tubular segment is composed of two types of cells, the intercalated cells and principal cells. The intercalated cells secrete hydrogen (H⁺) ions and reabsorb bicarbonate (HCO₃⁻) ions. Thus, they play a key role in acid–base regulation. H⁺ secretion by the intercalated cells is mediated by the action of a hydrogen-ATPase transporter, in which H⁺ are generated by the carbonic anhydrase-mediated reaction, in which water (H₂O) and carbon dioxide (CO₂) combine to form carbonic acid (H₂CO₃), which then dissociates to form H⁺ and HCO₃⁻. The H⁺ ions are then secreted into the tubular fluid and the HCO₃⁻ become available for reabsorption.

The principal cells reabsorb sodium and water from the tubule lumen and secrete potassium into the lumen. Sodium reabsorption and potassium secretion depend on the activity of a sodium–potassium ATPase pump located on the basolateral membrane (Fig. 24-10). This pump maintains a low sodium concentration inside the cell by moving sodium down its concentration gradient into the cell through special sodium channels. The pump also establishes a high concentration of potassium within the cell, causing it to diffuse down its concentration gradient across the luminal membrane into the tubular fluid.

**Regulation of Urine Concentration**

The ability of the kidney to respond to changes in the osmolality of the extracellular fluids by producing either a concentrated or dilute urine depends on the establishment of a high concentration of osmotically active particles in the interstitium of the kidney medulla and the action of the antidiuretic hormone (ADH) in regulating the water permeability of the surrounding medullary collecting tubules (see Understanding How the Kidney Concentrates Urine).

In approximately one fifth of the juxtamedullary nephrons, the loops of Henle and vasa recta descend into the medullary portion of the kidney, forming a counter-current system that controls water and solute movement so that water is kept out of the area surrounding the tubule and solutes are retained. The term countercurrent refers to a flow of fluids in opposite directions in adjacent structures. In this case, there is an exchange of solutes between the adjacent descending and ascending loops of Henle and between the ascending and descending sections of the vasa recta. Because of these exchange processes, a high concentration of osmotically active particles (approximately 1200 mOsm/kg H₂O) collects in the interstitium of the kidney medulla. The presence of these osmotically active particles in the interstitium surrounding the medullary collecting tubules facilitates the ADH-mediated reabsorption of water.

Antidiuretic hormone assists in the maintenance of the extracellular fluid volume by controlling the permeability of the medullary collecting tubules. Osmoreceptors in the hypothalamus sense an increase in osmolality of extracellular fluids and stimulate the release of ADH from the posterior pituitary gland. In exerting its effect, ADH, also known as vasopressin, binds to receptors on the basolateral side of the tubular cells. Binding of ADH to the vasopressin receptors causes water channels, known as aquaporin-2 channels, to move into the luminal side of the tubular cell membrane, producing a marked increase in water permeability. At the basolateral side of the membrane, water exits the tubular cell into the hyperosmotic interstitium of the medullary area, where it enters the peritubular capillaries for return to the vascular system. The aquaporin-2 channels are thought to have a critical role in inherited and acquired disorders of water reabsorption by the kidney, such as diabetes insipidus.

**Regulation of Renal Blood Flow and the GFR**

In the adult, the kidneys are perfused with 1000 to 1300 mL of blood per minute, or 20% to 25% of the cardiac output. This large blood flow is mainly needed to ensure a sufficient GFR for the removal of waste products from the blood, rather than for the metabolic needs of the kidney. Feedback mechanisms, both intrarenal (e.g., autoregulation, local hormones) and extrarenal (e.g., sympathetic nervous system, blood-borne hormones), normally keep blood flow and the GFR constant despite changes in arterial blood pressure.

**Neural and Humoral Control Mechanisms**

The kidney is richly innervated by the sympathetic nervous system. Increased sympathetic activity causes

(text continues on page 609)
The osmolarity of body fluids relies heavily on the ability of the kidney to produce dilute or concentrated urine. Urine concentration depends on three factors: (1) the osmolarity of interstitial fluids in the urine-concentrating part of the kidney, (2) the antidiuretic hormone (ADH), and (3) the action of ADH on the cells in the collecting tubules of the kidney.

**Osmolarity.** In approximately one fifth of the juxtamedullary nephrons, the loops of Henle and special hairpin-shaped capillaries called the vasa recta descend into the medullary portion of the kidney to form a countercurrent system—a set of parallel passages in which the contents flow in opposite directions. The countercurrent design serves to increase the osmolality in this part of the kidney by promoting the exchange of solutes between the adjacent descending and ascending loops of Henle and between the descending and ascending sections of the vasa recta. Because of these exchange processes, a high concentration of osmotically active particles (approximately 1200 mOsm/kg of H₂O) collects in the interstitium surrounding the collecting tubules where the ADH-mediated reabsorption of water takes place.

**Antidiuretic Hormone.** Antidiuretic hormone, which regulates the ability of the kidneys to concentrate urine, is synthesized by neurons in the hypothalamus and transported down their axons to the posterior pituitary gland and then released into the circulation. One of the main stimuli for synthesis and release of ADH is an increase in serum osmolarity. Antidiuretic hormone release is also controlled by cardiovascular reflexes that respond to changes in blood pressure or blood volume.
Action of ADH. Antidiuretic hormone, also known as vasopressin, acts at the level of the collecting tubule to increase water absorption. It exerts its action by binding to vasopressin receptors on the basolateral membrane of the tubular cell. Binding of ADH to the vasopressin receptors causes water channels (aquaporin-2 channels) to move into the luminal side of the cell membrane, which is normally impermeable to water. Insertion of the channels allows water from the tubular fluids to move into the tubular cell and then out into the surrounding hyperosmotic interstitial fluid on the basolateral side of the cell. From there it moves into the peritubular capillaries for return to the circulatory system. Thus, when ADH is present, the water that moved from the blood into the urine filtrate in the glomeruli is returned to the circulatory system, and when ADH is absent, the water is excreted in the urine.

Concentration of ADH results in vasoconstriction of the afferent and efferent arterioles and thus a decrease in renal blood flow. Intense sympathetic stimulation such as occurs in shock and trauma can produce marked decreases in renal blood flow and GFR, even causing blood flow to cease altogether.

Several humoral substances, including angiotensin II, ADH, and the endothelins, produce vasoconstriction of renal vessels. The endothelins are a group of peptides released from damaged endothelial cells in the kidney and other tissues. Although not thought to be an important regulator of renal blood flow during everyday activities, endothelin I may play a role in the reduction of blood flow in conditions such as postischemic renal failure (see Chapter 26).

Other substances such as dopamine, nitric oxide, and prostaglandins (i.e., E₂ and I₂) produce vasodilation. Nitric oxide, a vasodilator produced by the vascular endothelium, appears to be important in preventing excessive vasoconstriction of renal blood vessels and allowing normal excretion of sodium and water. Prostaglandins are a group of mediators of cell function that are produced locally and exert their effects locally. Prostaglandins do not appear to play a major role in regulating renal blood flow and GFR under normal conditions, but may protect the kidneys against the vasoconstricting effects of sympathetic stimulation and angiotensin II. This effect is important because it prevents severe and potentially harmful vasoconstriction and ischemia during conditions such as hemorrhage and shock. Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) that inhibit prostaglandin synthesis may decrease renal blood flow and GFR under certain conditions.

Autoregulatory Mechanisms

The constancy of blood flow through body tissues is maintained by a process called autoregulation. In most tissues other than the kidneys, autoregulation functions to maintain blood flow at a level consistent with the metabolic needs of the tissues. In the kidney, autoregulation of blood flow also functions to maintain a relatively constant GFR and to allow for the precise regulation of solute and water excretion.
Two major systems are credited with maintaining the constancy of renal blood flow and GFR: one responds to changes in arterial pressure and the other to changes in the sodium chloride concentration in the distal tubular fluid. Both serve to regulate the tone of the afferent arteriole. The pressure sensitive mechanism, termed the myogenic mechanism, relies on the intrinsic property of vascular smooth muscle that causes it to contract when stretched. Thus, when the arterial pressure rises and the afferent arteriole is stretched, the smooth muscle contracts; when arterial pressure falls, the smooth muscle relaxes.

The second mechanism, termed the tubuloglomerular feedback mechanism, involves a feedback loop in which the sodium chloride concentration in the tubular fluid is sensed by the juxtaglomerular apparatus ("juxta" meaning "next to") in the distal tubule. This feedback system, which is located at the site where the distal tubule extends back to the glomerulus and then passes between the afferent and efferent arterioles, includes a group of sodium sensing cells called the macula densa and special secretory cells in the walls of afferent and efferent arterioles called juxtaglomerular cells that synthesize and release the enzyme renin (Fig. 24-11A).

Because of its location between the afferent and efferent arterioles, the juxtaglomerular apparatus is thought to play an essential feedback role in linking the level of arterial blood pressure and renal blood flow to the GFR and the composition of the distal tubular fluid (see Fig. 24-11B). It is thought to monitor the arterial blood pressure by sensing both the stretch of the afferent arteriole and the concentration of sodium chloride in the tubular filtrate as it passes through the macula densa. This information is then used in determining how much renin should be released to keep the arterial blood pressure within its normal range and maintain a relatively constant GFR. A decrease in the GFR, for example, increases sodium chloride reabsorption, thereby decreasing the delivery of sodium chloride to the macula densa. The decrease in delivery of sodium chloride to the macula densa has two effects: it decreases resistance to blood flow in the afferent arteriole, which raises glomerular filtration pressure; and it increases the release of renin from the juxtaglomerular cells. The renin from these cells functions as an enzyme to convert the plasma protein angiotensinogen to angiotensin I, which is converted to angiotensin II in the lungs (see Chapter 18, Fig. 18-12). Angiotensin II acts to constrict the efferent arteriole as a means of producing a further increase in the glomerular filtration pressure; thereby returning the GFR toward a more normal range.

Effects of Increased Protein and Glucose Load

Although renal blood flow and glomerular filtration are relatively stable under most conditions, two factors can increase renal blood flow and glomerular filtration: (1) high protein intake, (2) an increase in blood glucose. With ingestion of a high-protein meal, renal blood flow increases 20% to 30% within 1 to 2 hours.
Although the exact mechanism for this increase is uncertain, it is thought to be related to the fact that amino acids and sodium are absorbed together in the proximal tubule via secondary active transport. As a result, delivery of sodium to the macula densa is decreased, which elicits an increase in renal blood flow through the juxtaglomerular apparatus feedback mechanism. The resultant increase in blood flow and GFR allows sodium excretion to be maintained at a near-normal level while increasing the excretion of the waste products of protein metabolism, such as urea. The same mechanism is thought to explain the large increases in renal blood flow and GFR that occur with high blood glucose levels in persons with uncontrolled diabetes mellitus.

Elimination Functions of the Kidney

The functions of the kidney focus on elimination of water, excess electrolytes, metabolic acids, and waste products from the blood. As renal function declines, there is an increase in serum levels of substances such as urea, creatinine, phosphate, and potassium. The effect of renal failure on the concentration of serum electrolytes and metabolic end products is discussed in Chapter 26.

Sodium and Potassium Elimination

Elimination of sodium and potassium is regulated by the GFR and by humoral agents that control their reabsorption. Aldosterone, a hormone secreted by the adrenal gland, functions in the regulation of sodium and potassium elimination by the principal cells in the distal and collecting tubules.

Sodium reabsorption in the distal and collecting tubules is highly variable and depends on the presence of aldosterone. In the presence of aldosterone, which stimulates sodium absorption and simultaneous excretion of potassium into the tubular fluid, almost all the sodium in the distal tubular fluid is reabsorbed, and the urine essentially becomes sodium free. In the absence of aldosterone, virtually no sodium is reabsorbed from the distal tubule and excessive amounts of sodium are lost in the urine. The remarkable ability of the distal tubular and collecting duct cells to alter sodium reabsorption in relation to changes in aldosterone allows the kidneys to excrete urine with sodium levels that range from a few tenths of a gram to 40 g/day.

Atrial natriuretic peptide (ANP) is also believed to have an important role in salt and water excretion by the kidney. It is synthesized by muscle cells in the atria of the heart and released when the atria are stretched. Increased levels of this peptide directly inhibit the reabsorption of sodium and water in the renal tubules. Atrial natriuretic peptide also inhibits renin secretion and therefore angiotensin II formation, which in turn reduces reabsorption of sodium. This decreased sodium reabsorption increases urine output and helps return blood volume to normal. Atrial natriuretic peptide levels, which become elevated when the atria are stretched in congestive heart failure, help to decrease vascular volume by increasing urine output.

Like sodium, potassium is freely filtered in the glomerulus and reabsorbed in the proximal and distal tubule. Unlike sodium, however, potassium is both reabsorbed from and secreted into the tubular fluid. The amount of potassium that is delivered to the distal tubule each day is only about 70 mEq, yet the average person consumes much or more in the diet. Therefore, the excess potassium that is not filtered in the glomerulus must be secreted into the tubular fluid so it can be eliminated in the urine. Potassium secretion occurs mainly in the distal and collecting tubules, with plasma potassium and aldosterone levels being the main physiological regulators of potassium transport.
Regulation of Body pH

The average North American diet results in the liberation of 40 to 80 mmol of H⁺ each day. Neither blood buffer systems nor the respiratory control mechanisms for carbon dioxide elimination can eliminate H⁺ from the body. This is accomplished by the kidneys. Virtually all the excess H⁺ excreted in the urine are secreted into the tubular fluid by means of tubular secretory mechanisms.

The lowest tubular fluid pH that can be achieved without damaging the kidney structures is about 4.5. The ability of the kidneys to excrete large amounts of H⁺ in the urine is accomplished by combining the excess ions with buffers in the urine. The three major urine buffers are HCO₃⁻, phosphate (HPO₄²⁻), and ammonia (NH₃). Bicarbonate ions, which are present in the urine filtrate, combine with H⁺ that has been secreted into the tubular fluid, resulting in formation of carbon dioxide and water. The carbon dioxide is then absorbed into the tubular cells and bicarbonate is regenerated. The phosphate ion is a metabolic end product that is filtered into the tubular fluid; it combines with a secreted hydrogen ion and is not reabsorbed. Ammonia is synthesized in tubular cells by deamination of the amino acid glutamine; it diffuses into the tubular fluid and combines with the hydrogen ion. An important aspect of this buffer system is that the deamination process increases whenever the body’s hydrogen ion concentration remains elevated for 1 to 2 days. These mechanisms for pH regulation are described more fully in Chapter 8.

Elimination of Organic Ions

The proximal tubule actively secretes large amounts of different organic anions. Exogenous anions (e.g., salicylates, penicillin) and those produced endogenously (e.g., bile acids, uric acid) are actively secreted into the tubular fluid. Most of the anions that are secreted use the same transport system, allowing the kidneys to rid the body of many different drugs and environmental agents. Because the same transport system is shared by different anions, there is competition for transport such that elevated levels of one substance tend to inhibit the secretion of other anions. The proximal tubules also possess an active transport system for organic cations that is analogous to that for organic anions.

Uric Acid Elimination

Uric acid is a product of purine metabolism (see Chapter 44). Excessively high blood levels (i.e., hyperuricemia) can cause gout, and excessive urine levels can cause kidney stones. Uric acid is freely filtered in the glomerulus and is reabsorbed and secreted into the proximal tubules, using the previously described anion transport system in the proximal tubule. Tubular reabsorption normally exceeds secretion, and the net effect is removal of uric acid from the filtrate. Although the rate of reabsorption exceeds secretion, the secretory process is homeostatically controlled to maintain a constant plasma level. Many persons with elevated uric acid levels secrete less uric acid than do persons with normal uric acid levels.

Uric acid uses the same transport systems as other anions, such as aspirin, sulfapyrazone, and probenecid. Small doses of aspirin compete with uric acid for secretion into the tubular fluid and reduce uric acid secretion, and large doses compete with uric acid for reabsorption and increase uric acid excretion in the urine. Because of its effect on uric acid secretion, aspirin is not recommended for treatment of gouty arthritis. Thiazide and loop diuretics (i.e., furosemide and ethacrynic acid) also can cause hyperuricemia and gouty arthritis, presumably through a decrease in extracellular fluid volume and enhanced uric acid reabsorption.

Urea Elimination

Urea is an end product of protein metabolism. The normal adult produces 25 to 30 g of urea a day; the quantity rises when a high-protein diet is consumed, when there is excessive tissue breakdown, or in the presence of gastrointestinal bleeding. With gastrointestinal bleeding, blood proteins are broken down to form ammonia in the intestine. The ammonia is then absorbed into the portal circulation and converted to urea by the liver before being released into the bloodstream. The kidneys, in their role as regulators of blood urea nitrogen (BUN) levels, filter urea in the glomeruli and then reabsorb it in the tubules. This enables maintenance of a normal BUN level, which ranges from 8 to 25 mg/dL (2.9 to 8.9 mmol/L). During periods of dehydration, the blood volume and GFR drop, and BUN levels increase. The renal tubules are permeable to urea, which means that the longer the tubular fluid remains in the kidneys, the greater is the reabsorption of urea into the blood. Only small amounts of urea are reabsorbed into the blood when the GFR is high, but relatively large amounts of urea are returned to the blood when the GFR is reduced.

Drug Elimination

Many drugs are eliminated in the urine. These drugs are selectively filtered in the glomerulus and reabsorbed or secreted into the tubular fluid. Drugs that are not bound to plasma proteins are filtered in the glomerulus and therefore able to be eliminated by the kidneys. Many drugs are weak acids or weak bases and are present in the renal tubular fluid partly as ionized water-soluble and nonionized lipid-soluble molecules. The nonionized lipid soluble form of a drug diffuses more readily across the lipid bilayer of the tubular cell membrane and then back into the bloodstream, whereas the ionized water-soluble form remains in the urine filtrate. The ratio of ionized
to nonionized drug depends on the pH of the urine. Aspirin, for example, is highly ionized in alkaline urine and in this form is rapidly excreted in the urine, and it is largely nonionized in acid urine and, as such, reabsorbed rather than excreted. Measures that alkalinate or acidify the urine may be used to increase elimination of drugs, particularly in situations of toxic overdose.

**Endocrine Functions of the Kidney**

In addition to their role in regulating fluid and electrolytes, the kidneys function as an endocrine organ in that they produce chemical mediators that travel through the blood to distant sites where they exert their actions. The kidneys participate in control of blood pressure through the renin-angiotensin-aldosterone mechanism, in calcium metabolism by activating vitamin D, and in regulating red blood cell production through the synthesis of erythropoietin.

**The Renin-Angiotensin-Aldosterone Mechanism**

The renin-angiotensin-aldosterone mechanism is important in short- and long-term regulation of blood pressure (see Chapter 18). Renin is an enzyme that is synthesized and stored in the juxtaglomerular cells of the kidney. This enzyme is thought to be released in response to a decrease in renal blood flow or a change in the composition of the distal tubular fluid, or as the result of sympathetic nervous system stimulation. Renin itself has no direct effect on blood pressure. Rather, it acts enzymatically to convert a circulating plasma protein called angiotensinogen to angiotensin I.

Angiotensin I, which has few vasoconstrictor properties, leaves the kidneys and enters the circulation; as it is circulated through the lungs, the angiotensin-converting enzyme catalyzes its conversion to angiotensin II. Angiotensin II is a potent vasoconstrictor, and it acts directly on the kidneys to decrease salt and water excretion. Both mechanisms have relatively short periods of action. Angiotensin II also stimulates the secretion of aldosterone by the adrenal gland, thereby exerting a more long-term effect on maintenance of blood pressure by increasing the reabsorption of sodium in the distal tubule. Renin also functions via angiotensin II to produce constriction of the efferent arteriole as a means of preventing a serious decrease in glomerular filtration pressure.

**Erythropoietin**

Erythropoietin is a polypeptide hormone that regulates the differentiation of red blood cells in the bone marrow (see Chapter 13). Between 89% and 95% of erythropoietin is formed in the kidneys. The synthesis of erythropoietin is stimulated by tissue hypoxia, which may be brought about by anemia, residence at high altitudes, or impaired oxygenation of tissues due to cardiac or pulmonary disease. Persons with chronic kidney disease often are anemic because of an inability of the kidneys to produce erythropoietin. This anemia usually is managed by the administration of a recombinant erythropoietin (epoetin alfa) produced through DNA technology to stimulate erythropoiesis.

**Vitamin D**

Activation of vitamin D occurs in the kidneys. Vitamin D increases calcium absorption from the gastrointestinal tract and helps to regulate calcium deposition in bone. It also has a weak stimulatory effect on renal calcium absorption. Although vitamin D is not synthesized and released from an endocrine gland, it is often considered as a hormone because of its pathway of molecular activation and mechanism of action.

Vitamin D exists in two forms: natural vitamin D (cholecalciferol), produced in the skin from ultraviolet irradiation, and synthetic vitamin D (ergocalciferol), derived from irradiation of ergosterol. The active form of vitamin D is 1,25-dihydroxycholecalciferol. Cholecalciferol and ergocalciferol must undergo chemical transformation to become active: first to 25-hydroxycholecalciferol in the liver and then to 1,25-dihydroxycholecalciferol in the kidneys. Persons with end-stage renal disease are unable to transform vitamin D to its active form and may require pharmacologic preparations of the active vitamin (calcitriol) for maintaining mineralization of their bones.

---

**SUMMARY CONCEPTS**

- The kidneys have multiple functions, including maintaining the volume and composition of body fluids through the regulation of electrolyte levels and excretion of various by-products of metabolism.
- Sodium and potassium levels are regulated by the GFR and by humoral agents such as aldosterone, which controls the final steps in regulating their absorption or elimination.
- The kidneys regulate the pH of body fluids by eliminating H+ and conserving or generating bicarbonate ions.
- Various products of metabolism and exogenous organic anions, such as drugs, are bound to plasma proteins and are therefore unavailable for filtration in the glomerulus. Thus, secretion of substances into tubular fluid provides the route for elimination in the urine.
- The kidneys also function as endocrine organs. They participate in control of blood pressure by way of the renin-angiotensin-aldosterone mechanism, help regulate red blood cell production through the synthesis of erythropoietin, and aid in calcium metabolism through the conversion of vitamin D to its active form.
Tests of Renal Function

The function of the kidneys is to filter the blood, selectively reabsorb those substances that are needed to maintain the constancy of body fluid, and excrete metabolic wastes. Blood and urine tests can provide valuable information about the kidneys’ ability to remove metabolic wastes and maintain the blood’s normal electrolyte and pH composition. As renal function declines, there is an increase in serum levels of substances such as urea, creatinine, phosphate, and potassium. Radiologic tests, endoscopy, and renal biopsy afford means for viewing the gross and microscopic structures of the kidneys and urinary system.

Renal Clearance and Glomerular Filtration Rate

Both the renal clearance and GFR provide information about the kidneys’ ability to filter and reabsorb and/or secrete substances into blood. Renal clearance measures the rate at which a substance is excreted into the urine and the GFR measures the volume of plasma that is filtered each minute.

In clinical practice, one way of estimating the clearance rate of endogenous creatinine is by collecting timed samples of blood and urine. Creatinine is a product of creatine metabolism in muscles; its formation and release are relatively constant and proportional to the amount of muscle mass present. Because creatinine is freely filtered in the glomeruli but is not reabsorbed from the tubules into the blood nor significantly secreted into the tubules from the blood, its blood and urine levels can be used to calculate the GFR.

Another serum protein, cystatin C can also be used as an estimate of GFR. It is produced by all body cells at a constant rate, is freely filtered at the glomerulus, and in several studies has shown a greater sensitivity in detecting a decrease in GFR than creatinine. Recent studies suggest that the use of a combined creatinine–cystatin C equation may provide a better estimate of GFR than either test used separately.

Blood Tests

Blood tests can provide valuable information about the kidneys’ ability to remove metabolic wastes from the blood and maintain normal electrolyte and pH composition of the blood. Normal blood values are listed in Table 24-1. Serum levels of potassium, phosphate, BUN, and creatinine increase in renal failure while serum pH, calcium, and bicarbonate levels decrease.

Serum Creatinine

Serum creatinine levels reflect the GFR. Because these measurements are easily obtained and relatively inexpensive, they often are used as a screening measure of renal function. The normal creatinine value is approximately 0.7 mg/dL of blood for a woman with a small frame, approximately 1.0 mg/dL of blood for a normal adult man, and approximately 1.5 mg/dL of blood (60 to 130 mmol/L) for a muscular man. There is an age-related decline in creatinine clearance in many elderly persons because muscle mass and the GFR decline with age. A normal serum creatinine level usually indicates normal renal function. In addition to its use in calculating the GFR, the serum creatinine level is used in estimating the functional capacity of the kidneys (Fig. 24-12). If the value doubles, the GFR—and renal function—probably has fallen to one half of its normal state. A rise in the serum creatinine level to three times its normal value suggests that there is a 75% loss of renal function, and with creatinine values of 10 mg/dL or more, it can be assumed that approximately 90% of renal function has been lost.

Blood Urea Nitrogen

Urea is formed in the liver as a by-product of protein metabolism and is eliminated entirely by the kidneys. Therefore, the BUN is related to the GFR but, unlike creatinine, it also is influenced by protein intake, gastrointestinal bleeding, and hydration status. In gastrointestinal bleeding, the blood is broken down by the intestinal flora, and the nitrogenous waste is absorbed into the portal vein and transported to the liver, where it is converted to urea. During dehydration, elevated BUN levels result from increased concentration. Approximately two

![FIGURE 24-12](image-url)
thirds of renal function must be lost before a significant rise in the BUN level occurs.

The BUN is less specific for renal insufficiency than creatinine, but the BUN–creatinine ratio may provide useful diagnostic information. The ratio normally is approximately 10:1. Ratios greater than 15:1 represent prerenal conditions, such as congestive heart failure and upper gastrointestinal tract bleeding, that produce an increase in BUN but not in creatinine. A ratio of less than 10:1 occurs in persons with liver disease and in those who receive a low-protein diet or chronic dialysis because BUN is more readily dialyzable than creatinine.

**Urine Tests**

Urine is a clear, amber-colored fluid that is approximately 95% water and 5% dissolved solids. The kidneys normally produce approximately 1.5 L of urine each day. Normal urine contains metabolic wastes and few or no plasma proteins, blood cells, or glucose molecules. Urine tests can be performed on a single urine specimen or on a 24-hour urine specimen. First-voided morning specimens are useful for qualitative protein and specific gravity testing. A freshly voided specimen is most reliable. Urine specimens that have been left standing may contain lysed red blood cells, disintegrating casts, and rapidly multiplying bacteria. Table 24-2 describes urinalysis values for normal urine.

Casts are molds of the distal nephron lumen. A gel-like substance called Tamm-Horsfall mucoprotein, which is formed in the tubular epithelium, is the major protein constituent of urinary casts. Casts composed of this gel but devoid of cells are called hyaline casts. These casts develop when the protein concentration of the urine is high (as in nephrotic syndrome), urine osmolality is high, and urine pH is low. The inclusion of granules or cells in the matrix of the protein gel leads to the formation of various other types of casts.

**Proteinuria**

Proteinuria represents excessive protein excretion in the urine. Because of the glomerular capillary filtration barrier, less than 150 mg/L of protein is excreted in the urine over 24 hours in a healthy person. Urine tests for proteinuria are used to detect abnormal filtering of albumin in the glomeruli or defects in its reabsorption in the renal tubules. A protein reagent dipstick can be used as a rapid screening test for the presence of proteins in the urine. Once the presence of proteinuria has been detected, a 24-hour urine test is often used to quantify the amount of protein that is present.

Albumin, which is the smallest of the plasma proteins, is filtered more readily than globulins or other plasma proteins. Thus, microalbuminuria tends to occur long before clinical proteinuria becomes evident. A dipstick test for microalbuminuria is available for screening purposes. The microalbuminuria dipstick method, however, only indicates an increase in urinary albumin that is below the detectable range of the standard proteinuria test. It does not specify the amount of albumin that is present in the urine. Therefore, a 24-hour urine collection is the standard method for detecting microalbuminuria (an albumin excretion >30 mg/day is abnormal).

**Specific Gravity and Osmolality**

The specific gravity of urine is a measure of its concentration of solutes. Urine specific gravity provides a valuable index of the hydration status and functional ability of the kidneys. The usual range is from 1.010 to 1.025 with normal fluid intake. Healthy kidneys can produce concentrated urine with a specific gravity of 1.030 to 1.040 during periods of dehydration, and a dilute urine with a specific gravity that approaches 1.000 during periods of taking too much fluid. With diminished renal function, there is a loss of renal concentrating ability, and the urine specific gravity may fall to levels of 1.006 to 1.010. These low levels are particularly significant if they occur during periods that follow a decrease in water intake (e.g., during the first urine specimen on arising in the morning).

Urine osmolality, which depends on the number of particles of solute in a unit of solution, is a more exact measurement of urine concentration than specific gravity. More information concerning renal function can be obtained if the serum and urine osmolality tests are done at the same time. The normal ratio between urine and serum osmolality is 3:1. A high urine-to-serum ratio is seen in concentrated urine. With poor concentrating ability, the ratio is low.

SUMMARY CONCEPTS

- The composition of urine and blood samples provides valuable information about kidney function.
- Blood tests that measure serum levels of pH, electrolytes, and by-products of metabolism provide information about renal function. Creatinine, a product of creatine metabolism in muscles, is freely filtered in the glomeruli and neither reabsorbed nor secreted into the tubules; therefore, serum creatinine levels are commonly used to estimate the GFR. Urea is formed in the liver as a by-product of protein metabolism and is eliminated entirely by the kidneys; thus, blood urea nitrogen (BUN) is related to the GFR but, unlike creatinine, is also influenced by protein intake, gastrointestinal bleeding, and hydration status.
- Urinalysis and urine specific gravity is used to assess the kidneys’ ability to concentrate urine. Dipstick and 24-hour urine tests for proteinuria and microalbuminuria are used to detect abnormal filtering of albumin in the glomeruli.

REVIEW EXERCISES

1. A 32-year-old woman with diabetes is found to have a positive result on a urine dipstick test for microalbuminuria. A subsequent 24-hour urine specimen reveals an albumin excretion of 50 mg (an albumin excretion >30 mg/day is abnormal).
   A. Use the structures of the glomerulus in Figure 24-5 to provide a possible explanation for this finding. Why specifically test for the albumin rather than the globulins or other plasma proteins?
   B. Strict control of blood sugars and treatment of hypertension have been shown to decrease the progression of kidney disease in persons with diabetes. Explain the physiologic rationale for these two types of treatments.

2. A 10-year-old boy with enuresis (bed-wetting) was placed on an ADH nasal spray at bedtime as a means of treating the disorder.
   A. Explain the rationale for using ADH to treat bed-wetting.

3. A 54-year-old man, seen by his physician for an elevated blood pressure, was found to have a serum creatinine of 2.5 mg/dL. He complains that he has been urinating more frequently than usual. His first morning urine specimen reveals a dilute urine with a specific gravity of 1.010.
   A. Explain the elevation of serum creatinine in terms of a decrease in renal function.
   B. Explain the inability of persons with early renal failure to produce a concentrated urine as evidenced by the frequency of urination and the low specific gravity of his first morning urine specimen.

The kidneys are subject to many of the same disease processes that affect other organs, including genetic and developmental defects, infections, immunologic disorders, and neoplasms. Although many disorders of renal function originate in the kidneys, others develop secondary to diseases such as systemic lupus erythematosus and diabetes mellitus. Some of these diseases are progressive, eventually leading to chronic kidney disease and the need for dialysis or transplantation. As a major cause of work loss, physicians’ visits, and hospitalizations, kidney diseases remain among the most costly illnesses throughout the industrial world.

The content in this chapter focuses on congenital and hereditary disorders of the kidney, disorders of glomerular function, tubulointerstitial disorders, obstructive disorders, and malignant neoplasms. Acute renal injury and failure and chronic kidney disease are discussed in Chapter 26, and disorders that predominantly affect the lower urinary tract and bladder are discussed in Chapter 27.

The kidneys begin to develop early in the fifth week of gestation and start to function approximately four weeks later. Urine formation begins at about the ninth week of gestation, with the rate of urine production increasing throughout gestation to reach a volume of about 50 mL/hour at term. The urine that is produced is excreted into the amniotic cavity and is the main constituent of amniotic fluid. In pregnancies that involve infants with nonfunctional kidneys or obstruction of urine outflow from the kidneys, the amount of amniotic fluid is small—a condition called oligohydramnios.

### Disorders of Kidney Development

About 10% of all people are born with potentially significant malformations of the urinary system. These disorders sometimes result from hereditary influences, but most often are the result of an acquired defect that arises during embryonic development.
Agenesis, Hypoplasia, and Dysplasia

Defects in development of renal structures are frequently observed during the 1st yr of life, when they collectively represent a significant cause of morbidity and mortality. Renal agenesis, hypogenesis, and dysplasia account for a significant portion of these defects.  

Renal Agenesis. The term agenesis refers to the complete failure of an organ to develop. Total agenesis of both kidneys is incompatible with extrauterine life. Infants are stillborn or die shortly after birth. Newborns with renal agenesis often have characteristic facial features, called Potter syndrome, that are caused by fetal compression due to a marked reduction in amniotic fluid levels. The eyes are widely separated and have epicanthic folds, the ears are set low, the nose is broad and flat, and the chin is receding. The most life-threatening component of Potter syndrome is pulmonary hypoplasia, which is caused by inadequate stimulation from the amniotic fluid and by compression of the chest wall. Bilateral renal agenesis, which has an incidence of 1 in 3000 births with a male predominance, is usually suspected when maternal ultrasound demonstrates oligohydramnios, nonvisualization of the bladder, and absent kidneys.  

Unilateral agenesis is more common than bilateral agenesis and is compatible with life if no other abnormality is present. The opposite kidney usually is enlarged as a result of compensatory hypertrophy. The disorder frequently goes undetected, unless discovered by chance observation on prenatal ultrasound.

Renal Hypoplasia. In renal hypoplasia, the kidneys are small in size and have less than the normal number of calyces and nephrons. Hypoplasia may affect one or both kidneys. When unilateral, the condition is usually discovered during examination for another urinary tract problem or hypertension. When both kidneys are affected, there is progressive development of renal failure. A history of polyuria and polydipsia is common.

Renal Dysplasia. A developmental disorder, renal dysplasia, is characterized by maldifferentiated primitive structures, primarily of the renal tubules. The condition can affect all or only part of the kidney. If the entire kidney is affected with multiple cysts, the condition is referred to as a multicystic dysplastic kidney disorder (MCDK). Bilateral MCDKs cause oligohydramnios and Potter syndrome and are incompatible with life. Multicystic dysplastic kidney disorder is generally unilateral. In most children with MCDK, a palpable mass is discovered shortly after birth, although small multicystic kidneys may not be apparent until years later. Management is controversial, with complete cyst regression occurring in nearly half of children by age 7 years. The risk of hypertension and Wilms tumors of the affected kidney is approximately 1 in 333. Because of the risk of these neoplasms, annual follow-up with sonography and blood pressure measurement is usually recommended. The most important aspect of follow-up is to make certain that the unaffected kidney is functioning properly.

Alterations in Kidney Position and Form

During embryonic life, the kidneys can develop in an abnormal location, usually just above the pelvic rim or within the pelvis. Because of the abnormal position, kinking of the ureters and obstruction of urine flow may occur.

One of the most common alterations in kidney form is an abnormality called a horseshoe kidney. This abnormality occurs in approximately 1 in every 500 to 1000 persons. In this disorder, the upper or lower poles of the two kidneys are fused, producing a horseshoe-shaped structure that is continuous along the midline of the body anterior to the great vessels. Most horseshoe kidneys are fused at the lower poles (Fig. 25-1). The condition usually does not cause problems because its collecting system develops normally and the ureters enter the bladder. If urinary flow is impeded, signs and symptoms and/or infection may appear.

Cystic Diseases of the Kidney

Renal cysts are epithelium-lined cavities filled with fluid or semisolid material. The cysts may be single or multiple, can vary in size from microscopic to several centimeters in diameter, and can be symptomatic or asymptomatic. Although they may arise as a developmental abnormality or be acquired later in life, most forms are hereditary. The inherited cystic kidney diseases, which are single-gene disorders and are inherited as mendelian traits, include autosomal dominant polycystic kidney disease,
Autosomal recessive polycystic kidney disease, and nephronophthisis and medullary cystic kidney diseases.

**Autosomal Dominant Polycystic Kidney Disease**

Autosomal dominant (adult) polycystic kidney disease (ADPKD) is the most common of all inherited kidney diseases, with 600,000 to 700,000 cases in the United States and about 12.5 million cases worldwide. About 5000 to 6000 new cases are diagnosed in the United States each year, about 40% before the age of 45. About 5% to 10% of these persons develop chronic kidney disease that requires dialysis or kidney transplant.

The disorder is characterized by multiple expanding cysts of both kidneys that ultimately destroy the surrounding kidney structures and cause renal failure (Fig. 25-2A). There are two genetic forms of ADPKD: polycystin-1 which is caused by mutations in the *PKD1* gene and accounts for 85% of cases; and polycystin-2, which is caused by mutations in the *PKD2* gene and accounts for most of the remaining 15% of cases. Although the two mutations produce almost identical renal and extrarenal disease, disease progression is typically more rapid in people with the *PKD1* gene.

Recent research suggests that the products of the polycystin genes are transmembrane proteins found on the primary cilia that line the apical surface of the tubular epithelial cells of the kidney. Because the cilia project out and above the tubular cell surface like antennas, they are currently thought to act as sensors of urinary flow and as signal transducers for tubular cell proliferation, differentiation, and apoptosis. The polycystin genes also regulate vascular development in other organs such as the liver, brain, and pancreas, accounting for the extrarenal manifestations that often accompany the disorder.

In ADPKD, cysts in the kidney increase in size over time, ultimately destroying normal renal tissue. The kidneys are usually enlarged and may achieve enormous sizes (Fig. 25-3). The external contours of the kidneys are distorted by numerous cysts, some as large as 5 cm in diameter, filled with straw-colored fluid. Cysts also may be found in the liver and, less commonly, the pancreas and spleen. Hepatic cysts, which occur in one third of persons with ADPKD, are generally asymptomatic and liver function is normal. Mitral valve prolapse and other valvular abnormalities are found in 20% to 25% of people, but most are asymptomatic. One of the most devastating extrarenal manifestations is a weakness in the walls of the cerebral arteries that can lead to aneurysm formation. It has been estimated that persons with ADPKD who have a family member with ADPKD and a history of intracranial aneurysm or cerebral hemorrhage have a 20% chance of developing an intracranial aneurysm.

The manifestations of ADPKD include pain from the enlarging cysts that may reach debilitating levels, episodes of gross hematuria from bleeding into a cyst, infected cysts from ascending UIIs, and hypertension resulting from compression of intrarenal blood vessels with activation of the renin-angiotensin mechanism. Renal colic caused by nephrolithiasis, or kidney stones, occurs in about 20% of persons with ADPKD. The progress of the disease is slow, and chronic kidney disease is uncommon before 40 years of age.

Ultrasonography usually is the preferred technique for the diagnosis of ADPKD in symptomatic patients and for screening of asymptomatic family members. Computed tomography (CT) may be used for detection of small cysts. Genetic linkage studies are now available...

**FIGURE 25-2.** Mechanism of cyst formation in polycystic kidney disease. (A) In autosomal dominant polycystic kidney disease, cystic outpouchings arise in every tubule segment and rapidly close off the nephron of origin. (B) In autosomal recessive polycystic kidney disease, cysts are derived from collecting tubules, which remain connected to the nephron of origin. (From Wilson PD. Polycystic kidney disease. N Engl J Med. 2004;350:155. Copyright © 2004. Massachusetts Medical Society.)

**FIGURE 25-3.** Gross pathology of polycystic kidneys. (From the Centers for Disease Control and Prevention Public Health Images Library. No. 861. Courtesy of Edwin P. Ewing, Jr.)
for diagnosis of ADPKD, but are usually reserved for cases in which radiographic imaging is negative and the need for a definitive diagnosis is essential, such as when screening family members for potential kidney donation. Magnetic resonance angiography is recommended for persons who have a family history of cerebral aneurysm or stroke and for those with new-onset or severe headache.

The treatment of ADPKD is largely supportive and aimed at slowing progression of the disease. Control of hypertension and prevention of ascending UTIs are important. Pain is a common complaint of persons with ADPKD, and a systematic approach is needed to differentiate the etiology of the pain and define an approach for management.

Cyclic adenosine monophosphate (cAMP) has been shown to increase proliferation of epithelial cells in cyst walls and the rate of fluid secretion into cysts. One of the prime mediators of cell proliferation, acting through cAMP, is arginine vasopressin (AVP), also known as the antidiuretic hormone. In studies using genetically produced polycystic animals, the use of vasopressin V2 receptor inhibitors reduced cyst growth and preserved renal function. Because an increase in urine osmolality serves to increase vasopressin levels, it is often recommended that persons with ADPKD drink approximately 3000 L of water throughout the waking hours to reduce plasma AVP levels. Normally cAMP is broken down by phosphodiesterases. Because caffeine raises cAMP levels by interfering with phosphodiesterase activity, it is also recommended that caffeinated beverages be avoided.

In addition to increasing water intake to decrease vasopressin levels, the angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor blockers (ARBs) may be used to interrupt the renin-angiotensin-aldosterone system as a means of reducing intraglomerular pressure and renal vasoconstriction. Although not approved by the Food and Drug Administration (FDA), there has been recent interest in the use of vasopressin receptor antagonists (vaptans) to decrease cyst development. Dialysis and kidney transplantation are reserved for those who progress to kidney failure.

**Autosomal Recessive Polycystic Kidney Disease**

Autosomal recessive (childhood) polycystic kidney disease (ARPKD) is characterized by cystic dilatation of the cortical and medullary collecting tubules (see Fig. 25-2B). It is rare compared with ADPKD, occurring in 1 to 20,000 live births. Autosomal recessive (childhood) polycystic kidney disease is caused by mutations in the PKHD1 gene. The gene product, fibrocystin, is found in the collecting ducts of the kidney, biliary ducts of the liver, and exocrine ducts of the pancreas, and appears to be involved in the regulation of cell proliferation and adhesion. Perinatal, neonatal, infantile, and juvenile subcategories have been defined, dependent on time of presentation. The perinatal and infantile types are most common. Serious manifestations are usually present at birth, with the infant progressing rapidly into renal failure.

The typical infant with ARPKD presents with bilateral flank masses, accompanied by severe renal failure, signs of impaired lung development, and variable degrees of liver fibrosis and portal hypertension. Potter facies and other defects associated with oligohydramnios may be present. Hypertension is usually noted within the first few weeks of life and is often severe. Approximately 75% of infants die during the perinatal period, often of pulmonary hypoplasia. Children and juveniles who survive infancy develop a distinctive type of liver fibrosis. In older children, liver disease is the predominant clinical concern.

The treatment of ARPKD is largely supportive. Aggressive ventilatory support is often necessary in the neonatal period because of pulmonary hypoplasia and hypoventilation. Modern neonatal respiratory technology and renal replacement therapy (e.g., dialysis and kidney transplant) have increased the 10-year survival rate of children surviving beyond the 1st year of life. Morbidity and mortality in the older child is related to complications of kidney failure and liver disease.

**Nephronophthisis and Medullary Cystic Kidney Disease**

Nephronophthisis and adult-onset medullary cystic kidney disease both produce progressive medullary tubulointerstitial cystic disease, but vary in terms of genetic causes and patterns of inheritance. Nephronophthisis has an autosomal recessive pattern of inheritance with onset in infancy, childhood, or adolescence. It is caused by mutations in NPHP genes, whose gene products are located on the primary cilia, similar to those of ADPKD and ARPKD. Medullary cystic kidney disease has an autosomal dominant pattern of inheritance, with onset in adolescence and progression to renal failure in adulthood that is caused by a mutation in the MCKD 1 or 2 genes.

Common characteristics of the two cystic diseases are small and shrunken kidneys and the presence of a variable number of cysts, usually concentrated at the corticomedullary junction area of the kidney. The initial insult involves the distal tubules, with tubular basement membrane disruption followed by chronic and progressive tubular atrophy involving both the medulla and cortex. Although the presence of medullary cysts is important, the cortical tubulointerstitial damage is the eventual cause of chronic kidney disease and failure.

Nephronophthisis can present as three clinical variants: infantile, juvenile, or adolescent. The juvenile form is most common and accounts for 5% to 10% of chronic kidney disease in children. Symptoms begin between 4 to 6 years of age, and progress to chronic kidney disease within 10 years. Some juvenile forms of nephronophthisis have extrarenal complications, including ocular motor abnormalities, retinitis pigmentosa, liver fibrosis, and cerebellar abnormalities. The onset and progression of the adolescent form causes chronic kidney failure at 10 to 20 years of age, and the infantile form before 2 years of age.

Children with nephronophthisis and adults with medullary cystic kidney disease present first with polyuria,
polydipsia, and enuresis (bed-wetting), which reflect impaired ability of the kidneys to concentrate urine. Other manifestations of the disorders include salt wasting, growth retardation, anemia, and progressive renal insufficiency.

**Simple and Acquired Renal Cysts**

Simple cysts are a common acquired disorder of the kidney. The cysts may be single or multiple, unilateral or bilateral, and are commonly 1 to 5 cm in diameter, but may reach 10 cm or more. The cysts usually are confined to the cortex. In rare instances, massive cysts as large as 10 cm in diameter are encountered. Most simple cysts do not produce signs or symptoms or compromise renal function. When symptomatic, they may cause flank pain, hematuria, infection, and hypertension related to ischemia-produced stimulation of the renin-angiotensin system. They are most common in persons older than 50 years. Although the cysts are benign, the main concern is to differentiate them from renal cell carcinoma. Ultrasound and CT scanning are the recommended procedures for evaluating these masses. An acquired form of renal cystic disease occurs in persons with chronic kidney disease who have undergone prolonged dialysis treatment. Although the condition is largely asymptomatic, the cysts may bleed, causing hematuria. Tumors, usually adenomas but occasionally adenosarcomas, may develop in the walls of these cysts.

**SUMMARY CONCEPTS**

- Congenital abnormalities of the kidney include agenesis or failure of the kidneys to develop, which is incompatible with life if both kidneys are affected; hypogenesis or failure of the kidneys to develop to normal size, which usually causes no problems unless both kidneys are affected; and renal dysplasia, which is characterized by disorganized and maldifferentiated development of kidney tissue, usually accompanied by cyst formation. Other developmental kidney defects can result in kidneys that lie outside their normal position or are fused to form horseshoe-shaped kidneys.
- Cystic diseases of the kidney are hereditary and nonhereditary disorders in which there is dilation of tubular structures with cyst formation.
- There are two forms of polycystic kidney disease: autosomal dominant (ADPKD) and autosomal recessive (ARPKD). Autosomal dominant (adult) polycystic kidney disease results in the formation of numerous fluid-filled cysts in the tubular structures of both kidneys with the threat of progression to chronic kidney disease. ARPKD, which is rare compared with ADPKD and usually presents as severe renal dysfunction during infancy, is characterized by cystic transformation of the collecting ducts.
- Nephronophthisis and adult-onset medullary cystic kidney disease are characterized by the presence of similar progressive medullary cystic disease, but with different genetic causes and inheritance. Nephronophthisis is an autosomal recessive disorder, with onset in infancy, childhood, or adolescence; whereas adult-onset medullary cystic kidney disease is an autosomal dominant disorder with onset in adolescence and renal failure in adulthood.
- Simple cysts are an acquired disorder of the kidney. They may be single or multiple, unilateral or bilateral, and are commonly 1 to 5 cm in diameter. Although the cysts are benign, the main concern is to differentiate them from malignancies.

**Disorders of Glomerular Function**

Glomerular disorders are one of the most common forms of kidney disease. The glomeruli may be the major site of disease (primary glomerular disease) or part of a disease affecting other organs (secondary glomerular disease). Hereditary glomerular diseases such as Alport syndrome, although relatively rare, are an important category of glomerular disease because of their association with progressive loss of renal function and transmission to future generations.

**Etiology and Pathogenesis of Glomerular Injury**

Many of the clinical manifestations of glomerular disorders result from dysfunction of specific components of the glomeruli, which consist of a network of capillaries, lined with a fenestrated endothelium invested in two layers of epithelium (Fig. 25-4A). The visceral epithelium is incorporated into and becomes an intricate part of the capillary wall, separate from the endothelium by a basement membrane. The parietal epithelium, which lines Bowman space within which urine collects, is attached to the basement membrane by long, footlike processes (podocytes) that encircle the outer surface of the capillaries. The glomerular capillary membrane is selectively permeable, allowing water and small particles (e.g., electrolytes and dissolved particles, such as glucose and amino acids) to leave the blood and enter the Bowman space while preventing larger particles (e.g., plasma proteins and blood cells) from leaving the blood.
The agents or events that trigger glomerular injury include infectious microorganisms, immunologic mechanisms, drugs, and environmental agents. Most cases of primary and many cases of secondary glomerular disease probably have an immune origin. Although many glomerular diseases are driven by immunologic events, a variety of metabolic (e.g., diabetes), hemodynamic (e.g., hypertension), and toxic (e.g., drugs, chemicals) stresses can induce glomerular injury, either alone or in concert with immunologic mechanisms.

Two types of immune mechanisms have been implicated in the development of glomerular disease: (1) injury resulting from antibodies reacting with fixed glomerular antigens or antigens planted within the glomerulus and (2) injury resulting from circulating antigen–antibody complexes that become trapped in the glomerular membrane. Immune mechanisms of glomerular disease.

(B) Antigen–antibody complexes circulating in the blood become trapped as they are filtered in the glomerulus.
Types of Glomerular Disease

The clinical manifestations of glomerular disorders generally fall into several categories: acute nephritic syndromes, rapidly progressive glomerulonephritis, nephrotic syndrome, IgA nephropathy, hereditary nephritis (e.g., Alport syndrome), and chronic glomerulonephritis. The nephritic syndromes produce a proliferative inflammatory response, whereas the nephrotic syndrome produces increased permeability of the glomerulus. Because most glomerular disorders can produce mixed nephritic and nephrotic syndromes, a definitive diagnosis often requires renal biopsy.

Many cases of glomerular disease result in mild asymptomatic illness that is not recognized or is brought to the attention of a health care professional during routine screening or physical examination for another purpose. Disorders such as IgA nephropathy and Alport syndrome often present with asymptomatic hematuria and/or proteinuria.

Acute Nephritic Syndrome

Acute nephritic syndrome is an acute inflammatory process that occludes the glomerular capillary lumen and damages the capillary wall. It may occur as a renal-limited primary disorder, such as acute postinfectious glomerulonephritis, or as a secondary complicating disorder in systemic diseases, such as SLE. In its most dramatic form, acute nephritic syndrome is characterized by sudden onset of hematuria (either microscopic or grossly visible, with red cell casts), variable degrees of proteinuria, diminished glomerular filtration rate (GFR), oliguria, and signs of impaired renal function. Extracellular fluid accumulation, edema, and hypertension develop because of the decreased GFR and enhanced tubular reabsorption of salt and water.

Acute Postinfectious Glomerulonephritis

Acute postinfectious glomerulonephritis usually occurs after infection with certain strains of group A beta-hemolytic streptococci and is caused by deposition of immune complexes. It also may occur after infections by other organisms, including staphylococci and a number of viral agents, such as those responsible for mumps, measles, and chickenpox. This type of glomerular disease is now rare in industrialized nations, but continues to be a common disorder in the underprivileged populations of the world. Although the disease is seen primarily in children, persons of any age can be affected.

The acute phase of postinfectious glomerulonephritis is characterized by diffuse glomerular enlargement and hypercellularity. The hypercellularity is caused by infiltration of leukocytes, both neutrophils and monocytes; proliferation of endothelial and mesangial cells; and formation of electron-dense subepithelial deposits, often having the appearance of “humps” (see Fig. 25-4B). There is also swelling of the endothelial cells, and the combination of proliferation, swelling, and leukocyte infiltration obliterates the glomerular capillary lumens. On immunofluorescence microscopy there are granular deposits of immunoglobulin G (IgG) and the complement component C3 in the mesangium and along the basement membrane (Fig. 25-6).

The classic case of poststreptococcal glomerulonephritis follows a streptococcal infection by approximately 7 to 12 days—the time needed for the development of antibodies. The primary infection usually involves the pharynx (pharyngitis), but can also result from a skin infection (impetigo). Oliguria, which develops as the GFR decreases, is one of the first symptoms. Proteinuria and hematuria follow because of increased glomerular capillary wall permeability. The red blood cells are degraded by materials in the urine, and cola-colored urine may be the first sign of the disorder. Sodium and water retention gives rise to edema (particularly of the face and hands) and hypertension. Important laboratory findings include an elevated antistreptococcal antibody (ASO) titer, a decline in serum concentrations of C3 and other components of the complement cascade, and cryoglobulins (i.e., large immune complexes) in the serum.

Treatment of acute poststreptococcal glomerulonephritis includes eliminating the streptococcal infection with antibiotics and providing supportive care. The disorder generally carries an excellent prognosis and rarely causes chronic kidney disease. In children, spontaneous resolution of the glomerular lesion and nephritic syndrome is usually the norm and occurs within 6 to 8 weeks. Adults tend to recover more slowly, often with some degree of persistent azotemia that may, in some cases, progress to chronic kidney disease.

Rapidly Progressive Glomerulonephritis

Rapidly progressive glomerulonephritis is a clinical syndrome characterized by signs of severe glomerular injury that does not have a specific cause. As its name indicates, this type of glomerulonephritis is rapidly progressive,
often within a matter of months. The disorder involves focal and segmental proliferation of glomerular cells and recruitment of monocytes and macrophages with the formation of crescent structures that obliterate the Bowman space.\(^5\) Rapidly proliferative glomerulonephritis may be caused by a number of immunologic disorders, some systemic and others restricted to the kidney. Among the diseases associated with this form of glomerulonephritis are immune complex disorders such as SLE, and an aggressive form of glomerulonephritis called Goodpasture syndrome.

**Goodpasture Syndrome.** An uncommon and aggressive form of glomerulonephritis, Goodpasture syndrome is caused by antibodies to the glomerular basement membrane (GBM). The anti-glomerular membrane (anti-GBM) antibodies cross-react with the pulmonary alveolar basement membrane to produce the syndrome of pulmonary hemorrhage associated with renal failure. The pathologic hallmark of anti-GBM glomerulonephritis is diffuse linear staining of glomerular basement membranes for IgG (Fig. 25-7). The cause of the disorder is unknown, although influenza infection and exposure to hydrocarbon solvent (found in paints and dyes) have been implicated in some persons, as have various drugs and cancers. There is a high prevalence of certain human leukocyte antigen subtypes (e.g., HLA-DRB1) in those affected, suggesting a genetic predisposition.\(^4\) Treatment includes plasmapheresis to remove circulating anti-GBM antibodies and immunosuppressive therapy (i.e., corticosteroids and cyclophosphamide) to inhibit antibody production.

**Nephrotic Syndrome**

The nephrotic syndrome is characterized by massive proteinuria (≥3.5 g/day in adults) and lipiduria (e.g., free fat, oval bodies, fatty casts), along with an associated hypoalbuminemia (<3 g/dL), generalized edema, and hyperlipidemia.\(^5,5,10\) The nephrotic syndrome is not a specific glomerular disease, but a constellation of clinical findings that result from an increase in glomerular permeability and loss of plasma proteins in the urine (Fig. 25-8).

The glomerular membrane acts as a size-specific barrier through which the glomerular filtrate must pass. An increase in permeability allows proteins to escape from the plasma into the glomerular filtrate, often leading to an excessive loss of albumin—the smallest and most abundant of the plasma proteins. Generalized edema, which is a hallmark of the nephrotic syndrome, results from a decrease in the plasma colloidal osmotic pressure due to the hypoalbuminemia that develops as albumin is lost from the vascular compartment (see Chapter 8). There is also salt and water retention, which aggravates the edema. Initially, the edema presents in dependent parts of the body such as the lower extremities, but becomes more generalized as the disease progresses (Fig. 25-9). Dyspnea due to pulmonary edema, pleural effusions, and diaphragmatic compromise due to ascites can develop in persons with nephrotic syndrome.

The hyperlipidemia that occurs in persons with nephrosis is characterized by elevated levels of triglycerides and low-density lipoproteins (LDLs). Levels of high-density lipoproteins (HDLs) usually are normal. It is thought that these abnormalities are related, at least in part, to increased synthesis of lipoproteins in the liver secondary to a compensatory increase in albumin production.\(^13\) Because of the elevated LDL levels, persons with nephrotic syndrome are at increased risk for development of atherosclerosis.
The largest proportion of protein lost in the urine is albumin, but globulins also may be lost. As a result, persons with nephrosis are often vulnerable to infections, particularly those caused by staphylococci and pneumococci. This decreased resistance to infection is probably related to the loss of both immunoglobulins and low-molecular-weight complement components in the urine. Many binding proteins also are lost in the urine. Consequently, the plasma levels of many ions (iron, copper, zinc) and hormones (thyroid and sex hormones) may be low. Many drugs require protein binding for transport. Hypoalbuminemia reduces the number of available protein-binding sites, thereby producing a potential increase in the amount of free (active) drug that is available.

Persons with nephrotic syndrome are also at risk for thrombotic complications. These complications reflect a disruption in the function of the coagulation system brought about by a loss of coagulation and anticoagulation factors in the urine. Renal vein thrombosis, once thought to be a cause of the disorder, is more likely a consequence of the hypercoagulable state. Other thrombotic complications include deep vein thrombosis and pulmonary emboli.

The glomerular changes that occur with nephrosis can develop as a primary disorder or secondary to changes caused by systemic diseases such as diabetes mellitus and SLE. Among the primary glomerular lesions leading to nephrotic syndrome are minimal-change disease (lipoid nephrosis), focal segmental glomerulosclerosis, and membranous glomerulonephritis. The relative frequency of these causes varies with age. In children younger than 15 years of age, nephrotic syndrome almost always is caused by primary idiopathic glomerular disease, whereas in adults it is often a secondary disorder.

**Minimal-Change Disease (Lipoid Nephrosis).** Minimal-change disease is characterized by diffuse loss (through fusion) of the podocytes or foot processes of the visceral epithelial cells of the glomeruli. It is most commonly seen in children (peak incidence at 2 to 6 years of age), but may occasionally occur in adults. Although the cause of minimal-change disease is unknown; children in whom the disease develops often have a history of recent upper respiratory infections or of receiving routine childhood immunizations. Minimal-change disease does not usually progress to renal failure, but can cause significant complications, including predisposition to infection with gram-positive organisms, tendency toward thromboembolic events, hyperlipidemia, and protein malnutrition. The prognosis in children with the disorder is good; more than 90% respond to a short course of glucocorticoids. Adults also respond to corticosteroids, but the response is slower.

**Membranous Glomerulonephritis.** Membranous glomerulonephritis is the most common cause of primary nephrosis in adults. The disorder is caused by diffuse thickening of the glomerular basement membrane due to deposition of immune complexes. The disorder may be idiopathic or associated with a number of disorders, including autoimmune diseases such as SLE, infections such as chronic hepatitis B, metabolic disorders such as diabetes mellitus and thyroiditis, and use of certain drugs such as gold compounds, penicillamine, and captopril.

The disorder usually begins with an insidious onset of the nephrotic syndrome with peripheral edema, hypoalbuminemia, and hyperlipidemia or, in a small percentage of patients, with nonnephrotic proteinuria. Hematuria and mild hypertension may be present. The progress of the disease is variable, with less than 40% eventually developing renal insufficiency. Spontaneous remissions and a relatively benign outcome occur more commonly in women and those with proteinuria in the nonnephrotic range. Treatment is controversial. Because of the variable course of the disease, the overall effectiveness of corticosteroids and other immunosuppressive therapy in controlling the progression of the disease has been difficult to evaluate.

**Focal Segmental Glomerulosclerosis.** Focal segmental glomerulosclerosis (FSGS) is characterized by sclerosis (i.e., increased collagen deposition) in some but not all glomeruli. Moreover, in the affected glomeruli, only a portion of the glomerular tuft is involved. Focal segmental glomerulosclerosis causes 30% of primary nephrotic syndrome in adults and 10% in children. It is more common in blacks than whites and is the leading cause of primary nephrotic syndrome in African Americans.
Focal segmental glomerulosclerosis can be viewed as a heterogeneous group of glomerular diseases with different causes, pathologies, and outcomes. The disorder may be idiopathic (primary) or occur secondary to reduced oxygen in the blood (e.g., sickle cell disease and cyanotic congenital heart disease), human immunodeficiency virus (HIV) infection, or intravenous drug abuse. It can also occur as a secondary event reflecting scarring from other glomerular disorders, such as IgA nephropathy. There is also evidence of a genetic basis for some cases of the disorder. Multiple factors probably lead to a common pathway of injury.

Clinical presentations and outcomes vary among the different patterns of injury. Most people with the disorder show persistent proteinuria and progressive decline in renal function. Many persons with the disorder progress to kidney failure within 5 to 20 years. The disorder usually is treated with corticosteroids. Although kidney transplantation is the preferred treatment for end-stage kidney disease, focal segmental glomerulonephritis occurs in half of these people.

**IgA Nephropathy**

IgA nephropathy (i.e., Berger disease) is a primary glomerulonephritis characterized by the presence of glomerular IgA immune complex deposits. It can occur at any age, but most commonly has its onset in the second and third decades of life. The disease occurs more commonly in men than women and is the most common cause of glomerular nephritis in Asians.

The disorder is characterized by the deposition of IgA-containing immune complexes in the mesangium of the glomerulus (Fig. 25-10). Once deposited in the kidney, the immune complexes are associated with glomerular inflammation. The cause of the disorder is unknown. Some people with the disorder have elevated serum IgA levels. Recent studies have focused on potential abnormalities of the IgA molecule as a factor in the pathogenesis of the disorder.

Early in the disease, many people with the disorder have no obvious symptoms and the disorder is discovered during routine screening or examination for another condition. In others, the disorder presents with gross hematuria that is preceded by upper respiratory tract infection, gastrointestinal tract symptoms, or a flulike illness. The hematuria usually lasts 2 to 6 days. Approximately one half of those with gross hematuria have a single episode, whereas the remainder experience a gradual progression of the disease with recurrent episodes of hematuria and mild proteinuria. Progression usually is slow, extending over several decades.

Immunofluorescence microscopy, using a specimen obtained through renal biopsy, is essential for diagnosis of IgA nephropathy. The diagnostic finding is mesangial staining for IgA that is more intense than staining for IgG or IgM. At present, there are no satisfactory treatment measures for IgA nephropathy. The role of immunosuppressive drugs such as steroids and cytotoxic drugs is not clear.

**Hereditary Nephritis (Alport Syndrome)**

Alport syndrome represents a hereditary defect of the glomerular basement membrane that results in hematuria and may progress to chronic renal failure. Approximately 85% of cases are inherited as an X-linked autosomal dominant trait, whereas others have autosomal dominant and recessive patterns of inheritance. In X-linked pedigrees, boys are usually affected more seriously than girls. Aflicted boys usually progress to renal failure as adults, but progression may occur during adolescence. Although many girls never have more than mild hematuria with or without mild proteinuria, some have more significant disease and may even progress to kidney failure.

Diagnosis of Alport syndrome is often made after examination of the urine of a child from a family with multiple cases of hereditary nephritis. Children may initially present with heavy microscopic hematuria (large amount of blood on dipstick), followed by the development of proteinuria. Many, but not all, persons with Alport syndrome have sensorineural deafness and various eye disorders, including lens dislocation, posterior cataracts, and corneal dystrophy. The hearing loss is bilateral and often is first detected during adolescence.

**Chronic Glomerulonephritis**

Chronic glomerulonephritis represents the chronic phase of a number of specific types of glomerulonephritis. Some forms of acute glomerulonephritis (e.g., poststreptococcal glomerulonephritis) undergo complete resolution, whereas others progress at variable rates to chronic glomerulonephritis. Some persons who present with chronic glomerulonephritis have no history of glomerular disease. These cases may represent the end result of relatively asymptomatic forms of glomerulonephritis. Histologically, the condition is characterized by small kidneys with sclerosed glomeruli. In most cases, chronic glomerulonephritis develops insidiously and slowly progresses to chronic kidney disease over a period of years (see Chapter 26).

![Figure 25-10](image-url)  
Glomerular Lesions Associated with Systemic Disease

Many systemic diseases (e.g., systemic lupus erythematosus, diabetes mellitus) are associated with glomerular injury. In some diseases the glomerular involvement may be the major clinical manifestation.

Systemic Lupus Erythematosus Glomerulonephritis.

Renal involvement is one of the most common complications of SLE. The pathogenesis of SLE (see Chapter 44) is uncertain, but appears to be related to dysregulated B-cell immunity with production of autoantibodies to a variety of nuclear, cytoplasmic, extracellular matrix, and cell membrane components. Most glomerular injury is triggered by the deposition of immune complexes within the glomerular wall. Immune complexes may derive from the circulation, develop locally, or both.

The clinical manifestations of SLE glomerulonephritis, commonly referred to as lupus nephritis, depend on the site of immune complex-mediated injury. Immune complexes confined to the mesangium cause less inflammation than subendothelial immune complexes, which have greater exposure to inflammatory cells and mediators in the blood and therefore are more likely to produce inflammation. Immune complexes may also localize in the renal interstitium, walls of interstitial vessels, and basement membranes, causing the tubulointerstitial inflammation that occurs in persons with SLE.

Because of the high risk for kidney disease, all persons with SLE should undergo routine urinalysis to monitor for the appearance of hematuria or proteinuria. If urinary abnormalities are noted, renal biopsy is often performed. Treatment depends on the extent of glomerular involvement. Oral corticosteroids and angiotensin-converting enzyme (ACE) inhibitors are the mainstays of treatment. Persons with more advanced disease may require treatment with immunosuppressive agents (e.g., intravenous cyclophosphamide or oral mycophenolate). Clinical trials using other immunosuppressive agents are ongoing.

Diabetic Glomerulosclerosis.

Diabetic nephropathy is a major cause of chronic kidney disease and the most common cause of kidney failure treated by renal replacement therapy in the United States. It occurs in both type 1 and type 2 diabetes mellitus.

The lesions of diabetic nephropathy most commonly involve the glomeruli and are associated with three glomerular syndromes: nonnephrotic proteinuria, nephrotic syndrome, and chronic renal failure. Widespread thickening of the glomerular capillary basement membrane occurs in almost all persons with diabetes and can occur without evidence of proteinuria. This is followed by a diffuse increase in mesangial matrix, with mild proliferation of mesangial cells. As the disease progresses, the mesangial cells impinge on the capillary lumen, reducing the surface area for glomerular filtration. In nodular glomerulosclerosis, also known as Kimmelstiel-Wilson syndrome, there is nodular deposition of hyaline in the mesangial portion of the glomerulus. As the sclerotic process progresses in the diffuse and nodular forms of glomerulosclerosis, there is complete obliteration of the glomerulus, with impairment of renal function.

Although the mechanisms of glomerular change in diabetes are uncertain, they are thought to represent enhanced or defective synthesis of the glomerular basement membrane and mesangial matrix with inappropriate incorporation of glucose into the noncellular components of these glomerular structures. Alternatively, hemodynamic changes that occur secondary to elevated blood glucose levels may contribute to the initiation and progression of diabetic glomerulosclerosis. It has been hypothesized that elevations in blood glucose produce an increase in GFR and glomerular pressure that leads to enlargement of glomerular capillary pores by a mechanism that is, at least partly, mediated by angiotensin II. This enlargement results in an increase in the protein content of the glomerular filtrate, which in turn requires increased endocytosis of the filtered proteins by tubular endothelial cells, a process that ultimately leads to nephron destruction and progressive deterioration of renal function.

The clinical manifestations of diabetic glomerulosclerosis are closely linked to those of diabetes. The increased GFR that occurs in persons with early alterations in renal function is associated with microalbuminuria, defined as urinary albumin excretion of 30 to 300 mg in 24 hours. Microalbuminuria is an important predictor of future diabetic nephropathies. In many cases, these early changes in glomerular function can be reversed by careful control of blood glucose levels (see Chapter 33). Inhibition of angiotensin by ACE inhibitors or ARBs has been shown to have a beneficial effect, possibly by reversing increased glomerular pressure. Hypertension and cigarette smoking have been implicated in the progression of diabetic nephropathy. Thus, control of blood pressure (to levels of 130/80 mm Hg or less) and smoking cessation are recommended as primary and secondary prevention strategies in persons with diabetes.

SUMMARY CONCEPTS

- Glomerulonephritis represents a group of kidney diseases that result from inflammation and injury of the glomerulus. It may occur as a primary condition in which the glomerular abnormality is the only disease present, or as a secondary condition in which the glomerular abnormality results from another disease, such as diabetes mellitus or SLE. Most cases of primary and many cases of secondary glomerular disease probably have an immune origin.
SUMMARY CONCEPTS (continued)

- Glomerular disorders alter the permeability of the glomerular capillary membrane to plasma proteins and blood cells to produce either a nephritic or nephrotic syndrome. The nephritic syndromes, which evoke an inflammatory response in the glomeruli and a decrease in glomerular permeability, are characterized by hematuria with red cell casts in the urine, diminished GFR, azotemia, oliguria, and hypertension. The nephrotic syndromes, which increase glomerular capillary membrane permeability, are characterized by massive proteinuria, hypoalbuminemia, generalized edema, lipiduria, and hyperlipidemia.
- Chronic glomerulonephritis represents the chronic phase of a number of specific types of glomerulonephritis.

Tubular and Interstitial Disorders

Several disorders cause histologic and functional alterations that affect renal tubular structures, including the proximal and distal tubules. Most of these disorders also affect the interstitial tissue that surrounds the tubules. Although these disorders, sometimes referred to as tubulointerstitial disorders, may occur in the progression of diseases that primarily affect the glomerulus or as secondary manifestations of other diseases such as diabetes mellitus, they can also occur as a primary event. These diseases have diverse causes and different pathogenic mechanisms. They include acute tubular necrosis (discussed in Chapter 26), tubulointerstitial nephritis, acute and chronic pyelonephritis, reflex nephropathy, and nephropathy induced by drugs and toxins.

Tubulointerstitial Nephritis

Tubulointerstitial nephritis represents acute or chronic inflammation of the renal tubules and surrounding interstitium. In chronic tubulointerstitial nephritis there is infiltration with mononuclear leukocytes, interstitial fibrosis, and widespread tubular atrophy.

The tubulointerstitial disorders are distinguished clinically from glomerular diseases by the absence, in the early stages, of such hallmarks of nephritis and nephrosis as hematuria and proteinuria, and by the presence of disorders in tubular function. These disorders, which are often subtle, include the inability to concentrate urine, as evidenced by polyuria and nocturia; interference with acidification of urine, resulting in metabolic acidosis; and diminished tubular reabsorption of sodium and other substances. In their advanced forms, however, they are difficult to distinguish from other causes of renal insufficiency.

Pyelonephritis

Pyelonephritis is a renal disease affecting the tubules, interstitium, and pelvis of the kidney. Acute pyelonephritis is caused by bacterial infection; whereas chronic pyelonephritis is a more complex disorder involving not only bacterial infection but other factors such as reflux. Most infections of the kidney are ascending infections that occur secondary to infections of the lower urinary tract (discussed in Chapter 27).

Acute Pyelonephritis

Acute pyelonephritis is an acute suppurative inflammation of the kidney caused by bacterial infection. Escherichia coli is the causative agent in about 80% of cases. Less common causative organisms include Enterobacteriaceae, Pseudomonas species, group B Streptococcus, Staphylococcus, and enterococci. There are two forms of acute pyelonephritis: uncomplicated and complicated. Uncomplicated acute pyelonephritis most commonly occurs in healthy young women without structural or urinary tract obstructions or other contributing factors. Complicated acute pyelonephritis occurs in children or adults with structural or functional urinary tract abnormalities or predisposing medical conditions. Factors that contribute to the development of complicated acute pyelonephritis are outflow obstruction, catheterization and urinary instrumentation, vesicoureteral reflux, pregnancy, and neurogenic bladder.

There are two routes by which bacteria can gain access to the kidney: ascending infection from the lower urinary tract and through the bloodstream (hematogenous spread). Ascending infection from the lower urinary tract is the most important and common route by which bacteria reach the kidney. The hematogenous route results from seeding of the kidneys by bacteria from distant loci in the course of sepsisemia or infective endocarditis. It is more likely to occur in debilitated, chronically ill persons and those receiving immunosuppressive therapy, and with nonenteric bacteria such as staphylococci and certain fungi.

Although outflow obstruction is an important predisposing factor in the pathogenesis of ascending infection, it is incompetence of the vesicoureteral orifice that allows bacteria to ascend the ureter into the renal pelvis. The ureter normally inserts into the bladder at a steep angle and in its most distal portion courses parallel to the bladder wall, forming a mucosal flap (Fig. 25-11A). The flap acts as a one-way valve: it is normally relaxed, allowing urine to flow into the bladder, but is compressed against the bladder wall during micturition, preventing urine from being forced into the ureter. In persons with vesicoureteral reflux, the ureter enters the bladder at an approximate right angle such that urine is forced into the ureter during micturition (Fig. 25-11B). It is seen most commonly in children with urinary tract infections.
(UTIs) and is believed to result from congenital defects in length, diameter, muscle structure, or innervation of the submucosal segment of the ureter. Vesicoureteral reflux is discussed further in Chapter 27.

The onset of acute pyelonephritis is usually abrupt, with shaking chills, moderate to high fever, and a constant ache in the loin area of the back that is unilateral or bilateral. Lower urinary tract symptoms, including dysuria, frequency, and urgency, also are common. There may be significant malaise, and the person usually looks and feels ill. Nausea and vomiting may occur along with abdominal pain. Palpation or percussion over the costovertebral angle on the affected side usually causes pain. Pyuria occurs but is not diagnostic because it also occurs in lower UTIs.

A second and infrequent form of acute pyelonephritis is characterized by ischemia and a condition known as papillary necrosis, the suppurative necrosis of one or several renal pyramids. It occurs most commonly in persons with diabetes mellitus who develop acute pyelonephritis when there is significant urinary tract obstruction. The development of papillary necrosis is associated with a much poorer prognosis. There is often evidence of overwhelming sepsis with frequent development of kidney failure.

Acute pyelonephritis is treated with appropriate antimicrobial drugs. Unless obstruction or other complications occur, the symptoms usually disappear within several days. Treatment with an appropriate antimicrobial agent usually is continued for 10 to 14 days. Persons with complicated acute pyelonephritis and those who do not respond to outpatient treatment may require hospitalization.

**Chronic Pyelonephritis and Reflux Nephropathy**

Chronic pyelonephritis represents a progressive process. There is scarring and deformation of the renal calyces and pelvis, along with atrophy and thinning of the overlying cortex (Fig. 25-12). The disorder involves a recurrent or persistent bacterial infection superimposed on urinary tract obstruction, urine reflux, or both. Chronic obstructive pyelonephritis can be bilateral, caused by conditions that obstruct bladder outflow; or unilateral, such as occurs with ureteral obstruction. Reflux, which is the most common cause of chronic pyelonephritis, results from superimposition of infection on congenital vesicoureteral reflux or intrarenal reflux.

The symptoms of chronic pyelonephritis may be similar to those of acute pyelonephritis, or its onset may be insidious. Often there is a history of recurrent episodes of UTI or acute pyelonephritis. Loss of tubular function and the ability to concentrate urine give rise to polyuria and nocturia, and mild proteinuria is common. Severe hypertension often is a contributing factor in the progress of the disease. Chronic pyelonephritis is a significant cause of chronic kidney disease and renal failure.

**Drug-Related Nephropathies**

Drug-related nephropathies involve functional or structural changes in the kidneys that occur after exposure to a drug. Because of their large blood flow and high filtration pressure, the kidneys are exposed to any substance that is in the blood. The kidneys also are active in the metabolic transformation of drugs and therefore are exposed to a number of toxic metabolites. Renal tubular cells, particularly proximal tubule cells, are vulnerable to the toxic effects of drugs because their role in concentrating and reabsorbing glomerular filtrate exposes them to high levels of circulating toxins. The tolerance to drugs varies with age and depends on renal function,
state of hydration, blood pressure, and the pH of the urine. Elderly persons are particularly susceptible to kidney damage caused by drugs and toxins. The dangers of nephrotoxicity are increased when two or more drugs capable of producing kidney damage are given at the same time.

Drugs and other toxic substances can damage the kidneys by causing a decrease in renal blood flow, directly damaging tubulointerstitial structures, producing hypersensitivity reactions, or obstructing urine flow. Some drugs, such as diuretics, high–molecular-weight radiocontrast media, the immunosuppressive drugs cyclosporine and tacrolimus, and the nonsteroidal anti-inflammatory drugs (NSAIDs), can cause acute kidney injury by decreasing renal blood flow (discussed in Chapter 26). Other drugs such as sulfonamides and vitamin C supplements can form crystals that cause kidney damage by obstructing urinary flow in the tubules.

Acute drug-related hypersensitivity reactions produce tubulointerstitial nephritis, with damage to the tubules and interstitium. This condition was observed initially in persons who were sensitive to the sulfonamide drugs; currently, it is observed most often with the use of methicillin and other synthetic antibiotics, and with the use of furosemide and the thiazide diuretics in persons sensitive to these drugs. The condition begins approximately 15 days (range, 2 to 40 days) after exposure to the drug. At the onset, there is fever, eosinophilia, hematuria, mild proteinuria, and, in approximately one fourth of cases, a rash. In approximately 50% of cases, signs and symptoms of acute renal failure develop. Withdrawal of the drug commonly is followed by complete recovery, but there may be permanent damage, usually in older persons. Drug nephritis may not be recognized in its early stage because it is relatively uncommon.

Chronic analgesic nephritis, which is associated with analgesic abuse, causes tubulointerstitial nephritis with renal papillary necrosis. Prostaglandins (particularly PGI₂ and PGE₂) are potent renal vasodilators that contribute to the regulation of renal blood flow. The deleterious effects of aspirin and other NSAIDs are thought to result from their ability to decrease prostaglandin synthesis and thus decrease renal blood flow. The susceptibility of the papillae to damage is believed to be related to the establishment of a renal gradient in which the papillary concentration of the drug is higher than in the cortex. Persons particularly at risk are the elderly because of age-related changes in renal function, individuals who are dehydrated or have a decrease in blood volume, and those with preexisting kidney disease or renal insufficiency.

Chinese herbal drugs have also been implicated in drug-related kidney damage. Early recognition of the problem surfaced in the early 1990s with reports of an unusually rapid and progressive form of renal failure in women with a shared history of chronic ingestion of slimming herbs, such as ephedra (ma huang), from China as part of a weight loss program. Growing evidence from both clinical and animal models suggests that this form of kidney damage is attributable, at least in part, to the presence of aristolochic acid in the slimming herb preparations.

Illicit drug use has also been implicated in a wide spectrum of kidney diseases. For example, acute renal failure has been reported in persons presenting with acute cocaine intoxication. The cause is probably multifactorial and involves direct vasoconstriction, altered systemic hemodynamics, and myoglobin-induced renal failure. The chronic inhalation of solvents (e.g., glue, paint thinner), aerosols, gases, and nitrates has also been associated with a variety of toxic kidney effects, including acute and chronic renal failure. The tubular manifestations of solvent abuse probably result from the interference with intracellular metabolic processes involved in membrane transport.
Obstructive Disorders

Urinary obstruction can occur in persons of any age and can involve any level of the urinary tract, from the urethra to the renal pelvis, and can occur as an acute or a chronic condition. Acute pyelonephritis typically is caused by ascending bladder infections or infections that come from the bloodstream; it usually is successfully treated with appropriate antimicrobial drugs. Chronic pyelonephritis is a progressive disease that produces scarring and deformation of the renal calyces and pelvis.

An obstruction that develops slowly and is longer lasting is said to be chronic and is usually caused by conditions such as congenital ureterovesical abnormalities. Bilateral acute urinary tract obstruction causes acute renal failure. Because many causes of acute obstruction are reversible, prompt recognition is important. When left untreated, an obstructed kidney undergoes atrophy, and in the case of bilateral obstruction, results in chronic kidney disease.

Mechanisms of Renal Damage

The destructive effects of urinary obstruction on kidney structures are determined by the degree (i.e., partial versus complete, unilateral versus bilateral) and the duration of the obstruction. The two most damaging effects of urinary obstruction are stasis of urine, which predisposes to infection and stone formation, and progressive dilation of the renal collecting ducts and renal tubular structures, which causes destruction and atrophy of renal tissue.

A common complication of urinary tract obstruction is infection. Stagnation of urine predisposes to infection, which may spread throughout the urinary tract. When present, urinary calculi serve as foreign bodies and contribute to the infection. Once established, the infection is difficult to treat. It often is caused by urea-splitting organisms (e.g., Proteus, staphylococci) that increase ammonia production and cause the urine to become alkaline. Calcium salts precipitate more readily in stagnant alkaline urine; thus, urinary tract obstructions also predispose to stone formation.

In situations of severe partial or complete obstruction, the impediment to the outflow of urine causes dilation of the renal pelvis and calyces associated with progressive atrophy of the kidney. Even with complete obstruction, glomerular filtration continues for some time. Because of the continued filtration, the calyces and pelvis of the affected kidney become dilated, often markedly so. The high pressure in the renal pelvis is transmitted back through the collecting ducts of the kidney, compressing renal vasculature and causing renal atrophy. Initially, the functional alterations are largely tubular, manifested primarily by impaired urine-concentrating ability. Only later does the GFR begin to diminish.

Hydronephrosis

Hydronephrosis refers to urine-filled dilation of the renal pelvis and calyces associated with progressive atrophy of the kidney due to obstruction of urine outflow. The degree of hydronephrosis depends on the duration, degree, and level of obstruction. In far-advanced cases, the kidney may be transformed into a thin-walled cystic structure with parenchymal atrophy, total obliteration of the pyramids, and thinning of the cortex (Fig. 25-14). The condition is usually unilateral; bilateral hydronephrosis occurs only when the obstruction is below the level of the ureterovesical junction. When the obstruction affects the outflow of urine from the distal ureter, the increased pressure dilates the ureter, a condition called hydroureter. Bilateral hydroureter may develop as a complication of bladder outflow obstruction due to prostatic hyperplasia (see Chapter 39).

Clinical Features

The manifestations of urinary obstruction depend on the site of obstruction, the cause, and the rapidity with which the condition developed. Most of the early symptoms are produced by the underlying pathologic process. Urinary tract obstruction encourages the growth of microorganisms and should be suspected in persons with recurrent urinary tract infections.

Complete or partial unilateral hydronephrosis may remain silent for long periods because the unaffected kidney can maintain adequate function. Obstruction may provoke pain due to distention of the collecting system and renal capsule. Whereas, acute supravesical obstruction, such as that due to a kidney stone lodged in the ureter, is associated with excruciating pain. More insidious causes of obstruction, such as narrowing of the ureteropelvic junction, may produce little pain but cause total destruction of the kidney.

Complete bilateral obstruction results in oliguria and anuria and renal failure. Acute bilateral obstruction may mimic prerenal failure. With partial bilateral obstruction, the earliest manifestation is an inability to concentrate urine, reflected by polyuria and nocturia. Hypertension is an occasional complication of urinary tract obstruction. It is more common in cases of unilateral obstruction in which renin secretion is enhanced, probably secondary to impaired renal blood flow. In these circumstances, removal of the obstruction often leads to a reduction in blood pressure. When hypertension accompanies bilateral obstruction, it is volume related. The relief of bilateral obstruction leads to a loss of volume and a decrease in blood pressure. In some cases, relieving the obstruction does not correct the hypertension.

Early diagnosis of urinary tract obstruction is important because the condition usually is treatable and a delay in therapy may result in permanent damage to the kidneys. Diagnostic methods vary with the symptoms. Ultrasonography has proved to be the single most useful noninvasive diagnostic modality for urinary obstruction. Radiologic methods, CT scans, and intravenous urography may also be used. Other diagnostic methods, such as urinalysis, are used to determine the extent of renal involvement and the presence of infection.

Treatment of urinary tract obstruction depends on the cause. Urinary stone removal may be necessary, or
surgical treatment of structural defects may be indicated. Treatment of complicating urinary tract infections due to urinary stasis is also important.

**Kidney Stones**

The most common cause of upper urinary tract obstruction is urinary calculi. Although stones can form in any part of the urinary tract, most develop in the kidneys. Kidney stones, also known as nephrolithiasis or renal calculi, are the third most common disorder of the urinary tract, exceeded only by urinary tract infections and prostate disorders.²⁸

Kidney stones are polycrystalline aggregates composed of materials that the kidneys normally excrete in the urine.⁴,⁵,²⁸–³¹ The etiology of urinary stone formation is complex. It is thought to encompass a number of factors, including increases in blood and urinary levels of stone-forming components and interactions among the components; anatomic changes in urinary tract structures; metabolic and endocrine influences; dietary and intestinal absorption factors; and urinary tract infections. Added to the mystery of stone formation is the fact that although both kidneys are exposed to the same urinary constituents, kidney stones tend to form in only one kidney.

Two factors implicated in kidney stone formation are a supersaturated urine and an environment that allows the stone to grow. The risk for stone formation is increased when the urine is supersaturated with stone components (e.g., calcium salts, uric acid, magnesium ammonium phosphate, and cystine). Supersaturation depends on urinary pH, solute concentration, ionic strength, and complexation. The greater the concentration of two ions, the more likely they are to precipitate. Complexation influences the availability of specific ions. For example, oxalate complexes with sodium and decreases the availability of free sodium ions to participate in stone formation.

In addition to supersaturated urine, kidney stone formation requires a nidus or nucleus that facilitates crystal aggregation. In supersaturated urine, stone formation begins with small clusters of crystals such as calcium oxalate. Most small clusters tend to disperse because the internal forces that hold them together are too weak to overcome the random tendency of ions to move apart. Larger ion clusters form nuclei and remain stable because the attraction forces balance surface losses. Once they are stable, nuclei can grow at levels of supersaturation below that needed for their creation. Organic materials, such as mucopolysaccharides derived from the epithelial cells that line the tubules, are also thought to act as nuclei for stone formation by lowering the level of supersaturation required for crystal aggregation.

The fact that many people experience supersaturation of their urine without developing kidney stones is believed to be due to the presence of natural stone inhibitors, including magnesium, citrate, and the Tamm-Horsfall mucoprotein. To date, the measurement and manipulation of stone inhibitors has not been part of clinical practice, with the exception of citrate.²⁸,²⁹ Urine citrate reduces supersaturation by binding calcium and inhibiting nucleation and growth of calcium crystals. Citrate is a normal by-product of the citric acid cycle in renal cells. Metabolic stimuli that consume this product (as with metabolic acidosis due to fasting or hypokalemia) reduce the urinary concentration of citrate. Citrate supplementation (potassium citrate) may be used in the treatment of some forms of hypocitraturic kidney stones.

**Types of Stones**

There are four basic types of kidney stones: calcium (i.e., oxalate or phosphate), magnesium ammonium phosphate, uric acid, and cystine stones.⁴,⁵,²⁸–³⁰ The causes and treatment measures for each of these types of renal stones are described in Table 25-2. Most kidney stones are polycrystalline aggregates composed of materials that the kidneys normally excrete in the urine. The etiology of urinary stone formation is complex. It is thought to encompass a number of factors, including increases in blood and urinary levels of stone-forming components and interactions among the components; anatomic changes in urinary tract structures; metabolic and endocrine influences; dietary and intestinal absorption factors; and urinary tract infections. Added to the mystery of stone formation is the fact that although both kidneys are exposed to the same urinary constituents, kidney stones tend to form in only one kidney.

Two factors implicated in kidney stone formation are a supersaturated urine and an environment that allows the stone to grow. The risk for stone formation is increased when the urine is supersaturated with stone components (e.g., calcium salts, uric acid, magnesium ammonium phosphate, and cystine). Supersaturation depends on urinary pH, solute concentration, ionic strength, and complexation. The greater the concentration of two ions, the more likely they are to precipitate. Complexation influences the availability of specific ions. For example, oxalate complexes with sodium and decreases the availability of free sodium ions to participate in stone formation.

In addition to supersaturated urine, kidney stone formation requires a nidus or nucleus that facilitates crystal aggregation. stones (70% to 80%) are calcium stones—calcium oxalate, calcium phosphate, or a combination of the two materials. Calcium stones usually are associated with increased concentrations of calcium in the blood and urine. Excessive bone resorption caused by immobility, bone disease, hyperparathyroidism, and renal tubular acidosis all are contributing conditions. High oxalate concentrations in the blood and urine predispose to formation of calcium oxalate stones.

Magnesium ammonium phosphate stones, also called struvite stones, form only in alkaline urine and in the presence of bacteria that possess an enzyme called urease, which splits the urea in the urine into ammonia and carbon dioxide. The ammonia that is formed takes up a hydrogen ion to become an ammonium ion, increasing the pH of the urine so that it becomes more alkaline. Because phosphate levels are increased in alkaline urine and because magnesium always is present in the urine, struvite stones form. These stones enlarge as the bacterial count grows, and they can increase in size until they fill an entire renal pelvis (Fig. 25-15). Because of their shape, they often are called staghorn stones. They almost always are associated with urinary tract infections and persistently alkaline urine. Because these stones act as a foreign body, treatment of the infection often is difficult. Struvite stones usually are too large to be passed and require lithotripsy or surgical removal.

Uric acid stones develop in conditions of gout and high concentrations of uric acid in the urine. Hyperuricosuria also may contribute to calcium stone formation by acting as a nucleus for calcium oxalate stone formation. Unlike radiopaque calcium stones, uric acid stones are not visible on x-ray films. Uric acid stones form most readily in urine with a pH of 5.1 to 5.9. Thus, these stones can be treated by raising (alkalinizing) the urinary pH to 6.0 to 6.5 with potassium alkali salts.

Cystine stones account for less than 1% of kidney stones overall but represent a significant proportion of childhood calculi. They are seen in cystinuria, which results from a genetic defect in renal transport of cystine. These stones resemble struvite stones except that infection is unlikely to be present.

Clinical Features

One of the major manifestations of kidney stones is pain. Depending on location, there are two types of pain associated with kidney stones: renal colic and noncolicky renal pain. Renal colic is the term used to describe the colicky pain that accompanies stretching of the collecting system or ureter. The symptoms of renal colic are caused by stones 1 to 5 mm in diameter that can move into the ureter and obstruct flow. Classic ureteral colic is manifested by acute, intermittent, and excruciating pain in the flank and upper outer quadrant of the abdomen on the affected side. The pain may radiate to the lower abdominal quadrant, bladder area, perineum, or scrotum in the man. The skin may be cool and clammy, and nausea and vomiting are common. Noncolicky pain is caused by stones that produce distention of the renal calyces or renal pelvis. The pain usually is a dull, deep ache in the flank or back that can vary in intensity from mild to severe. The pain is often exaggerated by drinking large amounts of fluid.

The diagnosis of kidney stones is based on symptomatology and diagnostic tests, which include urinalysis, plain film radiography (X-ray), intravenous pyelography, and abdominal ultrasonography. Urinalysis provides information related to hematuria, infection, presence of stone-forming crystals, and urine pH. Most stones are radiopaque and readily visible on a plain radiograph of the abdomen. The noncontrast spiral CT scan is the imaging modality of choice in persons with acute renal colic. Intravenous pyelography (IVP) uses an intravenously injected Contrast medium that is filtered in the glomeruli to visualize the collecting system of the kidneys and ureters. Abdominal ultrasonography is highly sensitive to hydronephrosis, which may be a manifestation of ureteral obstruction. An imaging technique called nuclear scintigraphy uses biphosphonate markers as a means of imaging stones. This method has been credited with identifying stones that are too small to be detected by other methods.

Treatment of acute renal colic usually is supportive. Pain relief may be needed during acute phases of obstruction, and antibiotic therapy may be necessary.
to treat urinary tract infections. Most stones that are less than 5 mm in diameter pass spontaneously. All urine should be strained during an attack in the hope of retrieving the stone for chemical analysis and determination of type. This information, along with a careful history and laboratory tests, provide the basis for long-term preventive measures.

A major goal of treatment in persons who have passed kidney stones or have had them removed is to prevent their recurrence. Prevention requires investigation into the cause of stone formation using urine tests, blood chemistries, and stone analysis. Underlying disease conditions, such as hyperparathyroidism, are treated. Adequate fluid intake reduces the concentration of stone-forming crystals in the urine and needs to be encouraged. Calcium supplementation with calcium salts such as calcium carbonate and calcium phosphate also may be used to bind oxalate in the intestine and decrease its absorption. Thiazide diuretics lower urinary calcium by increasing tubular reabsorption so that less remains in the urine. Drugs that bind calcium in the gut (e.g., cellulose phosphate) may be used to inhibit calcium absorption and urinary excretion.

Depending on the type of stone that is formed, dietary changes, medications, or both may be used to alter the concentration of stone-forming elements in the urine (Table 25-2). For example, persons who form calcium oxalate stones may need to decrease their intake of foods that are high in oxalate (e.g., spinach, Swiss chard, cocoa, chocolate, pecans, peanuts). Because of associated electrolyte disturbances and altered urine chemistry, obese persons are predisposed to hyperuricemia, gout, hypercitraturia, and uric acid stones. Weight loss may improve or undermine management of these stones; however, it can be detrimental if associated with a high animal protein diet, laxative abuse, rapid loss of lean tissue, or poor hydration. High acid diets, such as the Atkins diet, increase the risk of uric acid stones.

Measures to change the pH of the urine also can influence kidney stone formation. In persons who lose the ability to acidify or lower the pH of their urine, there is an increase in the divalent and trivalent forms of urine components that combine with calcium to form calcium phosphate stones. The formation of uric acid stones is increased in acid urine; stone formation can be reduced by raising the pH of urine to 6.0 to 6.5 with potassium alkali (e.g., potassium citrate) salts.

In some cases, stone removal may be necessary. Several methods are available for removing kidney stones: ureteroscopic removal, percutaneous removal, and extracorporeal lithotripsy. All of these procedures eliminate the need for an open surgical procedure, which is another form of treatment. Open stone surgery may be required to remove large calculi or those that are resistant to other forms of removal. A nonsurgical treatment, called extracorporeal shock-wave lithotripsy, uses acoustic shock waves to fragment calculi into sandlike particles that are passed in the urine over the next few days. Because of the large amount of stone particles that are generated during the procedure, a ureteral stent (i.e., a tubelike device used to hold the ureter open) may be inserted to ensure adequate urine drainage.

SUMMARY CONCEPTS

- Obstruction of urine flow can occur at any level of the urinary tract. Among the causes of urinary tract obstruction are developmental defects, pregnancy, infection and inflammation, kidney stones, neurologic defects, and prostatic hypertrophy.
- Obstructive disorders produce stasis of urine, increase the risk for infection and calculus formation, and produce progressive dilation of the renal collecting ducts and renal tubular structures, which cause renal atrophy.
- Hydronephrosis refers to urine-filled dilation of the renal pelvis and calyces associated with progressive atrophy of the kidney due to obstruction of urine outflow. Unilateral hydronephrosis may remain silent for long periods because the unaffected kidney can maintain adequate function. With partial bilateral obstruction, the earliest manifestation is an inability to concentrate urine, reflected by polyuria and nocturia. Complete bilateral obstruction results in oliguria, anuria, and renal failure.
- Kidney stones are a major cause of upper urinary tract obstruction. The development of kidney stones is influenced by the concentration of stone components in the urine, the ability of the stone components to complex and form stones, and the presence of substances that inhibit stone formation.
- There are four types of kidney stones: calcium (i.e., oxalate and phosphate) stones, which are associated with increased serum calcium levels; magnesium ammonium phosphate (i.e., struvite) stones, which are associated with urinary tract infections; uric acid stones, which are related to elevated uric acid levels; and cystine stones, which are seen in cystinuria. Treatment measures depend on stone type and include adequate fluid intake to prevent urine saturation, dietary modification to decrease intake of stone-forming constituents, treatment of urinary tract infections, measures to change urine pH, and the use of diuretics that decrease the calcium concentration of urine.
Malignant Tumors of the Kidney

There are two major groups of malignant tumors of the kidney: embryonic kidney tumors (i.e., Wilms tumor), which occur during childhood, and renal cell carcinoma, which occurs in adults.

**Wilms Tumor**

Wilms tumor, also known as nephroblastoma, is one of the most common primary neoplasms of young children. It usually presents between 3 and 5 years of age and is the second most common malignant abdominal tumor in children. It may occur in one or both kidneys. The incidence of bilateral Wilms tumor is 6% to 7%, with children having a horseshoe kidney being at twice the risk.

Histologically, the tumor is composed of elements that resemble normal fetal tissue: blastemic, stromal, and epithelial. An important feature of Wilms tumor is its association with other congenital anomalies, including aniridia (absence of the iris), hemihypertrophy (enlargement of one side of the face or body), and other congenital anomalies, usually of the genitourinary system. Several chromosomal abnormalities have been associated with Wilms tumor. One Wilms tumor gene, *WT1* located on chromosome 11, is a tumor-suppressor gene that regulates several other growth factor genes.

Wilms tumor usually is a solitary mass that occurs in any part of the kidney. It usually is sharply demarcated, variably encapsulated, and grows to a large size, distorting kidney structure (Fig. 25-16). The tumors usually are staged using the National Wilms Tumor Study Group classification. Stage I tumors are limited to the kidney and can be excised with the capsular surface intact. Stage II tumors extend into the renal capsule but can be excised. In stage III, extension of the tumor is confined to the abdomen, and in stage IV, hematogenous metastasis most commonly involves the lung.

The common presenting signs are a large asymptomatic abdominal mass and hypertension. The tumor is often discovered inadvertently, and it is not uncommon for the parent to discover it while bathing the child. Some children may present with abdominal pain, vomiting, or both. Microscopic and gross hematuria is present in 15% to 25% of children. CT scans are used to confirm the diagnosis.

Treatment involves surgery, chemotherapy, and sometimes radiation therapy. Long-term survival rates have increased to more than 70% for all stages and to 91% to 96% for stages I through III.

**Renal Cell Carcinoma**

Cancer of the kidney is the seventh leading malignancy among men and the twelfth among women, accounting for about 3% of all cancers. Incidence peaks between 55 and 84 years of age. Renal cell carcinoma accounts for approximately 80% to 90% of all kidney cancers. Most renal cell carcinomas are sporadic, but about 5% are inherited. Inherited tumors tend to be multifocal and bilateral, and appear at an earlier age than sporadic renal cell carcinomas.

A major advance in the understanding of renal cell carcinoma has been the realization that this neoplasm is not a single entity, but a collection of tumors that arise in different parts of the tubular or ductal epithelium. Clear cell carcinomas, so named because of their high cytoplasmic lipid content, accounts for 70% to 80% of all renal cell carcinomas. They arise from proximal tubular epithelial cells and appear as solitary unilateral lesions located predominantly in the renal cortex (Fig. 25-17). Papillary carcinomas, which are characterized by a papillary growth pattern, account for another 10% to 15% of renal cancers. Thought to arise from the proximal tubules, they can be multifocal and bilateral.

The cause of renal cell carcinoma remains elusive. Epidemiologic evidence suggests a correlation between heavy smoking and kidney cancer. Obesity also is a risk factor, particularly in women. Additional risk factors include occupational exposure to petroleum products, heavy metals, and asbestos. The risk for renal cell carcinoma also is increased in persons with acquired cystic kidney disease associated with chronic renal insufficiency.

Kidney cancer is largely a silent disorder during its early stages, and symptoms usually denote advanced
disease. Presenting features include hematuria, flank pain, and presence of a palpable flank mass. Gross or microscopic hematuria, which occurs in more than 50% of cases, is an important clinical clue. It is, however, intermittent and may be microscopic; as a result, the tumor may reach considerable size before it is detected. One of the features of renal cell carcinoma is its ability to metastasize. In about 25% of new cases, there is radiologic evidence of metastasis, with the most common sites being lung and bone metastases.

Ultrasonography and CT scanning are used to confirm the diagnosis. MRI may be used when involvement of the inferior vena cava with lymph node dissection is the treatment of choice for all resectable tumors. Nephron-sparing surgery may be done when both kidneys are involved or when the contralateral kidney is threatened by an associated disease such as hypertension or diabetes mellitus. Single-agent and combination chemotherapy have been used with limited success. The 5-year survival rate is 90% if the tumor has not extended beyond the renal capsule, but drops to 30% if metastasis has occurred.

**FIGURE 25-17.** Gross pathology of a bisected kidney showing large renal cell carcinoma. Much of the kidney has been replaced by gray and yellow tumor tissue. A little remaining renal cortex and pericapsular fat are visible at the bottom of this surgical specimen. (From the Centers for Disease Control and Prevention Public Health Images Library. No. 863. **REVIEW EXERCISES**

1. A 6-year-old boy is diagnosed with acute glomerulonephritis that developed after a streptococcal throat infection. At this time, the following manifestations are noted: decrease in urine output, increasing lethargy, hyperventilation, and generalized edema. Trace amounts of protein are detected in his urine. Blood analysis reveals the following: pH = 7.35, HCO₃⁻ = 18 mEq/L, hematocrit = 29%, Na = 132 mEq/L, K = 5.6 mEq/L, blood urea nitrogen (BUN) = 62 mg/dL, creatinine = 4.1 mg/dL, and albumin = 2 g/dL.

A. What is the probable cause of this boy’s glomerular disease?
B. Use the laboratory values in the Appendix to interpret his laboratory test results. Which values are significant and why?
C. Is he progressing to uremia? How can you tell?

2. A 36-year-old man is admitted to the emergency department with a sudden onset of severe, intermittent, cramping pain that makes him feel nauseated. He describes the pain as originating in the left groin and radiating toward the ankle. Microscopic examination of his urine reveals the presence of red blood cells. His temperature is normal, and he does not exhibit signs of sepsis.

A. What is the probable cause of this man’s pain?
B. What diagnostic measure could be used to confirm the cause of his pain?
C. A plain-film radiograph reveals a 4- to 5-mm kidney stone in the left ureter. What are the chances that this man will pass the stone spontaneously?
D. What type of medications and other treatments should this man receive?
E. Once the stone has been passed, what type of measures can he use to prevent stone recurrence?

**SUMMARY CONCEPTS**

- **There are two major groups of renal neoplasms:** embryonic kidney tumors (i.e., Wilms tumor), which occur during childhood, and renal cell carcinoma, which occurs in adults.
- Wilms tumor is one of the most common malignant tumors of children. The most common presenting signs are a large abdominal mass and hypertension. Treatment methods include surgery, chemotherapy, and sometimes radiation therapy, with long-term survival rates of up to 96% with an aggressive plan of treatment.
- Cancer of the kidney accounts for about 3% of all cancers, with renal cell carcinoma accounting for 80% to 90% of cases. The neoplasms are a collection of tumors from different parts of the nephron, each with different genetic profiles and histologic features that challenge both diagnostic and treatment methods. Many of these cancers are characterized by a lack of early warning signs, diverse clinical manifestations, and resistance to chemotherapy and radiation therapy.

Renal failure is a condition in which the kidneys fail to remove metabolic end products from the blood and regulate the fluid, electrolyte, and pH balance of the extracellular fluids. The underlying cause may be renal disease, systemic disease, or urologic defects of nonrenal origin. Renal failure can occur as an acute or a chronic disorder. Acute kidney injury is abrupt in onset and often is reversible if recognized early and treated appropriately. In contrast, chronic kidney disease is the end result of irreparable damage to the kidneys. It develops slowly, usually over the course of a number of years and often requires dialysis therapy or transplantation.

Acute Kidney Injury

Acute kidney injury (AKI), formerly known as acute renal failure, represents an abrupt decline in kidney function, resulting in an inability to maintain fluid and electrolyte balance and excrete nitrogenous wastes. Acute kidney injury is a common threat to seriously ill persons, in whom it is associated with a high rate of adverse outcomes, with mortality rates ranging between 25% and 80% depending on the cause and clinical status of the patient. This high mortality rate probably reflects the facts that AKI is often seen in elderly persons and that it is frequently superimposed on other life-threatening conditions, such as trauma, shock, and sepsis.

Acute renal injury is commonly defined as an abrupt (within 48 hours) reduction in kidney function based on an increase in serum creatinine level, a reduction in urine output, and the need for dialysis, or a combination of these factors. The range of clinical manifestations can vary from mild to severe, based on the degree of rise in creatinine levels and decrease in urine output.

Types of Acute Kidney Injury

Acute kidney injury can be caused by several types of conditions, including a decrease in blood flow without
ischemic injury; ischemic, toxic, or obstructive tubular injury; and obstruction of urinary tract outflow. The causes of AKI commonly are categorized as prerenal, intrarenal, and postrenal\(^1\) (Fig. 26-1). Collectively, prerenal and intrarenal causes account for 80% to 95% of AKI cases.\(^3\) Causes of kidney injury within these categories are summarized in Chart 26-1.

### Prerenal Injury

Prerenal kidney injury, the most common form of AKI, is characterized by a marked decrease in renal blood flow. It is reversible if the cause of the decreased renal blood flow can be identified and corrected before kidney damage occurs.

Normally, the kidneys receive 22% of the cardiac output.\(^8\) This large blood supply is required to remove metabolic wastes and regulate body fluids and electrolytes. Fortunately, the normal kidney can tolerate relatively large reductions in blood flow before renal damage occurs. As renal blood flow falls, the glomerular filtration rate (GFR) decreases, the amount of sodium and other substances that are filtered by the glomeruli is reduced, and the blood flow needed for the energy-dependent mechanisms that reabsorb these substances is reduced (see Chapter 24). As the GFR and urine output approach zero, oxygen consumption by the kidney approximates that required to keep renal tubular cells alive. When blood flow falls below this level, which is about 25% of normal, ischemic changes occur.\(^9\) Because of their high metabolic rate, the tubular epithelial cells are most vulnerable to ischemic injury. Improperly treated, prolonged renal hypoperfusion can lead to ischemic tubular necrosis with significant morbidity and mortality.

Causes of prerenal injury include profound depletion of vascular volume (e.g., hemorrhage, loss of extracellular fluid volume), impaired perfusion due to heart failure and cardiogenic shock, and decreased vascular filling because of increased vascular capacity (e.g., anaphylaxis or sepsis). Elderly persons are particularly at risk because of their predisposition to hypovolemia and their high prevalence of renal vascular disorders.

Some vasoactive mediators, drugs, and diagnostic agents stimulate intense intrarenal vasoconstriction and can induce glomerular hypoperfusion and prerenal injury. Examples include endotoxins, radiopaque contrast agents such as those used for cardiac catheterization, cyclosporine (an immunosuppressant drug that is used to prevent transplant rejection), amphotericin B (an antifungal agent), epinephrine, and high doses of dopamine.\(^3\) Many of these agents also cause acute tubular necrosis (to be discussed).

In addition, several commonly used classes of drugs can impair renal adaptive mechanisms and can convert compensated renal hypoperfusion into prerenal injury. For example, angiotensin II is a potent renal vasoconstrictor that preferentially constricts the efferent arterioles of the kidney as a means of preserving the GFR in situations of arterial hypotension or volume depletion. The angiotensin converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) reduce the effects of angiotensin II on renal blood flow. They also reduce intraglomerular pressure and may have a renal protective effect in persons with hypertension or type 2 diabetes. However, when combined with diuretics, they may cause prerenal injury in persons with decreased blood flow due to large-vessel or small-vessel kidney disease. Nonsteroidal anti-inflammatory drugs
removal of the necrotic cells and intratubular casts, and the process depends on recovery of the injured cells, particularly sensitive to ischemia and toxins. The tubular obstruction is characterized by destruction of tubular epithelial cells with acute suppression of renal function (Fig. 26-2). It can be caused by a number of conditions, including acute tubular damage due to ischemia, sepsis, nephrotoxic effects of drugs, tubular obstruction, and toxins from a massive infection. Tubular epithelial cells are particularly sensitive to ischemia and toxins. The tubular injury that occurs in ATN frequently is reversible. The process depends on recovery of the injured cells, removal of the necrotic cells and intratubular casts, and regeneration of tubular cells to restore the normal continuity of the tubular epithelium.

**Postrenal Injury**

Postrenal injury results from obstruction of urine outflow from the kidneys. The obstruction can occur in the ureter (i.e., calculi and strictures), bladder (i.e., tumors or neurogenic bladder), or urethra (i.e., prostatic hyperplasia). Prostatic hyperplasia is the most common underlying problem. Because both ureters must be occluded to produce renal injury, obstruction of bladder outflow rarely causes AKI unless one of the kidneys already is damaged or a person has only one kidney. The treatment of acute postrenal injury consists of treating the underlying cause of obstruction so that urine flow can be reestablished before permanent nephron damage occurs.

**Intrarenal Injury**

Intrarenal injury results from conditions that damage structures within the kidney. The major causes of intrarenal injury are ischemia associated with prerenal injury, injury to the tubular structures of the nephron, and intratubular obstruction. Acute glomerulonephritis and acute pyelonephritis also are intrarenal causes of AKI. However, injury to the tubular structures of the nephron (acute tubular necrosis) is the most common cause and often is ischemic or toxic in origin.

**Acute Tubular Necrosis.** Acute tubular necrosis (ATN) is characterized by the destruction of tubular epithelial cells with acute suppression of renal function (Fig. 26-2). It can be caused by a number of conditions, including acute tubular damage due to ischemia, sepsis, nephrotoxic effects of drugs, tubular obstruction, and toxins from a massive infection. Tubular epithelial cells are particularly sensitive to ischemia and toxins. The tubular injury that occurs in ATN frequently is reversible. The process depends on recovery of the injured cells, removal of the necrotic cells and intratubular casts, and regeneration of tubular cells to restore the normal continuity of the tubular epithelium. Acute tubular necrosis occurs most frequently in persons who have major surgery, severe hypovolemia, or overwhelming sepsis, trauma, or burns. Sepsis produces ischemia by provoking a combination of systemic vasoconstriction and intrarenal hypoperfusion. In addition, sepsis results in the generation of toxins that sensitize renal tubular cells to the damaging effects of ischemia. ATN complicating trauma and burns frequently is multifactorial in origin, resulting from the combined effects of hypovolemia, myoglobinuria, and other toxins released from damaged tissue. In contrast to prerenal injury, the GFR does not improve with the restoration of renal blood flow in AKI caused by ischemic ATN. Many drugs are nephrotoxic, causing tubular injury by inducing varying combinations of renal vasoconstriction, direct tubular damage, or intratubular obstruction. The kidney is particularly vulnerable to nephrotoxic injury because of its rich blood supply and ability to concentrate toxins to high levels in the medullary portion of the kidney. In addition, the kidney is an important site for metabolic processes that transform relatively harmless agents into toxic metabolites. Pharmacologic agents that are directly toxic to the renal tubule include antimicrobials such as aminoglycosides (e.g., gentamicin), cancer chemotherapeutic agents such as cisplatin and others.
The recovery phase is the period during which repair of renal tissue takes place. Its onset usually is heralded by a gradual increase in urine output and a fall in serum creatinine, indicating that the nephrons have recovered to the point at which urine excretion is possible. Diuresis often occurs before renal function has fully returned to normal. Consequently, BUN and serum creatinine, potassium, and phosphate levels may remain elevated or continue to rise even though urine output is increased. In some cases, the diuresis may result from impaired nephron function and may cause excessive loss of water and electrolytes. Eventually, renal tubular function is restored with improvement in concentrating ability. At about the same time, the creatinine and BUN begin to return to normal. In some cases, mild to moderate kidney damage persists.

**Diagnosis and Treatment**

Given the high morbidity and mortality rates associated with AKI, attention should be focused on prevention and early diagnosis. This includes assessment measures to identify persons at risk for development of AKI, including those with preexisting renal insufficiency and diabetes. These persons are particularly at risk for development of AKI due to nephrotoxic drugs (e.g., aminoglycosides and radiocontrast agents) or drugs such as NSAIDs that alter intrarenal hemodynamics. Elderly persons are susceptible to all forms of AKI because of the effects of aging on renal reserve.

Careful observation of urine output is essential for persons at risk for development of AKI. Urine tests that measure urine osmolality, urinary sodium concentration, and fractional excretion of sodium help differentiate prerenal azotemia, in which the reabsorptive capacity of the tubular cells is maintained, from tubular necrosis, in which these functions are lost. One of the earliest manifestations of tubular damage is the inability to concentrate the urine. Further diagnostic information that can be obtained from the urinalysis includes evidence of proteinuria, hemoglobinuria, myoglobinuria, and casts or crystals in the urine. Blood tests for BUN and creatinine provide information regarding the ability to remove nitrogenous wastes from the blood.

A major concern in the treatment of AKI is identifying and correcting the cause (e.g., improving renal perfusion, discontinuing nephrotoxic drugs). Fluids are carefully regulated in an effort to maintain normal fluid volume and electrolyte concentrations. Adequate caloric intake is needed to prevent the breakdown of body proteins, which increases nitrogenous wastes. Parenteral hyperalimentation may be used for this purpose. Because secondary infections are a major cause of death in persons with AKI, constant effort is needed to prevent and treat such infections.

Either hemodialysis (to be discussed) or continuous renal replacement therapy (CRRT) may be indicated when nitrogenous wastes and the water and electrolyte balance cannot be kept under control by other means. Venovenous or arteriovenous CRRT has emerged as a

---

ifosfamide, and radiocontrast agents. Several factors contribute to aminoglycoside nephrotoxicity, including a decrease in the GFR, preexisting renal disease, hypovolemia, and concurrent administration of other drugs that have a nephrotoxic effect. Cisplatin accumulates in proximal tubule cells, inducing mitochondrial injury and inhibition of adenosine triphosphatase (ATPase) activity and solute transport. Radiocontrast media–induced nephrotoxicity is thought to result from direct tubular toxicity and renal ischemia. The risk for renal damage caused by radiocontrast media is greatest in elderly persons and those with preexisting kidney disease, volume depletion, diabetes mellitus, and recent exposure to other nephrotoxic agents.

The presence of multiple myeloma light chains, excess uric acid, hemoglobin, or myoglobin in the urine is the most frequent cause of ATN due to intratubular obstruction. Both myeloma cast nephropathy (Chapter 11) and acute urate nephropathy (Chapter 8) usually are seen in the setting of widespread malignancy or massive tumor destruction by therapeutic agents. Hemoglobinuria results from blood transfusion reactions and other hemolytic crises. Skeletal and cardiac muscles contain myoglobin, which corresponds to hemoglobin in function, serving as an oxygen reservoir in the muscle fibers. Myoglobin normally is not found in the serum or urine. It has a low molecular weight; if it escapes into the circulation, it is rapidly filtered in the glomerulus. A life-threatening condition known as rhabdomyolysis occurs when increasing myoglobinuria levels cause myoglobin to precipitate in the renal tubules, leading to obstruction and damage to surrounding tubular cells. Myoglobinuria most commonly results from muscle trauma, but may result from extreme exertion, hyperthermia, sepsis, prolonged seizures, potassium or phosphate depletion, and alcoholism or drug abuse. Both myoglobin and hemoglobin discolor the urine, which may range from the color of tea to red, brown, or black.

**Clinical Manifestations of Acute Tubular Necrosis.** The clinical course of ATN, which is highly variable, is often divided into an initiation, maintenance and recovery phase. The onset or initiating phase, which lasts hours or days, is the time from the onset of the precipitating event (e.g., ischemic phase of prerenal failure or toxin exposure) until tubular injury occurs.

The maintenance phase can involve either an oliguric or nonoliguric phase. Nonoliguric ATN has a better outcome. Conversion from a nonoliguric to an oliguric state is characterized by a marked decrease in the GFR, accompanied by retention of metabolic wastes such as creatinine, urea, and sulfate, which normally are cleared by the kidneys. The urine output usually is lowest at this point. Fluid retention gives rise to edema, water intoxication, and pulmonary congestion. If the period of oliguria is prolonged, hypertension develops and with it signs of uremia (accumulation of nitrogenous wastes in the blood). When untreated, the neurologic manifestations of uremia progress from neuromuscular irritability to seizures, somnolence, coma, and death.

...
Acute kidney injury (AKI) is an abrupt reduction in kidney function, as evidenced by an elevation in serum creatinine, reduction in urine output, the need for dialysis, or a combination of these factors.

Acute kidney injury can result from decreased blood flow to the kidney (prerenal injury), from conditions that interfere with the elimination of urine from the kidney (postrenal injury), or from disorders that disrupt the structures in the kidney (intrarenal injury).

Acute tubular necrosis (ATN), due to ischemia, sepsis, or nephrotoxic agents, is the most common cause of acute intrarenal injury. Acute tubular necrosis typically progresses through three phases: the initiation phase, during which tubular injury is induced; the maintenance phase, during which the GFR falls, nitrogenous wastes accumulate, and urine output decreases; and the recovery or reparative phase, during which the GFR, urine output, and blood levels of nitrogenous wastes return to normal.

Because of the high morbidity and mortality rates associated with AKI, identification of persons at risk is important to clinical decision making. Acute kidney injury often is reversible, making early identification and correction of the underlying cause (e.g., improving renal perfusion, discontinuing nephrotoxic drugs) important. Treatment includes the judicious administration of fluids and hemodialysis or continuous renal replacement therapy.

Chronic kidney disease (CKD) is a pathophysiologic process that results in the loss of nephrons and a decline in renal function as determined by a measured or estimated decrease in the GFR that has persisted for more than 3 months. Chronic kidney disease can result from a number of conditions including diabetes, hypertension, glomerulonephritis, systemic lupus erythematosus, and polycystic kidney disease. The prevalence and incidence of the CKD continues to grow, reflecting the growing elderly population and the increasing number of people with diabetes and hypertension. In the United States alone, 26 million adults have CKD, and others are at increased risk.

Regardless of cause, all forms of CKD are characterized by a reduction in the GFR, reflecting a corresponding reduction in the number of functioning nephrons (Fig. 26-3). The rate of nephron destruction differs from case to case, ranging from several months to many years. Typically, the signs and symptoms of CKD occur gradually and do not become evident until the disease is far advanced. This is because of the amazing compensatory ability of the kidneys. As kidney structures are destroyed, the remaining nephrons undergo structural and functional hypertrophy, each increasing its function as a means of compensating for those that have been lost. In the process, each of the remaining nephrons must filter more solute particles from the blood. It is only when the few remaining nephrons are destroyed that the manifestations of kidney failure become evident.
Diagnostic Measures

The GFR is considered the best measure of overall function of the kidney. The normal GFR, which varies with age, sex, and body size, is approximately 120 to 130 mL/min/1.73 m² for normal young healthy adults.\(^\text{18,19}\) A GFR below 60 mL/min/1.73 m² represents a loss of one half or more of the level of normal adult kidney function.

In clinical practice, GFR is usually estimated using the serum creatinine concentration (see Chapter 24). Although the GFR can be obtained from measurements of creatinine clearance using timed (e.g., 24-hour) urine collection methods, the levels gathered are reportedly no more reliable than the estimated levels obtained by using serum creatinine levels.\(^\text{20}\) Because GFR varies with age, sex, ethnicity, and body size, the Modification of Diet in Renal Diseases (MDRD) equation that takes these factors into account is often used for estimating the GFR based on serum creatinine levels.\(^\text{18}\) (GFR calculators are available online at http://www.kidney.org/professionals/kdoqi/gfr.cfm.)

Proteinuria serves as a key adjunctive tool for measuring nephron injury and repair. Urine normally contains small amounts of protein. However, a persistent increase in protein excretion usually is a sign of kidney damage. The type of protein (e.g., low–molecular-weight globulins or albumin) depends on the type of kidney disease.\(^\text{21}\) For the diagnosis of CKD in adults and postpubertal children with diabetes, measurement of urinary albumin is preferred. In most cases, urine dipstick tests are acceptable for detecting albuminuria. If the urine dipstick test is positive (1+ or greater), albuminuria is usually confirmed by quantitative measurement of the albumin-to-creatinine ratio in a spot (untimed) urine specimen. Microalbuminuria, which is an early sign of diabetic kidney disease, refers to albumin excretion that is above the normal range but below the range normally detected by tests of total protein excretion in the urine. Populations at risk for CKD (i.e., those with diabetes mellitus, hypertension, or family history of kidney disease) should be screened for microalbuminuria at least annually as part of their health examination.\(^\text{21}\)

Other markers of kidney disease include abnormalities in urine sediment (red and white blood cells) and abnormal findings on imaging studies. Red blood cell indices, serum albumin levels, plasma electrolytes, and BUN are used to follow the progress of the disorder.

Clinical Stages

Chronic kidney disease is commonly classified using the internationally accepted Kidney Disease Outcome Quality Initiative (KDOQI) staging system of the National Kidney Foundation. This system uses the GFR to classify CKD into five stages, beginning with kidney damage accompanied by a normal or elevated GFR, progressing to CKD and, potentially, to kidney failure\(^\text{18,19}\) (Table 26-1). Kidney damage that is present but undetected due to a normal or increased GFR is classified as stage 1. Individuals with a mild decrease in GFR

GFR, glomerular filtration rate.

Chronic kidney disease is defined as either kidney damage or GFR <60 mL/min/1.73 m² for ≥3 months. Kidney damage is defined as pathologic abnormalities or markers of damage, including abnormalities in blood or urine tests or imaging studies.

of 60 to 89 mL/min/1.73 m² (corrected for body surface area) without kidney damage are classified as stage 2. Decreased GFR without recognized markers of kidney damage can occur in infants and older adults and is usually considered to be “normal for age.” Other causes of chronically decreased GFR without kidney damage in adults include removal of one kidney, extracellular fluid volume depletion, and systemic illnesses associated with reduced kidney perfusion, such as heart failure and cirrhosis.\(^\text{18}\) Even at this stage, there is often a characteristic loss of renal reserve.

Chronic kidney disease, or stage 3 or 4 kidney disease, is defined as either kidney damage or a GFR of 30 to 59 mL/min/1.73 m² for 3 months or longer.\(^\text{18}\) Stage 5 CKD represents a GFR of less than 15 mL/min/1.73 m² that is accompanied by most of the signs and symptoms of uremia or a need for dialysis or transplantation.\(^\text{18}\)

Clinical Manifestations

In its early stages, CKD is largely asymptomatic. When symptoms do appear, they develop slowly and are often nonspecific. Elevated levels of nitrogenous wastes in the blood, or azotemia, is often an early sign of kidney failure, occurring before other signs and symptoms become evident.\(^\text{22}\) Urea is one of the first nitrogenous wastes to accumulate in the blood, and the BUN level becomes increasingly elevated as CKD progresses.

Uremia, which literally means “urine in the blood,” is the term used to describe the clinical manifestations of kidney failure that are due to an accumulation of nitrogenous waste products in the blood. The uremic state is characterized by signs and symptoms of altered neuromuscular function (e.g., fatigue, peripheral neuropathy, restless leg syndrome, sleep disturbances, uremic encephalopathy); gastrointestinal disturbances such as anorexia and nausea; white blood cell and immune dysfunction; amenorrhea and sexual dysfunction; and
dermatologic manifestations such as pruritus. The onset of uremia in persons with CKD varies; some symptoms may be present to a lesser degree in persons with a GFR that is barely below 50% of normal. However, symptoms such as weakness and fatigue are often non-specific and difficult to identify.

The manifestations of progressive CKD include disorders of fluid, electrolyte, and acid–base balance, cardiovascular function, anemia and blood coagulation, mineral metabolism, neuromuscular function, immunity, and drug elimination. The underlying mechanisms for many of these manifestations are often interrelated. The point at which these disorders make their appearance and the severity of the manifestations are determined largely by coexisting disease conditions and the extent to which kidney function has been reduced. Many of them make their appearance before the GFR has reached the kidney failure stage.

**Fluid, Electrolyte, and Acid–Base Disorders**

The kidneys function in the regulation of sodium and water balance, excrete potassium, and regulate the pH balance of blood. Thus, CKD can produce fluid, electrolyte, and acid–base imbalances.

**Sodium and Water Balance.** The kidneys function in the regulation of extracellular fluid volume. They do this by either eliminating or conserving sodium and water. Chronic kidney disease can produce dehydration or fluid overload, depending on the pathologic process of the kidney disease. In addition to volume regulation, the ability of the kidneys to concentrate the urine is diminished. An early symptom of kidney damage is isosthenuria or polyuria with urine that is almost isotonic with plasma and varies little from voiding to voiding.

As renal function declines further, the ability to regulate sodium excretion is reduced. The kidneys normally tolerate large variations in sodium intake while maintaining normal serum sodium levels. In CKD, they lose the ability to regulate sodium excretion. There is impaired ability to adjust to a sudden reduction in sodium intake and poor tolerance of an acute sodium overload. Volume depletion with an accompanying decrease in the GFR can occur with a restricted sodium intake or excess sodium loss caused by diarrhea or vomiting. Salt wasting is a common problem in advanced kidney failure because of impaired tubular reabsorption of sodium. Increasing sodium intake in persons with kidney failure often improves the GFR and whatever renal function remains. In patients with associated hypertension, the possibility of increasing blood pressure or producing congestive heart failure often excludes supplemental sodium intake.

**Potassium Balance.** Approximately 90% of potassium excretion is through the kidneys. In CKD, potassium excretion by each nephron increases as the kidneys adapt to a decrease in the GFR. In addition, excretion in the gastrointestinal tract is increased. As a result, hyperkalemia usually does not develop until

---

**FIGURE 26-4.** Mechanisms and manifestations of chronic kidney disease.
kidney function is severely compromised. Because of this adaptive mechanism, it is usually not necessary to restrict potassium intake until the GFR has dropped below 5 to 10 mL/min/1.73 m². In persons with kidney failure, hyperkalemia often results from failure to follow dietary potassium restrictions; constipation; acute acidosis that causes the release of intracellular potassium into the extracellular fluid; trauma or infection that causes release of potassium from body tissues; or exposure to medications that contain potassium, prevent its entry into cells, or block its secretion in distal nephrons.

Acid–base Balance. The kidneys also regulate the pH of the blood by eliminating hydrogen ions produced in metabolic processes and regenerating bicarbonate. This is achieved through hydrogen ion secretion, sodium and bicarbonate reabsorption, and the production of ammonia, which acts as a buffer for titratable acids (see Chapter 8). With a decline in kidney function, these mechanisms become impaired and metabolic acidosis may occur when the person is challenged with an excessive acid load or loses excessive alkali, as in diarrhea. The acidosis that occurs in persons with kidney failure seems to stabilize as the disease progresses, probably as a result of the tremendous buffering capacity of bone. However, this buffering action is thought to increase bone resorption and contribute to the skeletal disorders that occur in persons with CKD.

Cardiovascular Complications

Cardiovascular disease continues to be a major cause of death in persons with CKD. In fact, persons with CKD are more likely to die of cardiovascular disease than kidney failure. Coexisting conditions that have been identified as contributing to the burden of cardiovascular disease include hypertension, diabetes mellitus, anemia, endothelial dysfunction, and vascular calcifications. Dyslipidemia is often an additional risk factor for cardiovascular disease in persons with CKD. The most common lipid abnormalities are hypertriglyceridemia, reduced high-density lipoprotein (HDL) levels, and increased concentrations of lipoprotein (a) (see Chapter 18).

Hypertension. Hypertension commonly is an early manifestation of CKD. The mechanisms that produce hypertension in CKD are multifactorial; they include an increased vascular volume, elevation of peripheral vascular resistance, decreased levels of renal vasodilator prostaglandins, and increased activity of the renin-angiotensin-aldosterone system. Early identification and aggressive treatment of hypertension has been shown to slow the progression of renal impairment in many types of kidney disease. Treatment involves salt and water restriction and the use of antihypertensive medications to control blood pressure. Many persons with CKD need to take several antihypertensive medications to control their blood pressure (see Chapter 18).

Heart Disease. The spectrum of heart diseases that occur with CKD include left ventricular hypertrophy, ischemic heart disease, and congestive heart failure. People with CKD tend to have an increased prevalence of left ventricular dysfunction, with both depressed left ventricular ejection fraction, as in systolic dysfunction, and impaired ventricular filling, as in diastolic failure (see Chapter 19). Multiple factors lead to development of left ventricular dysfunction, including extracellular fluid overload, shunting of blood through an arteriovenous fistula for dialysis, and anemia. Anemia, in particular, has been correlated with the presence of left ventricular hypertrophy. These abnormalities, coupled with the hypertension that often is present, cause increased myocardial work and oxygen demand, with eventual development of heart failure.

Gastrointestinal Disorders

Most people with CKD have gastrointestinal symptoms. Anorexia, nausea, and vomiting are common in persons with uremia, along with a metallic taste in the mouth that further depresses the appetite. Early-morning nausea is common. Ulceration and bleeding of the gastrointestinal mucosa may develop, and hiccups are common. A possible cause of nausea and vomiting is the decomposition of urea by intestinal flora, resulting in a high concentration of ammonia. Nausea and vomiting often improve with restriction of dietary protein and after initiation of dialysis, and disappear after kidney transplantation.

Disorders of Mineral Metabolism

Disorders of mineral and bone metabolism begin early in the course of CKD, and include a complex interaction between disturbances in calcium and phosphorous metabolism, parathyroid hormone (PTH), active vitamin D, bone abnormalities, and vascular or other soft tissue calcifications.

Calcium, Phosphorous, PTH, and Vitamin D Levels. The typical pattern of progression includes hyperphosphatemia, hypocalcemia, a decrease in active vitamin D levels, and secondary hyperparathyroidism. Regulation of serum phosphate levels requires a daily urinary excretion of phosphate equal to the amount that was ingested in the diet. With deteriorating renal function, phosphate excretion is impaired, causing serum phosphate levels to rise. As a result, serum calcium levels, which are inversely regulated in relation to serum phosphate levels, fall. The drop in serum calcium, in turn, stimulates parathyroid hormone (PTH) release, with a resultant increase in calcium resorption from bone. Although serum calcium levels are maintained through increased PTH function, this adjustment is accomplished at the expense of the skeletal system and other body organs.

The kidneys regulate vitamin D activity by converting the inactive form of vitamin D (25[OH] vitamin D₃) to calcitriol (1,25[OH] vitamin D₃), the active form of...
vitamin D. Reduced levels of 1,25(OH) vitamin D impair the absorption of calcium from the intestine. Calcitriol also has a direct suppressive effect on PTH production; therefore, reduced levels of calcitriol produce an increase in PTH levels. Most persons with CKD develop secondary hyperparathyroidism, the result of chronic stimulation of the parathyroid glands. Vitamin D also regulates osteoblast differentiation, thereby affecting bone replacement.

**Metastatic Calcifications.** When the calcium–phosphate product (serum calcium [mg/dL] × serum phosphate [mg/dL]) rises above 60 to 70, metastatic calcifications are commonly seen in arteries, visceral organs, and joints. Alkalemia, which often persists after hemodialysis and may even persist between dialysis treatments, may predispose to precipitation of calcium salts in soft tissues.  

**Vascular calcifications** may affect almost any of the medium-sized arteries, and has been seen in arteries of the forearm, wrist, eyes, feet, abdominal cavity, and brain. They are seen more frequently in people older than 40 years of age and in persons on hemodialysis. **Visceral calcifications** may be found in the myocardium, lungs, and stomach. In cardiac calcification, the deposits usually develop in the conduction system and may result in serious cardiac arrhythmias. When calcification occurs in the lungs, it causes a fibrotic response in the small arteries and alveolar septa, leading to restrictive and diffusion abnormalities. **Periarticular calcification** in the shoulders, wrists, phalangeal joints, hips, and ankles is common in people on dialysis. The major symptom associated with these deposits is limitations in joint movement because of the deposits.

**Bone Disease.** A hallmark of CKD is renal osteodystrophy or bone disease, which is typically accompanied by reductions in bone mass, alterations in bone microstructure, bone pain, and skeletal fracture. There are changes in bone turnover, mineralization, and bone volume, accompanied by bone pain and muscle weakness, risk of fractures, and other skeletal complications. Two major types of bone disease are commonly encountered in CKD: high-bone turnover due to enhanced bone resorption, and low-bone turnover due to impaired bone mineralization. Mild forms of defective bone metabolism may be observed in early stages of CKD (stage 2), and they become more severe as kidney function deteriorates. All of the bone disorders can cause bone pain, proximal muscle weakness, and increased risk of fractures.

**High-bone turnover osteodystrophy or osteitis fibrosa**, the most common type of disease, is the result of secondary hyperparathyroidism and the osteoclast stimulation effects of PTH. Because bone resorption and formation are coupled processes, osteoblast activity is also increased (see Chapter 42, Understanding Bone Remodeling). Although the osteoblasts produce excessive amounts of bone, mineralization fails to keep pace, and there is a decrease in bone density and formation of coarse fibrous bone. Cortical bone is affected more severely than cancellous bone.

Low-bone-turnover osteodystrophy or lack of bone mineralization leads to rickets in children and osteomalacia in adults. **Osteomalacia** is characterized by a slow rate of bone formation and defects in bone mineralization, which may be caused by vitamin D deficiency, excess aluminum deposition, or metabolic acidosis. Metabolic acidosis is thought to have a direct effect on both osteoblastic and osteoclastic activity, as well as on the mineralization process, by decreasing the availability of trivalent phosphate. Another type of low-bone-turnover osteodystrophy, *adynamic osteodystrophy*, which is almost as common as high-bone-turnover osteodystrophy and is especially common among persons with diabetes. It is characterized by a low number of osteoblasts, a normal or reduced number of osteoclasts, and reduced bone volume and mineralization that may result, in part, from excessive suppression of PTH production with calcitriol.

Early treatment of hyperphosphatemia and hypocalcemia is important to prevent or slow the development of skeletal complications. Phosphate-binding antacids (aluminum salts, calcium carbonate, or calcium acetate) may be prescribed to decrease absorption of phosphate from the gastrointestinal tract. Aluminum-containing antacids can contribute to the development of osteodystrophy, whereas calcium-containing phosphate binders can lead to hypercalcemia, thus worsening soft tissue calcification, especially in persons receiving vitamin D therapy. Phosphate-binding agents that do not contain calcium or aluminum (e.g., sevelamer, lanthanum) are now available. Pharmacologic forms of activated vitamin D often are used to increase serum calcium levels and, at least partially, reverse the secondary hyperparathyroidism and osteitis fibrosa that occur with CKD. Secondary hyperparathyroidism may also be treated by activating the calcium-sensing receptor on the parathyroid gland (see Chapter 8). The calcimimetic agent cinacalcet, the first representative of a new class of drugs that act through the calcium-sensing receptor, has been approved for treatment of secondary hyperparathyroidism in CKD.

**Hematologic Complications**

**Anemia.** Anemia tends to develop early in the course of CKD, often interfering with the quality of life. The anemia of CKD is due to several factors, including chronic blood loss, hemolysis, bone marrow suppression due to retained uremic factors, and decreased red cell production due to impaired production of erythropoietin and iron deficiency. The kidneys are the primary site for the production of the hormone erythropoietin, which controls red blood cell production. In renal failure, erythropoietin production usually is insufficient to stimulate adequate red blood cell production by the bone marrow. Among the causes of iron deficiency in persons with CKD are anorexia and dietary restrictions that limit intake, as well as the blood loss that occurs during dialysis.
When untreated, anemia causes or contributes to the weakness, fatigue, depression, insomnia, and decreased cognitive function that commonly accompany CKD. There also is an increasing concern regarding the physiologic effects of anemia on cardiovascular function. The anemia of renal failure produces a decrease in blood viscosity and a compensatory increase in heart rate. The decreased blood viscosity also exacerbates peripheral vasodilation and contributes to decreased vascular resistance. Cardiac output increases in a compensatory fashion to maintain tissue perfusion. Anemia also limits myocardial oxygen supply, particularly in persons with coronary heart disease, predisposing to angina pectoris and other ischemic events.

A remarkable advance in the treatment of anemia in CKD was realized when recombinant human erythropoietin (rhEPO) became available. Because iron deficiency is common among persons with CKD, iron supplementation often is needed. Iron can be given orally or intravenously. Intravenous iron is used for treatment of persons who are not able to maintain adequate iron status with oral iron. Although adverse reactions have been reported, intravenous preparations are generally safe and well tolerated.

**Coagulation Disorders.** The coagulation disorders of CKD are mainly caused by platelet dysfunction. Platelet counts may be slightly decreased and the bleeding time is prolonged because of abnormal adhesiveness and aggregation. Clinically, persons with CKD can experience epistaxis (nosebleeds), menorrhagia (excessive menstrual bleeding), gastrointestinal bleeding, and bruising of the skin and subcutaneous tissues. Coagulative function improves with dialysis but does not completely normalize, suggesting that uremia contributes to the problem. Persons with CKD also have greater susceptibility to thrombotic disorders, particularly if their underlying disease was characterized by a nephrotic presentation.

**Immunologic Disorders**

All aspects of inflammation and immune function may be affected adversely by the high levels of urea and metabolic wastes seen in CKD. A decreased granulocyte count, defective phagocyte function, impaired acute inflammatory response, and impaired humoral and cell-mediated immunity are typical. These immunologic abnormalities decrease the efficiency of the immune response to infection, which is a common complication of CKD. Skin and mucosal barriers to infection also may be defective. In persons who are maintained on dialysis, vascular access devices are common portals of entry for pathogens. Many persons with CKD fail to mount a fever with infection, making a diagnosis of infection more difficult. The delayed-type hypersensitivity response is also impaired. Although persons with CKD have normal humoral responses to vaccines, a more aggressive immunization program may be needed.

**Neuromuscular Complications**

Many persons with CKD have alterations in peripheral and central nervous system function. Peripheral neuropathy, or involvement of the peripheral nerves, affects the lower limbs more frequently than the upper limbs. It is symmetric, affects both sensory and motor function, and is associated with atrophy and demyelination of nerve fibers, possibly due to uremic toxins. Restless leg syndrome is a manifestation of peripheral nerve involvement and can be seen in as many as two thirds of persons on dialysis. This syndrome is characterized by creeping, pricking, and itching sensations that typically are more intense at rest. Temporary relief is obtained by moving the legs. A burning sensation of the feet, which may be followed by muscle weakness and atrophy, is a manifestation of uremia.

The central nervous system disturbances in uremia are similar to those caused by other metabolic and toxic disorders. Sometimes referred to as uremic encephalopathy, the condition is poorly understood and may result, at least in part, from an excess of toxic organic acids that alter neural function. Electrolyte abnormalities, such as sodium shifts, also may contribute. The manifestations are more closely related to the progress of the uremic state than to the level of the metabolic end products. Reductions in alertness and awareness are the earliest and most significant indications of uremic encephalopathy. These often are followed by an inability to fix attention, loss of recent memory, and perceptual errors in identifying persons and objects. Delirium and coma occur late in the disease course; seizures are the preterminal event.

Disorders of motor function commonly accompany the neurologic manifestations of uremic encephalopathy. During the early stages, there often is difficulty in performing fine movements of the extremities; the gait becomes unsteady and clumsy with tremulousness of movement. Asterixis (dorsiflexion movements of the hands and feet) typically occurs as the disease progresses. It can be elicited by having the person hyperextend his or her arms at the elbow and wrist with the fingers spread apart. If asterixis is present, this position causes side-to-side flapping movements of the fingers.

**Sexual Dysfunction**

Alterations in sexual function and reproductive ability are common in CKD. The cause probably is multifactorial and may result from high levels of uremic toxins, neuropathy, altered endocrine function, psychological factors, and medications (e.g., antihypertensive drugs).

Impotence occurs in as many as 56% of male patients on dialysis. Derangements of the pituitary and gonadal hormones, such as decreases in testosterone levels and increases in prolactin and luteinizing hormone levels, are common and cause erectile difficulties and decreased spermatocyte counts. Loss of libido may result from chronic anemia and decreased testosterone levels.

Impaired sexual function in women is manifested by abnormal levels of progesterone, luteinizing hormone, and prolactin. Hypofertility, menstrual abnormalities,
Chronic kidney disease is treated by conservative management to prevent or slow the rate of nephron destruction and, when necessary, by renal replacement therapy with dialysis or transplantation.

Conservative Medical Management

Conservative treatment, which includes measures to retard deterioration of renal function and assist the body in managing the effects of impaired function, can often delay the progression of CKD.\(^{13,39}\) Urinary tract infections should be treated promptly and medication nephrotoxic potential should be avoided. It should be noted that these strategies are complementary to the treatment of the original cause of the renal disorder, which is of the utmost importance and needs to be continually addressed.

Blood pressure control is important, as is control of blood glucose in persons with diabetes mellitus. In addition to reduction in cardiovascular risk, antihypertensive therapy in persons with CKD aims to slow the progression of nephron loss by lowering intraglomerular hypertension and hypertrophy.\(^ {18}\) Elevated blood pressure also increases proteinuria due to transmission of the elevated pressure to the glomeruli. This is the basis for the treatment guideline establishing 125/75 mm Hg as the target blood pressure for persons with CKD\(^ {18}\) (see Chapter 18). The angiotensin converting enzyme (ACE) and angiotensin receptor blockers (ARBx), which have a unique effect on the glomerular microcirculation (i.e., dilation of the efferent arteriole), are increasingly being used in the treatment of hypertension and proteinuria, particularly in persons with diabetes.\(^ {18}\)

It has also become apparent that smoking has a negative impact on kidney function, and it is one of the most remedial risk factors for CKD.\(^ {40}\) The mechanisms of smoking-induced renal damage appear to include both acute hemodynamic effects (i.e., increased blood pressure, intraglomerular pressure, and urinary albumin excretion) and chronic effects (endothelial cell dysfunction). Smoking is particularly nephrotoxic in elderly persons with hypertension and in those with diabetes. Importantly, the adverse effects of smoking appear to be independent of the underlying kidney disease.

Dietary Management

The goal of dietary management is to provide optimum nutrition, while maintaining tolerable levels of metabolic wastes.\(^ {31,42}\) The specific diet prescription depends on the type and severity of renal disease and on the dialysis modality. Because of the severe restrictions placed on food and fluid intake, these diets may be complicated and unappetizing.

Dietary proteins may be restricted as a means of decreasing the progress of renal impairment in persons with advanced CKD. Proteins are broken down to form nitrogenous wastes, and reducing the amount of protein in the diet lowers the BUN and reduces symptoms. Moreover, a high-protein diet is high in phosphates and inorganic acids. Considerable controversy exists over the degree of restriction needed. If the diet is too low in protein, protein malnutrition can occur, with a loss of strength, muscle mass, and body weight. With protein restriction, adequate calories in the form of carbohydrates and fat are essential to meet energy needs. If sufficient calories are not available, the limited protein in the diet is metabolized for energy production, or body tissue itself is used, resulting in decreased strength and mass, as just noted.

Sodium and fluid restrictions depend on the kidneys’ ability to excrete sodium and water and must be individually determined. Renal disease of glomerular origin is more likely to contribute to sodium retention, whereas disorders of tubular function tend to cause salt wasting. Fluid intake in excess of what the kidneys can excrete causes circulatory overload, edema, and water intoxication. Thirst is a common problem among patients on hemodialysis, often resulting in large weight gains between treatments. Inadequate intake, on the other hand, causes volume depletion and hypotension and can cause further decreases in the already compromised GFR. It is common practice to allow a daily fluid intake of 500 to 800 mL, which is equal to insensible water loss plus a quantity equal to the 24-hour urine output.

When the GFR falls to extremely low levels in CKD or during hemodialysis therapy, dietary restriction of potassium often becomes mandatory. Using salt substitutes that contain potassium or ingesting fruits, fruit juice, chocolate, potatoes, or other high-potassium foods can cause hyperkalemia.

Persons with CKD are usually encouraged to limit their dietary phosphorus as a means of preventing secondary hyperparathyroidism, renal osteodystrophy, and metastatic calcification. Unfortunately, many processed and convenience foods contain considerable

Skin Disorders

Skin disorders are common in persons with CKD.\(^ {13}\) The skin and mucous membranes often are dry, and subcutaneous bruising is common. Skin dryness is caused by a reduction in perspiration owing to the decreased size of sweat glands and the diminished activity of oil glands. Pruritus is common; it results from the high serum phosphate levels and the development of phosphate crystals that occur with hyperparathyroidism. Severe scratching and repeated needle sticks, especially with hemodialysis, break the skin integrity and increase the risk for infection. In the advanced stages of untreated kidney failure, urea crystals may precipitate on the skin as a result of the high urea concentration in body fluids. The fingernails may become thin and brittle, with a dark band just behind the leading edge of the nail followed by a white band. This appearance is known as Terry nails.

amounts of added phosphorus. Common foods containing phosphorus are restructured meats (e.g., chicken nuggets, hot dogs), processed and spreadable cheeses, instant products (e.g., puddings, sauces), refrigerated bakery products, and beverages. These phosphorus additives are highly absorbable. In a typical diet of grains, meats, and dairy products, only about 60% of phosphorus is absorbed, whereas phosphorus additives (e.g., polyphosphates, pyrophosphates) are almost 100% absorbed. Identifying these newer phosphorus-containing foods is often challenging because manufacturers are no longer required to list the phosphorus content on food labels.

Medication Management

Chronic kidney disease and its treatment can interfere with the absorption, distribution, and elimination of drugs. Many drugs are bound to plasma proteins, such as albumin for transport in the blood, with the unbound portion of the drug being free to act at the various receptor sites and metabolized. A decrease in plasma proteins, particularly albumin, that occurs in many persons with CKD results in less protein-bound drug and greater amounts of free drug.

In the process of metabolism, some drugs form intermediate metabolites that are toxic if not eliminated. Some pathways of drug metabolism, such as hydrolysis, are slowed with uremia. In persons with diabetes, for example, insulin requirements may be reduced as renal function deteriorates. Decreased elimination by the kidneys allows drugs or their metabolites to accumulate in the body and requires that drug dosages be adjusted accordingly. Some drugs contain unwanted nitrogen, sodium, potassium, and magnesium and must be avoided in patients with CKD. Penicillin, for example, contains potassium. Nitrofurantoin and ammonium chloride add to the body’s nitrogen pool. Administration of large quantities of phosphate-binding antacids to control hyperphosphatemia and hypocalcemia in patients with CKD interferes with the absorption of some drugs. Because of problems with drug dosing and elimination, persons with CKD should be cautioned against the use of over-the-counter remedies.

Dialysis and Transplantation

Dialysis or renal replacement therapy is indicated when advanced uremia or serious electrolyte imbalances are present. The choice between dialysis and transplantation is dictated by age, related health problems, donor availability, and personal preference. Although transplantation often is the preferred treatment, dialysis plays a critical role as a treatment method for kidney failure. It is life sustaining for persons who are not candidates for transplantation or who are awaiting transplantation. There are two broad categories of dialysis: hemodialysis and peritoneal dialysis.

Hemodialysis. The basic principles of hemodialysis have remained unchanged over the years, although new technology has improved the efficiency and speed of dialysis. A hemodialysis system, or artificial kidney, consists of three parts: a blood delivery system, a dialyzer, and a dialysis fluid delivery system. The dialyzer is usually a hollow cylinder composed of bundles of capillary tubes through which blood circulates, while the dialysate travels on the outside of the tubes. The walls of the capillary tubes in the dialysis chamber are made up of a semipermeable membrane material that allows all molecules except blood cells and plasma proteins to move freely in both directions—from the blood into the dialyzing solution and from the dialyzing solution into the blood. The direction of flow is determined by the concentration of the substances contained in the two solutions. The waste products and excess electrolytes in the blood normally diffuse into the dialyzing solution. If there is a need to replace or add substances, such as bicarbonate, to the blood, these can be added to the dialyzing solution (Fig. 26-5).

During dialysis, blood moves from an artery through the tubing and blood chamber in the dialysis machine and then back into the body through a vein. Access to the vascular system is accomplished through an external arteriovenous shunt (i.e., tubing implanted into an artery and a vein) or, more commonly, through an internal arteriovenous fistula (i.e., anastomosis of a vein to an artery, usually in the forearm). Heparin is used to prevent clotting during the dialysis treatment; it can be administered continuously or intermittently. Problems that may occur during dialysis, depending on the rates of blood flow and solute removal, include hypotension, nausea, vomiting, muscle cramps, headache, chest pain, and disequilibrium syndrome. Most persons are dialyzed three times each week for 3 to 4 hours. Many dialysis centers provide the option for patients to learn how to perform hemodialysis at home.

Peritoneal Dialysis. The same principles of diffusion, osmosis, and ultrafiltration that apply to hemodialysis apply to peritoneal dialysis, in which the thin serous membrane of the peritoneal cavity serves as the dialyzing membrane. The procedure is facilitated by the surgical implantation of a silastic catheter into the peritoneal cavity at a point below the umbilicus. The catheter is tunneled through subcutaneous tissue and exits on the side of the abdomen (Fig. 26-6). The dialysis process involves instilling a sterile dialyzing solution (usually 1 to 3 L) through the catheter over a period of approximately 10 minutes. The solution then is allowed to remain, or dwell, in the peritoneal cavity for a prescribed amount of time, during which the metabolic end products and extracellular fluid diffuse into the dialysis solution. At the end of the dwell time, the dialysis fluid is drained out of the peritoneal cavity by gravity into a sterile bag. The osmotic effects of glucose in the dialysis solution account for water removal.

Peritoneal dialysis can be performed at home or in a dialysis center and can be carried out by continuous ambulatory peritoneal dialysis (CAPD), continuous
cyclic peritoneal dialysis (CCPD), or nocturnal intermittent peritoneal dialysis (NIPD)—all with variations in the number of exchanges and dwell times. Individual preference, manual ability, lifestyle, knowledge of the procedure, and physiologic response to treatment are used to determine the type of dialysis that is used. The most common method is CAPD, a self-care procedure in which the person exchanges the dialysate four to six times a day. In CCPD, exchanges usually are performed at night, with the person connected to an automatic cycler. In the morning, with the last exchange remaining in the abdomen, the person is disconnected from the cycler and goes about his or her usual activities. In NIPD, the person is given approximately 10 hours of automatic cycling each night, with the abdomen left dry during the day.

Potential problems with peritoneal dialysis include infection, catheter malfunction, dehydration caused by excessive fluid removal, hyperglycemia, and hernia. The most serious complication is infection, which can occur at the catheter exit site, in the subcutaneous tunnel, or in the peritoneal cavity (i.e., peritonitis).

Transplantation. Greatly improved success rates have made kidney transplantation the treatment of choice for many patients with CKD. The availability of donor organs continues to limit the number of transplantations performed each year. Donor organs are obtained from cadavers and living related donors (e.g., parent, sibling). Transplants from living unrelated donors (e.g., spouse) have been used in cases of suitable ABO blood type and tissue compatibility. The success of transplantation depends primarily on the degree of histocompatibility, adequate organ preservation, and immunologic management. Maintenance immunosuppressive therapy plays an essential role in controlling T- and B-cell activation.
SUMMARY CONCEPTS

- Chronic kidney disease (CKD), which represents a progressive decline in kidney function due to the permanent loss of nephrons, can result from a number of conditions, including diabetes, hypertension, glomerulonephritis, and other kidney diseases. Regardless of the cause, the consequences of nephron destruction in CKD disrupt the filtration, reabsorption, and endocrine functions of the kidneys.
- The glomerular filtration rate (GFR) is considered the best measure of kidney function. Chronic disease is defined as either diagnosed kidney damage or a GFR of less than 60 mL/min/1.73 m² for 3 months or more, and kidney failure as a GFR of less than 15 mL/min/1.73 m², usually accompanied by most of the signs and symptoms of uremia or a need to start renal replacement therapy.
- The manifestations of CKD reflect alterations in fluid, electrolyte, and acid–base balance; anemia and coagulopathies; cardiovascular complications; disorders of calcium and phosphate metabolism and skeletal disorders; and impaired elimination of drugs that are excreted by the kidney. It also results in an accumulation of nitrogenous wastes and signs and symptoms of the uremic state, such as neuromuscular disorders, gastrointestinal disturbances, immune disorders, sexual dysfunction, and discomforting skin changes.
- Treatment measures for CKD can be divided into two types: conservative management and renal replacement therapy. The goals of conservative treatment are to prevent or retard deterioration in remaining renal function and assist the body in compensating for the existing impairment. Renal replacement therapy (dialysis or kidney transplantation) is indicated when advanced uremia and serious electrolyte problems are present.

Chronic Kidney Disease in Children and Elderly Persons

Although the spectrum of CKD among children and elderly persons is similar to that of adults, several unique issues affecting these groups warrant further discussion.

Chronic Kidney Disease in Children

Available data suggest that 1% to 2% of persons with CKD are in the pediatric age range. The causes of CKD in children include congenital malformations, inherited disorders, acquired diseases, and metabolic syndromes. The underlying cause correlates closely with the age of the child. In children younger than 5 years of age, CKD is commonly the result of congenital malformations, such as renal dysplasia or obstructive uropathy. After 5 years of age, acquired diseases (e.g., glomerulonephritis) and inherited disorders (e.g., familial juvenile nephronophthisis) predominate. CKD related to metabolic disorders, such as hyperoxaluria, and inherited disorders, such as polycystic kidney disease, may present throughout childhood.

The stages for progression of CKD in children are similar to those for adults: mild reduction of GFR to 60 to 89 mL/min/1.73 m²; moderate reduction of GFR to 30 to 59 mL/min/1.73 m²; severe reduction of GFR to 15 to 29 mL/min/1.73 m²; and kidney failure with a GFR of less than 15 mL/min/1.73 m², or a need for renal replacement therapy. Because the GFR is much lower in infancy and undergoes gradual changes in relation to body size during the first 2 years of age, these values apply only to children older than 2 years of age.

The manifestations of CKD in children are quite varied and depend on the underlying disease condition. Features of CKD during childhood include severe growth impairment, developmental delay, delay in sexual maturation, bone abnormalities, and development of psychosocial problems.

Critical growth periods occur during the first 2 years of life and during adolescence. Physical growth and cognitive development occur at a slower rate as consequences of CKD, especially among children with congenital kidney disease. Puberty usually occurs at a later age in children with CKD, partly because of endocrine abnormalities. Renal osteodystrophies are more common and extensive in children than in adults. The most common condition seen in children is high–bone-turnover osteodystrophy caused by secondary hyperparathyroidism. Some hereditary renal diseases, such as medullary cystic disease, have patterns of skeletal involvement that further complicate the problem of renal osteodystrophy. Clinical manifestations of renal osteodystrophy include muscle weakness, bone pain, and fractures with minor trauma. In growing children, rachitic bone changes, varus and valgus deformities of long bones, and slipped capital femoral epiphysis may be seen.

Factors related to impaired growth include deficient nutrition, anemia, renal osteodystrophy, chronic aci-dosis, and cases of nephrotic syndrome that require high-dose corticosteroid therapy. Nutrition is believed to be the most important determinant of growth during infancy. During childhood, growth hormone is important, and gonadotropin hormones become important during puberty. Parental height provides a means of assessing growth potential (see Chapter 32). For many children, catch-up growth is important because a growth deficit frequently is established during the first months of life. Recombinant human growth hormone therapy has been used to improve growth in children with CKD. Success of treatment depends on the level of bone maturation at the initiation of therapy.

All forms of renal replacement therapy can be safely and reliably used for children. Age is a defining factor
in dialysis modality selection. The majority of North American children are treated with CCPD or NIPD, which leaves the child and family free of dialysis demands during waking hours, with the exchanges being performed automatically during sleep by the machine. Renal transplantation is considered the best alternative for children. Early transplantation in young children is regarded as the best way to promote physical growth, improve cognitive function, and foster psychosocial development. Immunosuppressive therapy in children is similar to that used in adults. All immunosuppressive agents have side effects, including increased risk for infection. Corticosteroids, which have been the mainstay of chronic immunosuppressive therapy for decades, carry the risk for hypertension, orthopedic complications (especially aseptic necrosis), cataracts, and growth retardation.

**Chronic Kidney Disease in Elderly Persons**

Chronic kidney disease is rather common among the elderly, who comprise the fastest growing subpopulation of the persons with CKD. Aging is associated with structural and functional changes that predispose the aging kidney to insults that otherwise might not have serious consequences. With aging there is a decrease in renal mass and volume, a decrease in renal blood flow, decreased ability to concentrate the urine, and a decrease in the GFR. These changes occur at varying stages of aging depending on predisposing genetic factors and exposure to risk factors such as cardiovascular disease and diabetes mellitus.

The reduction in GFR related to aging is not accompanied by a parallel rise in the serum creatinine level because the serum creatinine level, which results from muscle metabolism, is significantly reduced in elderly persons because of diminished muscle mass and other age-related changes. The KDOQI guidelines suggest that the same criteria for establishing the presence of CKD in younger adults (i.e., GFR < 60 mL/min/1.73 m²) should be used for the elderly. Evaluation of elderly persons with a GFR of 60 to 89 mL/min/1.73 m² should include age-adjusted measurements of creatinine clearance, along with assessment of CKD risks, measurement of blood pressure, albumin-to-creatinine ratio in a “spot” urine specimen, and examination of the urine sediment for red and white blood cells.

The prevalence of concurrent chronic disease affecting the cerebrovascular, cardiovascular, and skeletal systems is higher in this age group. As a result, the presenting symptoms of kidney disease in elderly persons may differ from those observed in younger adults. For example, congestive heart failure and hypertension may be the dominant clinical features indicating the onset of acute glomerulonephritis, whereas oliguria and discolored urine more often are the first signs in younger adults. In addition, the course of CKD may be more complicated in older patients with numerous chronic diseases, and its treatment more challenging.

Treatment of the elderly with CKD is usually based on the severity of kidney function impairment and stratification of risk for progression to renal failure and cardiovascular disease. Persons with low risk may require only modification of dosages of medications excreted by the kidney, monitoring of blood pressure, avoidance of drugs and procedures that increase the risk of AKI, and lifestyle modification to reduce the risk of cardiovascular disease. Elderly persons with more severe impairment of kidney function may require renal replacement therapy. Treatment options for CKD in elderly patients include hemodialysis, peritoneal dialysis, and transplantation, and acceptance of death from uremia. Neither hemodialysis nor peritoneal dialysis has proved to be superior in the elderly. The choice of therapy should be individualized, taking into account underlying medical and psychosocial factors. Most professional groups support renal transplantation for older people with end stage kidney disease. In the past, reluctance to provide transplantation as an alternative may have been due, at least in part, to the scarcity of available organs and the view that younger persons are more likely to benefit for a longer time. The general reduction in T-lymphocyte function that occurs with aging has been suggested as a beneficial effect that increases transplant graft survival. With increasing experience, many transplantation centers have increased the age for acceptance on transplant waiting lists. When dialysis is not effective and transplantation is not an option, psychotherapy may help the person accept death from uremia.

**SUMMARY CONCEPTS**

- **Causes of CKD in infants and children include** congenital malformations (e.g., renal dysplasia and obstructive uropathy), inherited disorders (e.g., polycystic kidney disease), acquired diseases (e.g., glomerulonephritis), and metabolic syndromes (e.g., hyperoxaluria). Problems associated with CKD in children include growth impairment, delay in sexual maturation, and more extensive bone abnormalities than in adults. Although all forms of renal replacement therapy can be safely and reliably used in children, CCPD, NIPD, and transplantation optimize growth and development.

- **Normal aging** is associated with a decline in the GFR, which makes elderly persons more susceptible to the detrimental effects of nephrotoxic drugs and other conditions that compromise renal function. Current guidelines for diagnosis of CKD and stratification of risk for progression to kidney failure are the same as for younger adults. Treatment options for chronic renal failure in elderly patients are also similar to those for younger adults.
REVIEW EXERCISES

1. A 55-year-old man with diabetes and coronary heart disease, who had undergone cardiac catheterization with the use of a radiocontrast agent 2 days ago, is admitted to the emergency department with a flu-like syndrome including chills, nausea, vomiting, abdominal pain, fatigue, and pulmonary congestion. His serum creatinine is elevated, and he has protein in his urine. He is admitted to the intensive care unit with a tentative diagnosis of acute kidney injury due to radiocontrast nephropathy.

A. Radiocontrast agents are thought to exert their effects through decreased renal perfusion and through direct toxic effects on renal tubular structures. Explain how each of these phenomena contributes to the development of acute kidney injury.

B. Explain the elevated serum creatinine, proteinuria, and presence of pulmonary congestion.

2. A 35-year-old, 70-kg white man with diabetes mellitus is seen in the diabetic clinic for his 6-month check-up. His serum creatinine, which was slightly elevated at his last visit, is now 1.6 mg/dL.

A. Use the following website to estimate his GFR: http://www.kidney.org/professionals/kdoqi/gfr_calculator.cfm

B. Would he be classified as having chronic kidney disease? If so, what stage? What might be done to delay or prevent further deterioration of his kidney function?

3. Chronic kidney disease is accompanied by hyperphosphatemia, hypocalcemia, impaired activation of vitamin D, hyperparathyroidism, and skeletal complications.

A. Explain the impaired activation of vitamin D and its consequences on calcium and phosphate homeostasis, parathyroid function, and mineralization of bone in persons with CKD.

B. Explain the possible complications of the administration of activated forms of vitamin D on parathyroid function and calcium and phosphate homeostasis.

Although the kidneys control the formation of urine, its storage and periodic elimination depend on the coordinated activity of the smooth and striated muscle of the two functional units of the lower urinary tract—the urinary bladder, which serves as reservoir for urine storage and the urethra and urethral sphincter, which function as an outlet for urine elimination. Alterations in the storage and expulsion functions of the lower urinary tract can result in urine retention, which has deleterious effects on ureteral and, ultimately, renal function; or incontinence, with its accompanying social and hygienic problems. The discussion in this chapter focuses on the control of urine elimination, disorders of lower urinary tract structures and function, lower urinary tract infections, and bladder cancer.

**Control of Urine Elimination**

The urinary bladder is a freely movable organ located retroperitoneally on the pelvic floor, just posterior to the pubic symphysis. It consists of two main components: the body in which urine collects, and the bladder neck, which is a funnel-shaped extension of the body that connects with the urethra. In the male, the urethra continues anteriorly through the penis, with the prostate gland surrounding the neck of the bladder where it empties into the urethra. In the female, the bladder is located anterior to the vagina and uterus.

Urine passes from the kidneys to the bladder through the ureters. The interior of the bladder has openings for both the ureters and the urethra. The smooth triangular area that is bounded by these three openings is called the **trigone** (Fig. 27-1). There are no valves at the ureteral openings, but as the pressure of the urine in the bladder rises, the ends of the ureters are compressed against the bladder wall to prevent the backflow of urine.
the bladder. Urination. When it contracts, urine is expelled from alterations in the function of this sensory system.

It has been suggested that conditions such as overactive bladder and interstitial cystitis are associated with sensory neurons in the underlying smooth muscle fibers. This is followed by sensory information to afferent sensory neurons in the underlying smooth muscle fibers.

The urothelium is essentially impermeable to urine solutes and water. The tonicity and composition of the urine often is quite different from that of the blood, and the urothelium acts as an effective barrier to prevent the passage of water and other urine elements between the bladder and the blood. The surface of the urothelium is covered with a mucin layer that is thought to act as a nonspecific anti-adherence factor and as a defense mechanism against infection. The urothelium not only acts as a nonspecific anti-adherence factor and as a defense mechanism against infection. The urothelium acts as a barrier between the bladder contents and the underlying bladder tissues but also as a sensory organ by transmitting physical and chemical information to afferent sensory neurons in the underlying smooth muscle fibers. It has been suggested that conditions such as overactive bladder and interstitial cystitis are associated with alterations in the function of this sensory system.

The detrusor muscle is the muscle of micturition or urination. When it contracts, urine is expelled from the bladder. Muscles in the bladder neck, sometimes referred to as the internal urethral sphincter, are a continuation of the detrusor muscle. They run down obliquely behind the proximal urethra, forming the posterior urethra in males and the entire urethra in females. When the bladder is relaxed, these circular muscle fibers are closed and act as a sphincter. When the detrusor muscle contracts, the sphincter is pulled open as the shape of the bladder changes as urine is forced into the urethra.

Another muscle important to bladder function is the external sphincter, a circular muscle composed of striated skeletal muscle fibers that surrounds the urethra distal to the base of the bladder (see Fig. 27-1). The external sphincter operates as a reserve mechanism to stop micturition when it is occurring and to maintain continence in the face of unusually high bladder pressure. The skeletal muscle of the pelvic floor also contributes to the support of the bladder and the maintenance of continence.

**Bladder Structure**

The bladder, also known as the urinary vesicle, is composed of four layers: an outer serosal layer covers the upper surface of the bladder and is continuous with the peritoneum; beneath it is an external network of smooth muscle fibers called the detrusor muscle; this is followed by a submucosal layer formed largely of connective and elastic tissue; and an innermost layer of transitional epithelium, often referred to as the urothelium. Stretching of the bladder wall as a result of distention with urine is accomplished by flattening of its numerous mucosal folds and thick transitional epithelium (see Fig. 27-1).

The urothelium is essentially impermeable to urine solutes and water. The tonicity and composition of the urine often is quite different from that of the blood, and the urothelium acts as an effective barrier to prevent the passage of water and other urine elements between the bladder and the blood. The surface of the urothelium is covered with a mucin layer that is thought to act as a nonspecific anti-adherence factor and as a defense mechanism against infection. The urothelium not only acts as a barrier between the bladder contents and the underlying bladder tissues but also as a sensory organ by transmitting physical and chemical information to afferent sensory neurons in the underlying smooth muscle fibers. It has been suggested that conditions such as overactive bladder and interstitial cystitis are associated with alterations in the function of this sensory system.

The detrusor muscle is the muscle of micturition or urination. When it contracts, urine is expelled from the bladder. Muscles in the bladder neck, sometimes referred to as the internal urethral sphincter, are a continuation of the detrusor muscle. They run down obliquely behind the proximal urethra, forming the posterior urethra in males and the entire urethra in females. When the bladder is relaxed, these circular muscle fibers are closed and act as a sphincter. When the detrusor muscle contracts, the sphincter is pulled open as the shape of the bladder changes as urine is forced into the urethra.

Another muscle important to bladder function is the external sphincter, a circular muscle composed of striated skeletal muscle fibers that surrounds the urethra distal to the base of the bladder (see Fig. 27-1). The external sphincter operates as a reserve mechanism to stop micturition when it is occurring and to maintain continence in the face of unusually high bladder pressure. The skeletal muscle of the pelvic floor also contributes to the support of the bladder and the maintenance of continence.

**Neural Control of Bladder Function**

To maintain continence, or retention of urine, the bladder must function as a low-pressure storage system, with the pressure in the bladder being lower than that in the urethra. To ensure that this condition is met, the increase in intravesical pressure that accompanies bladder filling is almost imperceptible. Abnormal sustained elevations in intravesical pressures often are associated with vesicoureteral reflux (i.e., backflow of urine from the bladder into the ureter) and the development of ureteral dilation (see Chapter 25, Fig. 25-7). Although the pressure in the bladder is maintained at low levels, sphincter pressures remain high, preventing loss of urine as the bladder fills.

Micturition, or urination, involves the activity of both sensory and motor neurons. When the bladder is distended to 150 to 250 mL in the adult, the first sensation of fullness is transmitted to the spinal cord and then to the cerebral cortex, and at 350 to 450 mL there is a definite sense of bladder fullness. During the act of micturition, the detrusor muscle of the bladder fundus and bladder neck contract down on the urethra and the ureteral orifices are forced shut. The bladder neck is widened and shortened, and the external sphincter relaxes as urine moves out of the bladder. Descent of the diaphragm and contraction of the abdominal muscles raise intra-abdominal pressure and aid in the expulsion of urine from the bladder.

Normal bladder function requires coordinated interactions between the sensory and motor components of both the autonomic nervous system (ANS), which controls involuntary smooth muscle activity, and the somatic nervous system, which controls voluntary skeletal muscle activity. The motor components of the neural reflex that causes bladder emptying is controlled by the parasympathetic division of the ANS, and the relaxation and storage functions of the bladder is controlled by the sympathetic division. The somatic nervous system innervates the skeletal muscles of the external sphincter.
sphincter and the pelvic floor muscles that together control the outflow of urine. These functions are controlled by three neurologic centers: the spinal cord reflex centers, the micturition center in the pons, and cortical and subcortical centers.  

**Spinal Cord Centers**

The centers for reflex control of bladder function are located in the sacral (S1 through S4) and thoracolumbar (T11 through L2) segments of the spinal cord (Fig. 27-2). The parasympathetic neurons for the detrusor muscle of the bladder are located in the sacral segments of the spinal cord; their axons travel to the bladder by way of the pelvic nerve. The lower motor neurons for the external sphincter also are located in the sacral segments of the spinal cord. These neurons receive their control from the motor cortex through the corticospinal tract and send impulses to the external sphincter through the pudendal nerve. The bladder neck and trigone area of the bladder, because of their different embryonic origins, receive sympathetic outflow from the thoracolumbar (T11 to L2) segments of the spinal cord. In the male, the seminal vesicles, ampulla, and vas deferens also receive sympathetic innervation from the thoracolumbar segments of the cord.

The afferent input from the bladder and urethra is carried to the central nervous system (CNS) by fibers that travel with the parasympathetic (pelvic), somatic (pudendal), and sympathetic (hypogastric) nerves. The pelvic nerve carries sensory fibers from the stretch receptors in the bladder wall, the pudendal nerve carries sensory fibers from the external sphincter and pelvic muscles, and the hypogastric nerve carries sensory fibers from the trigone area.

**Pontine Micturition Center**

The immediate coordination of the normal micturition reflex occurs in the micturition center in the pons, facilitated by descending input from the forebrain and ascending input from the reflex centers in the spinal cord (Fig. 27-3). This center is thought to coordinate the activity of the detrusor muscle and the external sphincter. As bladder filling occurs, ascending spinal afferents relay this information to the micturition center, which also receives important descending information from the forebrain concerning behavioral cues for bladder emptying and urine storage. Descending pathways from the pontine micturition center produce coordinated inhibition or relaxation of the external sphincter. Disruption of pontine control of micturition, as in spinal cord injury, results in uninhibited spinal reflex-controlled contraction of the bladder without relaxation of the external sphincter, a condition known as detrusor–sphincter dyssynergia (to be discussed).

**Cortical and Subcortical Centers**

Cortical brain centers enable inhibition of the micturition center in the pons and conscious control of urination. Neural influences from the subcortical centers in the basal ganglia modulate the contractile response. They modify and delay the detrusor contractile response during filling and then modulate the expulsive activity of the bladder to facilitate complete emptying. In infants and young children the pathways to the cortical and subcortical centers are not fully developed and micturition occurs whenever the bladder is sufficiently distended. At about age 2 1/2 years it begins to come under cortical control; in most children, complete control is achieved by 3 years of age.

**Neuromediator Control of Bladder Function**

The neuromediators for the ANS play a central role in micturition and maintenance of continence. Parasympathetic innervation of the bladder is mediated by the neurotransmitter acetylcholine. Two types of cholinergic receptors, nicotinic and muscarinic, affect various aspects of micturition. Nicotinic (N) receptors are found in the synapses between the preganglionic and postganglionic neurons of the sympathetic and parasympathetic nervous systems, as well as motor endplates of the striated muscle fibers of the external sphincter and pelvic muscles. Muscarinic (M) receptors are found in the postganglionic parasympathetic endings of the detrusor muscle. Several subtypes of M receptors have been identified. Both M_2_ and M_3_ receptors appear to mediate detrusor muscle activity, with the M_3_ subtype mediating direct activation of detrusor muscle contraction. The M_2_ subtype appears to act indirectly by inhibiting sympathetically mediated detrusor muscle relaxation. The identification of muscarinic receptor subtypes has facilitated the development of medications...
that selectively target bladder structures while minimizing undesired side effects.

Although sympathetic innervation is not essential to the act of micturition, it allows the bladder to store a large volume without the involuntary escape of urine—a mechanism that is consistent with the fight-or-flight function of the sympathetic nervous system. The bladder is supplied with $\alpha_1$- and $\beta_2$-adrenergic receptors. The $\beta_2$-adrenergic receptors are found in the detrusor muscle. They produce relaxation of the detrusor muscle, increasing the bladder volume at which the micturition reflex is triggered. The $\alpha_1$-adrenergic receptors are found in the trigone area, including the intramural ureteral musculature, bladder neck, and internal sphincter. The activation of $\alpha_1$-adrenergic receptors produces contraction of these muscles. Sympathetic activity ceases when the micturition reflex is activated. During male ejaculation, which is mediated by the sympathetic nervous system, the musculature of the trigone area and that of the bladder neck and prostatic urethra contract and prevent the backflow of seminal fluid into the bladder.

Because of their effects on bladder function, drugs that selectively activate or block ANS outflow or receptor activity can alter urine elimination. Table 27-1 describes the action of drug groups that impair bladder function or can be used in the treatment of micturition disorders. For example, many of the nonprescription cold preparations contain $\alpha$-adrenergic agonists and antihistamine agents that have anticholinergic properties. These drugs can cause urinary retention. Many of the antidepressant and antipsychotic drugs also have anticholinergic actions that influence urination.

**Evaluation of Bladder Function**

Bladder function can be assessed by a number of methods. Reports or observations of frequency, hesitancy, straining to urinate, and a weak or interrupted urine
stream are suggestive of outflow obstruction. Palpation and percussion provide information about bladder distention.

Postvoid residual (PVR) urine volume provides information about bladder emptying. It can be estimated by abdominal palpation and percussion. Catheterization and ultrasonography can be used to obtain specific measurements of PVR. A PVR value of less than 50 mL is considered adequate bladder emptying, and more than 200 mL indicates inadequate bladder emptying.

Pelvic examination is used in women to assess peri neal skin condition, perivaginal muscle tone, genital atrophy, pelvic prolapse (e.g., cystocele, rectocele, uterine prolapse), pelvic mass, or other conditions that may impair bladder function (see Chapter 40). Bimanual examination (i.e., pelvic and abdominal palpation) can be used to assess PVR volume. Rectal examination is used to test for perineal sensation, sphincter tone, fecal impaction, and rectal mass. It is used to assess the contour of the prostate in men.

Urine tests provide information about kidney function and urinary tract infections. The presence of bacteriuria or pyuria suggests urinary tract infection and the possibility of urinary tract obstruction. Blood tests (i.e., blood urea nitrogen and creatinine) provide information about renal function.

Bladder structures can be visualized indirectly by taking x-ray films of the abdomen and through excretory urography, which involves the use of a radiopaque dye, computed tomographic (CT) scanning, magnetic resonance imaging (MRI), or ultrasonography. Urodynamic studies are used to evaluate bladder function and voiding problems. Cystoscopy enables direct visualization of the urethra, bladder, and ureteral orifices.

| Table 27-1: Action of Drug Groups on Bladder Function |
|---------------------------------|---------------------------------|---------------------------------|
| **Function**                      | **Drug Groups**                           | **Mechanism of Action**          |
| Detrusor Muscle                   | Increased tone and contraction            | Cholinergic drugs                |
| Inhibition of detrusor muscle     | Relaxation during filling                 | β2-Adrenergic blockers           |
| Decreased tone                   | Anticholinergic drugs and drugs with an  | Calcium channel blockers         |
| Internal Bladder Sphincter        | Increased tone                            | α1-Adrenergic agonists           |
| Decreased tone                   | α1-Adrenergic blockers                    | Block contraction of the smooth   |
| External Sphincter                | Decreased tone                            | muscle of the internal sphincter  |

**SUMMARY CONCEPTS**

- Although the kidneys control the formation of urine, its storage and periodic elimination depend on the coordinated activity of the smooth and striated muscle of the two functional units of the lower urinary tract—the urinary bladder, which serves as a storage reservoir; and the urethra and urethral sphincter, which function as an outlet for urine elimination.

- The bladder is composed of four layers: an outer serosal layer, a smooth muscle layer called the detrusor muscle, a submucosal layer of connective and elastic tissue, and an inner epithelial layer. The detrusor muscle is the muscle of micturition or passage of urine. The inner epithelial layer prevents substances in the urine from moving into the bloodstream and its mucin layer acts as defense against infection.

- Normal bladder function requires interaction between the sensory and motor components of both the autonomic nervous system (ANS), which controls the involuntary smooth muscle activity of the detrusor muscle, and the somatic nervous system, which controls voluntary skeletal muscle activity of the external sphincter. These functions are controlled by three ascending levels of nervous system control: the spinal cord reflex
Disorders of the Bladder and Lower Urinary Tract

Disorders of lower urinary tract structures and function include urinary obstruction with retention or stasis of urine, and urinary incontinence with involuntary loss of urine. Both types of disorders can have their origin in the structures of the lower urinary tract or in the neural mechanisms that control their function.

Lower Urinary Tract Obstruction and Stasis

In lower urinary tract obstruction and stasis, urine is produced normally by the kidneys but is retained in the bladder, a condition that predisposes to vesicoureteral reflux (VUR) and kidney damage. Obstructions can be classified according to their location (bladder neck, urethra, or external urethral meatus), cause (congenital or acquired), degree (partial or complete), and duration (acute or chronic).

The common sites of congenital obstructions are the external meatus (i.e., meatal stenosis) in boys and just inside the external urinary meatus in girls. Another congenital cause of urinary stasis is the damage to sacral nerves that is seen in spina bifida and meningocele (see Chapter 36). The acquired causes of lower urinary tract obstruction and stasis are numerous. In males, the most important cause of urinary obstruction is external compression of the urethra caused by enlargement of the prostate gland. Gonorrhea and other sexually transmitted infections contribute to the incidence of infection-produced urethral strictures. Bladder tumors and secondary invasion of the bladder by tumors arising in structures that surround the bladder and urethra can compress the bladder neck or urethra and cause obstruction. Obstructive disorders in women include conditions related to relaxation of the pelvic support structures, such as cystocele and rectocele. Because of the proximity of the involved structures, severe constipation and fecal impaction can compress the urethra and produce urethral obstruction.

Compensatory and Decompensatory Changes

The body compensates for the obstruction of urine outflow with mechanisms designed to prevent urine retention. These mechanisms can be divided into two stages: a compensatory stage and a decompensatory stage.

The degree to which these changes occur and their effect on bladder structure and urinary function depend on the extent of the obstruction, the rapidity with which it occurs, and the presence of other contributing factors, such as neurologic impairment and infection.

During the early stage of obstruction, the bladder begins to hypertrophy and becomes hypersensitive to afferent stimuli arising from stretch receptors in the bladder wall. The ability to suppress urination is diminished, and the bladder contractions can become so strong that they virtually produce bladder spasms. There is urgency, sometimes to the point of incontinence, and frequency of urination during the day and at night.

With continuation and progression of the obstruction, there is further hypertrophy of the bladder muscle, and the pressure generated by detrusor contraction can increase from a normal 20 to 40 cm H₂O to 50 to 100 cm H₂O to overcome the resistance from the obstruction. As the force needed to expel urine from the bladder increases, compensatory mechanisms may become ineffective, causing muscle fatigue before complete emptying can be accomplished. After a few minutes, voiding can again be initiated and completed, accounting for the frequency of urination.

Normally, the inner bladder surface forms smooth folds. With continued outflow obstruction, this smooth surface is replaced with coarsely woven structures (i.e., hypertrophied smooth muscle fibers) called trabeculae. Small pockets of mucosal tissue, called cellulae, commonly develop between the trabecular ridges. These pockets form diverticula when they extend between the actual fibers of the bladder muscle (Fig. 27-4). Because the diverticula have no muscle, they are unable to contract and expel their urine into the bladder, and secondary infections caused by stasis are common. Along with hypertrophy of the bladder wall, there is hypertrophy of the trigone area and the interureteric ridge, which is located between the two ureters. This causes backpressure on the ureters, the development of hydroureters, and, eventually, kidney damage. Stasis of urine also predisposes to urinary tract infections.

When compensatory mechanisms no longer are effective, signs of decompensation begin to appear. The period of detrusor muscle contraction becomes too short to expel the urine completely, and residual urine remains in the bladder. At this point, the symptoms of obstruction—frequency of urination, hesitancy, need to strain to initiate urination, a weak and small stream, and termination of the stream before the bladder is completely emptied—become pronounced. There may be signs of a complicating urinary tract infection such
as burning on urination and cloudy urine. With progressive decompensation, the bladder may become severely overstretched, with a residual urine volume of 1000 to 3000 mL. At this point, it loses its power of contraction and overflow incontinence occurs.

The immediate treatment of lower urinary tract obstruction and stasis is directed toward relief of bladder distention. This usually is accomplished through urinary catheterization. Long-term treatment is directed toward correcting the problem causing the obstruction.

**Neurogenic Bladder Disorders**

The urinary bladder is unique in that it is probably the only autonomically innervated visceral organ that is under CNS control. The neural control of bladder function can be interrupted at any level. It can be interrupted at the level of the peripheral nerves that innervate the bladder, the sacral cord reflex center, the ascending and descending tracts in the spinal cord, the pontine micturition center, or the cortical centers that are involved in voluntary control of micturition (see Fig. 27-3).

Neurogenic disorders of bladder function commonly are manifested in one of two ways: bladder overactivity with a failure to relax and store urine; or areflexic bladder dysfunction, with a failure to contract and empty. Neurogenic detrusor overactivity usually results from neural lesions located above the level of the sacral micturition reflexes; in contrast, failure to contract (areflexic bladder dysfunction) results from lesions at the level of the sacral micturition center or the peripheral nerves that innervate the bladder. Less commonly, disorders of micturition occur when the neural control of external sphincter function is disrupted. Table 27-2 describes the characteristics of neurogenic bladder according to the level of the lesion.

**Neurogenic Overactive Bladder: Failure to Store Urine**

Neurogenic detrusor overactivity, or spastic bladder, is usually characterized by reflex bladder spasms and a decrease in bladder volume. It commonly is caused by conditions that produce partial or extensive neural damage above the level of the micturition reflex center.

in the sacral cord (see Fig. 27-3). As a result, bladder function is regulated by segmental reflexes, without control from higher brain centers. The degree of bladder spasticity and dysfunction depends on the level and extent of neural dysfunction. Usually, both the ANS neurons controlling bladder function and the somatic neurons controlling the function of the striated muscles in the external sphincter are affected. The most common causes of neurogenic detrusor overactivity are spinal cord lesions such as spinal cord injury, vascular lesions, tumors, or herniated intervertebral disk, and multiple sclerosis.

Bladder Dysfunction Caused by Spinal Cord Injury. Bladder dysfunction is a common problem in persons with spinal cord injury (see Chapter 36). The immediate and early effects of spinal cord injury on bladder function are quite different from those that follow recovery from the initial injury. During the period immediately after spinal cord injury, a state of spinal shock develops in which all reflexes, including the micturition reflex, are depressed. During this stage, the bladder becomes atonic and cannot contract. Catheterization is necessary to prevent injury to urinary structures associated with overdistention of the bladder. Depression of reflexes lasts from a few weeks to 6 months (usually 2 to 3 months), after which the spinal reflexes return and become hyperactive.

After the acute stage of spinal cord injury, the micturition response changes to a segmental reflex. Because the sacral reflex arc remains intact, stimuli generated by bladder stretch receptors during filling produce frequent spontaneous contractions of the detrusor muscle. This creates a small, hyperactive bladder subject to high-pressure and short-duration uninhibited bladder contractions. Voiding is interrupted, involuntary, or incomplete. Dilation of the internal sphincter and spasticity of the external sphincter and perineal muscles occurs, producing resistance to bladder emptying. Overdistention of the bladder with hypertrophy of the trigone area develops, often leading to vesicoureteral reflux and risk for renal damage.

Overactive bladder due to spinal cord injuries at the cervical level is often accompanied by a condition known as autonomic hyperreflexia (see Chapter 36). Because the injury interrupts CNS control of sympathetic reflexes in the spinal cord, severe hypertension, bradycardia, and sweating can be triggered by even mild overdistention of the bladder or by insertion of a catheter.

Uninhibited Neurogenic Bladder. A mild form of reflex neurogenic bladder, sometimes called uninhibited bladder, can develop after a stroke, during the early stages of multiple sclerosis, or as a result of lesions located in the inhibitory centers of the cortex or associated structures. With this type of disorder, sacral reflex motor function and sensation are retained, the urine stream is normal, and there is no residual urine. There usually is reduced awareness of bladder fullness and a low bladder capacity due to reduced inhibition by the pontine micturition center or cortical centers.

Detrusor-Sphincter Dyssynergia. Lesions that affect the micturition center in the pons or impaire communication between the micturition center and spinal cord centers interrupt the coordinated activity of the detrusor muscle and the external sphincter. This is called detrusor–sphincter dyssynergia. Instead of relaxing during micturition, the external sphincter becomes more constricted. This condition can lead to elevated intravesical pressures, vesicoureteral reflux, and kidney damage.

Neurogenic Areflexic Bladder: Failure to Empty Urine

Detrusor muscle areflexia, or flaccid neurogenic bladder, occurs when there is injury to nerves in the micturition center of the sacral cord, the cauda equina, or peripheral nerves that supply the bladder. Atony of the detrusor muscle and loss of the perception of bladder fullness permit overstretching of the detrusor muscle; which in turn, leads to weak and ineffective bladder contractions. External sphincter tone and perineal muscle tone are diminished. Voluntary urination does not occur, but fairly efficient emptying usually can be achieved by increasing the intra-abdominal pressure or applying manual suprapubic pressure. Among the causes of areflexic neurogenic bladder are trauma, tumors, and congenital anomalies (e.g., spina bifida, meningomyelocele).

Bladder Dysfunction Caused by Peripheral Neuropathies. Disorders of the peripheral (pelvic, pudendal, and hypogastric) nerves that supply the muscles of micturition can selectively interrupt sensory or motor pathways for the bladder or involve both pathways.

Bladder atony with dysfunction is a frequent complication of diabetes mellitus. The disorder initially affects the sensory nerves of the bladder without involvement of the pudendal nerve. This leads to large residual volumes after micturition, sometimes complicated by infection. There frequently is a need for straining, accompanied by hesitancy, weakness of the urinary stream, dribbling, and a sensation of incomplete bladder emptying. The most common complications are vesicoureteral reflux and ascending urinary tract infection. Because persons with diabetes are already at risk for development of kidney disease, urinary stasis and reflux can have serious effects on renal function.

Nonrelaxing External Sphincter

Another condition that affects micturition and bladder function is the nonrelaxing external sphincter. This condition usually is related to a delay in maturation, developmental regression, psychomotor disorders, or locally irritative lesions. Inadequate relaxation of the external sphincter can also result from anxiety or depression. Any local irritation, including vaginitis or perineal irritation, can produce spasm of the sphincter through afferent sensory input from the pudendal nerve. In men, chronic prostatitis contributes to impaired relaxation of the external sphincter.
**Treatment**

The goals of treatment for neurogenic bladder disorders focus on preventing bladder overdistention, urinary tract infections, and potentially life-threatening kidney damage. The methods used in treatment are individualized based on the type of neurologic lesion that is involved; information obtained through the health history, including fluid intake; report or observation of voiding patterns; presence of other health problems; urodynamic studies when indicated; and the ability of the person to participate in the treatment. Treatment methods include catheterization, bladder training, pharmacologic manipulation of bladder function, and surgery.

Catheterization involves the insertion of a small-diameter latex or silicone tube into the bladder through the urethra. The catheter may be inserted on a one-time basis to relieve temporary bladder distention, left indwelling (i.e., retention catheter), or inserted intermittently. The methods used for bladder retraining depend on the type of lesion causing the disorder. Methods used to supplement bladder retraining include monitoring fluid intake to control urine volume and osmolality and prevent urinary tract infections, developing scheduled times for urination, and using body positions that facilitate micturition.

Pharmacologic manipulation includes the use of drugs to alter the contractile properties of the bladder, decrease the outflow resistance of the internal sphincter, and relax the external sphincter. Antimuscarinic drugs decrease detrusor muscle tone and increase bladder capacity in persons with spastic bladder dysfunction.7 Cholinergic drugs that stimulate parasympathetic receptors provide increased bladder tone and may prove helpful in the symptomatic treatment of milder forms of flaccid neurogenic bladder. Muscle relaxants may be used to decrease the tone of the external sphincter. Intravesical injection of medications such as capsaicin and resiniferatoxin, which are specific C-fiber afferent neurotoxins, may be used to decrease bladder hyperactivity. Botulinum toxin type A injections may be used to produce paralysis of the striated muscles of the external sphincter in persons with neurogenic overactive bladder.

The effects of the injection last about 6 months, after which the injection must be repeated.12

Among the surgical procedures used in the management of neurogenic bladder are sphincterectomy, reconstruction of the sphincter, and resection of the sacral reflex nerves that cause detrusor overactivity or the pudendal nerve that controls the external sphincter.12 Extensive research is being conducted on methods of restoring voluntary control of the storage and evacuation functions of the bladder through the use of implanted electrodes.

**Urinary Incontinence**

Urinary incontinence represents the involuntary loss of urine. It can occur without the person’s knowledge; at other times, the person may be aware of the condition but be unable to prevent it. A number of conditions can lead to incontinence, which is a common problem, particularly in older adults.8,16–19

**Types and Causes of Incontinence**

Urinary incontinence is commonly divided into three main types: stress incontinence, urge incontinence, and mixed incontinence, which is a combination of stress incontinence and urge incontinence. Other types of incontinence include overflow incontinence, which is a term used to describe leakage of urine associated with urinary retention, and nocturnal enuresis, which is the involuntary loss of urine during sleep. Post-micturition dribble and continuous urinary leakage are other forms of incontinence.17–20

**Stress Incontinence.** Stress incontinence represents the involuntary loss of urine that occurs when, in the absence of detrusor muscle action, the intravesical pressure exceeds the maximum urethral closure pressure.21–24 Among the proposed causes of stress incontinence are changes in the anatomic relationship between the bladder and the urethra, so that increases in intra-abdominal pressure are unevenly distributed to the urethra.8,19

Stress incontinence, which is a common problem in women of all ages, occurs as the result of weakness or disruption of pelvic floor muscles leading to poor support of the vesicourethral sphincters. Except during the act of micturition, intraurethral pressure is normally greater than intravesical pressure. The pressure difference between the urethra and bladder is known as the *urethral closure pressure*. If intra-abdominal pressure increases as it does during actions such as coughing, laughing, or sneezing, and if this pressure is not equally transmitted to the urethra, then incontinence occurs. Diminution of muscle tone associated with normal aging, childbirth, or surgical procedures can cause weakness of the pelvic floor muscles and decrease the urethral closure pressure, resulting in stress incontinence by changing the relationship between the bladder base and the posterior urethral junction.

Another cause of stress incontinence is intrinsic urethral deficiency, which may result from congenital sphincter weakness, as occurs with meningomyelocele. It also may be acquired as a result of trauma, irradiation, or sacral cord lesions. Stress incontinence in men may result from trauma or surgery to the bladder outlet, as occurs with prostatectomy.19,24 Neurologic dysfunction, as occurs with impaired sympathetic innervation of the bladder neck, impaired pelvic nerve innervation to the intrinsic sphincter, or impaired pudendal nerve innervation to the external sphincter, may also be a contributing factor.

**Urge Incontinence.** Urge incontinence is the involuntary loss of urine associated with a strong desire to void (urgency).8,19 It is often associated with overactive bladder, which the International Continence Society defines as “urinary urgency, usually accompanied by frequency and nocturia, with or without urinary incontinence, in
the absence of urinary tract infection or other obvious pathology.25

The symptoms of urge incontinence, which are caused by involuntary bladder contractions during filling, may occur alone or in any combination. They constitute overactive bladder when they occur in the absence of other pathologic processes.8,19,26–28 Regardless of the primary cause of overactive bladder, two types of mechanisms are thought to contribute to its symptomatology: those involving CNS and neural control of bladder sensation and emptying (neurogenic) and those involving the smooth muscle of the bladder itself (myogenic).8,26,27

The neurogenic theory for overactive bladder proposes that the CNS functions as an on–off switching circuit for voluntary control of bladder function. Neurogenic causes of overactive bladder include stroke, Parkinson disease, and multiple sclerosis. Other neurogenic causes of overactive bladder include increased sensitization of the afferent nerves that sense bladder filling or increased excitability to efferent nerves that produce bladder emptying.

The myogenic causes of overactive bladder are thought to result from changes in the properties of the smooth muscle of the bladder itself. Bladder outlet obstruction can prompt such changes. It is hypothesized that the sustained increase in intravesical pressure that occurs with the outlet obstruction causes a partial destruction of the nerve endings that control bladder excitability.7 This partial denervation produces hyperexcitability of the detrusor muscle, causing urgency and frequency of urination due to spontaneous bladder contractions. Disorders of detrusor muscle structure and excitability also can occur as the result of the aging process or disease conditions such as diabetes mellitus.Incomplete bladder emptying, a common companion of overactive bladder, often exacerbates symptoms.

**Overflow Incontinence.** Overflow incontinence is an involuntary loss of urine that occurs when intravesical pressure exceeds the maximal urethral pressure because of bladder distention in the absence of detrusor activity.8 It can occur with retention of urine owing to nervous system lesions or obstruction of the bladder neck or urethral stricture. Outflow obstruction may occur secondary to cystocele, uterine prolapse, or previous incontinence surgery in women. In men, one of the most common causes of obstructive incontinence is enlargement of the prostate gland. Person with this type of incontinence may experience dribbling, weak urinary stream, hesitancy, frequency, and nocturia.

**Other Causes of Incontinence.** Other causes of incontinence include decreased bladder compliance or distensibility. This abnormal bladder condition may result from radiation therapy, radical pelvic surgery, or interstitial cystitis. Many persons with this disorder have severe urgency related to bladder hypersensitivity that results in loss of bladder elasticity, such that any small increase in bladder volume or detrusor function causes a sharp rise in bladder pressure and severe urgency.

Incontinence may occur as a transient and correctable phenomenon, or it may not be totally correctable and may occur with various degrees of frequency. Incontinence may also present as nocturnal enuresis with involuntary loss of urine during sleep, as post-micturition dribble, or continuous urinary leakage.25 Among the transient causes of urinary incontinence are recurrent urinary tract infections; medications that alter bladder function or perception of bladder filling and the need to urinate; diuretics and conditions that increase bladder filling; restricted mobility; and a state of confusion. Night sedation may cause someone to sleep through the signal that normally would awaken them so they could get up and empty their bladder and avoid wetting the bed. Incontinence also may be caused by factors outside the lower urinary tract, such as the inability to locate, reach, or receive assistance in reaching an appropriate place to void.

**Diagnosis and Treatment**

Urinary incontinence is not a single disease but a symptom with many possible causes. As a symptom, it requires full investigation to establish its cause.20–24,27 This usually is accomplished through a careful history, physical examination, blood tests, and urinalysis. A voiding record (i.e., diary) may be used to determine the frequency, timing, and amount of voiding, as well as other factors associated with the incontinence. Because many drugs affect bladder function, a full drug history is essential. Estimation of the PVR volume is recommended for all persons with incontinence.

Treatment or management depends on the type of incontinence, accompanying health problems, and the person’s age. It includes behavioral methods; exercises to strengthen the pelvic floor muscles; pharmacologic measures; surgical interventions; and, when urine flow cannot be controlled, noncatheter devices to obstruct urine flow or collect urine as it is passed.28,29 Indwelling catheters, although a solution to the problem of urinary incontinence, usually are considered only after all other treatment methods have failed. In some types of incontinence, such as that associated with spinal cord injury or meningomyelocele, self-catheterization may provide the best means for controlling urine elimination (see Chapter 36).

Behavioral methods include fluid management, timed/prompted voiding, bladder retraining, and toileting assistance. Bladder retraining and biofeedback techniques seek to reestablish cortical control over bladder function by having the person ignore urgency and respond only to cortical signals during waking hours. Exercises of the pelvic muscles or Kegel exercises involve repetitive contraction and relaxation of the pelvic floor muscles and are an essential component of patient-dependent behavioral interventions.19

Pharmacologic treatment is aimed at using drugs to alter the physiologic mechanisms that contribute to the neurogenic or myogenic causes of incontinence.
persons, both male and female. Urinary incontinence is a common problem in elderly muscle instability.

Surgical intervention may be considered when other treatment methods have proved ineffective. The principal objective of surgical treatment of stress incontinence is to increase outlet resistance through restoration of the proper suspension and support of the vesicourethral segment of the urethra. A minimally invasive procedure for the treatment of stress incontinence due to internal sphincter weakness is the periurethral injection of a bulking agent. Surgically implanted artificial sphincters are available for use in treatment of incontinence due to severe sphincter damage. Other procedures remove outflow obstruction to reduce overflow incontinence and detrusor muscle instability.

Special Needs of Elderly Persons

Urinary incontinence is a common problem in elderly persons, both male and female. Incontinence increases social isolation, frequently leads to institutionalization, and predisposes to infections and skin breakdown. Many factors contribute to incontinence in elderly persons, including a reduction in bladder capacity and urethral closing pressure. Detrusor muscle function also tends to change with aging. There is often a reduction in the strength of bladder contraction and impairment in emptying that leads to larger PVR volumes. Detrusor overactivity is also common. It is characterized by symptoms of immediate urinary urgency and frequency and, in the case of involuntary urinary loss, urge incontinence. In men, benign prostatic hyperplasia may lead to outlet obstruction and overflow incontinence. Men may also develop stress incontinence following radical prostatectomy for treatment of prostate cancer or transurethral resection for treatment of benign prostatic hyperplasia. In each of these cases, bladder pressure exceeds the closure pressure at the urethral outlet, leading to urine leakage.

Furthermore, advancing age often results in restricted mobility, comorbid illness, infection, and constipation or stool impaction, all of which can precipitate urinary incontinence. Many elderly persons have difficulty getting to the toilet in time. This can be caused by arthritis that makes walking or removing clothing difficult or by failing vision that makes trips to the bathroom precarious, especially in new and unfamiliar surroundings. Impaired thirst or limited access to fluids can lead to constipation, in which the impacted stool produces urethral obstruction, causing overflow incontinence.

Medications prescribed for other health problems may also contribute to incontinence. Potent, fast-acting diuretics are known for their ability to cause urge incontinence. Diuretics, particularly in elderly persons, increase the flow of urine and may contribute to incontinence, particularly in persons with diminished bladder capacity and in those who have difficulty reaching the toilet in time. Drugs such as hypnotics, tranquilizers, and sedatives can interfere with the conscious inhibition of voiding, leading to urge incontinence.

Many nonurologic conditions predispose the elderly to urinary incontinence. The transient and often treatable causes of urinary incontinence may best be remembered with the acronym DIAPPERS, in which the D stands for dementia/dementias, I for infection (urinary or vaginal), A for atrophic vaginitis, P for pharmaceutical agents, P for psychological causes, E for endocrine conditions (diabetes), R for restricted mobility, and S for stool impaction. These eight transient causes of incontinence should be identified and treated before other treatment options are considered.

As with urinary incontinence in younger persons, incontinence in elderly persons requires a thorough history and physical examination to determine the cause of the problem. A voiding history is important. A voiding diary provides a means for the person to provide objective information about the number of bathroom visits, the number of protective pads used, and even the volume of urine voided. A medication history is also important because, as just noted, medications can affect bladder function.

Treatment of incontinence in the elderly usually starts with conservation measures before considering the use of medications or surgery. Conservative treatment may involve changes in the physical environment so that the person can reach the bathroom more easily or remove clothing more quickly. Habit training with regularly scheduled toileting—usually every 2 to 4 hours—often is effective. The treatment plan may require dietary changes to prevent constipation or a plan to promote adequate fluid intake to ensure adequate bladder filling and prevent urinary stasis and symptomatic urinary tract infections.

SUMMARY CONCEPTS

- Disorders of bladder structure and function include urinary obstruction with retention or stasis of urine, and urinary incontinence with involuntary loss of urine. Both types of disorders can have their origin in the structures of the lower urinary tract or in the neural mechanisms that control their function.

- In lower urinary tract obstructive disorders, urine is produced normally by the kidneys but is retained in the bladder, a condition that predisposes to kidney damage. Obstructions can be classified according to their location (bladder neck, urethra, or external urethral meatus), cause (congenital or acquired), degree (partial or complete), and duration (acute or chronic).
Neurogenic disorders of the bladder commonly are manifested by a neurogenic overactive or spastic bladder dysfunction, in which there is failure to store urine, or an aflexic or flaccid bladder dysfunction, in which bladder emptying is impaired. Neurogenic overactive bladder dysfunction results from neural lesions above the level of the sacral cord that allow neurons in the micturition center to function reflexively without control from higher central nervous system centers; in contrast, areflexic bladder dysfunction results from neural disorders affecting the motor neurons in the sacral cord or peripheral nerves that control detrusor muscle contraction and bladder emptying.

Incontinence represents the involuntary loss of urine. Stress incontinence is caused by the decreased ability of the vesicourethral sphincter to prevent the escape of urine during activities, such as lifting and coughing, that raise bladder pressure above the external sphincter pressure. Urge or overactive bladder incontinence is caused by disorders that result in hyperactive bladder contractions. Overflow incontinence is caused by overfilling of the bladder with escape of urine.

Urinary Tract Infections

Urinary tract infections (UTIs) include several distinct entities—asymptomatic bacteriuria, symptomatic lower UTIs such as cystitis, and upper UTIs such as pyelonephritis. Because of their ability to cause renal damage, upper UTIs are considered more serious than lower UTIs. Acute pyelonephritis (discussed in Chapter 25) represents an infection of the renal parenchyma and renal pelvis. The discussion in this chapter focuses on lower urinary tract infections.

Etiologic Factors

Most uncomplicated lower UTIs are caused by Escherichia coli. Other common uropathic pathogens include Enterococcus faecalis, Staphylococcus saprophyticus, Klebsiella pneumoniae, Proteus mirabilis, and Pseudomonas species. Most upper and lower UTIs are caused by bacteria that enter through the urethra. Although the distal portion of the urethra often contains pathogens, the urine formed in the kidneys and found in the bladder normally is sterile or free of bacteria. This is because of the washout phenomenon, in which urine from the bladder normally washes bacteria out of the urethra during urination.

Pathogen Virulence. Pathogen virulence derives from its ability to gain access to and thrive in the environment

There is an increased risk for UTIs in persons with urinary obstruction and reflux, in people with neurogenic disorders that impair bladder emptying, in women who are sexually active, in postmenopausal women, in men with diseases of the prostate, and in elderly persons. Instrumentation and urinary catheterization are the most common predisposing factors for nosocomial, or hospital-acquired, UTIs. Urinary tract infections occur more commonly in women with diabetes than in women without the disease. People with diabetes are also at increased risk for complications associated with UTIs, including pyelonephritis, and they are more susceptible to fungal infections (particularly Candida species) and infections with gram-negative pathogens other than E. coli, both of which are accompanied by increased severity and unusual manifestations.

Host–Agent Interactions

Because certain people tend to be predisposed to development of UTIs, considerable interest has been focused on host–pathogen interactions and factors that increase the risk for UTI.

Host Defenses. In the development of a UTI, host defenses are matched against the virulence of the pathogen. The host defenses of the bladder have several components, including the washout phenomenon, in which bacteria are removed from the bladder and urethra during urination; the protective mucin layer that lines the bladder and protects against bacterial invasion; and local immune responses. Immune mechanisms, particularly secretory immunoglobulin (Ig) A, appear to provide an important antibacterial defense. Phagocytic blood cells further assist in the removal of bacteria from the urinary tract.

There has been a growing appreciation of the protective function of the bladder’s mucin layer. It is thought that the epithelial cells that line the bladder produce protective substances that subsequently become incorporated into the mucin layer that adheres to the bladder wall. One theory proposes that the mucin layer acts by binding water, which then constitutes a protective barrier between the bacteria and the bladder epithelium. Elderly and postmenopausal women produce less mucin than younger women, suggesting that estrogen may play a role in mucin production in women.

Other important host factors include the normal flora of the periurethral area in women and prostate secretions in men. In women, the normal flora of the periurethral area, which consists of organisms such as Lactobacillus, provides a defense against the colonization of uropathic bacteria. Alterations in the periurethral environment, such as occurs with a decrease in estrogen levels during menopause or the use of antibiotics, can alter the protective periurethral flora, allowing uropathogens to colonize and enter the urinary tract. In men, the prostatic fluid has antimicrobial properties that protect the urethra from colonization.
of the urinary tract, to evade the destructive effects of the host’s immune system, and to develop resistance to antimicrobial agents. Not all bacteria are capable of adhering to and infecting the urinary tract. Of the many strains of *E. coli*, only those with increased ability to adhere to the epithelial cells of the urinary tract are able to produce UTIs. These bacteria have fine protein filaments, called *pili* or *fimbriae*, that help them adhere to receptors on the lining of urinary tract structures.

**Obstruction and Reflux**

Obstruction and reflux are other factors that increase the risk for UTIs. Any microorganisms that enter the bladder normally are washed out during voiding. When outflow is obstructed, urine remains in the bladder and acts as a medium for microbial growth; the microorganisms in the contaminated urine can then ascend along the ureters to infect the kidneys. The presence of residual urine correlates closely with bacteriuria and with its recurrence after treatment. Another aspect of bladder outflow obstruction and bladder distention is increased intravesical pressure, which compresses blood vessels in the bladder wall, leading to a decrease in the mucosal defenses of the bladder.

In UTIs associated with stasis of urine flow, the obstruction may be anatomic or functional. Anatomic obstructions include urinary tract stones, prostatic hyperplasia, pregnancy, and malformations of the ureterovesical junction. Functional obstructions include neurogenic bladder, infrequent voiding, detrusor (bladder) muscle instability, and constipation.

A phenomenon called *urethrovvesical reflux* occurs when urine from the urethra moves into the bladder. In women, urethrovvesical reflux can occur during activities such as coughing or squatting, in which an increase in intra-abdominal pressure causes the urine to be squeezed into the urethra and then to flow back into the bladder as the pressure decreases. This also can happen when voiding is abruptly interrupted. Because the urethral orifice frequently is contaminated with bacteria, the reflux mechanism may cause bacteria to be drawn back into the bladder. The *vesicoureteral reflux*, which occurs at the level of the bladder and ureter, allows urine and bacteria to ascend from the bladder to the kidney and is associated with pyelonephritis and infections of the upper urinary tract. (see Chapter 25, Fig. 25-11).

**Catheter-Induced Infection**

Urinary catheters are a source of urethral irritation and provide a means for entry of microorganisms into the urinary tract. Catheter-associated bacteriuria remains the most frequent cause of gram-negative sepsisemia in hospitalized patients. Studies have shown that bacteria adhere to the surface of the catheter and initiate the growth of a biofilm that then covers the surface of the catheter (see Chapter 14, Fig. 14-6). The biofilm tends to protect the bacteria from the action of antibiotics and makes treatment difficult. A closed drainage system (i.e., closed to air and other sources of contamination) and careful attention to perineal hygiene (i.e., cleaning the area around the urethral meatus) help to prevent infections in persons who require an indwelling catheter. Careful hand-washing and early detection and treatment of UTIs also are essential.

**Clinical Features**

The manifestations of UTI depend on whether the infection involves the lower (bladder) or upper (kidney) urinary tract and whether the infection is acute or chronic. An acute episode of cystitis (bladder infection) is characterized by frequency of urination, lower abdominal or back discomfort, and burning and pain on urination (i.e., dysuria). Occasionally, the urine is cloudy and foul smelling. In adults, fever and other signs of infection usually are absent. If there are no complications, the symptoms disappear within 48 hours of treatment. The symptoms of cystitis also may represent urethritis caused by *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, or herpes simplex virus, or vaginitis attributable to *Trichomonas vaginalis* or *Candida* species (see Chapter 41).

**Diagnosis and Treatment**

The diagnosis of UTI usually is based on symptoms and on examination of the urine for the presence of microorganisms. When necessary, x-ray films, ultrasonography, and CT and renal scans are used to identify contributing factors, such as obstruction.

Urine tests are used to establish the presence of bacteria in the urine and a diagnosis of UTI. A commonly accepted criterion for diagnosis of a UTI is the presence of 100,000 colony-forming units (CFU) or more bacteria per milliliter (mL) of urine. Colonization usually is defined as the multiplication of microorganisms in or on a host without apparent evidence of invasiveness or tissue injury. Pyuria (the presence of less than five to eight leukocytes per high-power field) indicates a host response to infection rather than asymptomatic bacterial colonization. A Gram stain may be done to determine the type (gram positive or gram negative) of organism that is present.

Chemical screening (urine dipstick) for markers of infection may provide useful information but is less sensitive than microscopic analysis. These tests are relatively inexpensive, are easy to perform, and can be done in the clinic setting or even in the home. A urine culture may be done to confirm the presence of pathogenic bacteria in urine specimens, allow for their identification, and permit the determination of their sensitivity to specific antibiotics.

The treatment of UTI is based on the pathogen causing the infection and the presence of contributing host-agent factors. Other considerations include whether the infection is acute, recurrent, or chronic. Most acute lower UTIs, which occur mainly in women and are generally caused by *E. coli*, are treated successfully with a short course of antimicrobial therapy. Forcing fluids
may relieve signs and symptoms, and this approach is used as an adjunct to antimicrobial treatment.

Recurrent lower UTIs are those that recur after treatment. They are due either to bacterial persistence or reinfection. Bacterial persistence usually is curable by removal of the infectious source (e.g., urinary catheter or infected bladder stones). Reinfection is managed principally through education regarding pathogen transmission and prevention measures. Cranberry juice or blueberry juice has been suggested as a preventive measure for persons with frequent UTIs. Studies suggest that these juices reduce bacterial adherence to the epithelial lining of the urinary tract. Because of their mechanism of action, these juices are used more appropriately in prevention rather than treatment of an established UTI.

Chronic UTIs are more difficult to treat. Because they often are associated with obstructive uropathy or reflux flow of urine, diagnostic tests usually are performed to detect such abnormalities. When possible, the condition causing the reflux flow or obstruction is corrected. Most persons with recurrent UTIs are treated with antimicrobial agents for longer periods of time in doses sufficient to maintain high urine levels of the drug, and they are examined for obstruction or other causes of infection. Men in particular should be investigated for obstructive disorders or a prostatic focus of infection.

Infections in Special Populations

Urinary tract infections affect persons of all ages. In infants, they occur more often in boys than in girls. After the first year of life UTIs occur more often in girls. Urinary tract infections are more common in women than men, specifically between 16 and 35 years of age, at which time women are 40 times more likely to develop a UTI than age-matched men. This is because of the shorter length of the female urethra and because the vaginal vestibule can be easily contaminated with fecal flora. In men, the longer length of the urethra and the antibacterial properties of the prostatic fluid provide some protection from ascending UTIs until approximately 60 years of age. After this age, prostatic hyperplasia becomes more common, and with it may come obstruction and increased risk for UTI (see Chapter 39).

Urinary Tract Infections in Non-pregnant Women

Approximately half of all adult women have at least one UTI during their lifetime. The anterior urethra usually is colonized with bacteria; urethral massage or sexual intercourse can force these bacteria back into the bladder. Using a diaphragm and spermicide enhances the susceptibility to infection. A nonpharmacologic approach to the treatment of frequent UTIs associated with sexual intercourse is to increase fluid intake before intercourse and to void soon after intercourse. This procedure uses the washout phenomenon to remove bacteria from the bladder.

Urinary Tract Infections in Pregnant Women

Pregnant women are at increased risk for UTIs. Normal changes in the functioning of the urinary tract that occur during pregnancy predispose pregnant women to UTIs. These changes involve the collecting system of the kidneys and include dilation of the renal pelvises, veses, and ureters that begins during the first trimester and becomes more pronounced during the third trimester. Dilation of the upper urinary system is accompanied by a reduction in the peristaltic activity of the ureters that is thought to result from the muscle-relaxing effects of progesterone-like hormones and mechanical obstruction from the enlarging uterus. In addition to the changes in the kidneys and ureters, the bladder becomes displaced from its pelvic position to a more abdominopelvic position, producing further changes in ureteral position.

The complications of asymptomatic UTIs during pregnancy include persistent bacteriuria, acute and chronic pyelonephritis, and preterm delivery of infants with low birth weight. Evidence suggests that few women become bacteriuric during pregnancy. Rather, it appears that symptomatic UTIs during pregnancy reflect preexisting asymptomatic bacteriuria and that changes occurring during pregnancy simply permit the prior urinary colonization to progress to symptomatic infection and invasion of the kidneys. Because bacteriuria may occur as an asymptomatic condition in pregnant women, it is recommended that a urine culture be obtained at the time of their first prenatal visit. A repeat culture should be obtained during the third trimester. Women with bacteriuria should be followed closely, and infections should be properly treated to prevent complications. The choice of antimicrobial agent should address the common infecting organisms and should be safe for both the mother and fetus.

Urinary Tract Infections in Children

Acute urinary tract infection is considered to be the most common serious bacterial infection in childhood, affecting as many as 8% of girls and 2% of boys during the first 7 to 8 years of life. In girls, the average age at first diagnosis is 5 years or younger, with peaks during infancy and toilet training. In boys, most UTIs occur during the first year of life and are more common in uncircumcised than in circumcised boys.

Vesicoureteral reflux (VUR), a common childhood disorder, is believed to predispose to UTI, with both VUR and UTI being associated with renal scarring and permanent kidney damage. Most UTIs that lead to scarring and diminished kidney growth occur in children younger than 4 years, especially infants younger than 1 year of age. The incidence of renal scarring is greatest in children with gross VUR or obstruction, in children with recurrent UTIs, and in those with a delay in treatment.

Childhood UTIs usually are ascending, with inoculation of feces from the urethra and periurethral...
tissues into the bladder. The most common pathogen is *Escherichia coli*, followed by *Klebsiella* and *Proteus* species. In uncircumcised boys, the bacterial pathogens arise from the flora beneath the prepuce. In girls, UTIs often occur at the onset of toilet training because of urination dysfunction that occurs at that age. The child is trying to retain urine to stay dry, yet the bladder may produce uninhibited contractions, forcing urine out. The result may be high-pressure, turbulent urine flow or incomplete bladder emptying, both of which predispose to bacteriuria. Similar problems can occur in school-age children who refuse to use the school bathroom. Constipation may increase the risk of UTI recurrence in children with VUR by compressing the bladder and bladder neck, resulting in increased bladder storage pressure and incomplete bladder emptying.

Unlike adults, children frequently do not present with the typical signs of a UTI. Many neonates with UTIs have bacteremia and may show signs and symptoms of septicemia, including fever, hypothermia, apneic spells, poor skin perfusion, abdominal distention, diarrhea, vomiting, lethargy, and irritability. Older infants may present with feeding problems, failure to thrive, diarrhea, vomiting, fever, and foul-smelling urine. Toddlers often present with abdominal pain, vomiting, diarrhea, abnormal voiding patterns, foul-smelling urine, fever, and poor growth. In older children with lower UTIs, the classic features—enuresis, frequency, dysuria, and suprapubic discomfort—are more common. Fever is a common sign of UTI in children, and the possibility of UTI should be considered in any child with unexplained fever.

Diagnosis is based on a careful history of voiding patterns and symptomatology; physical examination to determine fever, hypertension, abdominal or suprapubic tenderness, and other manifestations of UTI; and urinalysis to determine bacteriuria, pyuria, proteinuria, and hematuria. A positive urine culture that is obtained corroborates the diagnosis. Additional diagnostic methods may be needed to determine the cause of the disorder. Children with a relatively uncomplicated first UTI may turn out to have significant reflux. Therefore, even a single documented UTI in a child requires careful follow-up. Urinary symptoms in the absence of bacteriuria suggest vaginitis, urethritis, sexual molestation, the use of irritating bubble baths, pinworms, or viral cystitis. In adolescent girls, a history of dysuria, and vaginal discharge make vaginitis or vulvitis a consideration.

The approach to treatment is based on the clinical severity of the infection, the site of infection (i.e., lower versus upper urinary tract), the risk for sepsis, and the presence of structural abnormalities. The immediate treatment of infants and young children is essential. Most infants with symptomatic UTIs and many children with clinical evidence of acute upper UTIs require hospitalization, rehydration, and intravenous antibiotic therapy. Follow-up is essential for children with febrile UTIs to ensure resolution of the infection. Follow-up urine cultures often are done at the end of treatment. Imaging studies often are recommended for children after their first UTI to detect renal scarring, vesicoureteral reflux, or other abnormalities.

### Urinary Tract Infections in the Elderly

Urinary tract infections are relatively common in elderly persons. They are the second most common form of infection, after respiratory tract infections, among otherwise healthy community-dwelling elderly. They are particularly prevalent in elderly persons living in nursing homes or extended care facilities.

Most of these infections follow invasion of the urinary tract by the ascending route. Several factors predispose elderly persons to UTIs, including underlying genitourinary abnormalities, immobility resulting in poor bladder emptying, diminished bactericidal properties of the urine, and constipation. Prostatic hyperplasia with bladder outlet obstruction is the most important contributing factor in older men, while alteration in the bacterial flora of the vagina is the most important contributing factor in older women. Added to these risks are other health problems that necessitate catheterization or instrumentation of the urinary tract.

Elderly persons with bacteriuria have varying symptoms, ranging from the absence of symptoms to the presence of typical UTI symptoms. Even when symptoms of lower UTIs are present, they may be difficult to interpret because elderly persons without UTIs commonly experience urgency, frequency, and incontinence. Alternatively, elderly persons may have vague symptoms such as anorexia, fatigue, weakness, or change in mental status. Even with more serious upper UTIs (e.g., pyelonephritis), the classic signs of infection such as fever, chills, flank pain, and tenderness may be altered or absent. Sometimes, no symptoms occur until the infection is far advanced.

### Intermittent Cystitis/Painful Bladder Syndrome

Intermittent cystitis or painful bladder syndrome is a chronic, often debilitating, condition that is characterized by urinary frequency, urgency, and severe suprapubic pain. Unlike bladder inflammation caused by a bacterial infection, the condition occurs in the absence of other pathology. Although previously reported to be a disorder of middle-aged women, it is now known that the condition affects both men and women of all ages.

Although the pathophysiology of intermittent cystitis/painful bladder syndrome is incompletely understood, it is thought to involve permeability changes of the urothelium, along with mast cell activation and neurogenic inflammation. Damage to the protective mucosal lining leads to impaired urothelial cell-barrier function, allowing urinary solutes to penetrate the epithelium and activate sensory nerve endings, leading to pain and inflammation.

At present there are no definitive diagnostic tests for intermittent cystitis/painful bladder syndrome. Diagnostic steps involve ruling out other diseases and overlapping syndromes. Although not universally accepted, the potassium sensitivity test is widely used to aid in the diagnosis. The test involves the instillation of a
Cancer of the Bladder

Cancer of the bladder is the sixth most common malignancy in the United States, accounting for 7% of cancers in men and 3% of cancers in women. For some as-yet unexplained reason, African Americans have only half the risk of white European Americans. Most cancer of the bladder occur in older persons and is rare in those under the age of 50 years.

Approximately 90% to 95% of bladder cancers are derived from the transitional epithelial (urothelial) cells that line the bladder. These tumors can range from benign papillomas and low-grade papillary urothelial carcinomas to invasive urothelial cell carcinomas and highly malignant tumors.

Urothelial papillomas are rare benign tumors, of which there are two forms: exophytic papillomas and inverted papillomas. Exophytic papillomas have fonts or finger-like papillae with a central core of loose fibrovascular tissue covered by epithelium. Although considered benign some exophytic papillomas may recur or progress to carcinoma, thus long-term follow-up is necessary after excision. Inverted papillomas are benign nodular lesions that are cured by excision.

Papillary urothelial neoplasms of low malignant potential share many histologic features with papillomas; however, they have a thicker urothelium and diffuse nuclear enlargement (Fig. 27-5). They may recur after excision and only rarely recur as higher grade tumors associated with invasion and progression. Low-grade papillary urothelial carcinomas have fonts

![FIGURE 27-5. Urothelial neoplasms. Most tumors are located on the posterior and lateral walls; trigone and bladder neck are involved less commonly. Malignant tumors may be papillary or flat. Both flat and papillary tumors may be invasive or noninvasive. Benign transitional cell papillomas are rare. (Adapted from Damjanov I, McCure PA. The lower urinary tract and male reproductive system. In: Rubin R, Strayer DS, eds. Rubin's Pathology: Clinicopathologic Foundations of Medicine. 6th ed. Philadelphia, PA: Wolters Kluwer Health | Lippincott Williams & Wilkins; 2012:819.)](image-url)
lined with neoplastic epithelium. Although these tumors may recur and rarely invade the underlying bladder wall, they are seldom life-threatening. High-grade carcinomas can be papillary or flat; they tend to cover larger areas of the mucosal surface and carry a high risk of invasion into the detrusor muscle and surrounding tissues, and when associated with invasion, a significant metastatic potential. Bladder cancers are commonly staged according to the TNM classification (see Chapter 7) of the World Health Organization (WHO) with stage T3 carcinomas invading perivesical tissues and T4 carcinomas spreading to adjacent organs and distant metastases.

**Etiology and Pathogenesis**

Although the cause of bladder cancer is unknown, evidence suggests that its origin is related to local influences, such as carcinogens that are excreted in the urine and stored in the bladder. Cigarette smoking is an important risk factor, with 30% to 50% of all bladder cancers among males who are current or past smokers. Other risk factors include the presence of arsenic in the drinking water and industrial exposure to the breakdown products of aromatic amines used in the dye industry and to chemicals used in the manufacture of rubber, textiles, paint, and petroleum products. Both the heavy long-term use of cyclophosphamide, an immunosuppressive agent, and prior exposure to bladder radiation, often administered for other pelvic malignancies, also increase the risk of bladder cancer. Bladder cancer also occurs more frequently among persons harboring *Schistosoma haematobium*, a parasite that is endemic in Egypt and Sudan, in their bladder.

**Manifestations**

The most common sign of bladder cancer is painless hematuria. Gross hematuria is a presenting sign in 75% of persons with the disease, and microscopic hematuria is present in most others. Frequency, urgency, and dysuria occasionally accompany the hematuria. Because hematuria often is intermittent, the diagnosis may be delayed. Periodic urine cytology is recommended for all persons who are at high risk for the development of bladder cancer because of exposure to urinary tract carcinogens. Ureteral invasion leading to bacterial and obstructive renal disease and dissemination of the cancer are potential complications and ultimate causes of death. The prognosis depends on the histologic grade of the cancer and the stage of the disease at the time of diagnosis.

**Diagnosis and Treatment**

Diagnostic methods include cytologic studies, excretory urography, cystoscopy, and biopsy. Ultrasonography, CT scans, and MRI are used as aids for staging the tumor. Cytologic studies performed on biopsy tissues or cells obtained from bladder washings may be used to detect the presence of malignant cells. The treatment of bladder cancer depends on the type and extent of the lesion and the health of the patient. Endoscopic resection usually is done for diagnostic purposes and may be used as a treatment for superficial lesions. For small papillary tumors that are not high grade, the initial diagnostic transurethral resection may be the only surgical procedure done. Segmental surgical resection may be used for removing a large single lesion. When the tumor is invasive, a cystectomy with resection of the pelvic lymph nodes frequently is the treatment of choice. Cystectomy requires urinary diversion, an alternative reservoir, usually created from the ileum (e.g., an ileal loop), that is designed to collect the urine. External-beam radiation therapy is an alternative to radical cystectomy in some patients with deeply infiltrating bladder cancer.

Surgical treatment of superficial bladder cancer is often followed by intravesicular chemotherapy or immunotherapy, a procedure in which the therapeutic agent is directly instilled into the bladder. One of the agents used for this purpose is an attenuated strain of the tuberculosis bacillus, called *bacillus Calmette-Guérin* (BCG), which elicits an inflammatory response that destroys the tumor. Patients who are found to have regional invasion or distant metastases are often treated with systemic chemotherapeutic agents. Therapy can be given before planned cystectomy (neoadjuvant) in an attempt to decrease recurrence or in some cases to allow for bladder preservation. Alternatively, adjuvant chemotherapy may be administered after surgery to prevent tumor recurrence.
REVIEW EXERCISES

1. A 23-year-old man is recovering after the acute phase of a cervical (C6) spinal cord injury with complete loss of motor and sensory function below the level of injury. He is now experiencing spastic bladder contractions with involuntary and incomplete urination. Urodynamic studies reveal spastic contraction of the external sphincter with urine retention and high bladder pressures.
   A. Explain the reason for the involuntary urination and incomplete emptying of the bladder despite high bladder pressures.
   B. What are possible complications associated with overdistention and high pressure within the bladder?

2. A 66-year-old woman complains of leakage of urine during coughing, sneezing, laughing, or squatting down.
   A. Explain the source of this woman’s problem.
   B. One of the recommended treatments for stress incontinence is the use of Kegel exercises, which focus on strengthening the muscles of the pelvic floor. Explain how these exercises contribute to the control of urine leakage in women with stress incontinence.

3. A 26-year-old woman makes an appointment with her health care provider, complaining of urinary frequency, urgency, and burning. She reports that her urine is cloudy and smells abnormal. A urine dipstick indicates the presence of infection, a urine sample is obtained for culture, and she is given a prescription for antibiotics.
   A. What microorganism is most likely responsible for the infection?
   B. What factors may have predisposed her to this disorder?
   C. What could this woman do to prevent future infection?

The gastrointestinal (GI) tract is an amazing structure in which food is dismantled and its nutrients absorbed, wastes are collected and eliminated, and vitamins synthesized. The GI tract is also becoming increasingly recognized as an endocrine organ that produces and augments hormones that contribute to the regulation of appetite and food intake and function in the use and storage of nutrients.

As a matter of semantics, the GI tract also is referred to as the digestive tract, the alimentary canal, and, at times, the gut. The intestinal portion also may be called the bowel. For the purposes of this text, the liver and pancreas (discussed in Chapter 30), which produce secretions that aid in digestion, are considered accessory organs.

The major physiologic function of the GI tract is to provide the body with a continual supply of water and other nutrients. It carries out this function through processes involving motility, secretion, digestion, and absorption. In the digestive tract, as food moves slowly along its length it is systematically broken down into ions and molecules that can be absorbed into the blood.
and lymph. In the large intestine, unabsorbed wastes are collected for later elimination.

Structurally, the GI tract is a long, hollow tube, the lumen of which is an extension of the external environment (Fig. 28-1). Nutrients do not become part of the internal environment until they have passed through the intestinal wall and have entered the blood or lymph channels. For simplicity and understanding, the GI tract can be divided into three parts. The upper part—the mouth and pharynx, esophagus, and stomach—acts as an intake source and receptacle through which food passes and in which initial digestive processes take place. The middle portion—the duodenum, jejunum, and ileum of the small intestine—is where most digestive and absorptive processes occur. The lower segment—the cecum, colon, and rectum of the large intestine—serves as a storage channel for the efficient elimination of waste. The accessory organs, which include the salivary glands, liver, and pancreas, produce secretions that aid in digestion.

**Upper Gastrointestinal Tract**

The mouth forms the entryway into the GI tract for food; it contains the teeth, used in the mastication of food, and the tongue and other structures needed to direct food toward the pharynx and the esophagus. The mouth also serves as a receptacle for saliva produced by the salivary glands. Saliva moistens and lubricates food, so it is easier to swallow, and it contains enzymes (amylase and lipase) involved in the initial digestion of starches and lipids.

The esophagus is a straight, collapsible tube, about 25 cm (10 inches) in length, that lies behind the trachea and connects the pharynx with the stomach. The esophagus functions primarily as a conduit for the passage of food from the pharynx to the stomach. Its structure is uniquely designed for this purpose: the smooth muscle layers provide the peristaltic movements needed to move food along its length, and the mucosal and submucosal glands secrete mucus, which protects its surface and aids in lubricating food.
There are sphincters at either end of the esophagus. The upper sphincter, the pharyngoesophageal sphincter, consists of a circular layer of striated muscle. It keeps air from entering the esophagus and stomach during breathing. The lower esophageal sphincter, also called the gastroesophageal sphincter, lies just above the area where the esophagus joins the stomach. The circular muscle in this area normally remains tonically contracted, creating a zone of high pressure that serves to prevent reflux of gastric contents into the esophagus. During swallowing, there is “receptive relaxation” of the lower esophageal sphincter that allows for easy propulsion of the esophageal contents into the stomach. The lower esophageal sphincter passes through an opening, or hiatus, in the diaphragm as it joins with the stomach, which is located in the abdomen. The portion of the diaphragm that surrounds the lower esophageal sphincter helps to maintain the zone of high pressure to support the function of the lower esophageal sphincter.

The stomach is a pouchlike structure that lies in the left side of the abdomen and serves as a food reservoir during the early stages of digestion. The esophagus opens into the stomach through an opening called the cardiac orifice, so named because of its proximity to the heart. The small part of the stomach that surrounds the cardiac orifice is called the cardiac region; the domeshaped region that bulges above the cardiac region is called the fundus; the middle portion is called the body; and the funnel-shaped portion that connects with the small intestine is called the pyloric region (Fig. 28-2). The wider and more superior part of the pyloric region, the antrum, narrows to form the pyloric canal as it approaches the small intestine. At the end of the pyloric canal, the circular smooth muscle layer thickens to form the pyloric sphincter. This muscle serves as a valve that controls the rate of stomach emptying and prevents the regurgitation of intestinal contents back into the stomach.

The inner surface of the empty stomach reveals a number of longitudinal folds or ridges called rugae. The rugae, which serve to accommodate expansion and filling of the stomach, almost disappear when the stomach is distended with food.

**Small Intestine**

The small intestine, which forms the middle portion of the GI tract, consists of three subdivisions: the duodenum, jejunum, and ileum (see Fig. 28-1). The duodenum, which is approximately 22 cm (10 inches) long, connects the stomach to the jejunum and contains the opening for the common bile duct and the main pancreatic duct. Bile, a fluid synthesized by the liver that breaks down lipids, and pancreatic juices, which facilitate digestion of lipids, carbohydrates, and proteins, enter the intestine through these ducts. It is in the jejunum and ileum, which together are approximately 7 m (23 ft) long and must be folded onto themselves to fit into the abdominal cavity, that food is digested and absorbed.

**Lower Gastrointestinal Tract**

The large intestine, which forms the lower GI tract, is approximately 1.5 m (5 ft) long. It is divided into the cecum, colon, rectum, and anal canal (see Fig. 28-1). The cecum is a blind pouch that projects down at the junction of the ileum and the colon. The ileocecal valve lies at the upper border of the cecum and prevents the return of feces from the cecum into the small intestine. The appendix arises from the cecum approximately 2.5 cm (1 inches) from the ileocecal valve. The colon is further divided into ascending, transverse, descending, and sigmoid portions. The ascending colon extends from the cecum to the undersurface of the liver, where it turns abruptly to form the right colic (hepatic) flexure. The transverse colon crosses the upper half of the abdominal cavity from right to left and then curves sharply downward beneath the lower end of the spleen, forming the left colic (splenic) flexure. The descending colon extends from the colic flexure to the rectum. The rectum extends from the sigmoid colon to the anus. The anal canal passes between the two medial borders of the levator ani muscles. Powerful sphincter muscles guard against fecal incontinence.

**Gastrointestinal Wall Structure**

Below the upper third of the esophagus, the GI tract is essentially a four-layered hollow tube of varying diameter, but similar structural organization. It consists of four distinct layers: the inner mucosal layer; the underlying submucosal layer; the muscularis externa, and the outer serosal layer (Fig. 28-3).

**Mucosa**

The mucosa, or inner mucosal layer, is made up of an epithelium lining; an underlying loose connective tissue, called the lamina propriae; and the muscularis
The mucosa, composed of smooth muscle cells that can contract and change the shape and surface area of the mucosal layer. The mucosal layer performs numerous functions in its role as an interface between the body and the external environment, including production of the mucus that protects and lubricates the inner lining of the GI tract lumen, secretion of the digestive enzymes and substances that break food down, absorption of the breakdown products of digestion, and maintenance of a barrier to prevent the entry of noxious substances and pathogenic organisms. Lymphatics within the mucosa serve as the body’s first line of immune defense. The epithelial cells in the mucosal layer have a rapid turnover rate and are replaced every 4 to 5 days. Because of the regenerative capabilities of the mucosal layer, injury to this layer heals rapidly without leaving scar tissue.

Submucosa

The submucosal layer, or second layer, consists of dense connective tissue, aggregates of adipose tissue, and occasional glands. This layer contains the large blood vessels that send branches to the mucosa, muscular externa, and adventitia. It also contains the lymphatic vessels, as well as nerves that control motility and the secretory activity of glands in the mucosal layer.

Muscularis Externa

The muscularis externa consists of two concentric and relatively thick layers of smooth muscle: an inner layer made up of circularly arranged smooth muscle cells and an outer layer of longitudinally arranged smooth muscle. Located between the two muscle layers is a connective tissue layer that contains nerves that control smooth muscle movement, as well as blood and lymphatic vessels. Contraction of the smooth muscle in this layer mixes and churns the GI contents and facilitates its movement along the GI tract.

Serosa and Adventitia

The serosa and adventitia constitute the outermost layer of the GI tract. The serosa is a serous membrane consisting of a layer of simple squamous epithelium, called the mesothelium, and a small amount of underlying connective tissue. It is equivalent to the visceral peritoneum and is continuous with the mesentery and omentum that enclose and support the abdominal viscera. Instead of the serosa, an adventitia consisting only of connective tissue is found where the wall of the GI tract is directly attached to the body wall.

The peritoneum is a continuous transparent serous membrane that lines the abdominopelvic cavity and invests the stomach and intestines. It is the largest serous membrane in the body, having a surface area approximately equal to that of the skin. The peritoneum consists of two continuous layers: the visceral peritoneum and the parietal peritoneum, which line the wall of the abdominopelvic cavity. Between the two layers is the peritoneal cavity, a potential space containing fluid secreted by the serous membranes. This serous fluid forms a moist and slippery surface that prevents friction between the continuously moving abdominal structures.

The mesentery is the double layer of peritoneum that encloses a portion or all of one of the abdominal viscera and attaches it to the abdominal wall (Fig. 28-4A). The mesentery contains the blood vessels, nerves, and lymphatic vessels that supply the intestinal wall (Fig. 28-4B). It also holds the organs in place and stores fat. There are dorsal as well as ventral mesenteries; however, in most places the mesentery is dorsal and attaches to the posterior abdominal wall. The mesentery that encloses the jejunum and ileum is gathered in folds that...
attach to the dorsal abdominal wall along a short line of insertion, giving a fan-shaped appearance, with the intestines at the edge.

An omentum is a double-layered extension or fold of peritoneum that passes from the stomach or proximal part of the duodenum to adjacent organs in the abdominal cavity or abdominal wall. The greater omentum extends from the stomach to cover the transverse colon and the folds of the intestine, whereas the lesser omentum extends between the transverse fissure of the liver and the lesser curvature of the stomach (see Fig. 28-4C). The greater omentum always contains some fat, which in obese persons can be a considerable amount. It has considerable mobility and moves around in the peritoneal cavity with the peristaltic movements of the intestines, and it cushions the abdominal organs against injury and provides insulation against the loss of body heat. It often forms adhesions (i.e., bands of fibrous scar tissue) adjacent to inflamed organs such as the appendix, walling off the infection and thereby preventing its spread.

**SUMMARY CONCEPTS**

- The gastrointestinal (GI) tract is a long, hollow tube that is in contact with the external environment; food and fluids that enter the GI tract do not become part of the internal environment until they have been broken down and absorbed into the blood or lymph.
- The digestive and absorptive functions of the GI tract are distributed among structures of the upper, middle, and lower parts of the tract. The upper part—the mouth, esophagus, and stomach—acts as an intake source and receptacle through which food passes and in which initial digestive processes take place. The middle portion—the duodenum, jejunum, and ileum (continued)
Neural Control of Gastrointestinal Motility

The motility of the GI tract can be modulated by input from two sets of nerves, the intrinsic and extrinsic nervous systems. The intrinsic nervous system, called the enteric nervous system, has cell bodies that are contained within the wall of the GI tract. The extrinsic nervous system, which has nerves with cell bodies that are located outside the digestive tract, is part of the autonomic nervous system (ANS). In addition, a number of peptides, including neurotransmitters and GI hormones, assist in regulating GI motility.

Enteric Nervous System Innervation

The GI tract has a nervous system all its own called the enteric nervous system which lies entirely within the wall of the GI tract, beginning in the esophagus and continuing all the way to the anus. The enteric nervous system is composed of two plexuses: an outer myenteric (Auerbach) plexus and an inner submucosal (Meissner) plexus. These two plexuses are networks of nerve fibers and ganglion cell bodies. Interneurons in the plexuses connect afferent sensory fibers, efferent motor neurons, and secretory cells to form reflex circuits that are located within the GI tract wall.

The myenteric plexus consists mainly of a linear chain of interconnecting neurons that is located between the circular and longitudinal muscle layers of the muscular externa. Because it lies between the two muscle layers and extends all the way down the GI tract, it is concerned mainly with motility along the length of the gut. The submucosal plexus, which lies between the submucosal and mucosal layers of the wall, is mainly concerned with controlling the function of each segment of the GI tract. It integrates signals received from the mucosal layer into local control of motility, intestinal secretions, and absorption of nutrients.

The activity of the neurons in the myenteric and submucosal plexuses is regulated by local influences, input from the ANS, and interconnecting fibers that transmit information between the two plexuses. Mechanoreceptors monitor the stretch and distention of the GI tract wall, and chemoreceptors monitor the chemical composition (i.e., osmolarity, pH, and digestive products of protein and fat metabolism) of its contents. These receptors can communicate directly with ganglionic cells in the intramural plexuses or with visceral afferent fibers that influence ANS control of GI function.

Autonomic Innervation

The autonomic innervation of the GI system is mediated by both the sympathetic and parasympathetic nervous systems (see Chapter 34, Fig. 34-23). In general, stimulation of the parasympathetic nervous system causes a general increase in activity of the entire enteric nervous system, whereas sympathetic stimulation inhibits activity causing many effects.

Parasympathetic innervation to the stomach, small intestine, cecum, ascending colon, and transverse colon occurs through the vagus nerve. The remainder of the colon is innervated by parasympathetic fibers that exit the sacral segments of the spinal cord by way of the

Gastrointestinal Innervation and Motility

The motility of the GI tract propels food and fluids along its length, from mouth to anus, in a manner that facilitates digestion and absorption. The movements of the GI tract can be either rhythmic or tonic. The rhythmic movements move food forward and keep the GI contents mixed. Rhythmic movements are found in the esophagus, antrum of the stomach, and small intestine. The tonic movements consist of a constant level of contraction or tone without regular periods of relaxation. They are found in the lower esophagus, the upper region of the stomach, the ileocecal valve, and the internal anal sphincter.

All of the contractile tissue in the GI tract is smooth muscle, except for that in the mouth and pharynx, the upper third of the esophagus, and the external anal sphincter. Although the smooth muscle found in each region of the GI tract exhibits structural and functional differences, certain basic properties are common to all of the muscle cells. For example, all of the smooth muscle of the GI tract is unitary smooth muscle, in which all the cells are electrically coupled by low-resistance pathways so that electrical signals initiating muscle contractions can move rapidly from one fiber to the next.

Like the self-excitable cardiac muscle cells in the heart, some smooth muscle cells throughout the GI tract function as pacemaker cells. These cells display rhythmic, spontaneous oscillations in membrane potentials, called slow waves, ranging in frequency from about 3 per minute in the stomach to 12 per minute in the duodenum. Slow waves are generated by a thin layer of interstitial cells located between the longitudinal and circular muscle layers.
pelvic nerves. Preganglionic parasympathetic fibers can synapse with intramural plexus neurons, or they can act directly on intestinal smooth muscle. In addition, these same nerve bundles provide many afferent nerves whose receptors lie within the various tissues of the gut. Their nerves project to the spinal cord and brain to provide sensory input for integration. Most parasympathetic innervation is excitatory. Numerous vagovagal reflexes influence motility and secretions of the digestive tract.

Sympathetic innervation occurs through the thoracic chain of sympathetic ganglia and the celiac, superior mesenteric, and inferior mesenteric ganglia. The sympathetic nervous system exerts several effects on GI function. It controls the extent of mucus secretion by the mucosal glands, reduces motility by inhibiting the activity of intramural plexus neurons, enhances sphincter function, and increases the vascular smooth muscle tone of the blood vessels that supply the GI tract. Sympathetic stimulation suppresses the release of the excitatory neuromediators in the intramural plexuses, inhibiting GI motility.

Swallowing and Esophageal Motility

Chewing begins the digestive process—it breaks the food into particles of a size that can be swallowed, and lubricates it by mixing it with saliva. Although chewing usually is considered a voluntary act, it can be carried out involuntarily by a person who has lost the function of the cerebral cortex.

The swallowing reflex is a rigidly ordered sequence of events that results in the propulsion of food from the mouth to the stomach through the esophagus. Although swallowing is initiated as a voluntary activity, it becomes involuntary as food or fluid reaches the pharynx. Sensory impulses for the reflex begin at tactile receptors in the pharynx and esophagus and are integrated with the motor components of the response in an area of the reticular formation of the medulla and lower pons called the swallowing center. The motor impulses for the oral and pharyngeal phases of swallowing are carried in the trigeminal (V), glossopharyngeal (IX), vagus (X), and hypoglossal (XII) cranial nerves, and impulses for the esophageal phase are carried by the vagus nerve. Diseases that damage these brain centers or their cranial nerves disrupt the coordination of swallowing and predispose an individual to food and fluid lodging in the trachea and bronchi, leading to the risk of asphyxiation or aspiration pneumonia.

Swallowing consists of three phases: an oral, or voluntary, phase; a pharyngeal phase; and an esophageal phase. During the oral phase, the bolus of food is collected at the back of the mouth so the tongue can lift the food upward until it touches the posterior wall of the pharynx (Fig. 28-5A). At this point, the pharyngeal

(text continues on page 684)
Motility of the small intestine is organized to optimize the digestion and absorption of nutrients and the propulsion of undigested material toward the colon. Peristaltic movements mix the ingested foodstuffs with digestive enzymes and secretions and circulate the intestinal contents to facilitate contact with the intestinal mucosa. The regulation of motility results from an interplay of input from the (1) enteric and (2) autonomic nervous (ANS) systems and the intrinsic pacemaker activity of the (3) intestinal smooth muscle cells.

**Enteric Nervous System Innervation.** The gastrointestinal system has its own nervous system, called the enteric nervous system. The enteric nervous system is composed mainly of two plexuses: (1) the outer myenteric (Auerbach) plexus that is located between the longitudinal and circular layers of smooth muscle cells and (2) an inner submucosal (Meissner) plexus that lies between the mucosal and circular muscle layers. The myenteric plexus controls mainly intestinal movements along the length of the gut, whereas the submucosal plexus is concerned mainly with controlling the function within each segment of the intestine. Fibers in the submucosal plexus also use signals originating from the intestinal epithelium to control intestinal secretion and local blood flow.
ANS Innervation. The intestine is also innervated by the parasympathetic and sympathetic branches of the ANS (see Chapter 35, Fig. 35-23). Parasympathetic innervation is supplied mainly by the vagus nerve with postganglionic neurons located primarily in the myenteric and submucosal plexuses. Stimulation of these parasympathetic nerves causes a general increase in both intestinal motility and secretory activity. Sympathetic innervation is supplied by nerves that run between the spinal cord and the prevertebral ganglia and between these ganglia and the intestine. Stimulation of the sympathetic nervous system is largely inhibitory, producing a decrease in intestinal motility and secretory activity.

Intestinal Smooth Muscle. Intestinal smooth muscle has its own intrinsic slow-wave activity, which varies from about 12 waves minute in the duodenum to 8 or 9 waves per minute in the ileum. This slow-wave activity is thought to reside in a network of specialized pacemaker cells that are interposed between the smooth muscle cells. Slow waves are not action potentials and they do not directly induce muscle contraction; instead, they are rhythmic, wavelike fluctuations in the membrane potential that cyclically bring the membrane closer to threshold. If the peak voltage of the slow wave exceeds the cell's threshold potential, one or more action potentials may be triggered. Because action potentials occur at the peak of a slow wave, slow-wave frequency determines the rate of smooth muscle contractions. Stretching the intestinal smooth muscle and parasympathetic nervous system stimulation increase excitability of the smooth muscle cells, whereas sympathetic stimulation decreases excitability.
highly acid gastric contents. The digestive tract of the antrum and lead to gastric ulcers. Likewise, the duo-
double duodenal contents can damage the mucosal surface of
the larger particles to the body of the stomach for fur-
the entire terminal 5 to 10 cm of the antrum contracts,
the pyloric sphincter prevents
contents are emptied into the duodenum between con-
teach reentry site of the common duct and the main hepatic duct.

**Gastric Motility**

The stomach serves as a food storage reservoir where the
chemical breakdown of proteins begins and food is con-
verted into a creamy mixture called *chyme*. Although
an empty stomach has a volume of about 50 mL, it can
expand to as much as 1000 mL before the intraluminal
pressure begins to rise.

Motility of the stomach results in the churning and mixing of solid foods and regulates the emptying of
the chyme into the duodenum. Peristaltic mixing and
churning contractions begin in a pacemaker area in the
middle of the stomach and move toward the antrum.
They occur at a frequency of three to five contractions
per minute, each lasting 2 to 20 seconds. As the per-
ystaltic wave approaches the antrum, it speeds up, and
the entire terminal 5 to 10 cm of the antrum contracts,
occluding the pyloric opening. Contraction of the
antrum reverses the movement of the chyme, returning
the larger particles to the body of the stomach for fur-
ther churning and kneading. Because the pyloric sphinc-
ter is contracted during antral contraction, the gastric
contents are emptied into the duodenum between con-
tractions. Constriction of the pyloric sphincter prevents
the backflow of gastric contents and allows them to
flow into the duodenum at a rate commensurate with
the ability of the duodenum to accept them. This is
important because the regurgitation of bile salts and
duodenal contents can damage the mucosal surface of
the antrum and lead to gastric ulcers. Likewise, the du-
odenal mucosa can be damaged by the rapid influx of
highly acid gastric contents.

The rate at which the stomach empties is regulated by
neural and humoral signals from both the stomach and
the duodenum. However, the duodenum provides by far
the most potent of the signals, controlling the emptying of
the chyme at a rate no greater than the rate at which
the chyme can be digested and absorbed. Gastric emptying is
slowed by hypertonic solutions in the duodenum, by duo-
denal pH below 3.5, and by the presence of fatty acids,
amino acids, and peptides in the duodenum. The reflexes
are transmitted directly from the duodenum to the stom-
ach by the enteric nervous system and its connections with
the sympathetic and parasympathetic nervous systems.
Not only do nervous reflexes from the duodenum to the
stomach inhibit gastric emptying, but hormones released
from the duodenum and jejunum do so as well. These
include cholecystokinin and glucose-dependent insuli-
notropic peptide (formerly known as *gastric inhibitory
peptide*). The stimulus for releasing these inhibitory hor-
mones is mainly fats entering the duodenum; other foods
may decrease gastric emptying, but to a lesser degree.

**Small Intestinal Motility**

The rhythmic movements in the small intestine, like
those elsewhere in the gastrointestinal tract, are mixing
and propulsive. These movements involve segmentation
and peristaltic contractions. With *segmentation waves*,
slow contractions of the circular muscle layer occlude
the lumen and drive the contents forward and back-
ward (Fig. 28-6A). Most of the contractions that pro-
duce segmentation waves are local events involving only
1 to 4 cm of intestine at a time. They function mainly
to mix the chyme with the digestive enzymes from the
pancreas and to ensure adequate exposure of all parts of
the chyme to the mucosal surface of the intestine, where
absorption takes place. The frequency of segmenting
activity increases after a meal, presumably stimulated
by receptors in the stomach and intestine.

In contrast to the segmentation contractions, *peristaltic
movements* are rhythmic propulsive movements designed
to propel the chyme along the small intestine toward the
large intestine. They occur when the smooth muscle layer
constricts, forming a contractile band that forces the intra-
luminal contents forward. Normal peristalsis always moves
in the direction from the mouth toward the anus. Regular
peristaltic movements begin in the duodenum near the
entry sites of the common duct and the main hepatic duct.
These propulsive movements occur with synchronized
activity in a section 10 to 20 cm long. They are accom-
plished by contraction of the proximal portion of the intest-
te with the sequential relaxation of its distal, or caudal,
portion (Fig. 28-6B). After material has been propelled to
the ileocecal junction by peristaltic movement, stretching
of the distal ileum produces a local reflex that relaxes the
sphincter and allows fluid to squirt into the cecum.

Motility disturbances of the small intestine are com-
mon, and auscultation of the abdomen for the presence
of bowel sounds can be used to assess bowel activity.
Inflammatory changes often increase motility. In many
instances, it is not certain whether changes in motility
occur because of inflammation or are secondary to the effects of toxins or unabsorbed materials. Delayed passage of chyme in the small intestine also can be a problem. Transient interruption of intestinal motility often occurs after GI surgery. Intubation with suction often is required to remove the accumulating intestinal contents and gases until activity is resumed.

Colonic Motility and Defecation

The storage function of the colon dictates that movements in this section of the gut are different from those in the small intestine. Movements in the colon are of two types. First are the segmental mixing movements, called haustrations, so named because they occur within sacculations called haustra. These movements produce a local digging-type action, which ensures that all portions of the fecal mass are exposed to the intestinal surface. Second are the propulsive mass movements, in which a large segment of the colon (≥20 cm) contracts as a unit, moving the fecal contents forward as a unit. Mass movements last approximately 30 seconds, followed by a 2- to 3-minute period of relaxation, after which another contraction occurs. A series of mass movements lasts only for 10 to 30 minutes and may occur only several times a day. Defecation normally is initiated by the mass movements.

Defecation (discharge of feces from the rectum) is controlled by the action of two sphincters, the internal and external anal sphincters. The internal sphincter is a several-centimeters-long, circular thickening of smooth muscle that lies inside the anus. The external sphincter, which is composed of striated voluntary muscle, surrounds the internal sphincter. The external sphincter is controlled by nerve fibers in the pudendal nerve, which is part of the somatic nervous system and therefore under voluntary control. Defecation is controlled by defecation reflexes. One of these reflexes is the intrinsic myenteric reflex mediated by the local enteric nervous system. It is initiated by distention of the rectal wall, with initiation of reflex peristaltic waves that spread through the descending colon, sigmoid colon, and rectum. A second defecation reflex, the parasympathetic reflex, is integrated at the level of the sacral cord. When the nerve endings in the rectum are stimulated, signals are transmitted first to the sacral cord and then reflexively back to the descending colon, sigmoid colon, rectum, and anus by the pelvic nerves. These impulses greatly increase peristaltic movements as well as relax the internal sphincter.

To prevent involuntary defecation from occurring, the external anal sphincter is under the conscious control of the cortex. As afferent impulses arrive at the sacral cord, signaling the presence of a distended rectum, messages are transmitted to the cortex. If defecation is inappropriate, the cortex initiates impulses that constrict the external sphincter and inhibit efferent parasympathetic activity. Normally, the afferent impulses in this reflex loop fatigue easily, and the urge to defecate soon ceases. At a more convenient time, contraction of the abdominal muscles compresses the contents in the large bowel, reinitiating afferent impulses to the cord.

SUMMARY CONCEPTS

- Smooth muscle of the digestive tract propels food and fluids along its length with each part of the GI tract undergoing movements consistent with its digestive, absorptive, and storage functions.
- The smooth muscle in the wall of the GI tract undergoes cyclic self-propagating changes in membrane potentials, called slow waves, that maintain motility. Although the activity of GI smooth muscle is self-propagating, its rate and strength of contractions are regulated by input from the enteric and autonomic nervous systems.
- The enteric nervous system, which lies entirely within the gut, controls motility, intestinal (continued)
SUMMARY CONCEPTS (continued)

secretions, and absorptive functions of the different segments of the GI tract. The activity of the neurons in the enteric nervous system is regulated by both local influences, such as stretch and distention of the GI tract wall, and input from the autonomic nervous system.

- Autonomic signals to the gut are carried from the brain and spinal cord by the parasympathetic and sympathetic nervous systems, with parasympathetic stimulation increasing the activity of the enteric nervous system and sympathetic stimulation inhibiting its activity.

Secretory Functions of the Gastrointestinal Tract

The GI tract produces a number of secretions, including mucus, hydrochloric acid, digestive enzymes, and hormones. Secretory activity, like motility, is influenced by local, humoral, and neural influences. Neural control of GI secretory activity is mediated through the ANS, with parasympathetic stimulation increasing secretory activity and sympathetic stimulation inhibiting secretory activity. Many local influences, including the pH and osmolarity of the GI contents, act as stimuli for neural and hormonal mechanisms.

Gastrointestinal Secretions

Throughout the GI tract, secretory glands serve two basic functions: production of mucus to lubricate and protect the mucosal layer of the GI tract wall and secretion of fluids and enzymes to aid in the digestion and absorption of nutrients. Each day, approximately 7000 mL of fluid is secreted into the GI tract (Table 28-1). Approximately 50 to 200 mL of this fluid leaves the body in the stool; the remainder is reabsorbed in the small and large intestines. These secretions are mainly water and have sodium and potassium concentrations similar to those of extracellular fluid. Because water and electrolytes for digestive tract secretions are derived from the extracellular fluid compartment, excessive secretion or impaired absorption can lead to extracellular fluid deficit.

Salivary Secretions

Saliva is secreted by the salivary glands. The salivary glands consist of the parotid, submaxillary, sublingual, and buccal glands. Saliva has three functions. The first is protection and lubrication. Saliva is rich in mucus, which protects the oral mucosa and coats the food as it passes through the mouth, pharynx, and esophagus. The sublingual and buccal glands produce only mucus-type secretions. The second function of saliva is its protective antimicrobial action. The saliva cleans the mouth and contains the enzyme lysozyme, which has an antibacterial action. Third, saliva contains ptyalin and amylase, which initiate the digestion of dietary starches. Secretions from the salivary glands are primarily regulated by the ANS. Parasympathetic stimulation increases flow and sympathetic stimulation decreases flow of saliva. The dry mouth that accompanies anxiety attests to the effects of sympathetic activity on salivary secretions.

Gastric Secretions

The otherwise smooth lining of the stomach is dotted with gastric pits that form the openings for two types of glands: pyloric and oxyntic or gastric glands (Fig. 28-7). The pyloric glands secrete gastrin and mucus for protection of the pyloric mucosa, and are located in the antral portion, or distal 20%, of the stomach. The oxyntic glands are located on the inside surfaces of the body and fundus of the stomach, which occupies about 80% of the stomach. They contain three types of cells: mucous neck cells, which secrete mainly mucus; peptic (chief cells), which secrete large quantities of pepsinogen; and parietal (oxyntic cells), which secrete HCl and intrinsic factor, which is needed for vitamin B12 absorption (Fig. 28-7). The pepsinogen that is secreted by the peptic cells is rapidly converted to pepsin (a protein-digesting enzyme) when exposed to the low pH of the gastric juices. A few stem cells are also found in the gastric pits. These cells are the parent cells for all new cells of the gastric mucosa.

The cellular mechanism for HCl secretion by the parietal cells in the stomach involves the hydrogen ion (H+)/potassium ion (K+)-adenosine triphosphatase (ATPase) transporter and chloride ion (Cl-) channels located on their luminal membrane (Fig. 28-8). During the process of HCl secretion, carbon dioxide (CO2) produced by aerobic metabolism combines with water (H2O), catalyzed by the enzyme carbonic anhydrase, to form carbonic acid (H2CO3), which readily dissociates into H+ and bicarbonate (HCO3-). The HCO3- moves out of the cell and into blood from the basolateral membrane. At the luminal side of the membrane, H+ is secreted into the stomach by the H+/K+-ATPase transporter (also known as the proton pump). Chloride follows H+ into the stomach by diffusing through Cl- channels in the luminal membrane.

Three substances stimulate HCl secretion by the parietal cells: acetylcholine, gastrin, and histamine. Although each substance binds to different receptors on the parietal cell and has a different mechanism of action, they all serve to stimulate an increase in H+ secretion through the H+/K+-ATPase transporter. Acetylcholine is released
from vagal nerves innervating the stomach and binds to acetylcholine receptors on the parietal cells. Gastrin is secreted by G cells in the antrum of the stomach and reaches the parietal cells through the circulation. It binds to as-yet uncharacterized receptors on the parietal cells. Histamine is released from special endocrine cells in the gastric mucosa and diffuses to nearby parietal cells, where it binds to histamine-2 (H\textsubscript{2}) receptors.

One of the important characteristics of the gastric mucosa is resistance to the highly acid secretions that it produces. The mucosal surface is protected by prostaglandin E\textsubscript{2}, which inhibits acid secretion and stimulates mucus production. Hence, it is an important factor in the maintenance of the gastric mucosal barrier. Aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) decrease prostaglandin synthesis, which can impair the integrity of the mucosal surface. Ethyl alcohol, or refluxed bile salts from the intestine, can also disrupt this barrier. When this occurs, hydrogen ions move into the tissue. Hydrogen ions accumulate in the mucosal cells, intracellular pH decreases, enzymatic reactions become impaired, and cellular structures are disrupted. The result is local ischemia, vascular stasis, hypoxia, and tissue necrosis.

**Intestinal Secretions**

The small intestine, which is where most of the digestion and absorption of food takes place, secretes digestive juices and receives secretions from the liver and pancreas (see Chapter 30). An extensive array of mucus-producing glands, called Brunner glands, is concentrated at the site where the contents from the stomach and secretions from the liver and pancreas enter the duodenum. These glands secrete large amounts of alkaline mucus that protect the duodenum from the acid content in the gastric chyme and from the action of the digestive enzymes.
and water. The second type of secretion consists of surface enzymes that aid absorption. These enzymes include peptidases, which separate amino acids, and disaccharidases, which split sugars. Also present in intestinal secretions are mucins secreted by goblet cells. The mucins, which are glycoproteins high in carbohydrates, form a gel that serves to lubricate the mucosal surface and protect it from mechanical injury from solid food particles.

The crypts of Lieberkühn also function to replace epithelial cells. The epithelial cells lining the small intestine are constantly being sloughed off into the lumen and replaced as a result of the high mitotic index of the epithelial stem cells in the crypts. The epithelium is entirely replaced approximately every 4 to 5 days. Paneth cells, which are present in the bottom of the crypts, secrete antibacterial substances and are involved in the host defense system of the small intestine.

The large intestine secretes mainly mucus and bicarbonate. Mucus not only protects the mucosa of the colon, but also facilitates compaction of the feces. Bicarbonate adheres to the mucus and acts as a buffer, protecting the mucosa from acid by-products of bacterial metabolism within the feces.

ANS activity strongly influences mucus production in the bowel, as in other parts of the digestive tract. During intense parasympathetic stimulation, mucus secretion may increase to the point that the stool contains large amounts of obvious mucus.

### Gastrointestinal Hormones

The GI tract is the largest endocrine organ in the body. It produces hormones that act locally, pass into the general circulation for distribution to more distant sites, and interact with the CNS through the enteric and autonomic nervous systems. These hormones influence appetite, GI motility, enzyme activity, electrolyte levels, and the secretion and actions of hormones such as growth hormone, insulin, and glucagon. The actions of many of these hormones overlap: two or more GI hormones may affect the same process in the same direction, or they may inhibit each other. The GI tract hormones and their functions are summarized in Table 28-2.

The stomach is the source of two important GI hormones: gastrin and ghrelin. Gastrin is produced by G cells, located predominantly in the antrum of the

</table>
stomach. The primary function of gastrin is the stimulation of gastric acid secretion. Gastrin also has a trophic, or growth-producing, effect on the mucosa of the small intestine, colon, and acid-secreting area of the stomach. Removal of the tissue that produces gastrin results in atrophy of these structures. Ghrelin is a recently discovered peptide hormone produced by endocrine cells in the mucosal layer of the fundus of the stomach. It displays potent growth hormone–releasing activity and has a stimulatory effect on food intake and digestive function, while reducing energy expenditure. The isolation of this hormone has led to new insights into the gut–brain regulation of growth hormone secretion and energy balance.

The intestine is the source of secretin, cholecystokinin, and incretin hormones. Secretin, which is secreted by S cells in the mucosa of the duodenum and jejunum, inhibits gastric acid secretion. The entry of an acid chyme into the intestine stimulates the release of secretin, which inhibits the release of gastrin. Secretin also stimulates the pancreas to secrete large quantities of fluid with a high bicarbonate concentration and low chloride concentration. The primary function of cholecystokinin (CCK), secreted by I cells in the intestinal mucosa, is the stimulation of pancreatic enzyme secretion. It also potentiates the action of secretin, increasing the pancreatic bicarbonate response to low circulating levels of secretin; and regulates gallbladder contraction and gastric emptying. CCK has also been shown to inhibit food intake and to be an important mediator for appetite and amount of food consumed during a meal.

Several gut-derived hormones have been identified as having what is termed an incretin effect, meaning that they increase insulin release after an oral glucose load. This suggests that gut-derived factors can stimulate insulin secretion after a high-carbohydrate meal. The two hormones that account for about 90% of the incretin effect are glucagon-like peptide 1 (GLP-1), which is released from L cells in the distal small intestine, and glucose-dependent insulinotropic peptide (GIP), which is released by K cells in the upper small intestine (mainly the jejunum). Because increased levels of GLP-1 and GIP can lower blood glucose levels by augmenting insulin release in a glucose-dependent manner (i.e., at low blood glucose levels no further insulin is secreted, minimizing the risk of hypoglycemia), these hormones have been targeted as possible antidiabetic drugs. Moreover, GLP-1 can exert other metabolically beneficial effects, including suppression of glucagon release, slowing of gastric emptying, augmenting glucose clearance, and decreasing appetite and body weight.

The stomach, in addition to producing mucus, secretes hydrochloric acid (HCl); pepsinogen, which is converted to pepsin, which is important in protein metabolism; and intrinsic factor, which is involved in the absorption of vitamin B12.

The cells of the small intestine, where most digestion and absorption of foods take place, produces a watery alkaline fluid that aids in the digestive process and surface enzymes that aid in the digestion and absorption of carbohydrates and proteins. Digestive and absorptive processes in the small intestine are aided by bile from the liver and enzymes from the pancreas.

In addition to secreting fluids containing digestive enzymes, the GI tract produces and secretes hormones that act locally, then pass into the general circulation for distribution to more distant sites. Among the hormones produced by the GI tract are gastrin, ghrelin, secretin, cholecystokinin, and incretin hormones (glucagon-like peptide-1 [GLP-1] and glucose-dependent insulinotropic polypeptide [GIP]). These hormones influence appetite, GI motility, enzyme activity, electrolyte levels, and the secretion and action of hormones such as growth hormone, insulin, and glucagon.

**SUMMARY CONCEPTS**

- Secretory glands throughout the gastrointestinal tract serve two basic purposes: production of mucus to lubricate and protect its mucosal layer and secretion of fluids and enzymes to aid in the digestion and absorption of nutrients.

**Digestion and Absorption in the Gastrointestinal Tract**

Digestion involves the dismantling of foods into their constituent parts, a process that requires hydrolysis, enzyme cleavage, and fat emulsification. Hydrolysis is the breakdown of a compound that involves a chemical reaction with water. The importance of hydrolysis to digestion is evidenced by the amount of water (7 to 8 L) that is secreted into the GI tract daily. Enzyme cleavage requires the use of enzymes to cut substances into smaller components. Emulsification involves the breakdown of large globules of dietary fat into smaller particles.

Absorption is the process of moving nutrients and other materials from the external environment in the lumen of the GI tract into the blood or lymph of the internal environment. Absorption is accomplished by active transport and diffusion. A number of substances require a specific carrier or transport system. For example, vitamin B12 is not absorbed in the absence of intrinsic factor, which is secreted by the parietal cells of the stomach. Transport of amino acids and glucose occurs mainly in the presence of sodium. Water is absorbed passively along an osmotic gradient.
Small Intestinal Digestion and Absorption

Although some digestion of carbohydrates and proteins begins in the mouth and stomach respectively, digestion takes place mainly in the small intestine. The emulsification of fats to free fatty acids and monoglycerides takes place entirely in the small intestine. The liver, with its production of bile, and the pancreas, which supplies a number of digestive enzymes, play important roles in digestion.

The distinguishing characteristic of the small intestine is its large surface area, which in the adult is estimated to be approximately 250 m². Anatomic features that contribute to this enlarged surface area are the circular folds that extend into the lumen of the intestine and the villi, which are fingerlike projections of mucous membrane, numbering as many as 25,000, that line the entire small intestine (Fig. 28-10). Each villus is equipped with an artery, vein, and lymph vessel (i.e., lacteal), which bring blood to the surface of the intestine and transport the nutrients and other materials that have passed into the blood from the lumen of the intestine (see Fig. 28-9). Fats rely largely on the lymphatics for absorption. The villi are covered with cells called enterocytes that contribute to the absorptive and digestive functions of the small bowel, and goblet cells that provide mucus.

The enterocytes secrete enzymes that aid in the digestion of carbohydrates and proteins. These enzymes are called brush border enzymes because they adhere to the border of the microvilli that project from the surface of the enterocytes. In this way they have access to the carbohydrate and protein molecules as they come in contact with the absorptive surface of the intestine. This mechanism of secretion places the enzymes where they are needed and eliminates the need to produce enough enzymes to mix with the entire contents filling the lumen of the small bowel. The digested molecules diffuse through the membrane or are actively transported across the mucosal surface to enter the blood or, in the case of fatty acids, the lacteal. These molecules are then transported through the portal vein or lymphatics into the systemic circulation.

Carbohydrate Digestion and Absorption

Carbohydrates must be broken down into monosaccharides, or single sugars, before they can be absorbed from the small intestine. The average daily intake of carbohydrate in the American diet is approximately 350 to 400 g.

Digestion of starch begins in the mouth with the action of amylase. Pancreatic secretions also contain an amylase. Amylase breaks down starch into several disaccharides, including maltose, isomaltose, and α-dextrins. The brush border enzymes convert the disaccharides into monosaccharides that can be absorbed (Table 28-3). Sucrose yields glucose and fructose, lactose is converted to glucose and galactose, and maltose is converted to two glucose molecules. When the disaccharides are not broken down to monosaccharides, they cannot be absorbed but remain as osmotically active particles in the contents of the digestive system, causing diarrhea. For example, persons with a deficiency of lactase, the enzyme that breaks down lactose, experience diarrhea when they drink milk or eat dairy products.

Fructose is transported across the intestinal mucosa by facilitated diffusion, which does not require energy expenditure. Glucose and galactose move from the intestinal lumen into the intestinal cells by way of a sodium–glucose cotransporter (SGLT-1), against a chemical gradient. The energy for this step does not come directly from ATP, but from the sodium gradient created by the Na⁺/K⁺-ATPase pump located on the basolateral side of the membrane (Fig. 28-11). Glucose and galactose are transported from the cell into the blood across the basolateral membrane by facilitated diffusion using a glucose transporter-2 (GLUT-2) protein. Water absorption from the intestine is linked to absorption of osmotically active particles, such as glucose and sodium. It follows that an important consideration in facilitating the transport of water across the intestine (and decreasing diarrhea) after temporary disruption in bowel function is to include sodium and glucose in the fluids that are consumed.

**FIGURE 28-10.** The mucous membrane of the small intestine. Note the numerous villi on a circular fold.
Protein Digestion and Absorption

Protein digestion begins in the stomach with the action of pepsin. Pepsinogen, the enzyme precursor of pepsin, is secreted by the chief cells in response to a meal and acid pH. Acid in the stomach is required for the conversion of pepsinogen to pepsin. Pepsin is inactivated when it enters the intestine by the alkaline pH.

Proteins are broken down further by pancreatic enzymes, such as trypsin, chymotrypsin, carboxypeptidase, and elastase. As with pepsin, the pancreatic enzymes are secreted as precursor molecules. Trypsinogen, which lacks enzymatic activity, is activated by an enzyme located on the brush border cells of the duodenal enterocytes. Activated trypsin activates additional trypsinogen molecules and other pancreatic precursor proteolytic enzymes. The amino acids are then liberated on the surface of the mucosal surface of the intestine by brush border enzymes that degrade proteins into peptides that are one, two, or three amino acids long.

As with glucose, many amino acids are transported across the mucosal membrane in a sodium-linked process that uses ATP as an energy source. Some amino acids are absorbed by facilitated diffusion processes that do not require sodium.

Fat Digestion and Absorption

The average adult eats approximately 60 to 100 g of fat daily, principally as triglycerides. The first step in digestion of lipids is to break the large globules of dietary fat into smaller particles so that water-soluble digestive enzymes can act on the surface molecules. This emulsification process begins in the stomach with agitation of the globules and continues in the duodenum under the influence of bile from the liver (Fig. 28-12). Emulsification greatly increases the number of triglyceride molecules exposed to pancreatic lipase, which splits triglycerides into free fatty acids and monoglycerides. Bile salts play an additional role by forming micelles that transport these
substances to the surface of the intestinal villi, where they are taken into the epithelial cells and used to form new triglycerides. These new triglycerides are then released into the lymphatic system as chylomicrons. Small quantities of short- and medium-chain fatty acids are absorbed directly into the portal blood rather than being converted into triglycerides and absorbed by way of the lymphatics.

Fat that is not absorbed in the intestine is excreted in the stool. Steatorrhea is the term used to describe fatty stools. It usually indicates that there is 20 g or more of fat in a 24-hour stool sample.

Colonic Absorption and Intestinal Flora

When the remaining food residue moves into the colon, fluid not absorbed during movement of the meal through the small intestine is absorbed and the waste products are stored in the large intestine until they can be conveniently eliminated.

While in the colon, food residues are acted upon by a large and diverse bacterial community called the intestinal flora. The stomach and small intestine contain only a few species of bacteria, probably because the composition of luminal contents (i.e., acids, bile, pancreatic secretions) kills most ingested microorganisms, and the propulsive movements of these organs impedes their colonization. The large intestine, on the other hand, contains a large and complex microbial ecosystem. It has been estimated that each individual has 300 to 500 different species of intestinal bacteria, with anaerobic bacteria outnumbering aerobic bacteria by a large percentage.

The major metabolic function of the intestinal flora is the fermentation of undigestible dietary residue including resistant starches, cellulose, pectins and...
other forms of dietary fibers, and unabsorbed sugars. Fermentation of these residues is a major source of energy for the microorganisms in the colon. The metabolic end point is the generation of short-chain fatty acids, which play a major role in intestinal epithelial cell growth and differentiation. Colonic microorganisms also play a role in vitamin synthesis and in absorption of calcium, magnesium, and iron. Vitamin K, for example, is synthesized by the intestinal flora. Lastly, the resident gut flora provides a crucial line of resistance to colonization by exogenous microbes, and therefore is highly protective against invasion of tissues by pathogens. The administration of broad-spectrum antibiotics can disrupt the microbial balance and allow overgrowth of species with potential pathogenicity, such as Clostridium difficile (see Chapter 29).

**SUMMARY CONCEPTS**

- Digestion is the process of dismantling foods into their constituent parts, and absorption is the process of moving nutrients and other materials from the GI tract into the internal environment.
- Carbohydrates must be broken down into monosaccharides before they can be absorbed, a process that involves both salivary and pancreatic amylase and the brush border enzymes of the small intestine.
- Digestion of proteins begins in the stomach with the action of pepsin and continues in the small intestine facilitated by the action of the proteolytic pancreatic enzymes, which split the protein molecules into dipeptides, tripeptides, or amino acids that are absorbed through the wall of the intestine.
- Fats are emulsified by bile into small droplets, which are broken down by pancreatic lipase into triglycerides containing medium- and long-chain fatty acids. Bile salts form micelles that transport these substances to the surface of intestinal villi, where they are absorbed by lymphatics.
- Fluid not absorbed during movement of a meal through the small intestine is absorbed in the colon, and food residues are fermented by the intestinal flora, resulting in short-chain fatty acids, which support epithelial cell proliferation and differentiation, and protects the colonized host against invasion by pathogenic organisms. Colonic microorganisms also play a role in vitamin synthesis and in absorption of calcium, magnesium, and iron and the synthesis of vitamins, including vitamin K.

**Anorexia, Nausea, and Vomiting**

Anorexia, nausea, and vomiting are physiologic responses common to many GI disorders. These responses are protective to the extent that they signal the presence of disease and, in the case of vomiting, remove noxious agents from the GI tract. They also can contribute to impaired intake or loss of fluids and nutrients.

**Anorexia**

Anorexia represents a loss of appetite. Several factors influence appetite. One is hunger, which is stimulated by contractions of the empty stomach. Appetite or the desire for food intake is regulated by the hypothalamus and other associated centers in the brain. Smell plays an important role, as evidenced by the fact that appetite can be stimulated or suppressed by the smell of food. Loss of appetite is associated with emotional factors, such as fear, depression, frustration, and anxiety. Many drugs and disease states cause anorexia. For example, in uremia the accumulation of nitrogenous wastes in the blood contributes to the development of anorexia. Anorexia often is a forerunner of nausea, and most conditions that cause nausea and vomiting also produce anorexia.

**Nausea and Vomiting**

Nausea is an ill-defined and unpleasant subjective sensation. It stimulates the vomiting center in the brain stem and often precedes or accompanies vomiting. Anorexia usually precedes nausea, and stimuli such as foods and drugs that cause anorexia in small doses usually produce nausea when given in larger doses. A common cause of nausea is distention of the duodenum or upper small intestinal tract. Nausea frequently is accompanied by autonomic nervous system manifestations such as watery salivation and vasoconstriction with pallor, sweating, and tachycardia. Nausea may function as an early warning signal of a pathologic process.

As a basic physiologic protective mechanism, vomiting limits the possibility of damage from ingested noxious agents by emptying the contents of the stomach and portions of the small intestine. Nausea and vomiting may also represent a total-body response to drug therapy, including overdose, cumulative effects, toxicity, and side effects.

The act of vomiting consists of taking a deep breath, closing the airways, and producing a strong, forceful contraction of the diaphragm and abdominal muscles along with relaxation of the gastroesophageal sphincter. Respiration ceases during the act of vomiting. Vomiting may be accompanied by dizziness, lightheadedness, a decrease in blood pressure, and bradycardia. Retching is the term used to describe the rhythmic spasmodic movements of the diaphragm, chest wall, and abdominal muscles without the expulsion of vomitus (dry heaves).
The act of vomiting is integrated in the vomiting center, which is located in the dorsal portion of the reticular formation of the medulla near the sensory nuclei of the vagus (Fig. 28-13). The vomiting center can be activated directly by irritants or indirectly following input from four different sources: (1) the GI tract and other abdominal organs; (2) higher central nervous system centers that respond to certain sights, sounds, or emotions that induce vomiting; (3) the vestibular apparatus, which is responsible for motion sickness; and (4) the chemoreceptor trigger zone, which is activated by chemical agents such as drugs and toxins. Hypoxia exerts a direct effect on the vomiting center, producing nausea and vomiting. This direct effect probably accounts for the vomiting that occurs during periods of decreased cardiac output, shock, environmental hypoxia, and brain ischemia caused by increased intracranial pressure. Inflammation of any of the intra-abdominal organs, including the liver, gallbladder, or urinary tract, can cause vomiting because of the stimulation of the visceral afferent pathways that communicate with the vomiting center. Distention or irritation of the GI tract also causes vomiting through the stimulation of visceral afferent neurons. The chemoreceptor trigger zone is located outside the blood–brain barrier in a small area between the medulla and the floor of the fourth ventricle, where it is exposed to both blood and cerebrospinal fluid. This region may be stimulated by drugs, chemotherapeutic agents, toxins, uremia, acidosis, and pregnancy.

Several neurotransmitters and receptor subtypes are implicated as neuromediators in nausea and vomiting. Dopamine, serotonin, and opioid receptors are found in the GI tract and in the vomiting center and chemoreceptor trigger zone. Dopamine antagonists, such as prochlorperazine, depress vomiting caused by stimulation of the chemoreceptor trigger zone. Serotonin is believed to be involved in the nausea and emesis associated with cancer chemotherapy and radiation therapy. Serotonin (5-hydroxytryptamine [5HT]) antagonists (e.g., granisetron, ondansetron) are often effective in treating the nausea and vomiting associated with these stimuli. The recently developed neurokinin-1 (NK-1) receptor antagonists (e.g., aprepitant) may also be used for the treatment of acute and delayed chemotherapy-induced nausea and vomiting. These drugs act centrally to block the activation of the NK-1 receptors in the vomiting center. Motion sickness appears to be a CNS response to vestibular stimuli. Norepinephrine and acetylcholine receptors are located in the vestibular center. The acetylcholine receptors are thought to mediate the impulses responsible for exciting the vomiting center. Many of the motion sickness drugs (e.g., meclizine, dimenhydrinate, transdermal scopolamine) have a strong CNS anticholinergic effect and act on the receptors in the vomiting center and areas related to the vestibular system.

**SUMMARY CONCEPTS**

- The signs and symptoms of many GI tract disorders are manifested by anorexia, nausea, and vomiting.
- Anorexia, or loss of appetite, may occur alone or may accompany nausea and vomiting.
- Nausea, which is an ill-defined, unpleasant sensation, signals the stimulation of the medullary vomiting center. It often precedes vomiting and frequently is accompanied by autonomic responses, such as salivation and vasoconstriction with pallor, sweating, and tachycardia.
- Vomiting, which is integrated by the vomiting center, involves the sudden and forceful oral expulsion of the gastric contents. The vomiting center can be activated directly by irritants or indirectly following input from the GI tract and other abdominal organs; higher central nervous system centers; the vestibular apparatus, which is responsible for motion sickness; or the chemoreceptor trigger zone, which is activated by chemical agents such as drugs and toxins.
REVIEW EXERCISES

1. Persons receiving chemotherapeutic agents, which interfere with the mitosis of cancer cells as well as the cells of other rapidly proliferating tissues in the body, often experience disorders such as ulcerations in the mucosal tissues of the mouth and other parts of the GI tract. These disorders are resolved once the chemotherapy treatment has been completed.
   A. Explain.

2. People with gastroesophageal reflux (movement of gastric contents into the esophagus) often complain of heartburn that becomes worse as the pressure in the stomach increases.
   A. Explain.
   B. Use information on hormonal control of gastric emptying to explain why eating a meal that is high in fat content often exaggerates the problem.

3. Infections of the GI tract, such as the “GI flu,” often cause profound diarrhea.
   A. Describe the neural mechanisms involved in the increase in GI motility that produces the diarrhea.
   B. Explain the rationale for using a “drink” that contains both glucose and sodium to treat the fluid deficit that often occurs with diarrhea.

4. Explain the physiologic mechanisms associated with the occurrence of diarrhea in persons with:
   A. Lactase deficiency.
   B. Obstruction of bile flow into the intestine.
   C. Disruption of the normal intestinal flora due to antibiotic therapy.

5. Explain why anticholinergic drugs are often effective in treating the nausea and vomiting that accompany motion sickness but are relatively ineffective in treating the nausea and vomiting associated with chemotherapy agents used in the treatment of cancer.

Gastrointestinal disorders are not cited as the leading cause of death in developed countries of the world, nor do they receive the same publicity as heart disease and cancer. However, digestive diseases rank high in the total economic burden of illness, resulting in considerable human suffering, personal expenditures for treatment, and lost working hours, as well as a drain on the nation’s economy. In 2004 alone, digestive disorders accounted for an estimated 72 million ambulatory visits in the United States. Visits were common for all age groups, with the highest rate among persons 65 years and older. Even more important is the fact that proper nutrition or a change in health practices could prevent or minimize many of these disorders.

Disruption in structure and function can occur at any level of the gastrointestinal tract, from the esophagus to the colon and rectum. This chapter is divided into three sections: (1) disorders of the esophagus, (2) disorders of the stomach, and (3) disorders of the small and large intestines. Disorders of the hepatobiliary system and exocrine pancreas are presented in Chapter 30.

Disorders of the Esophagus

The esophagus is a fixed muscular tube through which swallowed food and liquids pass as they move from the pharynx to the stomach. It lies posterior to the trachea and larynx and extends through the mediastinum, intersecting the diaphragm at the level of the T11 or T12 vertebra. The wall of the esophagus is lined with a mucosal layer of abrassion-resistant nonkeratinized stratified epithelium; its submucosal layer contains mucus-secreting glands that produce a lubricating fluid that protects its mucosal surface and aids in the passage of food; and its muscularis layer provides the peristaltic movements needed to propel food along its length.

There are sphincters at either end of the esophagus: an upper esophageal, or pharyngoesophageal, sphincter that prevents reflux into the pharynx from the esophagus, and a lower esophageal, or gastroesophageal, sphincter that prevents reflux into the esophagus from...
the stomach. The lower esophageal sphincter is a physiologic rather than a true anatomic sphincter. That is, it acts as a valve, but the only structural evidence of a sphincter is a slight thickening of the circular smooth muscle. The smooth muscle fibers in this portion of the esophagus normally remain tonically constricted except at times when a bolus of food is about to pass into the stomach or if a person is vomiting. The lower esophageal sphincter passes through an opening, or hiatus, in the diaphragm as it joins with the stomach, which is located in the abdomen. The portion of the diaphragm that surrounds the lower esophageal sphincter helps to maintain the zone of high pressure needed to prevent reflux of stomach contents.

Disorders of Esophageal Structure and Function

The musculature of the pharyngeal wall and upper third of the esophagus is striated muscle, innervated by the glossopharyngeal and vagus nerves. The lower two thirds of the esophagus is smooth muscle, innervated by the vagus nerve. The act of swallowing depends on the coordinated action of the tongue, pharyngeal structures, and esophagus (see Chapter 28).

In general, swallowing can be divided into three stages (see Chapter 28, Fig. 28-6). The first, or voluntary, stage occurs in the mouth. Once the food has been chewed and well mixed with saliva, the bolus (food mass) is forced into the pharynx by the tongue. The second stage, the involuntary pharyngeal–esophageal phase, transports food through the pharynx and into the esophagus. The parasympathetic nervous system (primarily the vagus) controls this part of swallowing and promotes motility of the gastrointestinal tract from this point on. Once food reaches the distal end of the esophagus, it passes through the lower esophageal sphincter into the stomach (stage 3). The act of swallowing is complicated by the fact that the pharynx subserves respiration as well swallowing. Thus, it is important that breathing not be compromised because of swallowing.

Swallowing Disorders

Difficulty swallowing, often referred as dysphagia, can result from disorders that produce narrowing of the esophagus, lack of salivary secretion, weakness of the muscular structures that propel the food bolus, or disruption of the neural networks coordinating the swallowing mechanism. Lesions of the central nervous system (CNS), such as a stroke, often involve the cranial nerves that control swallowing. Cancer of the esophagus and strictures resulting from scarring can reduce the size of the esophageal lumen and make swallowing difficult. Scleroderma, an autoimmune disease that causes fibrous replacement of tissues in the muscularis layer of the gastrointestinal tract, is another important cause of dysphagia. Persons with dysphagia usually complain of choking, coughing, or an abnormal sensation of food sticking in the back of the throat or upper chest when they swallow.

The term achalasia means “failure to relax” and in the context of esophageal function denotes an incomplete relaxation of the lower esophageal sphincter in relation to swallowing. In primary achalasia, the mesenteric ganglia that carry the vagal fibers for the lower esophagus are usually absent from the body of the esophagus. The condition usually becomes manifest in young adulthood, but may appear in infancy and childhood. Achalasia produces functional obstruction of the esophagus so that food has difficulty passing into the stomach and the esophagus above the lower esophageal sphincter becomes distended. Stasis of food may produce inflammation and ulceration proximal to the lower esophageal sphincter, and there is danger of aspiration of esophageal contents into the lungs when the person lies down. The most serious aspect of the condition is the potential for developing esophageal cancer.

Treatment of swallowing disorders depends on the cause and type of altered function that is present. Treatment often involves a multidisciplinary team of health professionals, including a speech therapist. Mechanical dilation or surgical procedures may be done to enlarge the lower esophageal sphincter in persons with esophageal strictures.

Esophageal Diverticula

A diverticulum of the esophagus is an outpouching of the esophageal wall caused by a weakness of the muscularis layer or motility problems (e.g., diffuse esophageal spasm, achalasia). Esophageal diverticula tend to retain food. Complaints that the food stops before it reaches the stomach are common, as are reports of gurgling, belching, coughing, and foul-smelling breath. The trapped food may cause esophagitis and ulceration. Surgery is the optimal treatment for persons with severe symptoms or pulmonary complications.

Esophageal Lacerations

Longitudinal lacerations in the esophagus, also called Mallory-Weiss syndrome, represent nonpenetrating mucosal tears at the gastroesophageal junction. They are most often encountered in persons with chronic alcoholism after a bout of severe retching or vomiting, but may also occur during acute illness with severe vomiting. The presumed pathogenesis is inadequate relaxation of the esophageal sphincter during vomiting, with stretching and tearing of the esophageal junction during propulsive expulsion of gastric contents. The tears, which range in length from millimeters to a few centimeters, usually cross the gastroesophageal junction and also may be located in the proximal gastric mucosa. Esophageal lacerations account for about 10% of all upper gastrointestinal bleeding, which often presents as hematemesis. Most often bleeding is not severe and does not require surgical intervention. Healing is usually prompt, with minimal or no residual effects.
**Hiatal Hernia**

Hiatal hernia is characterized by a protrusion or herniation of the stomach through the esophageal hiatus of the diaphragm. There are two anatomic patterns of hiatal herniation: sliding (axial) and paraesophageal (nonaxial). The sliding hiatal hernia is characterized by a bell-shaped protrusion of the stomach above the diaphragm (Fig. 29-1A). Small sliding hiatal hernias are common and considered to be of no significance in asymptomatic people. In paraesophageal hiatal hernias, a separate portion of the stomach, usually along the fundus of the stomach, enters the thorax through a widened opening (Fig. 29-1B). The hernia progressively enlarges and increases in size. In extreme cases, most of the stomach herniates into the thorax. Large paraesophageal hernias may require surgical treatment.

**Gastroesophageal Reflux**

The term reflux refers to backward or return movement. In the context of gastroesophageal reflux, it refers to the backward movement of gastric contents into the esophagus, a condition that causes heartburn or pyrosis. Most people experience heartburn occasionally as a result of reflux. Such symptoms usually occur soon after eating, are short lived, and seldom cause more serious problems.

The lower esophageal sphincter regulates the flow of food from the esophagus into the stomach. Both internal and external mechanisms function in maintaining the antireflux function of the lower esophageal sphincter. The circular muscles of the distal esophagus constitute the internal mechanisms, and the portion of the diaphragm that surrounds the esophagus constitutes the external mechanism (Fig. 29-2). The oblique muscles of the stomach, located below the lower esophageal sphincter, form a flap that contributes to the antireflux function of the internal sphincter. Relaxation of the lower esophageal sphincter is a brainstem reflex that is mediated by the vagus nerve in response to a number of afferent stimuli. Transient relaxation with reflux is common after meals. Gastric distention and meals high in fat increase the frequency of relaxation. Normally, refluxed material is returned to the stomach by secondary peristaltic waves in the esophagus, with swallowed saliva neutralizing and washing away the refluxed acid.

**Gastroesophageal Reflux Disease**

The persistent reflux of gastric contents into the esophagus is referred to as gastroesophageal reflux disease (GERD). It is thought to be associated with a weak or incompetent lower esophageal sphincter that allows reflux to occur, the irritant effects of the refluxate, and decreased clearance of the refluxed acid from the esophagus after it has occurred. In most cases, reflux occurs during transient relaxation of the esophagus. Delayed gastric emptying also may contribute to reflux by increasing gastric volume and pressure. Esophageal mucosal injury may occur and is related to the destructive nature of the refluxate and the amount of time it is in contact with mucosa. The mucosa is partially protected by mucin and alkaline secretions from the submucosal glands. Injury occurs when the reflux episodes are frequent and prolonged. Agents that decrease the tone of the lower esophageal sphincter are often useful in treating GERD.

*FIGURE 29-1. Hiatal hernia. (A) Sliding hiatal hernia. (B) Paraesophageal hiatal hernia.*
sphincter (e.g., alcohol, chocolate, fatty foods, and heavy smoking) also cause reflux, as may central nervous system depressants, obesity, pregnancy, hiatal hernia, delayed gastric emptying, and increased gastric volume. Although acid damages the esophageal mucosa, the combination of acid and pepsin many be particularly injurious.

Clinical Manifestations. The most frequent symptom of GERD is heartburn. It frequently is severe, occurring 30 to 60 minutes after eating. It often is made worse by bending at the waist or assumption of the recumbent position and usually is relieved by sitting upright. The severity of heartburn is not indicative of the extent of mucosal injury; only a small percentage of people who complain of heartburn have mucosal injury. Often, the heartburn occurs during the night. Antacids provide prompt, although transient, relief. Other symptoms include belching and chest pain. The pain usually is located in the epigastric or retrosternal area and often radiates to the throat, shoulder, or back. Because of its location, the pain may be confused with angina. The reflux of gastric contents also may produce respiratory symptoms such as wheezing, chronic cough, and hoarseness.9

Diagnosis and Treatment. Diagnosis of GERD depends on a history of reflux symptomatology and selective use of diagnostic methods, including radiographic studies using a contrast medium such as barium, esophagoscopy, and ambulatory esophageal pH monitoring.8–10

The treatment of GERD usually focuses on conservative measures. These measures include avoidance of positions and conditions that increase gastric reflux.8–10

It is recommended that large meals and foods that reduce lower esophageal sphincter tone (e.g., caffeine, fats, chocolate) be avoided, that meals be eaten sitting up, and the recumbent position be avoided for several hours after a meal. Bending for long periods should be avoided because it tends to increase intra-abdominal pressure and cause gastric reflux. Sleeping with the head elevated helps to prevent reflux during the night. Weight loss usually is recommended in overweight people.

Pharmacologic treatment includes the use of antacids and inhibitors of gastric acid secretion. Antacids neutralize gastric acid and are used for rapid relief of occasional heartburn. Histamine-2 (H2)–receptor antagonists inhibit gastric acid production. They are available as over-the-counter drugs and often are recommended when additional treatment is needed. The proton pump inhibitors act by inhibiting the gastric proton pump, which regulates the final pathway for acid secretion (see Chapter 28, Fig. 28-10). These agents may be used for persons who continue to have daytime symptoms, recurrent strictures, or large esophageal ulcerations. Surgical treatment may be indicated in some people.

Complications. Complications of GERD result from persistent reflux, which produces a cycle of hyperemia, edema, and erosion of the mucosal surface of the esophagus. Esophageal mucosal damage is related to acidity of the refluxate. These complications include strictures of the esophagus and a condition called Barrett esophagus. Strictures are caused by a combination of scar tissue, spasm, and edema. They produce narrowing of the esophagus and cause dysphagia when the lumen becomes sufficiently constricted.

Barrett esophagus is characterized by a reparative process in which the squamous mucosa that normally lines the esophagus gradually is replaced by columnar epithelium resembling that in the intestines.11 The diagnosis of Barrett esophagus is based on endoscopic evidence of abnormal mucosa above the level of the gastroesophageal junction and histologically documented intestinal metaplasia (called specialized intestinal metaplasia) that predisposes to the development of adenocarcinoma.

Gastroesophageal Reflux in Children

Gastroesophageal reflux is a common problem in infants and children. The small reservoir capacity of an infant’s stomach coupled with frequent spontaneous reductions in sphincter pressure contribute to reflux. At least one episode of regurgitation a day occurs in as many as half of infants ages 0 to 3 months. By 6 months of age it becomes less frequent and usually abates as the child assumes a more upright posture and eats solid foods.12,13 Although many infants have minor degrees of reflux, complications such as esophageal damage and secondary respiratory disease can occur in children with more frequent or persistent episodes. The condition occurs more frequently in children with cerebral palsy, Down syndrome, and other neurologic disorders.

Clinical Manifestations. Clinical manifestations of reflux esophagitis include evidence of pain when swallowing, hematemesis, anemia due to esophageal bleeding, heartburn, irritability, and sudden or inconsolable crying. Parents often report feeding problems in their infants.12,13 These infants often are irritable and demonstrate early satiety. Sometimes the problems progress to actual resistance to feeding and failure to thrive. Tilting of the head to one side and arching of the back may be noted in children with severe reflux.12 This head positioning is thought to represent an attempt to protect the airway or reduce the pain-associated reflux. Sometimes regurgitation is associated with recurrent otalgia. The ear pain is thought to occur through referral from the vagus nerve in the esophagus to the ear. In some children, chronic regurgitation may prompt dental caries.

A variety of respiratory symptoms are caused by damage to the respiratory mucosa when gastric reflux enters the esophagus. Reflux may cause laryngospasm, apnea, and bradycardia. Asthma may co-occur with GERD in about 50% of asthmatic children. Asthmatic children who are particularly likely to have GERD as a provocative factor are those with symptoms of reflux, those with refractory or steroid-dependent asthma, and those with nocturnal worsening of symptoms.14

Diagnosis and Treatment. Diagnosis of gastroesophageal reflux in infants and children often is based on parental and clinical observations. The diagnosis may
Thus, nutritional deficiencies, as well as polycyclic compounds such as those found in fungus-contaminated food may be important contributing factors. Dysphagia is by far the most frequent complaint of persons with esophageal cancer. It is apparent first with ingestion of bulky food, later with soft food, and finally with liquids. Unfortunately, it is a late manifestation of the disease. Unintentional weight loss, anorexia, fatigue, and pain on swallowing also may occur.

Treatment of esophageal cancer depends on tumor stage. Surgical resection provides a means of cure when done in early disease and palliation when done in late disease. Radiation may be used as an alternative to surgery. Chemotherapy may be used before surgery to decrease the size of the tumor or it may be used along with irradiation and surgery in an effort to increase survival. The prognosis for persons with cancer of the esophagus, although poor, has improved. Even with modern forms of therapy, however, the long-term survival is limited because, in many cases, the disease has already metastasized by the time the diagnosis is made.

### Cancer of the Esophagus

Worldwide, the incidence of esophageal cancer varies widely, undoubtedly reflecting environmental and dietary influences. It is relatively uncommon in the United States, accounting for about 2% of cancer deaths. There are two types of esophageal cancer: adenocarcinoma and squamous cell carcinoma.

Adenocarcinomas typically arise in a background of Barrett esophagus and long-standing GERD. They usually occur in the distal third of the esophagus and may invade adjacent areas of the stomach. Risk of adenocarcinoma is greater in those with documented esophageal dysplasia and is further increased by tobacco use, obesity, and prior radiation therapy. Esophageal carcinomas occur more frequently in Caucasians and are seven times more common in men than women. Molecular studies have suggested that the pathogenesis of adenocarcinoma from Barrett esophagus is a multistep process, with the development of dysplasia being a critical step in the process. Thus, endoscopic surveillance of persons with Barrett esophagus provides the means for detecting adenocarcinoma at an earlier stage, when it is most amenable to curative surgical resection.

In contrast to adenomas, squamous carcinomas tend to occur in the middle of the esophagus. Risk factors include alcohol and tobacco use, esophageal injury, achalasia, and frequent consumption of very hot beverages. The regions with the highest incidences are Iran, central China, Hong Kong, Brazil, and South Africa. The majority of esophageal squamous carcinomas in Europe and the United States are at least partially attributable to alcohol and tobacco use. However, this form of cancer is also common in areas where alcohol and tobacco use are uncommon. Thus, nutritional deficiencies, as well as polycyclic hydrocarbons, nitrosamines, and other mutagenic compounds, are important contributing factors.

### SUMMARY CONCEPTS

- The esophagus is a fixed muscular tube through which swallowed food and liquids move as they pass from the pharynx to the stomach. Dysphagia refers to difficulty in swallowing; it can result from altered neuromuscular function or from disorders that produce narrowing of the esophagus.
- Achalasia is an incomplete relaxation of the lower esophageal sphincter during swallowing.
- A diverticulum of the esophagus is an outpouching of the esophageal wall caused by a weakness of the muscularis layer.
- Hiatal hernia is characterized by a protrusion or herniation of the stomach through the esophageal hiatus of the diaphragm. There are two anatomic patterns of herniation: the sliding or more common type, in which there is a bell-shaped protrusion of the stomach above the diaphragm, and the paraesophageal hernia, in which a portion of the stomach enters the thorax through a widened opening.
- Gastroesophageal reflux refers to the backward movement of gastric contents into the esophagus, a condition that causes heartburn. Persistent reflux of gastric contents into the esophagus can result in a condition called gastroesophageal reflux disease (GERD). Complications of GERD, which result from erosion and/or irritation of the mucosal surface of the esophagus, include esophagitis, strictures of the esophagus, and Barrett esophagus.
Gastroesophageal reflux is a common problem in infants and children. Symptoms are typically mild and abate in most children by 2 years of age. However, some infants and small children have significant reflux that interferes with feeding, causes esophagitis, and results in respiratory symptoms and other complications.

Cancer of the esophagus is a relatively uncommon form of cancer that is commonly linked to gastroesophageal reflux and Barrett esophagus (adenocarcinoma) or alcohol and tobacco use (squamous cell carcinoma).

Disorders of the Stomach

The stomach is a reservoir for contents entering the digestive tract. It lies in the upper abdomen, anterior to the pancreas, splenic vessels, and left kidney. Anteriorly, the stomach is bounded by the anterior abdominal wall and the left inferior lobe of the liver. While in the stomach, food is churned and mixed with hydrochloric acid (HCl) and pepsin before being released into the small intestine. Normally, the mucosal surface of the stomach provides a barrier that protects it from the hydrochloric acid and pepsin contained in gastric secretions. Disorders of the stomach include gastritis, peptic ulcer, and gastric carcinoma.

Gastric Mucosal Barrier

The stomach lining usually is impermeable to the acid it secretes, a property that allows the stomach to contain acid and pepsin without having its walls digested. Several factors contribute to the protection of the gastric mucosa, including an impermeable epithelial cell surface covering, coupled secretion of hydrogen (H+) and bicarbonate (HCO3-) ions, and the characteristics of gastric mucus. These mechanisms are collectively referred to as the gastric mucosal barrier.

The cells of the epithelial layer of the stomach are connected by tight junctions that prevent acid penetration, and they are covered with an impermeable hydrophobic lipid layer that prevents diffusion of ionized water-soluble molecules. Aspirin, which is nonionized and lipid soluble in acid solutions, rapidly diffuses across this lipid layer, increasing mucosal permeability and damaging epithelial cells. Gastric irritation and occult bleeding occur in a significant number of persons who take aspirin on a regular basis. Alcohol, which is lipid soluble, can also disrupt the mucosal barrier. When there is reflux of duodenal contents in the stomach, bile acids also can attack the lipid components of the mucosal barrier and produce gastric irritation.

Normally, the secretion of HCl by the parietal cells of the stomach is accompanied by secretion of HCO3- (see Chapter 28, Fig. 28-9). For every H+ that is secreted, a HCO3- is produced, and as long as HCO3- production is equal to H+ secretion, mucosal injury does not occur. Changes in gastric blood flow, as in shock, tend to decrease HCO3- production. This is particularly true in situations in which decreased blood flow is accompanied by acidosis. Prostaglandins, chemical mediators derived from cell membrane lipids, play an important role in protecting the gastric mucosa from injury. The prostaglandins exert their effects through several mechanisms, including improved mucosal blood flow, decreased acid secretion, increased bicarbonate secretion, and enhanced mucus production. The fact that drugs such as aspirin and the nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit prostaglandin synthesis contributes to their ability to produce gastric mucosal irritation and injury.

Gastritis

Gastritis refers to inflammation of the gastric mucosa. There are many causes of gastritis, most of which can be associated with either acute or chronic gastritis.

Acute Gastritis

Acute gastritis is characterized by an acute mucosal inflammatory process, usually transient in nature. The inflammation may be accompanied by hemorrhage into the mucosa of the stomach and, in severe cases, by sloughing of the superficial mucosa and acute gastric bleeding. The condition is most commonly associated with local irritants such as aspirin or other NSAIDs, alcohol, or bacterial toxins. Oral administration of corticosteroid drugs, which inhibit prostaglandin synthesis, may also cause acute hemorrhagic gastritis. Any serious illness or trauma that is accompanied by profound physiologic stress renders the gastric mucosa more vulnerable to acute hemorrhagic gastritis (discussed under stress ulcers). Uremia, treatment with cancer chemotherapy drugs, and gastric radiation are other causes of acute gastritis.

The complaints of persons with acute gastritis vary. Persons with aspirin-related gastritis can be totally unaware of the condition or may complain only of heartburn or sour stomach. Gastritis associated with excessive alcohol consumption is often a different situation; it often causes transient gastric distress, which may lead to vomiting and, in more severe situations, to bleeding and hematemesis. Gastritis caused by the toxins of infectious organisms, such as the staphylococcal enterotoxins, usually has an abrupt and violent onset, with gastric distress and vomiting ensuing approximately 5 hours after the ingestion of a contaminated food source. Acute gastritis usually is a self-limiting disorder, with complete regeneration and healing of the gastric mucosa occurring within several days of removal of the inciting agent.

Chronic Gastritis

Chronic gastritis is characterized by the absence of grossly visible erosions and the presence of chronic inflammatory changes, eventually leading to atrophy of
the glandular epithelium of the stomach. There are three major types of chronic gastritis: *Helicobacter pylori* gastritis, autoimmune gastritis, and chemical gastropathy.\(^7\)

**Helicobacter pylori Gastritis.** *H. pylori* gastritis is a chronic inflammatory disease of the antrum and body of the stomach caused by the bacterium *H. pylori*.\(^6,7,18,19\) It is the most common cause of chronic gastritis in the United States and is estimated to infect more than half of the world’s population, particularly in developing countries.

*H. pylori* are small, S-shaped, gram-negative rods that can colonize the mucus-secreting epithelial cells of the stomach (Fig. 29-3). The mode of transmission is not well-defined, although oral–oral, fecal–oral, and environmental spread are among the possible routes. *H. pylori* have multiple flagella, which allow them to move through the mucus layer of the stomach, and they secrete urease, which enables them to produce sufficient ammonia to buffer the acidity of their immediate environment. These properties help to explain why the organism is able to survive in the acidic environment of the stomach.

*H. pylori* produce enzymes and toxins that have the capacity to interfere with the local protection of the gastric mucosa against acid and produce a continuous inflammatory response. This inflammatory response initially consists of recruitment of neutrophils, followed by T and B lymphocytes. The inflammation may be confined to the superficial gastric epithelium or extend deeper into the gastric glands, resulting in varying degrees of atrophy (atrophic gastritis) and metaplasia that converts the gastric epithelium into intestinal-type epithelium.

Several *H. pylori* proteins are immunogenic and may induce intense systemic and mucosal immune responses. This antibody production does not lead to eradication of infection but may contribute to tissue damage.

The clinical course of *H. pylori* infection is highly variable and is influenced by both microbial and host factors. Acute infection with *H. pylori* may cause a transient illness characterized by nausea and abdominal pain that lasts for several days. After these symptoms resolve, most individuals progress to an asymptomatic infection with chronic mucosal inflammation. Chronic infection with *H. pylori* can lead to gastric atrophy and peptic ulcer, and is associated with increased risk of gastric adenocarcinoma and low-grade B-cell gastric lymphoma.

Noninvasive testing for the presence of *H. pylori* infection can be performed with the urea breath test or fecal antigen test. Blood tests to obtain serologic titers of *H. pylori* antibodies also can be done. The serologic test can establish that a person has been infected with *H. pylori*, but it cannot distinguish how recently the infection occurred.

The goal for *H. pylori* gastritis treatment is complete elimination of the organism. Current treatment requires combination therapy that includes the use of two antibiotics (clarithromycin, amoxicillin, metronidazole) with a proton pump inhibitor. *H. pylori* mutate rapidly to develop antibiotic-resistant strains. The combination of two or more antimicrobial agents increases the rates of cure and reduces the risk of resistant strains developing. In geographic areas with clarithromycin-resistant strains of *H. pylori*, quadruple therapy that includes bismuth is recommended. The proton pump inhibitors raise the intragastric pH to suppress bacterial growth and optimize antibiotic efficacy.

**Chronic Autoimmune Gastritis.** Autoimmune gastritis accounts for less than 10% of cases of chronic gastritis and is often associated with other autoimmune disorders such as type 1 diabetes mellitus, Hashimoto thyroiditis, and Addison disease.\(^6\) The disorder is characterized by autoantibodies to the gastric parietal cells and the intrinsic factor, defective gastric acid secretion, and vitamin B\(_{12}\) deficiency.\(^6,7\) In contrast to *H. pylori* gastritis, autoimmune gastritis typically affects the body and fundus of the stomach, sparing the antrum. Lack of intrinsic factor disables vitamin B\(_{12}\) absorption, leading to a B\(_{12}\) deficiency and slow-onset megaloblastic anemia (pernicious anemia, see Chapter 13). Atrophy of the fundic pyloric and chief cells can lead to development of metaplastic changes that predispose to the development of gastric adenocarcinoma.

Chronic autoimmune gastritis is noted for its slow onset and progression. Antibodies to parietal cells and intrinsic factor are present early in disease; progression to gastric atrophy probably occurs over several decades. Because of the slow onset and variable progression, persons with the disorder are diagnosed only after being affected for a number of years. Clinical presentation may be related to anemia. In addition, vitamin B\(_{12}\) deficiency may cause atrophic glossitis, in which the tongue becomes smooth and beefy red; malabsorptive diarrhea; and neuropathies. The most frequent manifestations of peripheral neuropathy

are paresthesias and numbness. Cerebral manifestations range from mild personality changes and memory loss to psychosis. In contrast to the anemia, neurologic changes are not reversed by vitamin B₁₂ replacement therapy.⁶

**Chemical Gastropathy.** Chemical gastropathy represents the effects of chronic gastric injury resulting from reflux of alkaline duodenal contents, pancreatic secretions, and bile into the stomach. It is most commonly seen in persons who have had gastroduodenostomy or gastrojejunostomy surgery. A milder form may occur in persons with gastric ulcer, gallbladder disease, or various motility disorders of the distal stomach.

**Ulcerative Disorders**

The lumen of the stomach is strongly acidic, a condition that contributes to digestion, but also has the potential to damage the mucosa and produce an ulcer. Among the conditions associated with ulceration of the gastric mucosa are peptic ulcer disease, Zollinger-Ellison syndrome, and stress ulcers.

**Peptic Ulcer Disease**

*Peptic ulcer disease* is a term used to describe a group of ulcerative disorders that occur in areas of the gastric and intestinal mucosa, mainly the proximal duodenum, that are exposed to acid–pepsin secretions.⁵,⁷,²⁰,²¹ Although the incidence and prevalence of peptic ulcer has declined substantially during the past 30 years, approximately 10% of people in Western industrial countries will develop a peptic ulcer during their lifetime.⁷

A peptic ulcer can affect one or all layers of the stomach or duodenum (Fig. 29-4). The ulcer may penetrate only the mucosal surface, or it may extend into the smooth muscle layers. Occasionally, an ulcer penetrates the outer wall of the stomach or duodenum. Spontaneous remissions and exacerbations are common. Healing of the muscularis layer involves replacement with scar tissue; although the mucosal layers that cover the scarred muscle layer regenerate, the regeneration often is less than perfect, which contributes to repeated episodes of ulceration.

**Etiology and Pathogenesis.** A variety of risk factors have been shown to have an association with peptic ulcer disease. The two most important are infection with the bacteria *H. pylori* and use of aspirin and/or NSAIDs.²⁰,²¹ In contrast to peptic ulcer from other causes, NSAID-induced gastric injury often occurs without symptoms, and life-threatening complications can develop without warning. There is reportedly less gastric irritation with the newer class of NSAIDs that selectively inhibit cyclooxygenase-2 (COX-2–selective NSAIDs), the principal enzyme involved in prostaglandin synthesis at the site of inflammation, than with the nonselective NSAIDs that also inhibit COX-1, the enzyme involved in prostaglandin production in the gastric mucosa.

Epidemiologic studies have identified independent factors that augment the effect of *H. pylori* infection and NSAID-produced peptic ulcer disease. These factors include advancing age, a prior history of peptic ulcer, NSAID use, and concurrent use of corticosteroid drugs. Smoking may augment the risk of peptic ulcer by impairing healing. Genetic factors may also play a role as supported by the fact that blood-group antigens correlate with peptic ulcer disease. People with type O blood and those who do not secrete antigens in their saliva or gastric juices are at greater risk of developing duodenal ulcers.³

**Clinical Manifestations.** The clinical manifestations of uncomplicated peptic ulcer focus on discomfort and pain. The pain, which is described as burning, gnawing, or cramplike, usually is rhythmic and frequently occurs when the stomach is empty—between meals and at 1 or 2 o’clock in the morning. The pain usually is located over a small area near the midline in the epigastrum near the xiphoid, and may radiate below the costal margins, into the back, or, rarely, to the right shoulder. Superficial and deep epigastric tenderness and voluntary muscle guarding may occur with more extensive lesions. An additional characteristic of ulcer pain is periodicity. The pain tends to recur at intervals of weeks or months. During an exacerbation, it occurs daily for a period of several weeks and then remits until the next recurrence. Characteristically, the pain is relieved by food or antacids.

**Complications.** The most common complications of peptic ulcer are hemorrhage, perforation, and gastric outlet obstruction. Hemorrhage is caused by bleeding from granulation tissue or from erosion of an ulcer into

![FIGURE 29-4. Gastric ulcer. The stomach has been opened to reveal a sharply demarcated, deep peptic ulcer on the lesser curvature. (From Rubin E, Farber JL, eds. A stress ulcer, sometimes called a Curling ulcer, refers to gastrointestinal ulcerations that develop in relation to major physiologic stress.22,23 Persons at high risk for development of stress ulcers include those with large-surface-area burns, trauma, sepsis, acute respiratory distress syndrome, severe liver failure, and major surgical procedures. These lesions occur most often in the fundus of the stomach and proximal duodenum and are thought to result from ischemia, tissue acidosis, and bile salts entering the stomach in critically ill persons with decreased gastrointestinal tract motility. Another form of stress ulcer, called Cushing ulcer, consists of gastric, duodenal, and esophageal ulcers arising in persons with intracranial injury, operations, or tumors. They are thought to be caused by hypersecretion of gastric acid resulting from stimulation of vagal nuclei by increased intracranial pressure.
Persons admitted to hospital intensive care units are at particular risk for development of stress ulcers. They usually manifest with painless upper gastrointestinal tract bleeding. H2-receptor antagonists and proton pump inhibitors are often used in the prevention and treatment of stress ulcers.

Cancer of the Stomach
Although the incidence of cancer of the stomach has declined over the past 50 years in the United States, it continues to remain a leading cause of cancer deaths worldwide.6 It is more common in lower socioeconomic groups and exhibits a male-to-female ratio of about 2:1.

Among the factors that increase the risk of gastric cancer are genetic predisposition, carcinogenic factors in the diet (e.g., N-nitroso compounds and benz[a]pyrene found in smoked and preserved foods), autoimmune gastritis, and gastric adenomas or polyps. The incidence of stomach cancer in the United States has decreased fourfold since 1930, presumably because of improved storage of food with decreased consumption of smoked and preserved foods.6,7 Chronic infection with H. pylori appears to serve as a co-factor in some types of gastric carcinomas. However, the vast majority of people with H. pylori infection do not develop gastric cancer, and not all H. pylori infections increase the risk of gastric

Zollinger-Ellison Syndrome
Zollinger-Ellison syndrome is a rare condition caused by gastrin-secreting tumors (gastrinomas) that are most commonly found in the small intestine or pancreas.7 In persons with this disorder, gastric acid secretion reaches such levels that ulceration becomes inevitable. The increased gastric secretions cause symptoms related to peptic ulcer. Diarrhea may result from hypersecretion of acid or from the activation of intestinal lipase and impaired fat digestion that occurs with a decrease in intestinal pH. Most gastrinomas are solitary or multifocal nodules that are potentially resectable. Over two thirds of gastrinomas are malignant and one third have metastasized at the time of diagnosis.8

Stress Ulcers
A stress ulcer, sometimes called a Curling ulcer, refers to gastrointestinal ulcerations that develop in relation to major physiologic stress.22,23 Persons at high risk for development of stress ulcers include those with large-surface-area burns, trauma, sepsis, acute respiratory distress syndrome, severe liver failure, and major surgical procedures. These lesions occur most often in the fundus of the stomach and proximal duodenum and are thought to result from ischemia, tissue acidosis, and bile salts entering the stomach in critically ill persons with decreased gastrointestinal tract motility. Another form of stress ulcer, called Cushing ulcer, consists of gastric, duodenal, and esophageal ulcers arising in persons with intracranial injury, operations, or tumors. They are thought to be caused by hypersecretion of gastric acid resulting from stimulation of vagal nuclei by increased intracranial pressure.
Persons admitted to hospital intensive care units are at particular risk for development of stress ulcers. They usually manifest with painless upper gastrointestinal tract bleeding. H2-receptor antagonists and proton pump inhibitors are often used in the prevention and treatment of stress ulcers.
cancer, suggesting that other factors may be involved. Autoimmune gastritis, like H. pylori infection, increases the risk of gastric cancer, presumably due to chronic inflammation and intestinal metaplasia.

Most gastric cancers involve the antrum of the stomach, with the lesser curvature being involved more often than the greater curvature. Compared with benign ulcers, which have smooth margins and are concentrically shaped, gastric cancers tend to be bulky and irregularly shaped and have firm and jagged edges. Unfortunately, stomach cancers often are asymptomatic until late in their course. Symptoms, when they do occur, usually are vague and include indigestion, anorexia, weight loss, vague epigastric pain, vomiting, and an abdominal mass. Because these symptoms are essentially nonspecific, early detection is often difficult.

Diagnosis of gastric cancer is accomplished by a variety of techniques, including barium x-ray studies, endoscopic studies with biopsy, and cytologic studies (e.g., Papanicolaou smear) of gastric secretions. Cytologic studies can prove particularly useful as routine screening tests for persons with atrophic gastritis or gastric polyps. Endoscopy and computed tomography (CT) scans often are used to delineate the spread of a diagnosed stomach cancer.

Depending on the location and extent of the lesion, surgery in the form of radical subtotal gastrectomy usually is the treatment of choice. Irradiation and chemotherapy have not proven particularly useful as primary treatment modalities in stomach cancer. These methods usually are used for palliative purposes or to control metastatic spread of the disease.

Summary Concepts

- The integrity of the mucosal layer of the stomach is maintained by tight intercellular junctions and the presence of a protective mucous layer. Prostaglandins serve as chemical messengers that protect the stomach lining by improving blood flow, increasing bicarbonate secretion, and enhancing mucus production. Major causes of gastric irritation and ulcer formation are aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs), which exert their destructive effects by irritating the stomach and inhibiting prostaglandin synthesis and Helicobacter pylori infection, which disrupts the mucosal barrier that protects the stomach from the harmful effects of its digestive enzymes.

- Gastritis refers to inflammation of the gastric mucosa. Acute gastritis is a transient inflammation of the gastric mucosa, most commonly caused by local irritants such as bacterial endotoxins, caffeine, alcohol, and aspirin. Chronic gastritis, which is characterized by the presence of chronic inflammatory changes leading eventually to atrophy of the glandular epithelium of the stomach, can be caused by H. pylori (H. pylori gastritis), autoantibodies (autoimmune gastritis), or chronic injury from reflux of alkaline duodenal contents, pancreatic secretions, and bile into the stomach (chemical gastropathy).

- Peptic ulcer disease occurs in areas of the upper gastrointestinal tract that are exposed to acid–pepsin secretions, most commonly the duodenum and stomach. The most common complications of peptic ulcers are hemorrhage, perforation, and gastric outlet obstruction.

- Cancer of the stomach, while having decreased in incidence in the United States, continues to be a leading cause of cancer deaths worldwide. Among the factors thought to predispose to stomach cancer are carcinogenic factors in the diet (e.g., N-nitroso compounds and benz[a]pyrene found in smoked and preserved food) and chronic gastritis. Because there are few early symptoms with this form of cancer, the disease often is far advanced at the time of diagnosis.

Disorders of the Small and Large Intestines

There are many similarities in conditions that disrupt the integrity and function of the small and large intestines. The walls of the small and large intestines consist of four layers: (1) an inner mucosal layer that lines the lumen of the intestine; (2) a submucosal layer that lies beneath the mucosal layer; (3) the muscularis externa, which has an inner circular layer and an outer longitudinal layer of smooth muscle; and (4) an outer serosal layer or visceral peritoneum that consists of a single layer of flat serous fluid–producing cells (see Chapter 28, Fig. 28-3). The visceral peritoneum is continuous with the parietal peritoneum, which lines the abdominopelvic cavity. Among the conditions that cause altered intestinal function are irritable bowel syndrome, inflammatory bowel disease, infectious enterocolitis, diverticulosis, appendicitis, disorders of bowel motility (i.e., diarrhea, constipation, and bowel obstruction), peritonitis, disorders of intestinal absorption, and cancer of the colon and rectum.

Irritable Bowel Syndrome

The term irritable bowel syndrome (IBS) is used to describe a functional gastrointestinal disorder characterized by a variable combination of chronic and recurrent intestinal symptoms not explained by structural or biochemical abnormalities. Prevalence estimates for IBS in North America range from 5% to 10%, with peak prevalence from 20 to 29 years of age.
Irritable bowel disease is characterized by persistent or recurrent symptoms of abdominal pain, altered bowel function, and varying complaints of flatulence, bloating, nausea and anorexia, constipation or diarrhea, and anxiety or depression. A hallmark of IBS is abdominal pain that is relieved by defecation and associated with a change in consistency or frequency of stools. Abdominal pain usually is intermittent, cramping, and in the lower abdomen. It does not usually occur at night or interfere with sleep. The condition is believed to result from dysregulation of intestinal motor and sensory functions modulated by the CNS. Persons with IBS tend to experience increased motility and abnormal intestinal contractions in response to psychological and physiologic stresses. Although changes in intestinal activity are normal responses to stress, these responses appear to be exaggerated in persons with IBS. Women tend to be affected more often than men. Menarche often is associated with onset of the disorder. Women frequently notice an exacerbation of symptoms during the premenstrual period, suggesting a hormonal component.

The diagnosis of IBS is usually based on signs and symptoms of abdominal pain or discomfort, bloating, and constipation or diarrhea, or alternating bouts of constipation and diarrhea. A commonly used set of diagnostic criteria requires continuous or recurrent symptoms of at least 12 weeks’ duration (which may be nonconsecutive) of abdominal discomfort or pain in the preceding 12 months, with two of three accompanying features: relief with defecation, onset associated with a change in bowel frequency, and associated with a change in form (appearance) of stool. Other symptoms that support the diagnosis of IBS include abnormal stool frequency (more than three times per day or less than three times per week), abnormal stool form (lumpy/hard or loose/watery), abnormal stool passage (straining, urgency, or feeling of incomplete evacuation), passage of mucus, and bloating or feeling of abdominal distention. A history of lactose intolerance should be considered because intolerance to lactose and other sugars may be a precipitating factor in some persons. The acute onset of symptoms raises the likelihood of organic disease, as do weight loss, anemia, fever, occult blood in the stool, nighttime symptoms, or signs and symptoms of malabsorption. These signs and symptoms require additional investigation.

The treatment of IBS focuses on methods of stress management, particularly those related to symptom production. Reassurance is important. Usually, no special diet is indicated, although adequate fiber intake usually is recommended. Avoidance of offending dietary substances such as fatty and gas-producing foods, alcohol, and caffeine-containing beverages may be beneficial. Various pharmacologic agents, including antispasmodic and anticholinergic drugs, have been used with varying success in treatment of the disorder. Alosetron is a serotonin antagonist that has been approved by the U.S. Food and Drug Administration (FDA) for treatment of women with severe IBS. The drug appears to act by reducing intestinal secretion, decreasing visceral afferent nerve activity (thereby reducing abdominal pain), and reducing intestinal motility. Because the drug has serious side effects, including severe constipation and ischemic colitis, its use is restricted to women with severe IBS with diarrhea who have not responded to conventional treatment and have been educated about the relative risks and benefits of the agent.

**Inflammatory Bowel Disease**

The term *inflammatory bowel disease* (IBD) is used to designate two related inflammatory intestinal disorders: Crohn disease and ulcerative colitis. Although the two diseases differ sufficiently to be distinguishable, they have many features in common. Both diseases produce inflammation of the bowel, both lack confirming evidence of a proven causative agent, both have a pattern of familial occurrence, and both can be accompanied by systemic manifestations. Crohn disease most commonly affects the distal small intestine and proximal colon but can affect any area of the gastrointestinal tract from the esophagus to the anus, whereas ulcerative colitis is confined to the colon and rectum (Fig. 29-5). In Crohn disease the inflammation is often transmural, whereas in ulcerative colitis it is typically confined to the mucosa.

The clinical manifestations of both Crohn disease and ulcerative colitis are ultimately the result of activation of inflammatory cells with elaboration of inflammatory mediators that cause nonspecific tissue damage. Both diseases are characterized by remissions and exacerbations of diarrhea, fecal urgency, and weight loss. Acute complications, such as intestinal obstruction, may develop during periods of fulminant disease. The distinguishing characteristics of Crohn disease and ulcerative colitis are summarized in Table 29-1.

A number of systemic manifestations have been identified in persons with Crohn disease and ulcerative colitis. These include axial arthritis affecting the spine and sacroiliac joints and oligoarticular arthritis affecting the large joints of the arms and legs; inflammatory conditions of the eye, usually uveitis; skin lesions, especially erythema nodosum; inflammation of the mucous membrane of the mouth (stomatitis); blood disorders (anemia, hypercoagulability); and inflammation of the bile. 

![Crohn disease and Ulcerative colitis](image-url)
The intestinal microbiome consists of the microorganisms that inhabit the gut. These organisms play a key role in development of the intestinal immune system and supplying the body with key nutrients such as vitamin B2. Although acquired shortly after birth, each person’s microbiome changes rapidly during the first year of life. Moreover, although each adult has a unique population of microbiota that remains fairly stable over time, changes occur in response to environmental and developmental factors, and disease. Despite the growing evidence that intestinal microorganisms contribute to IBD pathogenesis, their precise role remains to be described and is probably different in Crohn disease and ulcerative colitis.

A variety of epithelial defects have been described in both Crohn disease and ulcerative colitis. The intestinal epithelium at the interface between the intestinal microbiome and the wall of the gastrointestinal tract plays a critical role in preventing the entry of bacteria and shaping the mucosal immune response. An intact mucosal barrier depends on tight epithelial cell junctions that help to seal the space between the intestinal contents and the underlying tissues of the intestinal wall. Additional defenses against bacterial invasion consist of specialized epithelial cells, including the goblet cells, which secrete antimicrobial peptides (see Chapter 28, Fig. 28-11). The fact that fewer than 10% of individuals carrying the NOD2 mutations develop Crohn disease suggests that it is only one of many factors that contribute to the pathogenesis of the disease.

The causes of Crohn disease and ulcerative colitis are largely uncertain. There is growing evidence that the two diseases result from a combination of intestinal microorganisms, intestinal epithelial dysfunction, and aberrant immune responses in a genetically predisposed host. The genetic basis for IBD has long been suspected. The risk of disease is greater when there is an affected family member, with a family history of IBD being more common in Crohn disease than ulcerative colitis. Molecular linkage analyses of affected families have identified NOD2 (nucleotide oligomerization domain 2) as a susceptibility gene in Crohn disease. The NOD2 gene encodes a protein that is an intracellular receptor for a component of the cell wall of many microbes and is thought to play a role in host responses to these pathogens. It has been postulated that disease-associated NOD2 is less effective in recognizing and eliminating pathogens that contribute to the pathogenesis of the disease.

Crohn Disease

Crohn disease is a recurrent, granulomatous type of inflammatory response that can affect any area of the gastrointestinal tract. In half the cases, the disease affects mainly the ileum and cecum, only the small intestine in 15%, only the colon in 20%, and mainly the anorectal region in 15%. It is a slowly progressive, relentless, and often disabling disease. The disease usually strikes people in their twenties or thirties, with women being affected slightly more often than men.

Clinical Manifestations. A characteristic feature of Crohn disease is the sharply demarcated, granulomatous lesions that are surrounded by normal-appearing mucosal tissue. When the lesions are multiple, they often are referred to as skip lesions because they are interspersed between what appear to be normal segments of the bowel. All the layers of the bowel are involved, with the submucosal layer affected to the greatest extent. The surface of the inflamed bowel usually has a characteristic “cobblestone” appearance resulting from the fissions and crevices that develop, surrounded by areas of submucosal edema. There usually is a relative sparing of the smooth muscle layers of the bowel, with marked inflammatory and fibrotic changes of the submucosal layer. After a time, the bowel wall often becomes thickened and inflexible; its appearance has...
The clinical course of Crohn disease is variable; often, there are periods of exacerbations and remissions, with symptoms being related to the location of the lesions. The principal symptoms include intermittent diarrhea, colicky pain (usually in the lower right quadrant), weight loss, fluid and electrolyte disorders, malaise, and low-grade fever. Because Crohn disease affects the submucosal layer to a greater extent than the mucosal layer, there is less bloody diarrhea than with ulcerative colitis. Ulceration of the perianal skin is common, largely because of the severity of the diarrhea. The absorptive surface of the intestine may be disrupted; nutritional deficiencies may occur, related to the specific segment of the intestine involved. When Crohn disease occurs in childhood, one of its major manifestations may be retardation of growth and physical development.

Complications. Complications of Crohn disease include fistula formation, abdominal abscess formation, and intestinal obstruction. Fistulas are tubelike passages that form connections between different sites in the gastrointestinal tract. They also may develop between other sites, including the bladder, vagina, urethra, and skin. Perineal fistulas that originate in the ileum are relatively common. Fistulas between segments of the gastrointestinal tract may lead to malabsorption, syndromes of bacterial overgrowth, and diarrhea. They also can become infected and cause abscess formation.

Diagnosis and Treatment. The diagnosis of Crohn disease requires a thorough history and physical examination. Endoscopy is used for direct visualization of the affected areas, to determine extent of disease involvement, and to obtain biopsies. Measures are taken to exclude infectious agents as the cause of the disorder. This usually is accomplished by the use of stool cultures and examination of fresh stool specimens for ova and parasites. CT scans may be used to detect an inflammatory mass, fistula, or abscess. Radiographic contrast studies may be used to augment endoscopy or CT scans.

Treatment methods focus on terminating the inflammatory response and promoting healing, maintaining adequate nutrition, and preventing and treating complications. Nutritional deficiencies are common in Crohn disease because of diarrhea, steatorrhea, and other malabsorption problems. A nutritious diet that is high in calories, vitamins, and proteins is recommended. Because fats often aggravate the diarrhea, it is recommended that they be avoided. Elemental diets, which are nutritionally balanced but residue free and bulk free, may be given during the acute phase of the illness. These diets are largely absorbed in the jejunum and allow the inflamed bowel to rest. Total parenteral nutrition (i.e., parenteral hyperalimentation), which is administered intravenously, may be needed when food cannot be absorbed from the intestine.

Several medications have been successful in suppressing the inflammatory reaction in Crohn disease, including 5-aminosalicylic acid (5-ASA) agents, corticosteroids, antibiotics, immunosuppressant drugs (azathioprine, 6-mercaptopurine, methotrexate), and anti–tumor necrosis factor (TNF) therapies (infliximab and adalimumab). The 5-ASA agents act locally to affect multiple sites in the arachidonic acid pathway critical to the pathogenesis of inflammation. Much of the unformulated 5-ASA is absorbed from the small intestine and does not reach the distal small bowel or colon in appreciable amounts. To overcome the rapid absorption of 5-ASA, a number of formulations (e.g., sulfasalazine, mesalamine) have been designed to deliver the drug to the distal small bowel and colon. Corticosteroids are used to suppress the acute clinical symptoms in persons with small and large bowel disease. Metronidazole is an antibiotic used to treat bacterial overgrowth in the small intestine. Azathioprine, 6-mercaptopurine, methotrexate, and cyclosporine are immunomodulating drugs that are used in persons who do not respond to other forms of therapy. The anti-TNF agents are monoclonal antibodies that target the destruction of TNF-α, a mediator of the inflammatory response that is known to be important in granulomatous inflammatory processes such as Crohn disease. These agents are used to treat severe disease. Surgical resection of damaged bowel, drainage of abscesses, or repair of fistula tracts may be necessary.

Ulcerative Colitis
Ulcerative colitis is a nonspecific inflammatory condition of the colon. The disease is more common in the United States and Western countries. The disease may arise at any age, with a peak incidence in the third decade. Unlike Crohn disease, which can affect various sites in the gastrointestinal tract, ulcerative colitis is confined to the rectum and colon. The disease usually begins in the rectum and spreads proximally, affecting primarily the mucosal layer, although it can extend into the submucosal layer. The length of proximal extension varies. It may involve the rectum alone (ulcerative proctitis), the rectum and sigmoid colon (proctosigmoiditis), or the entire
Clinical Manifestations. Ulcerative colitis typically presents as a relapsing disorder marked by attacks of diarrhea. The diarrhea may persist for days, weeks, or months and then subside, only to recur after an asymptomatic interval of several months to years or even decades. Because ulcerative colitis affects the mucosal layer of the bowel, the stools typically contain blood and mucus. Nocturnal diarrhea usually occurs when daytime symptoms are severe. There may be mild abdominal cramping and fecal incontinence. Anorexia, weakness, and fatigability are common.

Based on clinical and endoscopic findings, the disease is characterized by its severity and extent. Severity is defined as mild, moderate, or severe. The most common form of the disease is the mild form, in which the person has less than four formed or liquid stools daily, with intermittent rectal bleeding. Because of rectal inflammation there may be urgency, accompanied by lower left quadrant cramping. Persons with moderate disease have more severe diarrhea and bleeding. Abdominal pain and tenderness may be present, but not severe. There may be fever and anemia. Persons with severe disease have more than 6 bloody bowel movements a day, resulting in severe anemia, hypovolemia, and impaired nutrition with hypoalbuminemia. A subset of persons with ulcerative colitis develop a more fulminant form of the disease with rapid progression over a matter of weeks to fever, prominent hypovolemia, hemorrhaging requiring transfusion, and abdominal distention with tenderness.

Complications. Cancer of the colon is one of the feared complications of ulcerative colitis. Because of the relatively high risk for development of cancer, regular annual or biannual surveillance colonoscopies with multiple biopsies are recommended for persons with extensive colitis, beginning 8 to 10 years after diagnosis.

Infectious Enterocolitis

A number of microbial agents, including viruses, bacteria, and protozoa, can infect the gastrointestinal tract, causing a broad range of symptoms including diarrhea, abdominal pain, perianal discomfort, ulceration, and hemorrhage. Infectious enterocolitis is a global problem, causing more than 3 million deaths annually and accounting for up to one half of deaths in children younger than 5 years in some countries. Although less common in industrialized countries, these disorders still

have infection rates second only to the common cold. Most infections are spread by the oral–fecal route, often through contaminated water or food.

**Viral Infections**

Most viral infections affect the superficial epithelium of the small intestine, destroying these cells and disrupting their absorptive function. Repopulation of the small intestinal villi with immature enterocytes and preservation of crypt secretory cells leads to net secretion of water and electrolytes compounded by incomplete absorption of nutrients and osmotic diarrhea. Symptomatic disease is caused by several distinct viruses, including the rotavirus, which most commonly affects children 6 to 24 months of age; the norovirus (previously known as the Norwalk virus), which is responsible for the majority of cases of nonbacterial food-borne epidemic gastroenteritis in all age groups; and enteric adenoviruses, which primarily affect children.6

**Rotavirus.** Worldwide, rotavirus is estimated to cause more than 111 million cases of diarrhea in children younger than 5 years of age. In the United States, the disease causes 3 million cases of diarrhea, 80,000 hospitalizations, and 20 to 40 deaths per year.31 The disease tends to be most severe in children 3 to 24 months of age. Infants younger than 3 months of age are relatively protected by transplacental antibodies and possibly by breast-feeding. The virus is spread by a fecal–oral route and outbreaks are common in children in day care centers. The virus is shed before and after days for clinical illness. Very few infectious virions are needed to cause disease in a susceptible host.

Rotavirus infection typically begins after an incubation period of less than 24 hours, with mild to moderate fever and vomiting, followed by onset of frequent watery stools. The fever and vomiting usually disappear on about the second day, but the diarrhea may continue for 5 to 7 days. Dehydration may develop rapidly, particularly in infants. Treatment is largely supportive.

Currently, there are two licensed vaccines that protect infants from rotavirus infection: a live, oral, pentavalent vaccine (RotaTeq) containing five reassortment rotaviruses isolated from human and bovine hosts, and a monovalent vaccine (Rotarix) that is effective against all of the serotypes that cause infection in children.31

**Bacterial Infections**

Infectious enterocolitis can be caused by a number of bacteria. There are several pathogenic mechanisms for development of bacterial enterocolitis: ingestion of preformed toxins that are present in contaminated food, infection by toxigenic organisms that proliferate in the gut lumen and produce an enterotoxin, and infection by enteroinvasive organisms that proliferate in the lumen and invade and destroy mucosal epithelial cells. The pathogenic effects of bacterial infections depend on the ability of the organism to adhere to the mucosal epithelial cells, elaborate enterotoxins, and then invade the mucosal epithelial cells.

In general, bacterial infections produce more severe effects than viral infections. The complications of bacterial enterocolitis result from massive fluid loss or destruction of intestinal mucosa and include dehydration, sepsis, and perforation. Among the organisms that cause bacterial enterocolitis are *Staphylococcus aureus* (toxins associated with “food poisoning”), *Shiga toxin-producing Escherichia coli*, *Shigella* species, nontyphoid salmonella, and campylobacter.32 Two particularly serious forms of bacterial enterocolitis are caused by *Clostridium difficile* and *E. coli* O157:H7.

**Clostridium difficile Colitis.** *C. difficile* (so named because it is difficult to culture) is a gram-positive, spore-forming bacillus that is part of the normal flora in some healthy people. The spores are resistant to the acid environment of the stomach and convert to vegetative forms in the colon.33 In general, *C. difficile* is noninvasive and development of *C. difficile* colitis requires disruption of normal intestinal flora, acquisition and germination of the spores, overgrowth of the bacillus, and toxin production. The toxins bind to and damage the intestinal mucosa, causing hemorrhage, inflammation, and necrosis. The toxins also interfere with protein synthesis, attract inflammatory cells, increase capillary permeability, and stimulate intestinal peristalsis. Treatment with broad-spectrum antibiotics predisposes to disruption of the normal protective bacterial flora of the colon. After antibiotic therapy has made the bowel susceptible to infection, colonization by *C. difficile* occurs by the oral–fecal route.34 *C. difficile* infection usually is acquired in the hospital, where the organism is commonly encountered. Nearly all antibiotics have been implicated in the disease.

A new and hypervirulent fluoroquinolone-resistant strain of *Clostridium difficile* (NAP1/B1/027) has been implicated in *C. difficile* outbreaks since the early 2000s.34,35 This epidemic form has caused more severe and refractory disease leading to complications that include intensive care unit admission, colectomies, and death. Before 2002, *C. difficile*-associated colitis was rare, but its prevalence has increased significantly.35 The risk of *C. difficile*-associated diarrhea is increased not only by factors, such as antibiotic exposure, but also by gastrointestinal surgery/manipulation, prolonged stay at a health care facility, serious underlying disease, immune-compromising conditions, and aging. Persons on proton pump inhibitors are at elevated risk, as are peripartum women and heart transplant recipients. However, *C. difficile* infection has emerged in populations not previously considered at risk.34,35 These include young and previously healthy persons who have not received antimicrobial therapy or been exposed to the hospital environment. In these cases the only risk factor was close contact with someone who had *C. difficile* infection.35

*C. difficile* colitis commonly manifests with diarrhea that is mild to moderate and sometimes is accompanied by lower abdominal cramping. Typically, symptoms begin within 1 to 2 weeks after antibiotic treatment has been initiated, although it can vary from 1 day to
6 weeks. In most cases systemic manifestations are absent and the symptoms subside after the antibiotic has been discontinued. A more severe form of colitis, pseudomembranous colitis, is characterized by an adherent inflammatory membrane overlying the areas of mucosal injury. It is a life-threatening form of the disease. Persons with the disease are acutely ill, with lethargy, fever, tachycardia, abdominal pain and distention, and dehydration. The smooth muscle tone of the colon may be lost, resulting in toxic dilation of the colon. Prompt therapy is needed to prevent perforation of the bowel.

The diagnosis of C. difficile colitis requires a careful history, with particular emphasis on antibiotic use. Diagnostic findings include a history of antibiotic use and laboratory tests that confirm the presence of C. difficile toxins in the stool. Patients with C. difficile infection should be put on contact precautions and placed in a single room with a bathroom or, if unavailable, with other infected patients.

Treatment includes the immediate discontinuation of antibiotic therapy. Specific treatment aimed at eradicating C. difficile is used when symptoms are severe or persistent. Metronidazole is the drug of first choice, with vancomycin being reserved for persons who cannot tolerate metronidazole or do not respond to the drug. Both drugs are given orally. Metronidazole is absorbed from the upper gastrointestinal tract and may cause side effects. Vancomycin is poorly absorbed, and its actions are limited to the gastrointestinal tract.

**Escherichia coli O157:H7 Infection.** Enterohemorrhagic *E. coli* O157:H7 has become recognized as an important cause of epidemic and sporadic colitis. *E. coli* O157:H7 is a strain of *E. coli* found in the feces and contaminated milk of healthy dairy and beef cattle, but it also has been found in contaminated pork, poultry, and lamb. Infection usually is by food-borne transmission, often by ingesting undercooked ground beef. The organism also can be transferred to nonmeat products such as fruits and vegetables. Transmission has also been reported in persons swimming in a fecally contaminated lake as well as among visitors to farms and petting zoos who are in direct contact with animals. Person-to-person transmission may occur, particularly in nursing homes, day care settings, and hospitals. The very young and the very old are particularly at risk for the infection and its complications.

Although most strains of *E. coli* are harmless, *E. coli* O157:H7 produce *Shigella*-like toxins that attach to and damage the mucosal lining of the intestine, causing bloody diarrhea. Subsequently, the *Shigella*-like toxins gain access to the circulatory system, where they damage the endothelium and initiate platelet activation. Two complications of the infection, hemolytic uremic syndrome and thrombotic thrombocytopenic purpura, reflect the effects of the *Shigella*-like toxins. The hemolytic uremic syndrome is characterized by hemolytic anemia, thrombocytopenia, and renal failure caused by platelet thrombi in the renal microvasculature. It occurs predominantly in infants and young children and is the most common cause of acute renal failure in children. It has a mortality rate of 3% to 5%, and one third of the survivors are left with permanent disability. Thrombotic thrombocytopenic purpura is manifested by thrombocytopenia, renal failure, fever, and neurologic manifestations caused by microthrombi in the brain.

No specific therapy is available for *E. coli* O157:H7 infection. Treatment is largely symptomatic and directed toward treating the effects of complications. The use of antibiotics or antidiarrheal agents in the early stages of diarrhea has been shown to increase the risk of hemolytic uremic syndrome because the gut is exposed to a greater amount of toxins for a longer time. Because of the seriousness of the infection and its complications, education of the public about techniques for decreasing primary transmission of the infection from animal sources is important. Undercooked meats and unpasteurized milk are sources of transmission. Food handlers and consumers should be aware of the proper methods for handling uncooked meat to prevent cross-contamination of other foods. Particular attention should be paid to hygiene in day care centers and nursing homes, where the spread of infection to the very young and very old may result in severe complications.

**Diverticular Disease**

Diverticulosis is a disorder characterized by pseudodiverticula of the colonic mucosa and submucosa. Although the disorder is prevalent in the developed countries of the world, it is almost nonexistent in many African nations and underdeveloped countries. This suggests that factors such as lack of fiber in the diet, a decrease in physical activity, and poor bowel habits (e.g., neglecting the urge to defecate), along with the effects of aging, contribute to the development of the disease.

True diverticula involve all layers of the intestinal wall. The abnormal structures in diverticulosis are instead pseudodiverticula, in which only the mucosa and submucosa are herniated through the muscle layers. The diverticula are often multiple, ranging from a solitary herniation to several hundred (Fig. 29-8). They are most often located in the sigmoid colon, but more extensive areas may be involved in severe cases. Microscopically, colonic diverticula are small, flashtike outpouchings, usually 0.5 to 1.0 cm in diameter, that occur in a regular distribution alongside the teniae coli (Fig. 29-9).

Colonic diverticula result from the unique structure and elevated luminal pressures in the sigmoid colon. In the colon, the longitudinal muscle does not form a continuous layer, as it does in the small bowel. Instead, there are three separate longitudinal bands of muscle called the teniae coli. In a manner similar to the small intestine, bands of circular muscle constrict the large intestine. As the circular muscle contracts at each of these points (approximately every 2.5 cm), the lumen of the bowel becomes constricted, so that it is almost occluded. The combined contraction of the circular muscle and the lack of a continuous longitudinal muscle
layer cause the intestine to bulge outward into pouches called *haustra*. Diverticula develop between the longitudinal muscle bands of the haustra, in the areas where blood vessels pierce the circular muscle layer to bring blood to the mucosal layer. An increase in intraluminal pressure in the haustra provides the force for creating these herniations.

Most people with diverticular disease remain asymptomatic. The disease often is found when x-ray studies are done for other purposes. Ill-defined lower abdominal discomfort, a change in bowel habits (e.g., diarrhea, constipation), bloating, and flatulence are common. Diverticulitis is a complication of diverticulosis in which there is inflammation and gross or microscopic perforation of the diverticula. One of the most common complaints of diverticulitis is pain in the lower left quadrant, accompanied by nausea and vomiting, tenderness in the lower left quadrant, a slight fever, and an elevated white blood cell count. These symptoms usually last for several days, unless complications occur, and usually are caused by localized inflammation of the diverticula with perforation and development of a small, localized abscess. Complications include perforation with peritonitis, hemorrhage, and bowel obstruction. Fistulas can form, usually involving the bladder (i.e., vesicosigmoid fistula) but sometimes involving the skin, perianal area, or small bowel. Pneumaturia (i.e., air in the urine) is a sign of vesicosigmoid fistula.

The diagnosis of diverticular disease is based on history and presenting clinical manifestations. The disease may be confirmed by CT scans or ultrasonographic studies. CT scans are the safest and most cost-effective method. Because of the risk of peritonitis, barium enema studies and endoscopy should be avoided in persons who are suspected of having acute diverticulitis. Flat abdominal radiographs may be used to detect complications associated with acute diverticulitis.

The usual treatment for diverticular disease is to prevent symptoms and complications. This includes increasing the bulk in the diet and bowel retraining so that the person has at least one bowel movement each day. The increased bulk promotes regular defecation and increases colonic contents and colon diameter, thereby decreasing intraluminal pressure. Acute diverticulitis is treated by withholding solid food and administering a broad-spectrum antibiotic. Hospitalization may be required for persons who show significant inflammation, are unable to tolerate oral fluids, or have significant comorbid conditions. Surgical treatment is reserved for complications.

**Appendicitis**

Acute appendicitis, or inflammation of the wall of the appendix, is extremely common. It is seen most frequently in the 20- to 30-year-old age group, but it can occur at any age. The appendix becomes inflamed, swollen, and gangrenous, and it eventually perforates if not treated. Although the cause of appendicitis is unknown, it is thought to be related to intraluminal obstruction with a fecolith (i.e., hard piece of stool) or to twisting.

Appendicitis usually has an abrupt onset, with pain referred to the epigastric or periumbilical area. This pain is caused by stretching of the appendix during the early inflammatory process. At approximately the same time that the pain appears, there are one or two episodes of nausea. Initially, the pain is vague, but over a period of 2 to 12 hours, it gradually increases and may become colicky. When the inflammatory process has extended to involve the serosal layer of the appendix and the peritoneum, the pain becomes localized to the lower right quadrant. There usually is an elevation in temperature and a white blood cell count greater than 10,000/mm³, with 75% or more polymorphonuclear cells. Palpation of the abdomen usually reveals a deep tenderness in
the lower right quadrant, which is confined to a small area approximately the size of the fingertip. It usually is located at approximately the site of the inflamed appendix. The person with appendicitis often is able to place his or her finger directly over the tender area. Rebound tenderness, which is pain that occurs when pressure is applied to the area and then released, and spasm of the overlying abdominal muscles are common.

Diagnosis is usually based on history and findings on physical examination. Ultrasonography or CT may be used to confirm the diagnosis. Treatment consists of surgical removal of the appendix. Complications include peritonitis, localized periappendiceal abscess formation, and septicemia.

Disorders of Intestinal Motility

Intestinal motility, or the movement of contents through the gastrointestinal tract, is controlled by neurons located in the submucosal and myenteric plexuses of the gut (see Chapter 28). The axons from the cell bodies in the myenteric plexus innervate the circular and longitudinal smooth muscle layers of the gut. These neurons receive impulses from local receptors located in the mucosal and muscle layers of the gut and extrinsic input from the parasympathetic and sympathetic nervous systems. As a general rule, the parasympathetic nervous system tends to increase the motility of the bowel, whereas sympathetic stimulation tends to slow its activity.

The large intestine has sphincters at both ends: the ileocecal sphincter, which separates it from the small intestine; and the anal sphincter, which prevents the movement of feces to the outside of the body. About 1500 mL of fluid and undigested food normally pass through the ileocecal valve into the large intestine each day. Most of the water and electrolytes in the fluid are absorbed in the colon, usually leaving less than 100 mL to be excreted in the feces. The large intestine can absorb a maximum of 5 to 8 L of fluid and electrolytes each day. When the total amount entering the large intestine through the ileocecal valve or by way of intestinal secretion exceeds this amount, the excess appears in the feces as diarrhea.

Diarrhea

The usual definition of diarrhea is excessively frequent passage of stools. Diarrhea can be acute or chronic and can be caused by infectious organisms, food intolerance, drugs, or intestinal disease. In developing countries, diarrhea is a common cause of mortality among children younger than 5 years of age, with an estimated 2 million deaths annually. Even though diarrheal diseases are less prevalent in the United States than in other countries, they place a burden on the health care system.

Acute Diarrhea. Acute diarrhea is predominantly caused by infectious agents and follows a self-limited course of less than 2 weeks. Acute diarrhea is commonly divided into noninflammatory (large-volume) and inflammatory (small-volume) diarrhea, based on the characteristics of the diarrheal stool. Enteric organisms cause diarrhea in several ways. Some organisms are noninvasive and do not cause inflammation, but secrete toxins that stimulate fluid secretion. Others invade and destroy intestinal epithelial cells, thereby altering fluid transport so that secretory activity continues while absorption activity is halted.

Noninflammatory diarrhea is associated with large-volume watery and nonbloody stools, periumbilical cramps, bloating, and nausea or vomiting. It is commonly caused by toxin-producing bacteria (e.g., enterotoxigenic E. coli, S. aureus, Vibrio cholerae) or other agents (e.g., viruses, Giardia) that disrupt the normal absorption or secretory process in the small bowel. Prominent vomiting suggests viral enteritis or S. aureus food poisoning. Although typically mild, diarrhea that originates in the small intestine can be voluminous and result in dehydration with hypokalemia and metabolic acidosis. Because tissue invasion and inflammation do not occur, leukocytes are not present in the feces.

Inflammatory diarrhea is usually characterized by the presence of fever and bloody diarrhea. It is caused by bacterial invasion of intestinal cells (e.g., Shigella, Salmonella, Yersinia, and Campylobacter) or the toxins associated with these organisms predominantly affect the colon, the diarrhea is small in volume (<1 L/day) and is associated with lower abdominal pain and the urgent desire to defecate. Infectious dysentery must be distinguished from acute ulcerative colitis, which may present with bloody diarrhea, fever, and abdominal pain. Diarrhea that persists for 14 days is usually not caused by bacterial pathogens (except for C. difficile), and the person should be evaluated for chronic diarrhea.

Chronic Diarrhea. Diarrhea is considered to be chronic when the symptoms persist for 3 to 4 weeks in children or adults and 4 weeks in infants. Chronic diarrhea is often associated with conditions such as irritable bowel and inflammatory bowel syndromes, malabsorption disorders, endocrine disorders (hyperthyroidism, diabetic autonomic neuropathy), or radiation colitis. There are four major causes of chronic diarrhea: presence of hyperosmotic luminal contents, increased intestinal secretory processes, inflammatory conditions, and infectious processes (Chart 29-1). A condition called factitious diarrhea is caused by indiscriminate use of laxatives or excessive intake of laxative-type foods.

In osmotic diarrhea, water is pulled into the bowel by the hyperosmotic nature of its luminal contents. It occurs when osmotically active particles are not absorbed. In persons with lactase deficiency, the lactose in milk cannot be broken down and absorbed. Magnesium salts, which are contained in milk of magnesia and many antacids, are poorly absorbed and cause diarrhea when taken in sufficient quantities. Another cause of osmotic diarrhea is decreased transit time, which interferes with absorption.
**Secretory diarrhea** occurs when the secretory processes of the bowel are increased. Secretory diarrhea also occurs when excess bile acids remain in the intestinal contents as they enter the colon. This often occurs with disease processes of the ileum because bile salts are absorbed there. It also may occur with bacterial overgrowth in the small bowel, which interferes with bile absorption.

**Inflammatory bowel disease** commonly is associated with acute or chronic inflammation or intrinsic disease of the colon, such as ulcerative colitis or Crohn disease. Inflammatory diarrhea usually is evidenced by frequency and urgency and colicky abdominal pain. It commonly is accompanied by tenesmus (i.e., ineffectual and painful straining at stool), fecal soiling of clothing, and awakening during the night with the urge to defecate.

Chronic parasitic infections may cause chronic diarrhea through a number of mechanisms. Pathogens most commonly associated with chronic diarrhea include the protozoans *Entamoeba histolytica*, *Giardia*, and *Cyclospora*. Immunocompromised individuals are particularly susceptible to infectious organisms such as *Cryptosporidia*, *cytomegalovirus* (CMV), and *Mycobacterium avium-intracellulare* complex that can cause both acute and chronic diarrhea (see Chapter 16).

**Diagnosis and Treatment.** The diagnosis of diarrhea is based on complaints of frequent stools and a history of accompanying factors such as concurrent illnesses, medication use, and exposure to potential intestinal pathogens. Disorders such as Crohn disease and ulcerative colitis should be considered. If the onset of diarrhea is related to travel outside the United States, the possibility of traveler’s diarrhea must be considered.

Although most acute forms of diarrhea are self-limited and require no treatment, diarrhea can be particularly serious in infants and small children, persons with other illnesses, and the elderly. Thus, the replacement of fluids and electrolytes is considered to be a primary therapeutic goal in the treatment of diarrhea. Oral replacement therapy (ORT) can be used in situations of uncomplicated diarrhea that can be treated at home. First applied to the treatment of diarrhea in developing countries, ORT can be regarded as a case of reverse technology, in which the protocols originally implemented in these countries have changed health care practices in industrialized countries as well. Complete ORT solutions contain carbohydrate, sodium, potassium, chloride, and base to replace that lost in the diarrheal stool.

Commonly used beverages such as apple juice and cola drinks, which have increased osmolality because of their high carbohydrate and low electrolyte content, are not recommended. The effectiveness of ORT is based on the coupled transport of sodium and glucose or other actively transported small molecules. ORT can be particularly effective in treating dehydration associated with diarrheal diseases in infants and small children. Children who are severely dehydrated with changes in vital signs or mental status require emergency intravenous fluid resuscitation. After initial treatment with intravenous fluids, these children can be given ORT.

Evidence suggests that feeding should be continued during diarrheal illness, particularly in children. Starch and simple proteins are thought to provide co-transport molecules with little osmotic activity, increasing fluid and electrolyte uptake by intestinal cells. The luminal contents associated with early refeeding are also known to contain growth factor for enterocytes and help facilitate repair after injury. It is recommended that children who require rehydration therapy because of diarrhea be fed an age-appropriate diet. Although there is little agreement on which foods are best, fatty foods and foods high in simple sugars are best avoided. Almost all infants with acute gastroenteritis can tolerate breast-feeding. For formula-fed infants, diluted formula does not provide an advantage over full-strength formula.

Drugs used in the treatment of diarrhea include diphenoxylate (Lomotil) and loperamide (Imodium), which are opium-like drugs. These drugs decrease gastrointestinal motility and stimulate water and electrolyte absorption. Adsorbents, such as kaolin and pectin, adsorb irritants and toxins in the bowel. These ingredients are included in many over-the-counter antidiarrheal preparations because they adsorb toxins responsible for certain types of diarrhea. Antidiarrheal medications should not be used in persons with bloody diarrhea, high fever, or signs of toxicity because of the risk of worsening the disease. Antibiotics should be reserved for use in persons with identified enteric pathogens.

**Constipation**
Constipation can be defined as the infrequent or difficult passage of stools. The difficulty with this definition arises from the many individual variations of function that are normal. What is considered normal for one person (e.g., two or three bowel movements per week) may be considered evidence of constipation by another.
Constipation can occur as a primary disorder of intestinal motility, as a side effect of drugs, as a problem associated with another disease condition, or as a symptom of obstructing lesions of the gastrointestinal tract. Some common causes of constipation are failure to respond to the urge to defecate, inadequate fiber in the diet, inadequate fluid intake, weakness of the abdominal muscles, inactivity and bed rest, pregnancy, and hemorrhoids.

The pathophysiology of constipation can be classified into three broad categories: normal-transit constipation, slow-transit constipation, and disorders of defecation. Normal-transit constipation (or functional constipation) is characterized by perceived difficulty in defecation and usually responds to increased fluid and fiber intake. Slow-transit constipation, which is characterized by infrequent bowel movements, is often caused by alterations in intestinal innervation. Hirschsprung disease is an extreme form of slow-transit constipation in which the ganglion cells in the distal bowel are absent because of a defect that occurred during embryonic development; the bowel narrows at the area that lacks ganglionic cells. Although most persons with this disorder present in infancy or early childhood, some with a relatively short segment of involved colon do not have symptoms until later in life. Defecatory disorders are most commonly due to dysfunction of the pelvic floor or anal sphincter.

Diseases associated with chronic constipation include neurologic diseases such as spinal cord injury, Parkinson disease, and multiple sclerosis; endocrine disorders such as hypothyroidism; and obstructive lesions in the gastrointestinal tract. Drugs such as narcotics, anticholinergic agents, calcium channel blockers, diuretics, calcium (antacids and supplements), iron supplements, and aluminum antacids tend to cause constipation. Elderly people with long-standing constipation may develop dilation of the rectum, colon, or both. This condition allows large amounts of stool to accumulate with little or no sensation. Constipation, in the context of a change in bowel habits, may be a sign of colorectal cancer.

Diagnosis of constipation usually is based on a history of infrequent stools, straining with defeation, the passing of hard and lumpy stools, or the sense of incomplete evacuation with defeation. Rectal examination is used to determine whether fecal impaction, anal stricture, or rectal masses are present. Constipation as a sign of another disease condition should be ruled out. Tests that measure colon transit time and defecatory function are reserved for refractory cases.

The treatment of constipation usually is directed toward relieving the cause. A conscious effort should be made to respond to the defeation urge. A time should be set aside after a meal, when mass movements in the colon are most likely to occur, for a bowel movement. Adequate fluid intake and bulk in the diet should be encouraged. Moderate exercise is essential, and persons on bed rest benefit from passive and active exercises. Laxatives and enemas should be used judiciously. They should not be used on a regular basis to treat simple constipation because they interfere with the defeation reflex and actually may damage the rectal mucosa.

**Acute Intestinal Obstruction**

Intestinal obstruction refers to impaired movement of intestinal contents in a cephalocaudal direction. The condition can be acute or chronic and may affect the small intestine or colon. In contrast to chronic obstructions, which often involve the colon and may last for weeks or months, acute obstructions usually present as severe disorders of the small intestine that are potentially lethal if not recognized early. Acute intestinal obstruction can be mechanical or nonmechanical, resulting from paralytic obstruction of the ileus.

Mechanical obstruction can result from a number of conditions, intrinsic or extrinsic, that encroach on the patency of the bowel lumen (Fig. 29-10). Major inciting causes include an external hernia (i.e., inguinal, femoral, or umbilical) and postoperative adhesions. Less common causes are strictures, tumors, foreign bodies, intussusception, and volvulus. Intussusception involves the telescoping of bowel into the adjacent segment (Figs. 29-10A and 29-11). It is the most common cause of intestinal obstruction in children younger than 2 years of age. The most common form is intussusception of the terminal ileum into the right colon, but other areas of the bowel may be involved. In most cases, the cause of the disorder is unknown. The condition can also occur in adults when an intraluminal mass or tumor acts as a traction force and pulls the segment along as it telescopes into the distal segment. Volvulus refers to a complete twisting of the bowel on an axis formed by its mesentery (see Fig. 29-10B). It can occur in any portion of the gastrointestinal tract, but most commonly involves the cecum, followed by the sigmoid colon. Mechanical bowel obstruction may be a simple obstruction, in which there is no alteration in blood flow, or a strangulated obstruction, in which there is impairment of blood flow and necrosis of bowel tissue.

Paralytic, or adynamic, obstruction of the ileus results from neurogenic or muscular impairment of peristalsis. Paralytic ileus is seen most commonly after abdominal surgery. It also accompanies inflammatory conditions of the abdomen, intestinal ischemia, pelvic fractures, and back injuries. It occurs early in the course of peritonitis and can result from chemical irritation caused by bile, bacterial toxins, electrolyte imbalances as in hypokalemia, and vascular insufficiency.

The major effects of intestinal obstruction are abdominal distention and loss of fluids and electrolytes. Distention is further aggravated by the accumulation of gases and fluid proximal to the site of obstruction. Approximately 70% to 80% of these gases are derived from swallowed air, and because this air is composed mainly of nitrogen, it is poorly absorbed from the intestinal lumen. As the process continues, the distention moves proximally (i.e., toward the mouth), involving additional segments of bowel. Either form of intestinal obstruction eventually may lead to strangulation (i.e., interruption of blood flow), gangrenous changes in the bowel wall, and, ultimately, perforation of the bowel. The increased pressure in the intestine tends to compromise mucosal blood flow, leading to
necrosis and movement of blood into the luminal fluids. This promotes rapid growth of bacteria, especially anaerobes that grow rapidly in this favorable environment and produce a lethal endotoxin.

The manifestations of intestinal obstruction depend on the degree of obstruction and its duration. The major symptoms of acute intestinal obstruction are pain, absolute constipation, abdominal distention, and vomiting. With mechanical obstruction, the pain is severe and colicky, in contrast with the continuous pain and silent abdomen of paralytic ileus. There also is borborygmus (i.e., rumbling sounds made by propulsion of gas in the intestine); audible, high-pitched peristalsis; and peristaltic rushes. Visible peristalsis may appear along the course of the distended intestine. Extreme restlessness and conscious awareness of intestinal movements are experienced along with weakness, perspiration, and anxiety. Should strangulation of the bowel occur, there is a change in symptoms. The character of the pain shifts from the intermittent colicky pain caused by the hyperperistaltic movements of the intestine to a severe and steady type of pain. Vomiting and fluid and electrolyte disorders occur with both types of obstruction.

Diagnosis of intestinal obstruction usually is based on history and physical findings. Plain film radiography of the abdomen may be used to detect the presence of a gas-filled bowel. CT scans and ultrasonography may also be used to detect the presence of mechanical obstruction. Treatment depends on the cause and type of obstruction. Most cases of adynamic obstruction respond to decompression of the bowel through nasogastric suction and correction of fluid and electrolyte imbalances. Strangulation and complete bowel obstruction require surgical intervention.

**Peritonitis**

Peritonitis is an inflammatory response of the serous membrane that lines the abdominal cavity and covers the visceral organs. It can be caused by bacterial invasion or chemical irritation. Most commonly, enteric bacteria enter the peritoneum because of a break in the wall of one of the abdominal organs. The most common causes of peritonitis are perforated peptic ulcer, ruptured appendix, perforated diverticulum, gangrenous bowel, pelvic inflammatory disease, and gangrenous gallbladder. Other causes are abdominal trauma and wounds.

The peritoneum has several characteristics that increase its vulnerability to or protect it from the effects
of peritonitis. One weakness of the peritoneal cavity is that it is a large, unbroken space that favors the dissemination of contaminants. For the same reason, it has a large surface that permits rapid absorption of bacterial toxins into the blood. The peritoneum is particularly well adapted for producing an inflammatory response as a means of controlling infection. It tends, for example, to exude a thick, sticky, and fibrinous substance that adheres to other structures, such as the mesentery and omentum, as a means of sealing off the perforation and localizing the process. Localization is enhanced by sympathetic stimulation that limits intestinal motility. Although the diminished or absent peristalsis that occurs tends to give rise to associated problems, it does inhibit the movement of contaminants throughout the peritoneal cavity.

The onset of peritonitis may be acute, as with a ruptured appendix, or it may have a more gradual onset, as occurs in pelvic inflammatory disease. Pain and tenderness are common symptoms. The pain usually is more intense over the inflamed area. The person with peritonitis usually lies still because any movement aggravates the pain. Breathing often is shallow to prevent movement of the abdominal muscles. The abdomen usually is rigid and sometimes described as boardlike because of reflex muscle guarding. Vomiting is also common. Fever, an elevated white blood cell count, tachycardia, and hypotension are common. Paralytic ileus occurs shortly after the onset of widespread peritonitis and is accompanied by abdominal distention. One of the most important manifestations of peritonitis is the translocation of extracellular fluid into the peritoneal cavity and into the bowel as a result of bowel obstruction. Nausea and vomiting cause further losses of fluid. The fluid loss may encourage development of hypovolemia and shock.

Treatment measures for peritonitis are directed toward preventing the extension of the inflammatory response, correcting the fluid and electrolyte imbalances that develop, and minimizing the effects of paralytic ileus and abdominal distention. Oral fluids are forbidden. Nasogastric suction, which entails the insertion of a tube placed through the nose into the stomach or intestine, is used to decompress the bowel and relieve the abdominal distention. Fluid and electrolyte replacement is essential. These fluids are prescribed on the basis of frequent blood chemistry determinations. Antibiotics are given to combat infection. Narcotics often are needed for pain relief. Surgical intervention may be needed to remove an acutely inflamed appendix or close the opening in a perforated peptic ulcer.

**Disorders of Intestinal Absorption**

Malabsorption is characterized by defective absorption of fats, carbohydrates, proteins, vitamins, minerals, and water from the intestine. It can selectively affect a single component, such as vitamin B₁₂ or lactose, or its effects can extend to all the substances absorbed in a specific segment of the intestine.6,7

Malabsorption results from disturbances that impair one or more phases of nutrient absorption: intraluminal digestion, terminal digestion, transepithelial transport, and lymphatic transport. Intraluminal digestion involves the processing of proteins, carbohydrates, and fats into forms that are suitable for absorption. The most common causes are pancreatic insufficiency, hepatobiliary disease, and intraluminal bacterial growth. Terminal digestion involves the hydrolysis of carbohydrates and peptides, respectively, by brush border enzymes of the small intestine. Disorders of transepithelial transport are caused by mucosal lesions that impair uptake and transport of available intraluminal nutrients across the mucosal epithelium.
surface of the intestine. They include disorders such as celiac disease and Crohn disease. Disorders of lymphatic transport interfere with the transport of absorbed lipids. The process can be interrupted by congenital defects, neoplasms, trauma, and selected infectious diseases.

**Malabsorption Syndrome**

In many malabsorption disorders one or more of the intestinal absorptive processes predominate, but more than one usually contributes to the manifestations of the disorder. As a result, malabsorption syndromes resemble each other more than they differ. Weakness, muscle wasting, and weight loss occur despite normal or excessive caloric intake.

General symptoms include diarrhea (from nutrient malabsorption and intestinal secretion), flatulence, bloating, abdominal cramps, and weight loss. A hallmark of malabsorption is *steatorrhea*, characterized by fatty, bulky, yellow-gray, and foul-smelling stools. Along with loss of fat in the stools, there is failure to absorb the fat-soluble vitamins. This can lead to easy bruising and bleeding because of vitamin K deficiency, as well as bone pain and a predisposition to the development of fractures and tetany from vitamin D and calcium deficiency. In addition, there may be macrocytic anemia and peripheral neuropathy as a result of vitamin B_{12} deficiency. Table 29-2 describes the signs and symptoms of impaired absorption of dietary constituents.

**Celiac Disease**

Celiac disease, also known as *celiac sprue* and *gluten-sensitive enteropathy*, is an immune-mediated disorder triggered by ingestion of gluten-containing grains (wheat, barley, and rye).[53-56] Until recently, celiac disease was considered to be a rare malabsorption syndrome that manifested during early childhood, but today it is known

| Iron | Duodenum and jejunum | Normal pH (hydrochloric acid secretion) | Iron-deficiency anemia, Glossitis |
to be one of the most common genetic diseases, with a mean prevalence of 1% in the general population. The disease is recognized not only in Europe and in countries populated by persons of European ancestry, but also in the Middle East, Asia, South America, and North Africa.

The disease results from an inappropriate T-cell-mediated immune response against the gliadin fraction of gluten contained in the diet. Almost all persons with the disorder share the major histocompatibility complex class II allele HLA-DQ2 or HLA-DQ8. Several non–HLA genes that may influence susceptibility to the disease have been identified, but their role has not been confirmed. Persons with the disease have increased levels of antibodies to a variety of antigens, including transglutaminase, endomysium, and gliadin. The resultant immune response produces an intense inflammatory reaction that results in loss of absorptive villi from the small intestine. When the resulting lesions are extensive, they may impair absorption of macronutrients (i.e., proteins, carbohydrates, fats) and micronutrients (i.e., vitamins and minerals). Small-bowel involvement is most prominent in the proximal part of the small intestine, where the exposure to gluten is greatest.

Populations at higher risk for celiac disease include persons with type 1 diabetes mellitus, those with other autoimmune endocrine disorders such as autoimmune thyroid disorders or Addison disease, first- and second-degree relatives of persons with celiac disease, and individuals with Turner syndrome. Various malignancies also appear to be a direct result of celiac disease, in that the increased incidence seen in persons with celiac disease returns to that of the general population after several years of a gluten-free diet. These malignancies include head and neck squamous cell carcinoma, small intestinal adenocarcinoma, and non-Hodgkin lymphoma.

The clinical manifestations of celiac disease vary greatly according to age group. Infants and young children generally present with diarrhea, abdominal distention, failure to thrive, and, occasionally, severe malnutrition. Beyond infancy, the manifestations tend to be less dramatic. Older children may present with anemia, constitutional short stature, dental enamel defects, and constipation. Among adults, women constitute about 75% of newly diagnosed cases of celiac disease. The classic presentation in adults is diarrhea, which may be accompanied by abdominal pain or discomfort. It has been observed that fewer persons with celiac disease are presenting with the so-called “classic manifestations” of the disease. While diarrhea is still the most frequent mode of presentation, others include iron deficiency, osteoporosis, and recognition of mucosal changes in persons undergoing endoscopy for esophageal reflux or dyspepsia. A prior diagnosis of irritable bowel syndrome is common.

Celiac disease is also becoming increasingly recognized in the elderly population. Rather than symptoms related to severe malabsorption, this age group often presents with anemia, accelerated osteoporosis, and osteomalacia. Although abdominal symptoms are still common in elderly persons, these individuals tend to present with milder symptoms such as abdominal bloating, flatulence, and abdominal discomfort, which make diagnosis difficult.

The diagnosis of celiac disease is based on clinical manifestations and confirmed by serologic tests and intestinal biopsy. Based on very high sensitivities, the best available tests are the immunoglobulin (Ig) A anti-human tissue transglutaminase (TTG) and IgA endomysial antibody (EMA) immunofluorescence tests. Biopsies of the proximal small bowel are indicated in persons with a positive celiac disease antibody test. Usually, additional laboratory tests are done to determine if the disorder has resulted in nutritional disorders such as iron-deficiency anemia.

The primary treatment of celiac disease consists of removal of gluten and related proteins from the diet. Gluten is the primary protein in wheat, barley, and rye. Oat products, which are nontoxic, may be contaminated with wheat during processing. Many gluten-free types of bread, cereals, cookies, and other products are available. Meats, vegetables, fruits, and dairy products are free of gluten as long as they are not contaminated during processing. Complete exclusion of dietary gluten generally results in rapid and complete healing of the intestinal mucosa.

**Colorectal Neoplasms**

**Adenomatous Polyps**

Adenomatous polyps (adenomas) are benign neoplasms that arise from the mucosal epithelium of the intestine. They are composed of neoplastic cells that have proliferated in excess of those needed to replace the cells that normally are shed from the mucosal surface. The most common and clinically important neoplastic polyps are colonic adenomas that are precursors in the majority of colorectal adenocarcinomas.

Adenomas can range in size from a barely visible nodule to a large, sessile mass. They can be classified as tubular, villous, or tubulovillous adenomas. *Tubular adenomas*, which constitute approximately 65% of benign large bowel adenomas, typically are smooth-surfaced spheres, usually less than 2 cm in diameter, that are attached to the mucosal surface by a stalk. Although most tubular adenomas display little epithelial dysplasia, approximately 20% show a range of dysplastic changes, from mild nuclear changes to frank invasive carcinoma. *Villous adenomas* constitute 10% of adenomas of the colon. They typically are broad-based, elevated lesions with a shaggy, cauliflower-like surface and are found predominantly in the rectosigmoid colon. In contrast to tubular adenomas, villous adenomas are more likely to contain malignant cells. When invasive carcinoma develops, there is no stalk to isolate the tumor and invasion is directly into the wall of the colon. *Tubulovillous adenomas* manifest both tubular and villous architecture. They are intermediate between tubular and villous adenomas in terms of invasive carcinoma risk.

The pathogenesis of adenoma formation involves neoplastic alterations in the replication of the colonic crypt cells (Fig. 29-13). There may be diminished apoptosis (see Chapter 2), persistence of cell replication, and failure of cell maturation and differentiation of the cells that migrate to the surface of the crypts. Normally, DNA synthesis ceases as the cells reach the upper two
thirds of the crypts, after which they mature, migrate to
the surface, and become senescent. They then become
apoptotic and are shed from the surface.\(^7\) Adenomas
arise from a disruption in this sequence, such that the
epithelial cells retain their proliferative ability through-
out the entire length of the crypt. Aberrations in cell
differentiation can lead to dysplasia and progress to the
development of invasive adenocarcinoma.

**Colorectal Cancer**

Adenocarcinoma of the colon is the most common malig-
nancy of the gastrointestinal tract and is the major cause
of morbidity and mortality worldwide.\(^6,7,58-60\) It affects
approximately 150,000 Americans annually, approxi-
mately one third of whom die.\(^6\) It affects approximately
250,000 persons annually in Europe and approximately
1 million persons worldwide.

**Epidemiology.** The incidence of colorectal cancer
peaks at 60 to 70 years of age, and fewer than 20% of
cases occur before age 50.\(^7\) Its incidence is increased
among persons with a family history of cancer, persons
with Crohn disease or ulcerative colitis, and those with
familial adenomatous polyposis of the colon. Persons
with a familial risk—those who have two or more
first- or second-degree relatives (or both) with colorec-
tal cancer—make up approximately 20% of all persons
with colorectal cancer.\(^6,7\) Familial adenomatous polyposis
is a rare autosomal dominant trait linked to a mutation
in the long arm of chromosome 5. Persons with the disor-
der develop multiple adenomatous polyps of the colon at
an early age.\(^7\) Carcinoma of the colon is inevitable, often
by 40 years of age, unless a total colectomy is performed.

Diet also is thought to play a role.\(^7\) Attention has
focused on dietary fat intake, refined sugar intake,
fiber intake, and the adequacy of such protective
micronutrients as vitamins A, C, and E in the diet. It
has been hypothesized that a high level of fat in the diet
increases the synthesis of bile acids in the liver, which
may be converted to potential carcinogens by the bacte-
rial flora in the colon. The proliferation of colonic bacte-
ria is enhanced by a high dietary level of refined sugars.
Dietary fiber is thought to increase stool bulk and thereby
dilute and remove potential carcinogens. Refined diets
often contain reduced amounts of vitamins A, C, and E,
which may act as oxygen free radical scavengers.

In addition to dietary modification, pharmacologic
chemoprevention has become an area of great interest.
Several studies indicate that aspirin or other NSAIDs
may protect against colorectal cancer.\(^62\) An analysis of
the incidence of colorectal cancer in the Nurses’ Health
Study showed a decreased incidence of colorectal cancer
among women who took four to six aspirins per week.
Although the mechanism of aspirin’s action is unknown,
it may be related to its effect on the synthesis of pros-
taglandins, one or more of which may be involved in
signal systems that influence cell proliferation or tumor
growth. Aspirin inhibits cyclooxygenase, the enzyme
that catalyzes the conversion of arachidonic acid in cell
membranes to prostaglandins. One form of cyclooxy-
genase, COX-2, promotes inflammation and cell pro-
liferation, and colorectal cancers often overexpress this
enzyme.

**Clinical Manifestations.** Cancer of the colon is usu-
ally present for a long period of time before it produces
symptoms.\(^58,59\) Bleeding is a highly significant early
symptom and usually is the one that causes persons to
seek medical care. Other symptoms include a change in
bowel habits, diarrhea or constipation, and sometimes a
sense of urgency or incomplete emptying of the bowel.
Pain usually is a late symptom.
Diagnosis and Treatment. Cancer of the colon may be detected with a high degree of reliability with barium enema or colonoscopy. Colonoscopy permits biopsy for pathologic confirmation. CT scans, pelvic magnetic resonance imaging (MRI), and ultrasonography may be used to determine the extent of the lesions and whether metastasis has occurred.

The only recognized treatment for cancer of the colon and rectum is surgical removal. Preoperative radiation therapy may be used and has in some cases demonstrated increased 5-year survival rates. Postoperative adjuvant chemotherapy may be used. Radiation therapy and chemotherapy are used as palliative treatment methods.

The prognosis for persons with colorectal cancer depends largely on the stage of the tumor. Colorectal cancer commonly is classified into four TNM (tumor, node, and metastasis) stages.\(^5\) In this system, a stage I tumor is limited to invasion of the mucosal and submucosal layers of the colon and has a 5-year survival rate of 90% to 100%. Stage IV (metastatic) tumors penetrate the serosa or adjacent organs and have a much poorer prognosis.

Screening. The single most important prognostic indicator of colorectal cancer is the extent (stage) of the tumor at the time of diagnosis. The challenge, therefore, is to discover the tumors at their earliest stages. Among the methods used for early detection of colorectal cancers are the digital rectal examination and the fecal occult blood test, usually done during routine physical examinations; x-ray studies using barium (e.g., barium enema); and flexible sigmoidoscopy and colonoscopy.\(^5\)\(^,\)\(^5\)\(^9\)

Almost all cancers of the colon and rectum bleed intermittently, although the amount of blood is small and usually not apparent in the stools. It therefore is feasible to screen for colorectal cancers using commercially prepared tests for occult blood in the stool. The sensitivity of fecal occult blood tests is improved by performing stool tests on three different occasions. Digital rectal examinations are most helpful in detecting neoplasms of the rectum. Rectal examination should be considered a routine part of a good physical examination. Flexible sigmoidoscopy involves examination of the rectum and sigmoid colon with a hollow, lighted tube that is inserted through the rectum. The procedure is performed without sedation and is well tolerated. Approximately 40% of cancers and polyps are out of the reach of the sigmoidoscope, emphasizing the need for fecal occult blood tests. Polyps can be removed or tissue can be obtained for biopsy during the procedure.

Colonoscopy provides a means for direct visualization of the rectum and colon. The colonoscope consists of a flexible, 4-cm–diameter glass fiber bundle that contains approximately 250,000 glass fibers and has a lens at either end to focus and magnify the image. Light from an external source is transmitted by the fiber-optic viewing bundle. Instruments are available that afford direct examination of the sigmoid colon or the entire colon. This method is used for screening persons at high risk for development of cancer of the colon (e.g., those with ulcerative colitis) and for those with symptoms. Colonoscopy also is useful for obtaining a biopsy and for removing polyps. Although this method is one of the most accurate for detecting early colorectal cancers, it is not suitable for mass screening because it is expensive and time consuming and must be done by a person who is highly trained in the use of the instrument.

It is recommended that persons at average risk for colonic adenomatous polyps or cancer should undergo colonoscopy every 10 years or alternative screening tests at periodically prescribed intervals beginning at age 50.\(^6\)\(^,\)\(^9\) Persons who are members of high-risk groups, such as those with a family history of adenomatous polyps or disorders that predispose to colon cancer (e.g., ulcerative colitis), should undergo periodic surveillance more frequently.

SUMMARY CONCEPTS

- Disorders of the small and large intestines include inflammatory bowel disease, infectious enterocolitis, diverticular disease, appendicitis, disorders of motility, peritonitis, alterations in intestinal absorption, and colorectal cancer.
- The term inflammatory bowel disease is used to designate two inflammatory conditions: Crohn disease, which affects the small and large bowel, and ulcerative colitis, which affects the colon and rectum. Both are chronic diseases characterized by remissions and exacerbations of diarrhea, weight loss, fluid and electrolyte disorders, and systemic signs of inflammation.
- Enterocolitis includes viral (e.g., rotavirus) and bacterial (e.g., C. difficile and E. coli O157:H7) infections.
- Diverticulitis is a condition in which the mucosa and submucosa of the colon herniate through the muscularis layer, and diverticulitis, in which there is inflammation and gross or microscopic perforation of the diverticulum.
- Diarrhea, constipation, and irritable bowel syndrome represent disorders of intestinal motility. Diarrhea or excessively frequent passage of stools can be caused by infectious organisms, food intolerance, drugs, or intestinal disease. Constipation or the infrequent passage of stools is commonly caused by failure to respond to the urge to defecate, inadequate fiber or fluid intake, weakness of the abdominal muscles, inactivity and bed rest, or pregnancy. Irritable bowel syndrome is characterized by a variable combination of chronic and recurrent intestinal symptoms, that are not related to a structural or biochemical abnormality.

(continued )
SUMMARY CONCEPTS (continued)

- Peritonitis is an inflammatory response of the serous membrane that lines the abdominal cavity and covers the visceral organs. It can be caused by bacterial invasion or chemical irritation resulting from perforation of the viscera or abdominal organs.

- Malabsorption results from the impaired absorption of nutrients and other dietary constituents. It can involve a single dietary constituent, such as vitamin B₁₂, or extend to involve all of the substances absorbed in a particular part of the small intestine. Malabsorption can result from diseases of the small bowel and disorders that impair digestion and, in some cases, obstruction of lymph flow can interfere with the transport of fats into the general circulation. Celiac disease is an immune-mediated disorder triggered by ingestion of gluten-containing grains (including wheat, barley, and rye).

- Colorectal cancer, the second most common fatal cancer, is seen most commonly in persons older than 50 years of age. Most, if not all, cancers of the colon and rectum arise in preexisting adenomatous polyps. Programs that provide careful follow-up for persons with adenomatous polyps and removal of all suspect lesions have substantially reduced the incidence of colorectal cancer.

REVIEW EXERCISES

1. A 40-year-old man reports to his health care provider complaining of “heartburn” that occurs after eating and also wakes him at night. He is overweight, admits to enjoying fatty foods, and usually lies down on the sofa and watches TV after dinner. He also complains that lately he has been having a cough and some wheezing. A diagnosis of GERD was made.
   A. Explain the cause of heartburn and why it becomes worse after eating.
   B. Persons with GERD are advised to lose weight, avoid eating fatty foods, remain sitting after eating, and sleep with their head slightly elevated. Explain the possible relationship between these situations and the occurrence of reflux.
   C. Explain the possible relationship between GERD and the respiratory symptoms this man is having.

2. A 36-year-old woman who has been taking aspirin for back pain experiences a sudden episode of tachycardia and feeling faint, accompanied by the vomiting of a coffee-ground emesis and the passing of a tarry stool. She relates that she has not had any signs of a “stomach ulcer” such as pain or heartburn. A. Relate the mucosal protective effects of prostaglandins to the development of peptic ulcer associated with aspirin or NSAID use.
   B. Explain the apparent suddenness of the bleeding and the fact that the woman did not experience pain as a warning signal.
   C. Among the results of her initial laboratory tests is an elevated blood urea nitrogen (BUN) level. Explain the reason for the elevated BUN.

3. A 29-year-old woman has been diagnosed with Crohn disease. Her medical history reveals that she began having symptoms of the disease at 24 years of age and that her mother died of complications of the disease at 54 years of age. She complains of diarrhea and chronic cramping abdominal pain.
   A. Define the term inflammatory bowel disease and compare the pathophysiologic processes and manifestations of Crohn disease and ulcerative colitis.
   B. Describe the possible association between genetic and environmental factors in the pathogenesis of Crohn disease.
   C. Relate the use of the monoclonal antibody infliximab to the pathogenesis of the inflammatory lesions that occur in Crohn disease.

REFERENCES

The liver, the gallbladder, and the pancreas are classified as accessory organs of the gastrointestinal tract. The liver produces and the gallbladder stores and concentrates bile that is involved in the digestion of fats. The liver also plays an important role in the uptake, storage, and distribution of both nutrients and vitamins; it synthesizes most of the body’s circulating plasma proteins; and it degrades and eliminates drugs and toxins. The exocrine pancreas secretes enzymes that are involved in the digestion of carbohydrates, lipids, and proteins.

This chapter is divided into two parts: the first focuses on functions and disorders of the liver, and the second on disorders of the gallbladder, biliary tract, and pancreas.

The Liver and Hepatobiliary System

The liver is the largest visceral organ in the body, weighing approximately 1.5 kg (3.3 lb) in the adult. It is located immediately under the diaphragm in the upper right and partially in the upper left quadrants of the abdominal cavity, protected by the rib cage (Fig. 30-1). Anatomically, the liver is divided by deep grooves into two large lobes (the right and left lobes) and two smaller lobes (the caudate and quadrate lobes). Each lobe is divided into numerous lobules by small blood vessels and fibrous strands that form a supporting framework for them. The liver is enclosed in a capsule of fibrous connective tissue (Glisson capsule); a serous covering (visceral peritoneum) surrounds the capsule, except where the liver adheres to the diaphragm.

The liver is unique among the abdominal organs in having a dual blood supply consisting of a venous (portal) supply through the hepatic portal vein and an arterial
supply through the hepatic artery. Approximately 300 mL of blood per minute enters the liver through the hepatic artery; another 1050 mL/min enters by way of the valveless portal vein. The venous blood delivered by the hepatic portal vein comes from the digestive tract and major abdominal organs, including the pancreas and spleen (Fig. 30-2). The portal blood supply carries nutrient and toxic materials absorbed in the intestine, blood cells and their breakdown products from the spleen, and insulin and glucagon from the pancreas. Although the blood from the portal vein is incompletely saturated with oxygen, it supplies approximately 60% to 70% of the oxygen needs of the liver. The venous outflow from the liver is carried by the valveless hepatic

**FIGURE 30-1.** The liver and biliary system, including the gallbladder and bile ducts.

**FIGURE 30-2.** The portal circulation. Blood from the gastrointestinal tract, spleen, and pancreas travels to the liver through the portal vein before moving into the vena cava for return to the heart.
veins, which empty into the inferior vena cava just below the level of the diaphragm. The pressure difference between the hepatic vein and the portal vein normally is such that the liver stores approximately 450 mL of blood. This blood can be shifted back into the general circulation during periods of hypovolemia and shock. In right heart failure in which the pressure in the vena cava increases, blood backs up and accumulates in the liver.

The lobules are the functional units of the liver. The classic lobule consists of stacks of anastomosing plates of hepatocytes one cell thick. Each lobule is organized around a central vein that empties into the hepatic veins and from there into the inferior vena cava. The terminal bile ducts and small branches of the portal vein and hepatic artery are located at the periphery of the lobule. Plates of hepatic cells radiate centrifugally from the central vein like spokes on a wheel (Fig. 30-3). These hepatic plates are separated by wide, thin-walled vascular channels, called hepatic sinusoids, that extend from the periphery of the lobule to its central vein. The sinusoids are supplied by blood from the portal vein and hepatic artery. The sinusoids are in intimate contact with the hepatocytes and provide for the exchange of substances between the blood and liver cells.

The hepatic sinusoids are lined with two types of cells: the typical capillary endothelial cells and Kupffer cells. Kupffer cells (also called reticuloendothelial cells) are large resident macrophages that are capable of removing and phagocytizing old and defective blood cells, bacteria, and other foreign material from the portal blood as it flows through the sinusoid. This phagocytic action removes enteric bacilli and other harmful substances that filter into the blood from the intestine.

The lobules also are supplied by small tubular channels, called bile canaliculi, which lie between the cell membranes of adjacent hepatocytes. The bile that is produced by the hepatocytes flows into the canaliculi and then to the periphery of the lobules. From there it drains into progressively larger ducts until it reaches the right and left hepatic ducts, which merge as the common hepatic duct. This in turn unites with the cystic duct emerging from the gallbladder, forming the common bile duct (see Fig. 30-1). The common bile duct, which is approximately 10 to 15 cm long, descends and passes behind the pancreas and enters the descending duodenum. The pancreatic duct joins the common bile duct at a short dilated tube called the hepatopancreatic ampulla (also called ampulla of Vater), which empties into the duodenum through the duodenal papilla. Muscle tissue at the junction of the papilla, sometimes called the sphincter of Oddi, regulates the flow of bile into the duodenum. When this sphincter is closed, bile moves back into the common duct and gallbladder. The intrahepatic and extrahepatic bile ducts often are collectively referred to as the hepatobiliary tree.

**Physiologic Functions of the Liver**

The liver is one of the most versatile and active organs in the body, with a remarkable ability to regenerate after hepatic tissue loss. It produces bile, metabolizes
hormones and drugs, synthesizes plasma proteins and blood clotting factors, stores vitamins and minerals, maintains blood glucose levels, and regulates very-low-density lipoprotein (VLDL) levels. In its capacity for metabolizing drugs and hormones, the liver serves as an excretory organ. In this respect, the bile, which carries the end products of substances metabolized by the liver, is much like the urine, which carries the body wastes filtered by the kidneys. These functions, many of which are disrupted by the liver diseases discussed in this chapter, are summarized in Table 30-1.

**Metabolic Functions**

The liver is involved in many metabolic pathways including carbohydrate metabolism and maintenance of blood glucose, lipid metabolism, and protein synthesis and conversion of ammonia to urea. In addition to nutrients, several vitamins (e.g., A, D, K) are also taken up from the bloodstream and then stored or biochemically converted in the liver.

**Carbohydrate Metabolism.** The liver plays an essential role in carbohydrate metabolism and glucose homeostasis (Fig. 30-4A). It stores excess glucose as glycogen and synthesizes glucose from amino acids and other substrates as a means of maintaining blood glucose during periods of fasting or increased need. The liver also converts excess carbohydrates to triglycerides for storage in adipose tissue.

**Pathways of Lipid Metabolism.** Although most cells of the body metabolize fat, certain aspects of lipid metabolism occur mainly in the liver. These include the oxidation of free fatty acids to ketoacids; synthesis of cholesterol, phospholipids, and lipoproteins; and formation of triglycerides from carbohydrates and proteins (Fig. 30-4B). To derive energy from neutral fats (triacylglycerols), the molecule must first be split into glycerol and fatty acids, and then the fatty acids split into two-carbon acetyl-coenzyme A (acetyl-CoA units). Acetyl-CoA is readily channeled into the citric acid cycle to produce adenosine triphosphate ([ATP], see Chapter 1, Understanding Cell Metabolism). Because the liver cannot use all the acetyl-CoA that is formed, it converts the excess into acetoacetic acid, a highly soluble ketoacid that is released into the bloodstream and transported to other tissues, where it is used for energy. The acetyl-CoA derived from fat metabolism is also used to synthesize cholesterol and bile acids. Cholesterol has several fates in the liver. It can be esterified and stored, exported bound to VLDLs, or converted to bile acids.

**Protein Synthesis and Conversion of Ammonia to Urea.** In addition to its role in carbohydrate and lipid metabolism, the liver is also an important site for

</table>
protein synthesis and degradation. It produces proteins for its own cellular needs, as well as secretory proteins (e.g., plasma proteins, fibrinogen, and coagulation factors) that are released into the circulation. One of the most important of these secretory proteins is albumin. Albumin contributes significantly to the plasma colloidal osmotic pressure (see Chapter 8) and to the binding and transport of numerous substances such as hormones, fatty acids, and bilirubin.

Proteins are made up of amino acids. Protein synthesis and degradation involves two major reactions: transamination and deamination \(^1\) (Fig. 30-4C). In transamination, an amino group \((\text{NH}_3)\) is transferred to an acceptor substance. The process is catalyzed by amino-transferases, enzymes that are found in high amounts in the liver. As a result of transamination, amino acids can participate in the intermediary metabolism of carbohydrates and lipids. During periods of fasting or starvation, amino acids are used for producing glucose (i.e., gluconeogenesis). Most of the nonessential amino acids are synthesized in the liver by transamination.

Oxidative deamination involves the removal of the amino group and a hydrogen atom from an amino acid. This yields ammonia \((\text{NH}_3)\). Because ammonia is very toxic to body tissues, particularly neurons, the ammonia that is released during the deamination process is rapidly removed from the blood by the liver and combined with carbon dioxide to form urea. Essentially all urea formed in the body is synthesized by the urea cycle in the liver and then excreted by the kidneys.

Although urea is mostly excreted by the kidneys, some diffuses into the intestine, where it is converted to ammonia by enteric bacteria. The intestinal production of ammonia also results from bacterial deamination of unabsorbed amino acids and proteins derived from the diet, exfoliated cells, or blood in the gastrointestinal tract. Ammonia produced in the intestine is absorbed into the portal circulation and transported to the liver,
where it is converted to urea before being released into the systemic circulation. Intestinal production of ammonia is increased after ingestion of high-protein foods and gastrointestinal bleeding, a process that becomes impaired in persons with advanced liver disease.

Bile Formation and Flow
The secretion of bile is essential for digestion and absorption of dietary fats and fat-soluble vitamins from the intestine. The liver produces approximately 600 to 1200 mL of yellow-green bile daily. Bile contains water, bile salts, bilirubin, cholesterol, and certain by-products of metabolism. Of these, only bile salts, which are formed from cholesterol, are important in digestion. The other components of bile depend on the secretion of sodium, chloride, bicarbonate, and potassium by the bile ducts.

Bile salts serve an important function in digestion; they aid in emulsifying dietary fats, and they are necessary for the formation of the micelles that transport fatty acids and fat-soluble vitamins to the surface of the intestinal mucosa for absorption. Approximately 94% of bile salts that enter the intestine are reabsorbed into the portal circulation by an active transport process that takes place in the distal ileum. From the portal circulation, the bile salts move into the liver cells and are recycled. Normally, bile salts travel this entire circuit approximately 18 times before being expelled in the feces. The system for recirculation of bile is called the enterohepatic circulation.

Bilirubin Formation and Jaundice
Bilirubin is the substance that gives bile its color. It is formed from aging red blood cells. In the process of degradation, the hemoglobin from the red blood cell is broken down to form biliverdin, which is rapidly converted to free bilirubin (Fig. 30-5). Free bilirubin (unconjugated), which is insoluble in plasma, is transported in the blood attached to plasma albumin. As it passes through the liver, unconjugated bilirubin is absorbed through the hepatocytes’ cell membrane and released from its albumin carrier molecule. Once inside the hepatocyte, unconjugated bilirubin combines with glucuronic acid (a molecule similar to glucose) to create a water-soluble form called conjugated bilirubin, which is secreted as a constituent of bile. In this form, it passes through the bile ducts into the small intestine. In the intestine, approximately one half of the bilirubin is converted into urobilinogen by the intestinal flora. Urobilinogen is either absorbed into the portal circulation or excreted in the feces. Most of the urobilinogen that is absorbed is returned to the liver to be reexcreted into the bile. A small amount of urobilinogen, approximately 5%, is absorbed into the general circulation and then excreted by the kidneys.

Usually, only a small amount of bilirubin is found in the blood; the normal level of total serum bilirubin is 0.1 to 1.2 mg/dL (2 to 21 µmol/L). Laboratory measurements of bilirubin usually determine the unconjugated and conjugated bilirubin as well as the total bilirubin. These are reported as the direct (conjugated) bilirubin and the indirect (unconjugated) bilirubin.

Jaundice (i.e., icterus) is a yellowish discoloration of the skin and deep tissues resulting from abnormally high levels of bilirubin in the blood. Jaundice becomes evident when the serum bilirubin levels rise above 2 to 2.5 mg/dL (34.2 to 42.8 µmol/L). Because normal skin has a yellow cast, the early signs of jaundice often are difficult to detect, especially in persons with dark skin. Bilirubin has a special affinity for elastic tissue. The sclera of the eye, which contains a high proportion of elastic fibers, usually is one of the first structures in which jaundice can be detected (Fig. 30-6).

The four major causes of jaundice are excessive destruction of red blood cells, impaired uptake of bilirubin by the liver cells, decreased conjugation of bilirubin, and obstruction of bile flow in the canaliculi of the hepatic lobules or in the intrahepatic or extrahepatic bile ducts. From an anatomic standpoint, jaundice can be categorized as prehepatic, intrahepatic, and posthepatic. Chart 30-1 lists the common causes of prehepatic, intrahepatic, and posthepatic jaundice.

The major cause of prehepatic jaundice is excessive hemolysis of red blood cells. Hemolytic jaundice occurs when red blood cells are destroyed at a rate in excess of the liver’s ability to remove the bilirubin from the blood. It may follow a hemolytic blood transfusion reaction or may occur in diseases such as hereditary...
spherocytosis, in which the red cell membranes are defective, or in hemolytic disease of the newborn. In prehepatic jaundice, there is mild jaundice, the unconjugated bilirubin is elevated, the stools are of normal color, and there is no bilirubin in the urine. Because the hepatic mechanisms for conjugating and excreting bilirubin are not fully mature during the first 2 weeks of life, many newborn infants develop a transient and mild unconjugated hyperbilirubinemia, termed neonatal or physiologic jaundice of the newborn. Abnormally high or sustained levels of unconjugated bilirubin are abnormal, however, and require investigation and treatment (see Chapter 13).

Intrahepatic or hepatocellular jaundice is caused by disorders that directly affect the ability of the liver to remove bilirubin from the blood or conjugate it so it can be eliminated in the bile. Liver diseases such as hepatitis and cirrhosis are the most common causes of intrahepatic jaundice. Drugs such as the anesthetic agent halothane, oral contraceptives, estrogen, anabolic steroids, isoniazid, trimethoprim-sulfamethoxazole, amoxicillin-clavulanic acid, and chlorpromazine may also be implicated in this type of jaundice. Because intrahepatic jaundice usually interferes with all phases of bilirubin metabolism—uptake, conjugation, and excretion—both conjugated and unconjugated bilirubin are elevated, the urine often is dark because of bilirubin in the urine, and the serum alkaline phosphatase (ALP), an enzyme present in the bile duct epithelium and canalicular membrane of hepatocytes, is slightly elevated.

Posthepatic or obstructive jaundice, also called cholestatic jaundice, occurs when bile flow is obstructed between the liver and the intestine, with the obstruction located at any point between the junction of the right or left hepatic duct and the point where the common bile duct opens into the intestine. Among the causes are strictures of the bile duct, gallstones, and tumors of the bile duct or the pancreas. Conjugated bilirubin levels usually are elevated, the stools are clay colored because of the lack of bilirubin in the bile, the urine is dark, the levels of serum ALP are markedly elevated, and the amionotransferase levels are slightly increased. Blood levels of bile acids often are elevated in obstructive jaundice. As the bile acids accumulate in the blood, pruritus develops. A history of pruritus preceding jaundice is common in obstructive jaundice.

### Cholestasis

Cholestasis represents a pathologic condition of impaired bile formation and bile flow, leading to accumulation of bile pigment in the parenchymal tissues of the liver. As a result, materials normally transferred to the bile, including bilirubin, cholesterol, and bile acids, accumulate in the blood. The condition may be caused by intrinsic liver disease affecting the intrahepatic canaliculi and bile ducts, in which case it is referred to as intrahepatic cholestasis. Alternatively, it can be caused by obstruction of the large bile ducts, for example by strictures, gallstones, or neoplasms, a condition known as extrahepatic cholestasis. Genetic disorders involving the transport of bile into the canaliculi also can result in cholestasis.

The morphologic features of cholestasis depend on the underlying cause. Common to all types of obstructive and hepatocellular cholestasis is the accumulation of bile pigment in the liver. Elongated green-brown plugs of bile are visible in the dilated bile canaliculi. Rupture of the canaliculi leads to extravasation of bile and subsequent degenerative changes in the surrounding hepatocytes. Prolonged obstructive cholestasis leads not only to fatty changes in the hepatocytes but also to destruction of the supporting connective tissue.
Unrelieved obstruction leads to biliary tract fibrosis and ultimately to end-stage biliary cirrhosis.

Pruritus is the most common presenting symptom in persons with cholestasis, probably related to an elevation in plasma bile acids. Skin xanthomas (focal accumulations of cholesterol) may occur as the result of hyperlipidemia and impaired excretion of cholesterol. A characteristic laboratory finding is elevated levels of serum ALP. Other manifestations of reduced bile flow relate to intestinal absorption, including nutritional deficiencies of the fat-soluble vitamins A, D, E, and K.

Tests of Hepatobiliary Function

The history and physical examination, in most instances, provide clues about liver function. Diagnostic tests help to evaluate liver function and the extent of liver damage. Laboratory tests commonly are used to assess liver function and confirm the diagnosis of liver disease.

Liver function tests, including serum levels of liver enzymes, are used to assess injury to liver cells, the liver's ability to synthesize proteins, and the excretory functions of the liver. Elevated serum enzyme test results usually indicate liver injury earlier than other indicators of liver function. The key enzymes are alanine aminotransferase (ALT) and aspartate aminotransferase (AST), which are present in liver cells. ALT is liver specific, whereas AST is derived from organs other than the liver. In most cases of liver damage, there are parallel rises in ALT and AST. The most dramatic rise is seen in cases of acute hepatocellular injury, as occurs with viral hepatitis, autoimmune hepatitis, hypoxic or ischemic injury, acute toxic injury, or Reye syndrome. The liver's synthetic capacity is reflected in measures of serum protein levels (albumin) and prothrombin time (i.e., synthesis of coagulation factors). Deficiencies of fibrinogen and coagulation factors (II, VII, IX, and X) may occur.

Serum bilirubin, $\gamma$-glutamyltransferase (GGT), and ALP measure hepatic excretory function. Alkaline phosphatase is present in the membranes between liver cells and the bile duct and is released by disorders affecting the bile duct. $\gamma$-glutamyltransferase, which is thought to function in the transport of amino acids and peptides into liver cells, is a sensitive indicator of hepatobiliary disease but not used much clinically as it has limited use in specific disease diagnosis.

Ultrasonography provides information about the size, composition, and blood flow of the liver. It is used predominantly in detecting stones in the gallbladder or biliary tree. Computed tomography (CT) scanning and magnetic resonance imaging (MRI) provide information similar to that obtained by ultrasonography, but offer greater detail regarding composition, and blood and/or bile flow through the liver. Selective angiography of the celiac, superior mesenteric, or hepatic artery may be used to visualize the hepatic or portal circulation.

A liver biopsy affords a means of examining liver tissue without surgery. There are several methods for obtaining liver tissue: percutaneous liver biopsy, which uses a suction, cutting, or spring-loaded cutting needle; laparoscopic liver biopsy; and fine needle biopsy, which is performed under ultrasonographic or CT guidance.

The type of method used is based on the number of specimens needed and the amount of tissue required for evaluation. Laparoscopic liver biopsy provides the means for examining abdominal masses and staging liver cancers.

SUMMARY CONCEPTS

- The liver, which is the largest and most versatile organ in the body, is located between the gastrointestinal tract and the systemic circulation. Venous blood from the intestine flows through the liver before it is returned to the heart, allowing nutrients to be removed for processing and storage, and bacteria and other foreign matter to be removed before the blood is returned to the systemic circulation.
- The main functions of the liver include synthesis of plasma proteins, maintenance of blood glucose levels, regulation of circulating lipoprotein levels, and vitamin and mineral storage. The liver also plays an essential role in the metabolism and elimination of harmful toxins and drugs, conversion of ammonia to urea, and removal of bilirubin, a product of hemoglobin breakdown, from the blood.
- Serum liver enzymes, especially alanine aminotransferase (ALT) and aspartate aminotransferase (AST), are used to assess injury to liver cells; plasma proteins (e.g., serum albumin) and blood clotting factors (prothrombin time) provide information related to the liver's synthetic capacity; and serum bilirubin, serum $\gamma$-glutamyltransferase (GGT), and alkaline phosphatase (ALP) are used as measures of hepatic excretory function.

Disorders of Hepatic and Biliary Function

The structures of the hepatobiliary system are subject to many of the same pathologic conditions that affect other body systems. This section focuses on alterations in liver function due to viral and autoimmune hepatitis; intrahepatic biliary disorders; drug- and alcohol-induced liver disease; nonalcoholic fatty liver disease; the hepatic syndromes of cirrhosis, portal hypertension, and liver failure; and cancer of the liver.
**Hepatitis**

Hepatitis refers to the acute or chronic inflammation of the liver. Although hepatitis viruses account for many cases of chronic hepatitis, there are many other causes including chronic alcoholism, drug toxicities, and autoimmune disorders. The discussion in this section focuses on viral and autoimmune hepatitis.

**Viral Hepatitis**

Viral hepatitis refers to hepatic infections due to a group of viruses known as hepatotropic viruses (hepatitis A [HAV], hepatitis B [HBV], hepatitis C [HCV], hepatitis D [HDV], and hepatitis E [HEV]) that have a particular affinity for the liver.3,4 Although all of the hepatotropic viruses cause hepatitis, they differ in terms of their mode of transmission and incubation period; mechanism, degree, and chronicity of liver damage; and ability to evolve to a carrier state. Acute hepatitis may also occur in the course of other viral infections such as infectious mononucleosis, caused by the Epstein-Barr virus; and cytomegalovirus infection, particularly in newborn or immunosuppressed persons. These other forms of hepatitis must be distinguished from those caused by hepatotropic viruses.

**Syndromes of Viral Hepatitis.** The clinical course of viral hepatitis can involve a number of syndromes, including acute asymptomatic hepatitis with only serologic evidence of infection, acute symptomatic hepatitis, and chronic hepatitis, which can produce a carrier state. Fulminant hepatic failure, a syndrome of hepatic insufficiency with rapid progression to liver failure, occurs in a small percentage of persons with hepatitis B.3

The manifestations of acute symptomatic viral hepatitis can be divided into three phases: the prodromal or preicterus period, the icterus period, and the convalescent period. The onset of the prodromal period may vary from abrupt to insidious, with general malaise, myalgia, arthralgia, easy fatigability, and severe anorexia out of proportion to the degree of illness. Gastrointestinal symptoms such as nausea, vomiting, and diarrhea or constipation may occur. Abdominal pain is usually mild and felt on the right side. Chills and fever may mark an abrupt onset. In persons who smoke, there may be distaste for smoking that parallels the anorexia. Serum levels of AST and ALT show variable increases during the preicterus phase and precede a rise in bilirubin that accompanies the onset of the icterus or jaundice phase of infection. The icterus phase, if it occurs, usually follows the prodromal phase within 5 to 10 days. The prodromal symptoms may become worse with the onset of jaundice, followed by progressive clinical improvement. Severe pruritus and liver tenderness are common during the icterus period. The convalescent phase is characterized by an increased sense of well-being, return of appetite, and disappearance of jaundice. The acute illness usually subsides gradually over a 2- to 3-week period, with complete clinical recovery by approximately 9 weeks in hepatitis A and 16 weeks in uncomplicated hepatitis B.

Chronic hepatitis is defined as symptomatic, biochemical, or serological evidence of continuing or relapsing disease that has persisted for more than 6 months.3 The clinical features of chronic hepatitis are extremely variable and not predictive of outcome. In many people the only manifestation is a persistent elevation of serum aminotransferases. If there are symptoms, the most frequently reported ones are fatigue, abdominal discomfort, and joint or muscle aches. However, even asymptomatic persons with normal serum aminotransferase levels are at risk for developing liver damage.

Infection with HBV/HDV, and HCV, can produce a carrier state in which the person does not have symptoms but harbors the virus and can therefore transmit the disease. There is no carrier state for HAV infection. There are two types of carriers: healthy carriers who have few or no ill effects, and those with chronic disease who may or may not have symptoms. Factors that increase the risk of becoming a carrier are age at time of infection and immune status. The carrier state for infections that occur early in life, as in infants of HBV-infected mothers, may be as high as 90% to 95%, compared with 1% to 10% of infected adults.3

**Hepatitis A.** Hepatitis A is usually a benign and self-limited disease caused by a small, nonenveloped, single-stranded ribonucleic acid (RNA) picornavirus. Lack of a lipid envelope confers resistance to lysis by bile acids in the intestine. Infection is contracted primarily by the fecal–oral route.8

Hepatitis A occurs throughout the world and is endemic in countries with poor sanitation. At special risk of infection are persons traveling abroad who have not been vaccinated or previously exposed to the virus. HAV has a short incubation period, with an average of 25 to 30 days. The virus replicates in the liver, is excreted in the bile, and is shed in the stool. The fecal shedding of HAV occurs for 2 to 3 weeks before the development of symptoms and ends about 1 week after the onset of jaundice.3 Because young children are asymptomatic, they play an important role in the spread of the disease. Oral behavior and lack of toilet training promote viral spread among children attending day care centers, who then carry the virus home to older siblings and parents. Infected workers in food industries may also be a source of spread. HAV usually is not transmitted by transfusion of blood or plasma derivatives, presumably because its short period of viremia usually coincides with clinical illness, so that the disease is apparent and blood donations are not accepted.

The onset of symptoms usually is abrupt and includes fever, malaise, nausea, anorexia, abdominal discomfort, dark urine, and jaundice. The likelihood of having symptoms is related to age. Children younger than 6 years often are asymptomatic. The illness in older children and adults usually is symptomatic and jaundice occurs in approximately 70% of cases.8 Symptoms usually last approximately 2 months. HAV infection does not cause chronic hepatitis or induce a carrier state, and only rarely causes acute fulminant hepatitis.3,8
The virus usually is transmitted through inoculation in the development of hepatitis D (delta hepatitis). It also participates in acute hepatitis, chronic hepatitis, hepatocellular carcinoma, and fulminant hepatic failure. It also participates in the development of hepatitis D (delta hepatitis). The complete hepatitis B virion, also called a Dane particle, consists of an outer envelope and an inner nucleocapsid that contains the viral DNA and viral polymerase activity (Fig. 30-8). HBV infection can produce a virus (HAV), HAV viremia, and HAV antibody (IgM and IgG anti-HAV) changes in hepatitis A. Antibodies to HAV (anti-HAV) appear early in the disease and tend to persist in the serum (Fig. 30-7). The immunoglobulin M (IgM) antibodies (see Chapter 15) usually appear during the first week of symptomatic disease and begin to decline in a few months. Their presence coincides with a decline in fecal shedding of the virus. Peak levels of IgG antibodies occur after 1 month of illness and may persist for years; they provide long-term protective immunity against reinfection. The presence of IgM anti-HAV is indicative of acute hepatitis A, whereas IgG anti-HAV merely documents past infection.

HAV vaccine is available for persons at high risk for HAV exposure. These include international travelers to regions where sanitation is poor and endemic HAV infections are high, children living in communities with high rates of HAV infection, homosexually active men, and users of illicit drugs. A public health benefit also may be derived from vaccinating persons with increased potential for transmitting the disease (e.g., food handlers). The Centers for Disease Control and Prevention (CDC) has recently recommended vaccination of children in states, counties, and communities with high rates of infection. Persons who have been exposed to HAV are advised to receive postexposure prophylaxis with a single dose of HAV vaccine or immune globulin (IgG) as soon as possible. The immune globulin is preferred for persons older than 40 years or younger than 1 year of age and for those who are immunocompromised or have chronic liver disease.

Hepatitis B. Hepatitis B is caused by a hepatotropic deoxyribonucleic acid (DNA)-containing Hepadnavirus. The complete hepatitis B virion, also called a Dane particle, consists of an outer envelope and an inner nucleocapsid that contains the viral DNA and viral polymerase that exhibits both DNA polymerase and reverse transcriptase activity (Fig. 30-8). HBV infection can produce acute hepatitis, chronic hepatitis, hepatocellular carcinoma, and fulminant hepatic failure. It also participates in the development of hepatitis D (delta hepatitis). The virus usually is transmitted through inoculation with infected blood or serum. However, the viral antigen can be found in most body secretions and can be spread by oral or sexual contact.

Hepatitis B has a longer incubation period and represents a more serious health problem than hepatitis A. More than 2 billion people—one third of the world’s population—alive today have been infected with HBV, and of these more than 240 million remain infected. Worldwide, perinatal (vertical) transmission is the predominant mode of HBV transmission, whereas intravenous drug use and unprotected sexual intercourse are the main routes of transmission in low-prevalence areas such as the United States. Although the virus can be spread through transfusion or administration of blood products, routine screening methods have appreciably reduced transmission through this route.

Three well-defined antigens are associated with the HBV virus: a core antigen, HBeAg; HBeAg, a precore protein; and a surface antigen, HBsAg. These HBV antigens evoke specific antibodies: anti-HBc, anti-HBe, and anti-HBs. The antigens and their antibodies serve as serologic markers for following the natural course of the disease (see Fig. 30-8). HBsAg is the viral antigen measured most often in acute HBV infection. The immune response to HBsAg is characterized by the presence of IgM anti-HBs and the absence of antibodies to HBcAg, indicating the first exposure to HBV. HBsAg is rapidly cleared from the infected individual as the immune response is established. HBsAg usually appears during the first week of symptomatic disease and begins to decline in a few months.
routinely in blood. It appears before onset of symptoms, peaks during overt disease, and then declines to undetectable levels in 3 to 6 months. Persistence beyond 6 months indicates continued viral replication, infectivity, and chronic hepatitis. HBeAg appears in the serum soon after HBsAg and signifies active viral replication. IgM anti-HBe becomes detectable shortly before the onset of symptoms, concurrent with the onset of an elevation in serum transaminases. Over the months, the IgM antibody is replaced by IgG anti-HBe. Anti-HBe is detectable shortly after the disappearance of HBeAg and its appearance signals the onset of resolution of the acute illness. IgG anti-HBs, a specific antibody to HBsAg, occurs in most individuals after clearance of HBsAg. Development of anti-HBs signals recovery from HBV infection, non-infectivity, and protection from future HBV infection. Anti-HBs is the antibody present in persons who have been successfully immunized against HBV.

The presence of viral DNA (HBV DNA) in the serum is the most reliable indicator of HBV infection. It is transiently present during the presymptomatic period and for a brief time during the acute illness. The presence of RNA polymerase, the enzyme used in viral replication, usually is transient but may persist for years in persons who are chronically infected.

Hepatitis B can be prevented by vaccination and by the screening of donor blood, organs, and tissues. The vaccine, which is prepared from purified HBsAg produced in yeast, induces a protective antibody response in 95% of vaccinated infants, children, and adolescents. The CDC recommends vaccination of all children 0 to 18 years of age as a means of preventing HBV transmission. The vaccine also is recommended for all unvaccinated adults who are at high risk for infection, international travelers to regions with high or intermediate levels of endemic HBV infection, persons with human immunodeficiency virus (HIV) infection, persons with chronic liver disease, injection drug users, and all other persons seeking protection. It is also recommended that all pregnant women be routinely tested for HBsAg during an early prenatal visit and that infants born to HBsAg-positive mothers receive appropriate doses of hepatitis B immune globulin (HBIG) and hepatitis B vaccine.

**Hepatitis C.** The hepatitis C virus, discovered in 1989, is a member of the *Flaviviridae* family. It is a small, enveloped, single-stranded RNA virus. The virus is genetically unstable, giving rise to multiple genotypes and subtypes. This allows a divergent population of closely related variants to circulate in infected persons. One of the HCV envelope proteins, the E2 protein, which is the target for anti-HCV antibodies, is the most variable region of the entire viral genome. It is likely that the wide diversity of genotypes contributes to the pathogenicity of the virus, allowing it to escape the actions of host immune mechanisms and antiviral medications, and to difficulties in developing a preventive vaccine.

Hepatitis C is the most common cause of chronic hepatitis, cirrhosis, and hepatocellular cancer in the world. Before 1990, the main route of transmission of HCV was through contaminated blood transfusions or blood products. With implementation of HCV testing in blood banks, the current risk of HCV infection from blood transfusion is almost nonexistent in the United States and other developed countries. Currently, recreational injection drug use is the most common mode of HCV transmission in the United States. Other risk factors include needlestick injuries in health care settings and birth to an HCV-infected mother. In fact, the risk from needle sticks is much higher than for human immunodeficiency virus (HIV).

The incubation period for HCV infection ranges from 2 to 26 weeks (average, 6 to 12 weeks). Children and adults who acquire the infection usually are asymptomatic or have nonspecific signs and symptoms such as fatigue, malaise, anorexia, and weight loss. A minority of persons develop sufficient elevations in bilirubin to produce overt jaundice or the development of dark urine. Only a few persons who are newly infected with HCV will clear the infection, with the majority going on to develop chronic hepatitis. Factors associated with spontaneous clearing of HCV infection appear to include younger age, female sex, and certain histocompatibility genes. The most serious consequences of chronic HCV infection are progressive liver fibrosis leading to cirrhosis, and hepatocellular cancer.

Both HCV RNA and anti-HCV antibody tests are available for detecting the presence of HCV infection (Fig. 30-9). Unlike hepatitis A and B, antibodies to HCV are not protective, but they serve as markers for the disease. With anti-HCV antibody tests, infection often can be detected as early as 6 to 8 weeks after exposure, but false-negative results can occur in immunocompromised people and early in the course of the disease. Direct measurement of HCV RNA in the serum can detect the virus as early as 1 to 2 weeks after exposure with viral tests that use polymerase chain reaction (PCR) methods (see Chapter 14).

**Hepatitis D and E.** Hepatitis D virus, or the delta hepatitis agent, is a defective RNA virus that requires concomitant infection with HBV for its own replication.
Acute hepatitis D occurs in two forms: coinfection that occurs simultaneously with acute hepatitis B, and a superinfection in which hepatitis D is imposed on chronic hepatitis B. The delta agent often increases the severity of HBV infection.

The routes of transmission of hepatitis D are similar to those for hepatitis B. In the United States, infection is restricted largely to persons at high risk for HBV infection, particularly injecting drug users. The greatest risk is in HBV carriers; these persons should be informed about the dangers of HDV superinfection. Hepatitis D is diagnosed by detection of antibody to HDV (anti-HDV) in the serum or HDV RNA in the serum. There is no specific treatment for hepatitis D. Because the infection is linked to hepatitis B, prevention of hepatitis D should begin with prevention of hepatitis B through vaccination.

The hepatitis E virus is an enveloped, single-stranded RNA virus. It is transmitted by the fecal–oral route and causes manifestations of acute hepatitis that are similar to hepatitis A. It does not cause chronic hepatitis or the carrier state. A distinguishing feature of HEV infection is the high mortality rate (approximately 20%) among pregnant women, owing to the development of fulminant hepatitis. The infection occurs primarily in developing countries of the world. The only reported cases in the United States have been in persons who have recently traveled to hepatitis E-endemic areas.

Chronic Viral Hepatitis. Chronic hepatitis is defined as a chronic inflammatory reaction of the liver, or positive viral serologies of more than 6 months’ duration. Chronic viral hepatitis is the principal cause of chronic liver disease, cirrhosis, and hepatocellular cancer in the world and now ranks as the chief reason for liver transplantation in adults. Of the hepatotropic viruses, only three are known to cause chronic hepatitis—HBV, HDV, and HCV. In both HBV and HCV, fibrosis and clinical manifestations of chronic disease result from host immune responses directed against viral antigens. In response to these viral antigens, the host immune system directs cytotoxic T lymphocytes and cytokines to inhibit viral replication (Chapter 15), the effects of which induce inflammation and liver injury.

There are several treatment options for chronic viral hepatitis. Drugs used in the treatment of chronic hepatitis B include the recombinant human interferon-2α and peginterferon or nucleotide analog antiretroviral agent. Persons with active viral replication may be treated with recombinant human interferon-2α and peginterferon. Peginterferons were developed by adding a polyethylene glycol (PEG) moiety to an interferon molecule (PEG-IFN), resulting in a prolonged serum half-life and the ability to administer the compound once weekly. Nucleoside and nucleotide analogs (e.g., entecavir, tenofovir) have shown good efficacy and better tolerance and may be used instead of interferon for treatment of chronic HBV infection. The current treatment for persons with chronic hepatitis C is a combination of peginterferon (alpha-2b or alpha-2a) plus ribavirin (a nucleoside analog), plus sofosbuvir (a polymerase inhibitor) or sofosbuvir plus ribavirin. Treatment for HCV is 70% to 80% effective, but is costly and has side effects. These side effects range from flu-like symptoms, which are almost universal, to more serious and less common side effects, such as psychiatric symptoms (depression, anxiety), thyroid dysfunction, and bone marrow suppression. Although most persons with HCV infection are candidates for treatment, many have other health problems that are contraindications to therapy.

Liver transplantation is a treatment option for those with advanced decompensated cirrhosis from viral hepatitis. Liver transplantation, however, is not a cure for viral hepatitis, as it often reoccurs in the transplanted liver.

Autoimmune Hepatitis

Autoimmune hepatitis is a chronic and progressive form of hepatitis of unknown origin that is associated with high levels of serum immunoglobulins, including autoantibodies. Although the disorder is usually seen in young women, it can occur in either sex at any age.

Clinical and laboratory observations have led to the hypothesis that autoimmune hepatitis is a multifactorial disorder, with genetic and environmental factors playing important roles. Most knowledge about the genetics of the disease has focused on the human leukocyte antigen (HLA) genes that reside in the major histocompatibility complex (MHC), located on the short arm of chromosome 6 (see Chapter 15). The environmental agents assumed to induce autoimmune hepatitis are viruses, immunizations, herbal products such as black cohosh, and medications such as minocycline, methyldopa, atorvastatin, simvastatin, interferons, and nitrofurantoin. Autoantibodies, in particular antinuclear antibody and anti–smooth muscle antibody, have been found in serum of those with autoimmune hepatitis, although the exact function of these antibodies in this condition is unknown.

Two distinct types of autoimmune hepatitis have been broadly identified based on the presence of circulating antibodies. Type I autoimmune hepatitis, the most common form of the disease, is characterized by increased levels of anti–smooth muscle and antinuclear autoantibodies. Approximately 30% of cases occur in women younger than 40 years of age, a third of whom have other autoimmune diseases. Type II autoimmune hepatitis, a rare disorder, occurs mainly in children 2 to 14 years of age and is characterized by the presence of antibody to liver and kidney microsomes and liver cytosol. The disorder is often accompanied by other autoimmune disorders, especially type 1 diabetes mellitus and thyroiditis. The genetic component for this type of autoimmune hepatitis is less well defined than for type 1.

Clinical manifestations of the disorder cover a spectrum that extends from no apparent symptoms to the signs of liver failure. Physical examination may reveal no abnormalities, but may also reveal hepatomegaly, splenomegaly, jaundice, and signs and symptoms of chronic liver disease. In asymptomatic cases, the disorder may be discovered when abnormal serum enzyme levels are identified during performance of routine screening tests.
The differential diagnosis includes measures to exclude other causes of liver disease, including hepatitis B and C. A characteristic laboratory finding is that of a marked elevation in serum gamma globulins. A biopsy is used to confirm the diagnosis. Corticosteroid and immunosuppressant drugs are the treatment of choice. Although some persons remain in remission after drug treatment is withdrawn, most require long-term maintenance treatment. Liver transplantation may be required for persons who are refractory to or intolerant of immunosuppressive therapy and in whom end-stage liver disease develops.

**Acute Fulminant Hepatitis**

Acute fulminant hepatitis or hepatic failure is hepatic insufficiency that progresses from onset of hepatitis symptoms to hepatic encephalopathy within 2 to 3 weeks in persons who do not have chronic liver disease. Viral hepatitis is responsible for about 10% of cases of fulminant hepatitis, with about 80% of those being caused by HBV and the rest by HAV. Acetaminophen (TYLENOL) toxicity (to be discussed) is the most common cause, accounting for at least 46% of cases in the United States. Other causes include idiosyncratic drug reactions (new or the second most common cause), poisonous mushrooms, fatty liver of pregnancy, and other disorders of fatty acid oxidation.

Acute fulminant liver failure often presents with gastrointestinal symptoms, signs of the systemic inflammatory response (see Chapter 20), and hemorrhagic phenomenon. Jaundice may be absent or minimal early, but laboratory tests show severe hepatocellular damage. The blood ammonia level is typically elevated and correlates with the development of encephalopathy and cerebral edema. Survival of more than a week may permit replication of residual hepatocytes.

The treatment for acute liver failure is directed toward correcting the underlying liver abnormality and providing supportive care. Liver transplantation is the only option for persons who do not succumb to secondary infections or other organ failure. The mortality rate of fulminant hepatitis is about 85% without transplant and about 35% with transplant.

**Intrahepatic Biliary Disorders**

Intrahepatic biliary diseases disrupt the flow of bile through the liver, causing cholestasis and biliary cirrhosis. Among the causes of intrahepatic biliary disease are primary biliary cirrhosis and secondary biliary cirrhosis.

**Primary Biliary Cirrhosis**

Primary biliary cirrhosis is a chronic disease of the liver characterized by the autoimmune destruction of the medium-sized intrahepatic bile ducts with cholestasis and eventual development of cirrhosis and liver failure. Cirrhosis develops only after many years; thus, the name primary biliary cirrhosis is somewhat misleading for persons diagnosed early in the precirrhotic stage. The disease is seen most commonly in women 40 to 60 years of age. Both the incidence and prevalence are increasing, and geographic clustering of the disease has been reported, suggesting genetic and environmental factors are important in its pathogenesis. Family members of persons with the disease have increased risk of developing the disease. The disease may be associated with other autoimmune disorders such as Sjögren syndrome (sicca complex of dry eyes and mouth), autoimmune thyroid disease, rheumatoid arthritis, Raynaud phenomenon, and celiac disease.

The disorder is characterized by an extremely insidious onset, and persons may be symptom-free for many years. Morphologically, there is progressive scarring and destruction of liver tissue. The liver becomes enlarged and takes on a green hue because of the accumulated bile. The earliest symptoms are unexplained pruritus (itching), weight loss, and fatigue, followed by dark urine and pale stools. Vitamin D malabsorption–related osteoporosis occurs in up to one third of persons with the disorder. Jaundice is a late manifestation of the disorder, as are other signs of liver failure. Serum alkaline phosphatase (ALP) levels are elevated in persons with primary biliary cirrhosis.

Treatment for primary biliary cirrhosis is ursodeoxycholic acid (ursodiol), a drug that increases bile flow and decreases the toxicity of bile contents, and has been shown to decrease the rate of clinical deterioration. Cholestyramine, a bile-acid–binding drug, or rifampicin can be beneficial for treatment of pruritus. Liver transplantation, however, remains the only treatment for advanced disease. Primary biliary cirrhosis does not recur after liver transplantation if appropriate immunosuppression is used.

**Secondary Biliary Cirrhosis**

Secondary biliary cirrhosis results from prolonged obstruction of the extrabiliary tree. The most common cause is choledolithiasis (gallstones). Other causes of secondary biliary cirrhosis are malignant neoplasms of the biliary tree or head of the pancreas and strictures of the common duct caused by previous surgical procedures. Extrahepatic biliary cirrhosis may benefit from surgical procedures designed to relieve the obstruction.

**Drug- and Alcohol-Induced Liver Disease**

By virtue of its many enzyme systems that are involved in biochemical processes, the liver has an important role in the metabolism of many drugs and chemical substances. The liver is particularly important in the metabolism of lipid-soluble substances that cannot be directly excreted by the kidney.

**Drug Metabolism**

There are two major types of reactions involved in the hepatic detoxification and metabolism of drugs and other chemicals: phase 1 and phase 2 reactions.
These reactions, often referred to as biotransformations, are important considerations in drug therapy.

**Phase 1 reactions** result in the chemical modification of reactive drug groups through oxidation, reduction, hydroxylation, or other chemical reactions. Many of these reactions involve drug-metabolizing enzymes that are located in the lipophilic endoplasmic reticulum membranes of liver cells. One of the enzymes involved is the product of a gene superfamily called cytochrome P450 (abbreviated CYP or CYP P450). Multiple isoforms of the CYP enzyme have been identified and trace to the metabolism of specific drugs and to potential interactions among drugs. Of these isoforms, the CYP3A4 enzyme accounts for approximately 50% of the liver’s drug-metabolizing activity.22

Many gene members of the CYP enzyme system can have their activity induced or suppressed as they undergo the task of metabolizing drugs. For example, drugs such as alcohol and barbiturates can induce certain members to increase enzyme production, accelerating drug metabolism and decreasing the pharmacologic action of the drug and of coadministered drugs that use the same member of the CYP system. In the case of drugs metabolically transformed to reactive intermediates, enzyme induction may exacerbate drug-mediated tissue toxicity. Certain drugs can also inhibit enzymes in the CYP system. For example, the antibiotic erythromycin and the antifungal agents fluconazole,itraconazole, and ketoconazole inhibit CYP3A4 enzyme activity, as does grapefruit juice, thereby decreasing the metabolism of drugs that use this enzyme system.23

**Phase 2 reactions**, which involve the conversion of lipid-soluble derivatives to water-soluble substances called conjugates, may follow phase 1 reactions or proceed independently. Conjugation, a process that couples the drug with an activated endogenous compound such as glutathione, renders the drug more water soluble so it can be excreted in the bile or urine. Although many water-soluble drugs and endogenous substances are excreted unchanged in the urine or bile, lipid-soluble substances tend to accumulate in the body unless they are converted to less active compounds or water-soluble metabolites. Because the endogenous substrates used in the conjugation process are obtained from the diet, nutrition plays a critical role in phase 2 reactions.

In addition to its role in metabolism of drugs and chemicals, the liver also is responsible for hormone inactivation or modification. Insulin and glucagon are inactivated by proteolysis or deamination. Thyroxine and triiodothyronine are metabolized by reactions involving deiodination. Steroid hormones such as the glucocorticoids are first inactivated by a phase 1 reaction and then conjugated by phase 2 reactions.

**Drug-Induced Liver Disease**

Many widely used therapeutic drugs, including over-the-counter medications and “natural” products, can cause hepatic injury.23 Hepatotoxicity is the leading cause of acute liver failure in the United States. The drug most commonly involved is acetaminophen, with half the cases reported to be unintentional overdoses.24 Unintentional overdoses may occur when people unknowingly take several over-the-counter preparations that contain acetaminophen (e.g., an acetaminophen-containing cold preparation and acetaminophen pain medication). Numerous host factors contribute to the susceptibility to drug-induced liver disease, including genetic predisposition, age, underlying chronic liver disease, diet and alcohol consumption, and the use of multiple interacting drugs.

Drugs and chemicals can exert their effects by causing hepatocyte injury and death or by cholestatic liver damage due to injury of biliary drainage structures. Drug reactions can be acute or chronic, and predictable based on the drug’s chemical structure and metabolites or unpredictable (idiosyncratic) based on individual characteristics of the person receiving the drug.

**Direct Predictable Injury.** Some drugs are known to have toxic effects on the liver. Examples are acetaminophen, isoniazid, and phenytoin. Direct hepatic damage, which is often age and dose dependent, usually results from drug metabolism and the generation of toxic metabolites. Because of the greater activity of the drug-metabolizing enzymes in the central zones of the liver, these agents typically cause centrilobular necrosis. The injury is characterized by marked elevations in ALT and AST values with minimally elevated ALP. Bilirubin levels invariably are increased, and the prognosis often is worse when hepatocellular necrosis is accompanied by jaundice.

**Idiosyncratic Reactions.** In contrast to direct predictable drug reactions, idiosyncratic reactions are unpredictable, not related to dose, and sometimes accompanied by features suggesting an allergic reaction. Drugs are relatively small molecules and, therefore, unlikely to provoke an immune response. However, in the process of biotransformation, drugs may combine with enzymes, producing a compound large enough to serve as an antigen and induce the formation of antibodies or a direct cytotoxic T-cell response. In some cases, the reaction results directly from a metabolite that is produced only in certain persons based on a genetic predisposition. For example, certain people are capable of rapid acetylation of isoniazid, an antituberculosis drug.

**Cholestatic Reactions.** Cholestatic drug reactions result in decreased secretion of bile or obstruction of the biliary tree. Acute intrahepatic cholestasis is one of the most frequent types of idiosyncratic drug reactions. Among the drugs credited with causing cholestatic drug reactions are estradiol; chlorpromazine, an antipsychotic drug; and some of the antibiotics, including amoxicillin/clavulanic acid, erythromycin, and nafcillin. Typically, cholestatic drug reactions are characterized by an early onset of jaundice and pruritus, with little alteration in the person’s general feeling of well-being. Most instances of acute drug-induced cholestasis subside once the drug is withdrawn.
Alcohol Metabolism

Alcohol is readily absorbed from the stomach and intestine. It is then distributed to all of the tissues and fluids in the body in direct proportion to the blood level. Most of the alcohol that a person drinks is metabolized by the liver. In the liver, alcohol metabolism proceeds simultaneously by two major pathways: the alcohol dehydrogenase (ADH) system and the microsomal ethanol-oxidizing system (MEOS).25,26 Both pathways lead to the production of acetaldehyde which has many toxic effects and is responsible for some of the acute effects of alcohol.

Alcohol oxidation by ADH involves a reduction in the adenine dinucleotide (NAD–to–nicotinamide adenine dinucleotide [NADH]) ratio (see Chapter 1, Understanding Cell Metabolism), with a consequent decrease in NAD and increase in NADH. Since NAD is required for fatty acid oxidation, its deficiency is a main cause of the accumulation of fat in the liver of alcoholics. It also causes lactic acidosis in alcoholics.25

Metabolism of alcohol by the MEOS system involves the CYP drug-metabolizing enzymes, located in the smooth endoplasmic reticulum. One of these metabolizing enzymes also oxidizes a number of other compounds, including various drugs (e.g., acetaminophen, isoniazid), toxins (e.g., carbon tetrachloride, halothane), industrial solvents, and carcinogenic agents (e.g., aflatoxin, nitrosamines). Induction of this system by alcohol enhances the susceptibility of alcoholics to the hepatotoxic effects of these and other compounds metabolized by the same system.25

Alcohol-Induced Liver Disease

About 2 million people in the United States are suspected of having alcoholic liver disease, which causes 27,000 deaths each year.1 Most of these deaths are attributable to liver failure, bleeding esophageal varices, or kidney failure. Because only approximately 10% to 15% of alcoholics develop cirrhosis, genetic and environmental factors are thought to contribute to alcoholic liver disease.5

The spectrum of alcoholic liver disease includes fatty liver disease, alcoholic hepatitis, and cirrhosis.3,4 Fatty liver disease is characterized by the accumulation of fat in hepatocytes, a condition called steatosis (Fig. 30-10). As a consequence, the liver becomes yellow and enlarges. The pathogenesis of fatty liver is not completely understood and can depend on the amount of alcohol consumed, dietary fat content, body stores of fat, hormonal status, and other factors. There is evidence that ingestion of large amounts of alcohol can cause fatty liver changes even with an adequate diet. For example, young, nonalcoholic volunteers had fatty liver changes after 2 days of consuming an excess amount of alcohol, even though adequate carbohydrates, fats, and proteins were included in the diet. The fatty changes that occur with ingestion of alcohol usually do not produce symptoms and are reversible after the alcohol intake has been discontinued.

Alcoholic hepatitis is characterized by inflammation and necrosis of liver cells caused by excessive alcohol intake.3,4,27 The cardinal sign of alcoholic hepatitis is rapid onset of jaundice. Other manifestations include fever, hepatic tenderness, pain, anorexia, nausea, ascites, and liver failure. Persons with severe alcoholic hepatitis may have encephalopathy. The immediate prognosis correlates with severity of liver cell injury. In some cases, the disease progresses rapidly to liver failure and death. The mortality rate in the acute stage ranges from 10% to 50% depending on severity of inflammation.4,28 In persons who survive and continue to drink, the acute phase often is followed by persistent alcoholic hepatitis with progression to cirrhosis in a matter of 1 to 2 years.

Alcoholic cirrhosis is the end result of repeated bouts of drinking-related hepatocyte injury and regeneration. The gross appearance of the early cirrhotic liver is one of fine, uniform nodules on its surface. The condition has traditionally been called micronodular or Laennec cirrhosis. Initially, the developing fibrous septa extend through the sinusoids from the central to the portal regions and the entrapped hepatocytes generate uniform micronodules. With more advanced cirrhosis, regenerative processes cause the nodules to become larger and more irregular in size and shape. As this occurs, the nodules cause the liver to become relobilized through the formation of new portal tracts and venous outflow channels. The nodules may compress the hepatic veins, curtailing blood flow out of the liver and producing portal hypertension, extrahepatic portosystemic shunts, and cholestasis.
Nonalcoholic Fatty Liver Disease

The term *nonalcoholic fatty liver disease* (NAFLD) is often used to describe fatty liver disease arising from causes other than alcohol. The condition can range from simple steatosis (fatty infiltration of the liver) to nonalcoholic steatohepatitis (steatosis with inflammation and hepatocyte necrosis and cirrhosis). Although steatosis alone does not appear to be progressive, approximately 20% of persons with nonalcoholic steatohepatitis progress to cirrhosis over the course of a decade. Obesity, type 2 diabetes, metabolic syndrome, and hyperlipidemia are coexisting conditions frequently associated with fatty liver disease (see Chapter 33). The condition is also associated with other nutritional abnormalities, surgical conditions, and drugs.

The pathogenesis of NAFLD is thought to involve both lipid accumulation within hepatocytes and formation of free radicals, in a manner similar to that which occurs with alcohol metabolism. The primary metabolic abnormalities leading to lipid accumulation are poorly understood but are thought to include alternations in the pathways for uptake, synthesis, degradation, or secretion of hepatic lipids resulting from insulin resistance. Obesity increases the synthesis and reduces the oxidation of free fatty acids. Type 2 diabetes or insulin resistance also increases adipose tissue lipolysis and the subsequent production of free fatty acids. When the capacity of the liver to export triglyceride is exceeded, excess fatty acids contribute to the development of steatosis and fatty liver disease. Both ketones and free fatty acids are inducers of previously described CYP enzymes of the MEOS pathway, which results in free radical formation, including hydrogen peroxide and superoxide. Abnormal lipid peroxidation ensues, followed by direct hepatocyte injury, release of toxic by-products, inflammation, and fibrosis.

Nonalcoholic fatty liver disease is usually asymptomatic, although fatigue and discomfort in the right upper quadrant of the abdomen may be present. Mildly to moderately elevated serum levels of AST, ALT, or both are the most common and often the only abnormal laboratory findings. Other abnormalities, including hypoalbuminemia, a prolonged prothrombin time, and hyperbilirubinemia, may be present in persons with cirrhotic-stage liver disease. The diagnosis of NAFLD can be made clinically with plasma liver aminotransferase levels, ultrasonography, and exclusion of alcohol. Liver biopsy is not routinely used unless there is concern for nonalcoholic steatohepatitis or advanced fibrosis.

The aim of treatment is to slow progression of NAFLD and to prevent liver-related illness. Both weight loss and exercise improve insulin resistance and are recommended in conjunction with treatment of associated metabolic disturbances. Alcohol use should be avoided. Vitamin E replacement has recently been found to improve steatosis in those with aggressive steatosis who do not have diabetes or cirrhosis. Oxidative stress in the liver results from an imbalance between production of reactive oxygen species (free radicals) and decreased antioxidant defenses. Vitamin E is an antioxidant that prevents propagation of free radicals and thereby decreases liver inflammation caused by oxidative stress. Disease progression is slow and the magnitude of disease-related morbidity and mortality is uncertain. Liver transplantation is an alternative for some persons with end-stage liver disease, but NAFLD may recur or develop after liver transplantation.

Hepatic Syndromes

Like other organs, the liver responds to a variety of insults with similar cellular and tissue responses, including hepatocyte degeneration, necrosis and apoptosis, and fibrosis. Clinically, these changes can lead to one or more characteristic syndromes, including cirrhosis, portal hypertension, and liver failure.

Cirrhosis

Cirrhosis represents the end stage of chronic liver diseases in which much of the functional liver tissue has been replaced by fibrous tissue. Although cirrhosis usually is associated with alcoholism, it can develop in the course of other disorders, including viral hepatitis, nonalcoholic liver disease, and biliary disease. Cirrhosis also accompanies metabolic disorders that cause the deposition of minerals in the liver. Two of these disorders are hemochromatosis (i.e., iron deposition) and Wilson disease (i.e., copper deposition).

Cirrhosis is characterized by diffuse fibrosis and conversion of normal liver architecture into nodules containing proliferating hepatocytes encircled by fibrosis. The formation of nodules, which vary in size from very small (<3 mm, micronodules) to large (several centimeters, macronodules), represents a balance between regenerative activity and constrictive scarring. The fibrous tissue that replaces normally functioning liver tissue forms constrictive bands that disrupt flow in the vascular channels and biliary duct systems of the liver. The disruption of vascular channels predisposes to portal hypertension and its complications; obstruction of biliary channels and exposure to the destructive effects of bile stasis; and loss of liver cells, leading to liver failure.

The manifestations of cirrhosis are variable, ranging from asymptomatic hepatomegaly to hepatic failure (Fig. 30-11). Often there are no symptoms until the disease is far advanced. The most common signs and symptoms of cirrhosis are weight loss (sometimes masked by ascites), cachexia, weakness, and anorexia. Diarrhea frequently is present, although some persons may complain of constipation. There may be abdominal pain because of liver enlargement or stretching of the liver’s fibrous tissue capsule. This pain is located in the epigastric area or in the upper right quadrant and is described as dull, aching, and causing a sensation of fullness.

The late manifestations of cirrhosis are related to portal hypertension and liver cell failure. Splenomegaly, ascites, and portosystemic shunts (i.e., esophageal varices, gastric varices, and caput medusae) result from portal hypertension. Other complications include bleeding due...
Portal Hypertension

Portal hypertension is characterized by increased resistance to flow in the portal venous system and sustained increase in portal venous pressure. Normally, venous blood returning to the heart from the abdominal organs collects in the portal vein and travels through the liver before entering the vena cava (see Fig. 30-2). Portal hypertension can be caused by a variety of conditions that increase resistance to hepatic blood flow, including prehepatic, posthepatic, and intrahepatic obstructions. Prehepatic causes of portal hypertension include obstructive thrombosis, narrowing of the portal vein before it enters the liver, and massive splenomegaly with increased splenic blood flow. The main posthepatic causes are right-sided heart failure and hepatic vein outflow obstruction. The dominant intrahepatic cause of portal hypertension is cirrhosis, in which bands of fibrous tissue and fibrous nodules distort the architecture of the liver and increase the resistance to blood flow.

The major clinical consequences of portal hypertension arise from the increased pressure and dilation of the venous channels behind the obstruction. In addition, collateral channels open that connect the portal circulation with the systemic venous circulation. The complications of the increased portal vein pressure and the opening of collateral channels are ascites, congestive splenomegaly, and the formation of portosystemic shunts with bleeding from esophageal varices.

Ascites. Ascites occurs when the amount of fluid in the peritoneal cavity is increased. It is a late-stage manifestation of cirrhosis and portal hypertension. Ascites usually becomes clinically evident when at least 500 mL of fluid has accumulated. However, the amount may be so great (frequently several liters) that it not only distends the abdomen, but also interferes with breathing. The fluid is generally serous, having less than 3 g of protein (largely albumin) and a concentration of solutes (glucose, sodium, and potassium) similar to that in the blood.

Although the mechanisms responsible for the development of ascites are not completely understood, several factors appear to contribute to fluid accumulation, including an increase in hydrostatic pressure due to portal hypertension, salt and water retention by the kidney, and decreased colloidal osmotic pressure due to impaired synthesis of albumin by the liver. Diminished blood volume (i.e., underfill theory) and excessive blood volume (i.e., overfill theory) have been used to explain the increased salt and water retention by the kidney. According to the underfill theory, a contraction in the effective blood volume causes the kidney to retain salt and water. The effective blood volume may be reduced because of loss of fluid into the peritoneal cavity or because of vasodilation caused by the presence of circulating vasodilating substances. The overfill theory proposes that the initial event in the development of ascites is renal retention of salt and water caused by disturbances in the liver itself. These disturbances include failure of the liver to metabolize aldosterone, causing an increase in salt and water retention by the kidney. Another likely contributing factor in the pathogenesis of ascites is a decreased colloidal osmotic pressure, which limits reabsorption of fluid from the peritoneal cavity (see Chapter 8).

Treatment of ascites usually focuses on dietary restriction of sodium and administration of diuretics. Water intake also may need to be restricted. Because of the many limitations in sodium restriction, the use of diuretics has become the mainstay of treatment for ascites.

**FIGURE 30-11.** Clinical manifestations of cirrhosis.
Two classes of diuretics are used: a diuretic that acts in the distal part of the nephron to inhibit aldosterone-dependent sodium reabsorption, and a loop diuretic such as furosemide (see Chapter 24). Oral potassium supplements often are given to prevent hypokalemia. Large-volume paracentesis (removal of 5 L or more of ascitic fluid) may be done in persons with massive ascites and pulmonary compromise. Because the removal of fluid produces a decrease in vascular volume along with increased plasma renin activity and aldosterone-mediated sodium and water reabsorption by the kidneys, a volume expander such as albumin usually is administered to maintain the effective circulating volume. A transjugular intrahepatic portosystemic shunt may be inserted in persons with refractory ascites (to be discussed).

**Spontaneous bacterial peritonitis** is a potential complication in persons with both cirrhosis and ascites. The infection is serious and carries a high mortality rate even when treated with antibiotics. Presumably, the peritoneal fluid is seeded with bacteria from the blood or lymph or from passage of bacteria through the bowel wall. Symptoms include fever and abdominal pain. Other symptoms include worsening of hepatic encephalopathy, diarrhea, hypothermia, and shock. It is diagnosed by a neutrophil count of 250/mm³ or higher and a protein concentration of 1 g/dL or less in the ascitic fluid.

**Splenomegaly.** The spleen enlarges progressively in portal hypertension because of shunting of blood into the splenic vein. The enlarged spleen often gives rise to sequestration of a significant number of blood elements and development of a syndrome known as **hypersplenism**. Hypersplenism is characterized by a decrease in the life span of all the formed elements of the blood and a subsequent decrease in their numbers, leading to anemia, thrombocytopenia, and leukopenia. The decreased life span of the blood elements is thought to result from an increased rate of removal because of the prolonged transit time through the enlarged spleen.

**Portosystemic Shunts and Esophageal Varices.** With the gradual obstruction of venous blood flow in the liver, the pressure in the portal vein increases, and large collateral channels develop between the portal and systemic veins that supply the lower rectum and esophagus and the umbilical veins of the falciform ligament that attaches to the anterior wall of the abdomen. The collaterals between the inferior and internal iliac veins may give rise to hemorrhoids. In some persons, the fetal umbilical vein is not totally obliterated; it forms a channel on the anterior abdominal wall. Dilated veins around the umbilicus are called **caput medusae**. Portopulmonary shunts also may develop and cause blood to bypass the pulmonary capillaries, interfering with blood oxygenation and producing cyanosis.

Clinically, the most important collateral channels are those connecting the portal and coronary veins that lead to reversal of flow and formation of thin-walled varicosities in the submucosa of the esophagus and stomach (Fig. 30-13). These thin-walled varices are subject to rupture, producing massive and sometimes fatal hemorrhage. Impaired hepatic synthesis of coagulation factors and decreased platelet levels (i.e., thrombocytopenia) due to splenomegaly may further complicate the control of esophageal bleeding.

Treatment of portal hypertension and esophageal varices is directed at prevention of initial hemorrhage, management of acute hemorrhage, and prevention of recurrent hemorrhage. Pharmacologic therapy is used to lower portal venous pressure and prevent initial hemorrhage. Nonselective β-adrenergic blocking drugs (propranolol, nadolol) commonly are used for this purpose. These agents reduce portal venous pressure by decreasing splanchnic blood flow and thereby decreasing blood flow in collateral channels.

Several methods are used to control acute hemorrhage, including pharmacologic therapy, balloon tamponade, and emergent endoscopic therapy. Pharmacologic methods include the administration of octreotide, a long-acting synthetic analog of somatostatin. Somatostatin,
of the hepatic vein and the portal vein using a catheter inserted through the internal jugular vein. A limitation of the procedure is that stenosis and thrombosis of the stent can occur over time, with consequent risk of rebleeding. A complication that is associated with the creation of a portosystemic shunt is hepatic encephalopathy, which is thought to result when ammonia and other neurotoxic substances from the gut pass directly into the systemic circulation without going through the liver.

**Liver Failure**

The most severe clinical consequence of liver disease is hepatic failure. It may result from sudden and massive liver destruction, as in fulminant hepatitis, or be the result of progressive damage to the liver, as occurs in chronic liver disease. Whatever the cause, 80% to 90% of hepatic functional capacity must be lost before hepatic failure occurs. In many cases, the effects of progressive liver disease are hastened by diseasestate complications that result in gastrointestinal bleeding, systemic infection, electrolyte disturbances, or superimposed diseases such as heart failure.

**Manifestations.** The manifestations of liver failure reflect the various synthesis, storage, metabolic, and elimination functions of the liver (Fig. 30-14). *Fetor hepaticus* refers to a characteristic musty, sweetish odor of the breath in the person in advanced liver failure, resulting from the metabolic by-products of the intestinal bacteria.

Liver failure can cause anemia, thrombocytopenia, coagulation defects, and leukopenia. Anemia may be caused by blood loss, excessive red blood cell destruction, and impaired formation of red blood cells. A folic acid deficiency may lead to severe megaloblastic anemia. Changes in the lipid composition of the red blood cell membrane increase hemolysis. Because many clotting factors are synthesized by the liver, their decline in liver disease contributes to bleeding disorders. Malabsorption of the fat-soluble vitamin K contributes further to the impaired synthesis of these clotting factors. Thrombocytopenia often occurs as the result of splenomegaly. These factors increase the risk of easy bruising as well as abnormal menstrual bleeding and bleeding from the esophagus and other segments of the gastrointestinal tract.

**Endocrine disorders,** particularly disturbances in gonadal (sex hormone) function, are common accompaniments of cirrhosis and liver failure. Women may have menstrual irregularities (usually amenorrhea), loss of libido, and sterility. In men, testosterone levels usually fall, the testes atrophy, and loss of libido, impotence, and gynecomastia occur. A decrease in aldosterone metabolism may contribute to salt and water retention by the kidney, along with a lowering of serum potassium resulting from increased elimination of potassium.

Liver failure also brings on numerous skin disorders. These lesions, called variously vascular spiders, telangiectases, spider angiomas, and spider nevi, are seen most
often in the upper half of the body. They consist of a central pulsating arteriole from which smaller vessels radiate. Palmar erythema is redness of the palms, probably caused by increased blood flow from higher cardiac output. Clubbing of the fingers may be seen in persons with cirrhosis. Jaundice usually is a late manifestation of liver failure.

The hepatorenal syndrome refers to a functional renal failure sometimes seen during the terminal stages of liver failure with ascites. It is characterized by progressive azotemia, increased serum creatinine levels, and oliguria. Although the basic cause is unknown, a decrease in renal blood flow is believed to play a part. Ultimately, when renal failure is superimposed on liver failure, azotemia and elevated levels of blood ammonia occur; this condition is thought to contribute to hepatic encephalopathy and coma.

Hepatic encephalopathy refers to the totality of central nervous system manifestations of liver failure. It is characterized by neural disturbances ranging from a lack of mental alertness to confusion, coma, and convulsions. A very early sign of hepatic encephalopathy is a flapping tremor called asterixis. Various degrees of memory loss may occur, coupled with personality changes such as euphoria, irritability, anxiety, and lack of concern about personal appearance and self. Speech may be impaired, and the person may be unable to perform certain purposeful movements. The encephalopathy may progress to decerebrate rigidity and then to a terminal deep coma.

Although the cause of hepatic encephalopathy is unknown, the accumulation of neurotoxins, which appear in the blood because the liver has lost its detoxifying capacity, is believed to be a factor. Hepatic encephalopathy develops in approximately 10% of persons with portosystemic shunts. One of the suspected neurotoxins is ammonia. A particularly important function of the liver is the conversion of ammonia, a by-product of protein and amino acid metabolism, to urea. The ammonium ion is produced in abundance in the intestinal tract, particularly in the colon, by the bacterial degradation of luminal proteins and amino acids. Normally, these ammonium ions diffuse into the portal blood and are transported to the liver, where they are converted to urea before entering the general circulation. When the blood from the intestine bypasses the liver or the liver is unable to convert ammonia to urea, ammonia moves directly into the general circulation and from there to the cerebral circulation. Hepatic encephalopathy may become worse after a large protein meal or gastrointestinal tract bleeding. Narcotics and tranquilizers are poorly metabolized by the liver, and administration of these drugs may contribute to central nervous system depression and precipitate hepatic encephalopathy.

Lactulose is a drug often used in hepatic encephalopathy. It is not absorbed from the small intestine but moves directly to the large intestine, where it is broken down by colonic bacteria to small organic acids that cause production of large, loose stools with a low pH.
The low pH favors the conversion of ammonia to ammonium ions, which are not absorbed by the blood. The acid pH also inhibits the intestinal degradation of amino acids, proteins, and blood. A nonabsorbable antibiotic, such as neomycin, or rifaximin may also be given to eradicate bacteria from the bowel and thus prevent this cause of ammonia production.38

Treatment. The treatment of liver failure is directed toward symptom management; preventing infections; providing sufficient calories and protein to rebuild and maintain protein stores; and correcting fluid and electrolyte imbalances. In many cases, liver transplantation remains the only effective treatment. Currently, 1-year survival rates approach 90%, and a 5-year survival rate of 70% to 80% is achieved at many transplantation centers in the United States.39 Unfortunately, the shortage of donor organs severely limits the number of transplantations that are done, and many persons die each year while waiting for a transplant. Innovative methods developed to deal with the shortage include split liver transplantation, in which a cadaver liver is split and transplanted into two recipients, and living donor transplantation, in which a segment or lobe from a living donor is transplanted.39

Cancer of the Liver

Malignant tumors of the liver can be primary or metastatic. Although primary tumors of the liver are relatively rare in developed countries of the world, the liver shares with the lung the distinction of being the most common site of metastatic tumors.

Primary Liver Cancers

There are two major types of primary liver cancer: hepatocellular carcinoma, which arises from the liver cells, and cholangiocarcinoma, which is a primary cancer of bile duct cells.3,4

Hepatocellular Carcinoma. Hepatocellular carcinoma, the most common form of liver cancer, is the fifth most common cancer and third leading cause of cancer-related mortality worldwide.40 In Europe, Australia, and the United States, the incidence is approximately 3 cases per 100,000. There has been an increased incidence, however, in developed countries as a consequence of chronic HCV infection.40

Among the factors identified as etiologic agents in liver cancer are chronic hepatitis B and C, chronic alcoholism, nonalcoholic fatty liver disease, and long-term exposure to environmental agents such as aflatoxin.3,41 Aflatoxins, produced by food spoilage molds in certain areas endemic for hepatocellular carcinoma, are particularly potent carcinoogenic agents.3 They are activated by hepatocytes and their products incorporated into the host DNA with the potential for developing cancer-producing mutations.

The manifestations of hepatocellular cancer often are insidious in onset and masked by those related to cirrhosis or chronic hepatitis. The initial symptoms include weakness, anorexia, weight loss, fatigue, bloating, a sensation of abdominal fullness, and a dull, ach ing abdominal pain.40,41 Ascites, which often obscures weight loss, is common. Jaundice, if present, usually is mild. There may be a rapid increase in liver size and worsening of ascites in persons with preexisting cirrhosis. Various paraneoplastic syndromes (e.g., disturbances due to ectopic hormone or growth factor production by the tumor (see Chapter 7) have been associated with hepatocellular cancer, including erythrocytosis (erythropoietin), hypoglycemia (insulin-like growth factor), and hypercalcemia (parathyroid-related protein). Serum α-fetoprotein, which is present during fetal life but barely detectable in the serum after the age of 2 years, is present in 50% of persons with hepatocellular carcinoma.4 However, the test lacks specificity and is not very useful as a surveillance or diagnostic tool. Diagnostic methods include ultrasonography, CT scans, and MRI. Liver biopsy may be used to confirm the diagnosis.

Hepatocellular carcinoma is often far advanced at the time of diagnosis. The treatment of choice is hepatic resection if conditions permit. Depending on size and placement of the tumor, other available treatments include liver transplantation, tumor-directed radio-frequency ablation, chemoembolization, and radioembolization.41,42 Image-guided ablation is now the conventional treatment for early-stage hepatocellular cancer. Ablation induces tumor necrosis by injection of chemicals (ethanol, acetic acid) or temperature modification (radiofrequency, microwave, laser, or cryoablation) into the tumor area. Sorefenib, a chemotherapeutic agent that is taken orally, has recently been approved for the treatment of hepatocellular carcinoma.41,42

Cholangiocarcinoma. Cholangiocarcinoma is a malignancy of the biliary tree, arising from bile ducts within and outside the liver. It accounts for 7.6% of cancer deaths worldwide and 3% of cancer deaths in the United States.3 The etiology, clinical features, and prognosis vary considerably with the part of the biliary tree that is the site of origin. Cholangiocarcinoma is not associated with the same risk factors as hepatocellular carcinoma. Instead, most of the risk factors revolve around long-standing inflammation and injury of the bile duct epithelium. Cholangiocarcinoma often presents with pain, weight loss, anorexia, and abdominal swelling or awareness of a mass in the right hypochondrium. Tumors affecting the central or distal bile ducts may present with jaundice.

Metastatic Tumors

Metastatic tumors of the liver are much more common than primary tumors.3,4 Common sources include colorectal, breast, lung, and urogenital cancer. In addition, tumors of neuroendocrine origin spread to the liver. It often is difficult to distinguish primary from metastatic tumors with the use of CT scans, MRI, or ultrasonography. Usually the diagnosis is confirmed by biopsy.
The liver is subject to most of the disease processes that affect other body structures, such as infections, autoimmune disorders, toxic injury, metabolic diseases, and neoplasms.

Hepatitis is characterized by inflammation of the liver. Viral hepatitis is caused by hepatitis viruses A, B, C, D, and E, which differ in terms of mode of transmission, incubation period, mechanism, degree and chronicity of liver damage, and ability to evolve to a carrier state. Autoimmune hepatitis involves the immune destruction of hepatocytes causing inflammation.

Intrahepatic biliary diseases disrupt the flow of bile through the liver, causing cholestasis and biliary cirrhosis. Causes of intrahepatic biliary diseases include primary biliary cirrhosis, primary sclerosing cholangitis, and secondary biliary cirrhosis.

The liver, which is the major drug-metabolizing and detoxifying organ in the body, is subject to potential damage from an enormous array of pharmaceutical and environmental chemicals. There are two types of drug reactions: predictable, based on the drug's chemical structure and metabolites, and idiosyncratic, based on individual characteristics of the person receiving the drug.

Cirrhosis represents the end stage of chronic liver disease in which much of the liver's functional tissue has been replaced by fibrous tissue that disrupts venous blood flow predisposing to portal hypertension and its complications, loss of liver cells, and eventual liver failure.

Portal hypertension is characterized by increased resistance to flow and increased pressure in the portal venous system, the pathologic consequences of which include ascites, the formation of collateral bypass channels (e.g., esophageal varices), and splenomegaly.

The manifestations of liver failure reflect the various functions of the liver, including hematologic disorders, disruption of endocrine function, skin disorders, hepatorenal syndrome, and hepatic encephalopathy.

There are two types of primary cancers of the liver. Hepatocellular cancer, the most common form, is derived from hepatocytes and their precursors and is associated with conditions such as chronic hepatitis B and C infection and alcoholic cirrhosis. Cholangiocarcinoma, or bile duct cancer, arises from the biliary epithelium, typically following long-standing inflammation of the bile ducts.

Disorders of the Hepatobiliary System and Exocrine Pancreas

The hepatobiliary system consists of the gallbladder; the left and right hepatic ducts, which come together to form the common hepatic duct; the cystic duct, which extends to the gallbladder; and the bile duct, which is formed by the union of the common hepatic duct and the cystic duct (Fig. 30-15). The bile duct descends posteriorly to the first part of the duodenum, where it comes in contact with the main pancreatic duct. These ducts unite to form the hepatopancreatic ampulla. The circular muscle around the distal end of the bile duct is thickened to form the sphincter of the bile duct.

The pancreas lies transversely in the posterior part of the upper abdomen (see Fig. 30-1). The head of the pancreas is at the right of the abdomen; it rests against the curve of the duodenum in the area of the hepatopancreatic ampulla and its entrance into the duodenum. The body of the pancreas lies beneath the stomach, with the tail touching the spleen. The pancreas is virtually hidden because of its posterior position; unlike many other organs, it cannot be palpated. Because of the position of the pancreas and its large functional reserve, symptoms from conditions such as cancer of the pancreas do not usually appear until the disorder is far advanced.

Disorders of the Hepatobiliary System

The gallbladder is a distensible, pear-shaped muscular sac located on the ventral surface of the liver. It has an outer serous peritoneal layer, a middle smooth muscle layer, and an inner mucosal layer that is continuous with the lining of the bile duct. The function of the gallbladder is to store and concentrate bile. In the gallbladder, water and electrolytes are absorbed from the bile, causing the concentration of bile salts and lecithin to increase, along with that of cholesterol; in this way, the solubility of cholesterol is maintained.

Entrance of food into the intestine causes the gallbladder to contract and the sphincter of the bile duct to relax, such that bile stored in the gallbladder moves into the duodenum. The stimulus for gallbladder contraction is primarily hormonal. Products of food digestion, particularly lipids, stimulate the release of a gastrointestinal hormone called cholecystokinin from the mucosa of the duodenum. Cholecystokinin provides a strong stimulus for gallbladder contraction. The role of other gastrointestinal hormones in bile release is less clearly understood.

Passage of bile into the intestine is regulated largely by the pressure in the common bile duct. Normally, the gallbladder regulates this pressure. It collects and stores bile as it relaxes and the pressure in the common bile duct decreases, and it empties bile into the intestine as the gallbladder contracts, producing an increase in common duct pressure. After gallbladder surgery, the
pressure in the common bile duct changes, causing it to dilate. The flow of bile then is regulated by the duct sphincters.

Common disorders of the biliary system are cholelithiasis (i.e., gallstones) and inflammation of the gallbladder (cholecystitis) or common bile duct (cholangitis). Cancer of the gallbladder is less common.

**Cholelithiasis**

Cholelithiasis is caused by precipitation of substances contained in bile, mainly cholesterol and bilirubin. Approximately 80% of gallstones are composed primarily of cholesterol; the other 20% are black or brown pigment stones consisting of calcium salts with bilirubin. Pigment stones containing bilirubin are seen in persons with hemolytic disease (e.g., sickle cell disease) and hepatic cirrhosis. Many stones have a mixed composition. Figure 30-16 shows a gallbladder with numerous cholesterol gallstones.

Three factors contribute to the formation of gallstones: abnormalities in the composition of bile, stasis of bile, and inflammation of the gallbladder. The formation of cholesterol stones is associated with obesity and occurs more frequently in women, especially women who have had multiple pregnancies or who are taking oral contraceptives. All of these factors cause the liver to excrete more cholesterol into the bile. Estrogen reduces the synthesis of bile acid in women. Gallbladder sludge (thickened gallbladder mucoprotein with tiny trapped cholesterol crystals) is thought to be a precursor of gallstones. Sludge frequently occurs with pregnancy, starvation, and rapid weight loss. Drugs that lower serum cholesterol levels, such as clofibrate, also cause increased cholesterol excretion into the bile. Malabsorption disorders stemming from ileal disease or intestinal bypass surgery tend to interfere with the absorption of bile salts, which are needed to maintain the solubility of cholesterol. Inflammation of the gallbladder alters the absorptive characteristics of the mucosal layer, allowing excessive absorption of water and bile salts.

At least 10% of adults have gallstones. There is an increased prevalence with age, and approximately twice as many white women as men have gallstones. They are extremely common among Native Americans, which suggests that a genetic component may have a role in gallstone formation.

Many persons with gallstones have no symptoms. Gallstones cause symptoms when they obstruct bile flow. Small stones (<8 mm in diameter) pass into the common duct, producing symptoms of indigestion and biliary colic. Larger stones are more likely to obstruct flow and cause jaundice. The pain of biliary colic is usually located in the upper right quadrant or epigastric area and may be referred to the upper back, right shoulder, or midscapular region. Typically the pain is abrupt in onset, increases steadily in intensity, persists for 2 to 8 hours, and is followed by soreness in the upper right quadrant.

**Acute Cholecystitis**

Acute cholecystitis is a diffuse inflammation of the gallbladder, usually secondary to obstruction of the gallbladder outlet. Most cases of acute cholecystitis
Persons with acute cholecystitis usually experience an onset of right upper quadrant or epigastric pain, frequently associated with mild fever, anorexia, nausea, vomiting.\(^\text{43-45}\) Whereas in biliary colic the cystic duct obstruction is transient, in acute cholecystitis it is persistent. Persons with acute cholecystitis usually, but not always, have experienced previous episodes of biliary pain. The pain may appear with remarkable suddenness and constitute a surgical emergency. In the absence of medical attention, the attack usually subsides in 7 to 10 days and frequently within 24 hours. In persons who recover, recurrence is common. The onset of acalculous cholecystitis tends to be more insidious because the manifestations are obscured by the underlying conditions precipitating the attack. In the severely ill patient, early recognition is crucial because a delay in treatment can prove life-threatening. Persons with acute cholecystitis usually have an elevated white blood cell count and many have mild elevations in AST, ALT, ALP, and bilirubin.

**Chronic Cholecystitis**

Chronic cholecystitis results from repeated episodes of acute cholecystitis or chronic irritation of the gallbladder by stones.\(^\text{3,4}\) It is characterized by varying degrees of chronic inflammation. Gallstones almost always are present. Cholelithiasis with chronic cholecystitis may be associated with acute exacerbations of gallbladder inflammation, common duct stones, pancreatitis, and, rarely, carcinoma of the gallbladder.

The manifestations of chronic cholecystitis are more vague than those of acute cholecystitis. There may be intolerance to fatty foods, belching, and other indications of discomfort. Often, there are episodes of colicky pain with obstruction of biliary flow caused by gallstones. The gallbladder, which in chronic cholecystitis usually contains stones, may be enlarged, shrunken, or of normal size.

**Diagnosis and Treatment of Gallbladder Disease**

The methods used to diagnose gallbladder disease include ultrasonography, cholescintigraphy (nuclear scanning), and CT scans.\(^\text{43-45}\) Ultrasonography is widely used in diagnosing gallbladder disease and has largely replaced the oral cholecystogram in most medical centers. It can detect stones as small as 1 to 2 cm, and its overall accuracy in detecting gallbladder disease is high. In addition to stones, ultrasonography can detect wall thickening, which indicates inflammation. It also can rule out other causes of right upper quadrant pain such as tumors. Cholescintigraphy, also called a gallbladder scan, relies on the ability of the liver to extract a rapidly injected radiouclide, technetium-99m, bound to one of several iminodiacetic acids, that is excreted into the bile ducts. Serial scanning images are obtained within several minutes of the injection of the tracer and every 10 to 15 minutes during the next hour. The gallbladder scan is highly accurate in detecting acute cholecystitis. Although CT is not as accurate as ultrasonography in detecting gallstones, it can show thickening of the gallbladder wall or pericholecystic fluid associated with acute cholecystitis.

Gallbladder disease usually is treated by removing the gallbladder. The gallbladder stores and concentrates bile, and its removal usually does not interfere with digestion. Laparoscopic cholecystectomy has become the treatment of choice for symptomatic gallbladder disease.\(^\text{45}\) The procedure involves insertion of a
enth decade of life. The onset of symptoms usually is common in women and occurs more often in the seventh decade of life. The onset of symptoms usually is

Choledocholithiasis and Cholangitis

Choledocholithiasis refers to stones in the common duct and cholangitis to inflammation of the common bile duct.

Common bile duct stones usually originate in the gallbladder, but can form spontaneously in the common duct.

The manifestations of choledocholithiasis are similar to those of gallstones and acute cholecystitis. There is a history of acute biliary colic and right upper abdominal pain, with chills, fever, and jaundice associated with episodes of abdominal pain. Bilirubinuria and an elevated serum bilirubin are present if the common duct is obstructed. Complications include acute supplicative cholangitis accompanied by pus in the common duct. It is characterized by the presence of an altered sensorium, lethargy, and septic shock. Acute supplicative cholangitis represents an endoscopic or surgical emergency. Common duct stones can obstruct the outflow of the pancreatic duct, causing secondary pancreatitis.

Ultrasonography, CT scans, and radionuclide imaging may be used to demonstrate dilation of bile ducts and impaired blood flow. Endoscopic ultrasonography and magnetic resonance cholangiography are used for detecting common duct stones. Both percutaneous transhepatic cholangiography (PTC) and endoscopic retrograde cholangiopancreatography (ERCP) provide a direct means for determining the cause, location, and extent of obstruction. Percutaneous transhepatic cholangiography involves the injection of dye directly into the biliary tree. It requires the insertion of a thin, flexible needle through a small incision in the skin with advancement into the biliary tree. Endoscopic retrograde cholangiopancreatography involves the passage of an endoscope into the duodenum and the passage of a catheter into the hepatopancreatic ampulla. Endoscopic retrograde cholangiopancreatography can be used to enlarge the opening of the sphincter of the bile duct, which may allow the lodged stone to pass, or an instrument may be inserted into the bile duct to remove the stone.

Common duct stones in persons with cholecystitis usually are treated by stone extraction followed by laparoscopic cholecystectomy. Antibiotic therapy, with an agent that enters the bile, is used to treat supplicative cholangitis. Emergency decompression of the common duct, usually by ERCP, may be necessary for persons who are septic or fail to improve with antibiotic treatment.

Cancer of the Gallbladder

Cancer of the gallbladder is the fifth most common cancer of the gastrointestinal tract. It is slightly more common in women and occurs more often in the seventh decade of life. The onset of symptoms usually is insidious, and they resemble those of cholecystitis; the diagnosis often is made unexpectedly at the time of gallbladder surgery. About 80% to 85% of persons with gallbladder cancer have cholelithiasis. Because of its ability to produce chronic irritation of the gallbladder mucosa, it is believed that cholelithiasis plays a role in the development of gallbladder cancer. It is seldom resectable at the time of diagnosis, and the mean 5-year survival rate has remained a dismal 1% for many years.

Disorders of the Exocrine Pancreas

The pancreas is both an exocrine and endocrine organ (see Chapter 33). The exocrine pancreas is made up of lobules that consist of acinar cells, which secrete digestive enzymes into a system of microscopic ducts. These ducts empty into the main pancreatic duct, which extends from left to right through the substance of the pancreas. The main pancreatic duct and the bile duct unite to form the hepatopancreatic ampulla, which empties into the duodenum. The sphincter of the pancreatic duct controls the flow of pancreatic secretions into the bile duct (see Fig. 30-15).

The secretions of the pancreatic acinar cells contain proteolytic enzymes, including trypsin and several others, that break down dietary proteins. The pancreas also secretes pancreatic amylase, which breaks down starch, and lipases, which hydrolyze triglycerides into glycerol and fatty acids. The pancreatic enzymes are secreted in the inactive form and become activated in the intestine. This is important because the enzymes would digest the tissue of the pancreas itself if they were secreted in the active form. The acinar cells also secrete a trypsin inhibitor, which prevents trypsin activation. Because trypsin activates other proteolytic enzymes, the trypsin inhibitor prevents subsequent activation of the other enzymes.

Although the enzymes of the pancreatic secretions are secreted entirely by the acinar cells, the other two important ingredients—bicarbonate ions and water—are secreted entirely by the epithelial cells that line the ductules and ducts leading from the acinar cells. When the pancreas is stimulated to secrete copious amounts of digestive enzymes, the epithelial cells increase their production of bicarbonate that serves to neutralize the hydrochloric acid emptied into the stomach from the duodenum.

Two types of pancreatic disease are discussed in this chapter: acute and chronic pancreatitis and cancer of the pancreas.

Acute Pancreatitis

Acute pancreatitis represents a reversible inflammatory process of the pancreatic acini brought about by premature activation of pancreatic enzymes. Although the disease process may be limited to pancreatic tissue, it also can involve peripancreatic tissues or those of more distant organs.

The pathogenesis of acute pancreatitis involves the autodigestion of pancreatic tissue by inappropriately activated pancreatic enzymes. The process is thought to begin with the activation of trypsin. Once activated, trypsin can then activate a variety of digestive enzymes
that cause pancreatic injury, resulting in an intense inflammatory response. The acute inflammatory response itself causes substantial tissue damage and may progress beyond the pancreas to produce a systemic inflammatory response syndrome and multiorgan failure (see Chapter 20). Although a number of factors are associated with the development of acute pancreatitis, in the United States alcohol abuse and gallstones account for 70% to 80% of all cases.47–51 The precise mechanisms whereby alcohol exerts its action are largely unknown; however, alcohol is known to be a potent stimulator of pancreatic secretions, and it also is known to cause partial obstruction of the sphincter of the pancreatic duct. In the case of biliary tract obstruction due to gallstones, pancreatic duct obstruction or biliary reflux is believed to activate the enzymes in the pancreatic duct system. Acute pancreatitis also is associated with hyperlipidemia, hypercalcemia, infections (particularly viral), abdominal and surgical trauma, and drugs such as thiazide diuretics.

Clinical Manifestations. The manifestations of acute pancreatitis can range from mild with minimal organ dysfunction to severe and life-threatening. Overall, about 20% of persons with acute pancreatitis have a severe course, and 10% to 30% of those with severe pancreatitis die.49,50 The diagnosis of acute pancreatitis is made by the presence of 2 or 3 of the following symptoms: (1) abdominal pain; which is usually severe, located in the epigastic or left upper quadrant and may radiate to the back, chest, or flank areas; (2) serum amylase or lipase greater than 3 times the upper limit of normal; and (3) classic signs on abdominal imaging. Serum lipase may remain elevated slightly longer than amylase. However, the level of elevation of the serum amylase or lipase does not correlate with the severity of the disorder. The white blood cell count may also be increased, and hyperglycemia and an elevated serum bilirubin level may be present. Abdominal ultrasonography is usually performed to assess for gallstones. Both CT scans and dynamic contrast-enhanced CT of the pancreas are used to detect necrosis and fluid accumulation.

Physical examination findings are variable and include fever, tachycardia, hypotension, severe abdominal tenderness, respiratory distress, and abdominal distention. Recognized markers of severe disease include laboratory values that measure the inflammatory response (e.g., C-reactive protein), scoring systems that assess inflammation or organ failure, and findings on imaging studies. Clinical findings such as thirst, poor urine output, progressive tachycardia, tachypnea, hypoxemia, agitation, confusion, a rising hematocrit level, and lack of improvement in symptoms within the first 48 hours are warning signs of impending severe disease. Complications include the systemic inflammatory response, acute respiratory distress syndrome, acute tubular necrosis, and organ failure. An important disturbance related to acute pancreatitis is the loss of a large volume of fluid into the retroperitoneal and peripancreatic spaces and the abdominal cavity. Signs of hypocalcemia may develop, probably as a result of the precipitation of serum calcium in the areas of fat necrosis.

Treatment. Determination of the cause is important in guiding the immediate management and preventing recurrence. Treatment measures depend on the severity of the disease. Persons who present with persistent or severe pain, vomiting, dehydration, or signs of impending severe acute pancreatitis require hospitalization. Treatment measures are directed at pain relief, “putting the pancreas to rest” by withholding oral foods and fluids, and restoration of lost plasma volume. Meperidine rather than morphine usually is given for pain relief because it causes fewer spasms of the sphincter of the pancreatic duct. Gastric suction is instituted to treat distention of the bowel and prevent further stimulation of the secretion of pancreatic enzymes. Intravenous fluids and electrolytes are administered to replace those lost from the circulation and to combat hypotension and shock. Intravenous colloid solutions are given to replace the fluid that has become sequestered in the abdomen and retroperitoneal space.

Complications. Sequelae in persons surviving an episode of severe acute pancreatitis include fluid collections and infection.49 In 40% to 60% of persons with acute necrotizing pancreatitis, the necrotic debris becomes infected, usually by gram-negative organisms from the alimentary canal, further complicating the condition.47 Fluid collections with a high level of pancreatic enzymes are usually associated with pancreatic duct disruptions and may eventually form pseudocysts (a collection of pancreatic fluid enclosed in a layer of inflammatory tissue). A pseudocyst most often is connected to a pancreatic duct, so that it continues to increase in mass. The symptoms depend on its location; for example, jaundice may occur when a cyst develops near the head of the pancreas, close to the common duct. Pseudocysts may resolve or, if they persist, may require surgical intervention.

Chronic Pancreatitis

Chronic pancreatitis is characterized by progressive and permanent destruction of the exocrine pancreas, fibrosis, and, in the later stages, destruction of the endocrine pancreas.3,4,52,53 Most factors that cause acute pancreatitis can also cause chronic pancreatitis. However, the chief distinction between the two conditions is the irreversibility of pancreatic function that is characteristic of chronic pancreatitis. By far the most common cause of chronic pancreatitis is long-term alcohol abuse. Less common causes are long-standing obstruction of the pancreatic duct by pseudocysts, calculi, or neoplasms, autoimmune disorders, primary sclerosing cholangitis, inflammatory bowel disease, cystic fibrosis (discussed in Chapter 23), and hereditary pancreatitis, a rare autosomal dominant disorder.

Chronic pancreatitis is manifested by episodes that are similar, albeit of lesser severity, to those of acute pancreatitis. Patients have persistent, recurring episodes of epigastric and upper left quadrant pain; the attacks often are precipitated by alcohol abuse or overeating. Anorexia, nausea, vomiting, constipation, and flatulence are common. Eventually the disease progresses to the
extent that endocrine and exocrine pancreatic functions become deficient. At this point, signs of diabetes mellitus and the malabsorption syndrome (e.g., weight loss, fatty stools [steatorrhea]) become apparent.

Treatment consists of measures to treat coexisting biliary tract disease. A low-fat diet usually is prescribed. The signs of malabsorption may be treated with pancreatic enzymes. When diabetes is present, it is treated with insulin. Alcohol is forbidden because it frequently precipitates attacks. Because of the frequent episodes of pain, narcotic addiction is a potential problem in persons with chronic pancreatitis. Surgical intervention sometimes is needed to relieve the pain and usually focuses on relieving any obstruction that may be present.

**Cancer of the Pancreas**

Pancreatic cancer is now the fourth leading cause of death from cancer in the United States, preceded only by lung, colon, and breast cancer.\(^{47,48}\) Considered to be one of the most deadly malignancies, pancreatic cancer is associated with a 5-year survival rate of only 4% to 6%.\(^{47,48,54–56}\) The incidence of pancreatic cancer seems to be increasing in all countries studied and has tripled in the United States over the past 50 years.\(^{48}\)

The cause of pancreatic cancer is unknown. Age is a major risk factor. Pancreatic cancer rarely occurs in persons younger than 50 years of age, and the risk increases with age. The most significant and reproducible environmental risk factor is cigarette smoking, which doubles the risk.\(^{47,48,54–56}\) Diabetes and chronic pancreatitis also are associated with pancreatic cancer, although neither the nature nor the sequence of the possible cause-and-effect relation has been established. There has been a recent focus on the molecular genetics of pancreatic cancer.

**Clinical Manifestations.** Almost all pancreatic cancers are adenocarcinomas of the ductal epithelium, and symptoms are primarily caused by mass effect rather than disruption of exocrine or endocrine function. The clinical manifestations depend on the size and location of the tumor as well as its metastasis.\(^{54–56}\) Pain, jaundice, and weight loss constitute the classic presentation of the disease. The most common pain is a dull epigastric pain often accompanied by back pain, often worse in the supine position, and relieved by sitting forward. Patients may also present with diabetes or impaired glucose tolerance. Because of the proximity of the pancreas to the common duct and the hepatopancreatic ampulla, cancer of the head of the pancreas tends to obstruct bile flow. Jaundice frequently is the presenting symptom of a person with cancer of the head of the pancreas, and it usually is accompanied by complaints of pain and pruritus. Cancer of the body of the pancreas usually impinges on the celiac ganglion, causing pain. The pain usually worsens with ingestion of food or assumption of the supine position. Cancer of the tail of the pancreas usually has metastasized before symptoms appear.

Migratory thrombophlebitis (deep vein thrombosis) develops in about 10% of persons with pancreatic cancer, particularly when the tumor involves the body or tail of the pancreas. Thrombi develop in multiple veins, including the deep veins of the legs, the subclavian vein, the inferior and superior mesenteric veins, and even the vena cava. It is not uncommon for the migratory thrombophlebitis to provide the first evidence of pancreatic cancer, although it may present in other cancers as well. The mechanism responsible for the hypercoagulable state is largely unclear, but may relate to activation of clotting factors by proteases released from the tumor cells.\(^{48}\)

**Diagnosis and Treatment.** Patient history, physical examination, and elevated serum bilirubin and alkaline phosphate levels may suggest the presence of pancreatic cancer but are not diagnostic.\(^{54–56}\) The serum cancer antigen (CA) 19–9, a Lewis blood group antigen, may help confirm the diagnosis in symptomatic patients and may help predict prognosis and recurrence after resection. However, CA 19–9 lacks the sensitivity and specificity to effectively screen asymptomatic patients.\(^{56}\) Ultrasonography and CT scanning are the most frequently used diagnostic methods to confirm the disease. Intravenous and oral contrast–enhanced spiral CT is the preferred method for imaging the pancreas. Percutaneous fine needle aspiration cytology of the pancreas has been one of the major advances in the diagnosis of pancreatic cancer. Unfortunately, the smaller and more curable tumors are most likely to be missed by this procedure. Endoscopic retrograde cholangiopancreatography may be used for evaluation of persons with suspected pancreatic cancer and obstructive jaundice.

Most cancers of the pancreas have metastasized at the time of diagnosis. Surgical resection of the tumor is done when the tumor is localized or as a palliative measure. Radiation therapy may be useful when the disease is localized but not resectable. The use of irradiation and chemotherapy for pancreatic cancer continues to be investigated. Pain control is one of the most important aspects in the management of persons with end-stage pancreatic cancer.

---

**SUMMARY CONCEPTS**

- The biliary tract, which consists of the bile ducts and gallbladder, serves as a passageway for the delivery of bile from the liver to the intestine.

- The most common causes of biliary tract disease are cholelithiasis and cholecystitis. Three factors contribute to the development of cholelithiasis: abnormalities in the composition of bile, stasis of bile, and inflammation of the gallbladder. Cholelithiasis, in turn, predisposes to obstruction of bile flow, causing biliary colic and acute or chronic cholecystitis.
The pancreas is an endocrine and exocrine organ. The exocrine function of the pancreas produces digestive enzymes that are secreted in an inactive form and transported to the small intestine through the main pancreatic duct, which empties into the hepatopancreatic ampulla and then into the duodenum through the sphincter of Oddi.

- Acute pancreatitis is an inflammatory condition of the pancreas due to inappropriate activation of pancreatic enzymes, with manifestations that can range from mild to severe and life-threatening.
- Chronic pancreatitis causes progressive destruction of the endocrine and exocrine pancreas. It is characterized by episodes of pain and epigastric distress that are similar but less severe than those that occur with acute pancreatitis.
- Pancreatic cancer, the cause of which is unknown, is considered to be one of the most deadly malignancies.

3. A 40-year-old woman presents in the emergency department with a sudden episode of vomiting and severe right epigastric pain that developed after eating a fatty evening meal. Although there is no evidence of jaundice in her skin, the sclera of her eyes is noted to have a yellowish discoloration. Palpation reveals tenderness of the upper right quadrant with muscle splinting and rebound pain. Right upper quadrant abdominal ultrasonography confirms the presence of gallstones. The woman is treated conservatively with pain and antiemetic medications. She is subsequently scheduled for a laparoscopic cholecystectomy.

A. Relate this woman’s signs and symptoms to gallstones and their effect on gallbladder function.
B. Explain the initial appearance of jaundice in the eyes as opposed to the skin. Which of the two laboratory tests for bilirubin would you expect to be elevated—direct (conjugated) or indirect (unconjugated or free)?
C. What effect will removal of the gallbladder have on the woman’s digestive system?

**REFERENCES**

The endocrine system is involved in all of the integrative aspects of life, including growth, sex differentiation, metabolism, and adaptation to an ever-changing environment. This chapter focuses on general aspects of endocrine function, organization of the endocrine system, hormone receptors and hormone actions, and regulation of hormone levels.

The Endocrine System

The endocrine system uses chemical messengers called hormones as a means of controlling the flow of information between the different tissues and organs of the body. It does not act alone, however, but interacts with the nervous system to coordinate and integrate the activity of body cells. Each system can function alone or in concert with other systems as a single neuroendocrine system, performing the same general functions within the body of communication, integration, and control.

Although both the endocrine and nervous systems function in regulating body functions, the means and speed of control used by these two systems are different. The nervous system functions by means of neurotransmitter molecules transported by neurons over a short distance to muscles and glands that respond within milliseconds (see Chapter 34). The endocrine system, on the other hand, uses hormones released from glands into the blood and transported throughout the body to influence the activity of body tissues. Tissue and organ responses to
endocrine hormones tend to take much longer than the response to neurotransmitters, but once initiated they tend to be much more prolonged than those induced by the nervous system.

The glands of the endocrine system are widely scattered throughout the body (Fig. 31-1). These glands include the pituitary, thyroid, parathyroid, and adrenal glands. In addition, several organs of the body contain discrete areas of endocrine tissue and produce hormones as well as exocrine products. Such organs, which include the pancreas and the gonads (testes and ovaries), are also major endocrine glands. The hypothalamus also falls into this category. In addition to its neural functions, it releases hormones that influence the secretion of hormones by other endocrine organs.

Besides the major endocrine glands, there are endocrine cells within organs whose primary function is not endocrine. These include cells within the heart that produce atrial natriuretic factor, cells within the kidney that produce erythropoietin, and numerous cell types within the gastrointestinal tract that produce hormones.

**Hormones**

The effects of hormones are many and varied. Their actions are involved in regulating water and electrolyte balance; responding to adverse conditions, such as infection, trauma, and stress; sequentially integrating the processes of growth and development; contributing to the processes of reproduction, including gamete (ovum and sperm) production, fertilization, and maintenance of a pregnancy; and digesting, using, and storing nutrients.

A characteristic of endocrine hormones is that a single hormone can exert various effects in different tissues or, conversely, a single function can be regulated by several different hormones. For example, estradiol, which is produced by the ovary, can act on the ovarian follicles to promote their maturation, on the uterus to stimulate its growth and maintain the cyclic changes in the uterine mucosa, on the mammary gland to stimulate ductal growth, on the hypothalamic-pituitary system to regulate the secretion of gonadotropins and prolactin, on the bone to maintain skeletal integrity, and on general metabolic processes to affect adipose tissue distribution. Lipolysis, which is the release of free fatty acids from adipose tissue, is an example of a single function that is regulated by several hormones, including the catecholamines, insulin, and glucagon, and also by the cytokine tumor necrosis factor-a. Table 31-1 lists the major actions and sources of body hormones.

Although some hormones are released into the bloodstream and transported to distant target sites, where they exert their actions, other hormones and hormone-like substances never enter the bloodstream but instead act locally in the vicinity in which they are released (Fig. 31-2). When they act locally on cells other than those that produce the hormone, the action is called paracrine. The action of sex steroids on the ovary is a paracrine action. Hormones also can exert an autocrine action on the cells from which they were produced. For example, the release of insulin from pancreatic beta cells can inhibit its release from the same cells.

**Structural Classification**

Hormones, which have diverse chemical structures ranging from single amino acids to complex proteins and lipids, can be divided into three categories: (1) amines and amino acid hormones; (2) peptides, polypeptides, proteins, and glycoproteins; and (3) steroids (Table 31-2).

The first category, the amines and amino acid hormones, includes norepinephrine and epinephrine, which are derived from a single amino acid (i.e., tyrosine), and the thyroid hormones, which are derived from two iodinated tyrosine amino acid residues. The second category, the peptide, polypeptide, protein, and glycoprotein hormones, can be as small as thyrotropin-releasing hormone (TRH), which contains 3 amino acids, and as large and complex as growth hormone (GH) and follicle-stimulating hormone (FSH), which have approximately 200 amino acids. Glycoproteins are large peptide hormones associated with a carbohydrate (e.g., FSH). The third category consists of the steroid hormones, such as the glucocorticoids, which are derivatives of cholesterol.

A group of compounds that have a hormone-like action are the eicosanoids, which are derived from polyunsaturated fatty acids in the cell membrane. Among these, arachidonic acid is the most important and abundant precursor of the various eicosanoids (see Chapter 3, Fig. 3-4). The most important of the eicosanoids are the prostaglandins, leukotrienes, and thromboxanes. These fatty acid derivatives are produced by most body cells, are rapidly cleared from the
circulation, and are thought to act mainly by paracrine and autocrine mechanisms. Eicosanoid synthesis often is stimulated in response to hormones, and they serve as mediators of hormone action.

An extension of the endocrine system is represented by numerous cell types with enzymes that modify inactive precursors or less active hormones into highly active hormones. An example is the conversion of the inactive circulating plasma protein angiotensinogen to highly active angiotensin II by the enzymatic action of renin, which is produced by the kidney, and angiotensin-converting enzyme, which is present in the lung (see Chapter 18, Fig. 18-13). Another example is the activation of vitamin D by two subsequent hydroxylation reactions in the liver and kidney to produce the highly bioactive form of vitamin D.

**Hormone Synthesis**

The mechanisms for hormone synthesis and release vary with hormone structure. Protein and polypeptide hormones are synthesized and stored in vesicles in the cytoplasm of the cell until secretion is required. Other hormones, such as the lipid-soluble steroid hormones, are released as they are synthesized.

**Vesicle-Mediated Synthesis.** The protein and polypeptide hormones comprise the most prominent class of hormones whose synthesis and release is vesicle mediated. These hormones are synthesized in the rough endoplasmic reticulum of the endocrine cell in a manner similar to the synthesis of other proteins (see Chapter 1). The appropriate amino acid sequence is dictated by messenger ribonucleic acids (mRNAs) from the nucleus. Usually, synthesis involves the production of a precursor hormone, which is modified by the addition of peptides or sugar units. These precursor hormones often contain extra peptide units that ensure proper folding of the molecule and insertion of essential linkages. If extra amino acids are present, as in insulin, the precursor hormone is called a prohormone.

After synthesis and sequestration in the endoplasmic reticulum, the protein and peptide hormones move into the Golgi complex, where they are packaged in vesicles. It is in the Golgi complex that prohormones are converted into hormones. Stimulation of the endocrine cell causes the vesicles to move to the cell membrane and release their hormones.

The vesicle-mediated pathway is also used for secretion of a number of nonpolypeptide hormones and neurotransmitters such as the catecholamines (epinephrine and norepinephrine). However, these small molecules do not pass through the full range of intracellular mechanisms seen in the synthesis and secretion of the larger protein and polypeptide hormones.

**Non–Vesicle-Mediated Synthesis.** Hormones synthesized by non–vesicle-mediated pathways include the glucocorticoids, androgens, estrogens, and mineralocorticoids—all steroids derived from cholesterol. These hormones are synthesized in the smooth endoplasmic reticulum, and steroid-secreting cells can be identified by their large amounts of smooth endoplasmic reticulum. Certain steroids serve as precursors for the production of other hormones. In the adrenal cortex, for example, progesterone and other steroid intermediates are enzymatically converted into aldosterone, cortisol, or androgens (see Chapter 32).

The release of hormones synthesized by non–vesicle-mediated pathways is not fully understood. Historically it was thought to occur by simple diffusion. In recent years, however, specific transporters have been implicated in directing some of these classes of hormones out of the cell. Whether all hormones produced by non–vesicle-mediated pathways depend on transporters for their secretion remains a subject for further investigation.

**Hormone Transport and Clearance from the Blood**

The signaling of the endocrine system relies on mechanisms that transport blood-borne chemical messengers to the site of action, and then clear them from the blood once their action is no longer needed.

**Transport Mechanisms.** Hormones that are released into the bloodstream circulate as either free or unbound molecules or as hormones attached to transport carriers (Fig. 31-3). Peptide hormones and protein hormones...

</tbody>
</table>
are water soluble and usually circulate unbound in the blood. Steroid hormones and thyroid hormones are carried by specific carrier proteins synthesized in the liver. The extent of carrier binding influences the rate at which hormones leave the blood and enter the cells.

The half-life of a hormone—the time it takes for the body to reduce the concentration of the hormone by one half—is positively correlated with its percentage of protein binding. Thyroxine, which is more than 99% protein bound, has a half-life of 6 days. Aldosterone, which is only 15% bound, has a half-life of only 25 minutes.

Drugs that compete with a hormone for binding with transport carrier molecules increase hormone action by increasing the availability of the active unbound hormone. For example, aspirin competes with thyroid hormone for binding to transport proteins; when this drug is administered to persons with excessive levels of circulating thyroid hormone, such as during thyroid crisis, serious effects may occur due to the dissociation of free hormone from the binding proteins.

**Inactivation and Elimination.** Hormones secreted by endocrine cells must be inactivated continuously to prevent their accumulation. Intracellular and extracellular mechanisms participate in the termination of hormone function. Most peptide hormones and catecholamines are water soluble and circulate freely in the blood. They are usually degraded by enzymes in the blood or tissues and then excreted by the kidneys and liver. For example, the catecholamines are rapidly degraded by catechol O-methyl transferase (COMT) and monoamine oxidase (MAO). Because of their short half-life, their production is measured by some of their metabolites. In general, peptide hormones also have a short life span in the circulation. Their major mechanism of degradation is through binding to cell surface receptors, with subsequent uptake and degradation by peptide-splitting enzymes in the cell membrane or inside the cell.

Steroid hormones are bound to protein carriers for transport and are inactive in the bound state. Their activity depends on the availability of transport carriers. Unbound adrenal and gonadal steroid hormones are conjugated in the liver, which renders them inactive, and then excreted in the bile or urine. Thyroid hormones also are transported by carrier molecules. The free hormone is rendered inactive by the removal of amino acids (i.e., deamination) in the tissues, and the hormone is conjugated in the liver and eliminated in the bile.
Receptor Control of Hormone Function

Hormones produce their effects through interaction with high-affinity receptors, which in turn are linked to one or more effector systems within the cell (see Understanding Hormone Receptors). These mechanisms involve many of the cell’s metabolic activities, ranging from ion transport at the cell surface to stimulation of nuclear transcription of complex molecules. The rate at which hormones react depends on their mechanism of action. Thyroid hormone, which controls cell metabolism and synthesis of intracellular signaling molecules, requires days for its full effect to occur.

Control of Receptor Number and Affinity

Hormone receptors are complex molecular structures that are located either on the surface or inside target cells. The function of these receptors is to recognize a specific hormone and translate the hormonal signal into a cellular response. The structure of these receptors varies in a manner that allows target cells to respond to one hormone and not to others. For example, receptors in the thyroid are specific for thyroid-stimulating hormone, and receptors on the gonads respond to the gonadotropic hormones.

The response of a target cell to a hormone varies with the number of receptors present and with the affinity of these receptors for hormone binding. A variety of factors influence the number of receptors that are present on target cells and their affinity for hormone binding.

The number of hormone receptors on a cell may be altered for any of several reasons. Antibodies may destroy or block the receptor proteins. Increased or decreased hormone levels often induce changes in the activity of the genes that regulate receptor synthesis. For example, decreased hormone levels often produce an increase in receptor numbers by means of a process called up-regulation; this increases the sensitivity of the body to existing hormone levels. Likewise, sustained levels of excess hormone often bring about a decrease in receptor numbers by down-regulation, producing a decrease in hormone sensitivity. In some instances, the reverse effect occurs, and an increase in hormone levels appears to recruit its own receptors, thereby increasing the sensitivity of the cell to the hormone. The process of up-regulation and down-regulation of receptors is regulated largely by inducing or repressing the transcription of receptor genes.

The affinity of receptors for binding hormones is also affected by a number of conditions. For example, the pH of the body fluids plays an important role in the affinity of insulin receptors. In ketoacidosis, a lower pH reduces insulin binding.

Receptor Activation and Signaling

Some hormone receptors are located on the surface of the cell and act through second messenger mechanisms, and others are located within the cell, where they modulate the synthesis of enzymes, transport proteins, or structural proteins. The receptors for thyroid hormones, which are found in the nucleus, are thought to be directly involved in controlling the activity of genes located on one or more of the chromosomes in the nucleus. Chart 31-1 lists examples of hormones that act through the two types of receptors.

Cell Surface Receptors. Because of their low solubility in the lipid layer of cell membranes, peptide hormones and catecholamines cannot readily cross the cell membrane. Instead, these hormones interact with surface receptors in a manner that incites the generation of an intracellular signal or message. The intracellular signal system is termed the second messenger, and the hormone is considered to be the first messenger. For example, the first messenger glucagon binds to surface receptors on liver cells to incite glycogen breakdown by way of the second messenger system.

The most widely distributed second messenger is cyclic adenosine monophosphate (cAMP), which is formed from adenosine triphosphate (ATP) by the enzyme adenylyl cyclase, a membrane-bound enzyme that is located on the inner aspect of the cell membrane (see Chapter 1, Fig. 1-9). Adenylyl cyclase is functionally coupled to various cell surface receptors by the regulatory actions of G proteins. A second messenger similar to cAMP is cyclic guanosine monophosphate (cGMP), derived from guanosine triphosphate (GTP). As a result of binding to specific cell receptors, many peptide hormones incite a series of enzymatic reactions that produce an almost immediate increase in cAMP and target cell response. Some hormones act to decrease cAMP levels and have an opposite effect on cell responses.

In some cells, the binding of a hormone or neurotransmitter to a surface receptor acts directly, rather than through a second messenger, to open an ion channel in

**CHART 31-1 Hormone–Receptor Interactions**

**Second Messenger Interactions**
- Glucagon
- Insulin
- Epinephrine
- Parathyroid hormone (PTH)
- Thyroid-stimulating hormone (TSH)
- Adrenocorticotropic hormone (ACTH)
- Follicle-stimulating hormone (FSH)
- Luteinizing hormone (LH)
- Antidiuretic hormone (ADH)
- Secretin

**Intracellular Interactions**
- Estrogens
- Testosterone
- Progesterone
- Adrenal cortical hormones
- Thyroid hormones
- Vitamin D
- Retinoids
the cell membrane. The influx of ions then serves as an intracellular signal to convey the hormone’s message to the interior of the cell. In many instances, the activation of hormone receptors results in the opening of calcium channels, with the increasing intracellular concentration of calcium ions acting as the signal that elicits the cellular response.

**Nuclear Receptors.** A second type of receptor mechanism is involved in mediating the action of thyroid and steroid hormones, as well as vitamin D, retinoic acid, and other molecules. In contrast to peptide and catecholamine hormones, these hormones enter the cell and bind to receptors in the cell nucleus that are gene regulatory proteins. Many of these hormones and molecules bind to receptors in the cytoplasm, and the hormone–receptor complexes then travel to the nucleus. Nuclear receptors can also be activated by second messenger signaling pathways, thereby linking cell surface receptors to nuclear receptor activation pathways.

Several subfamilies of nuclear receptors are currently recognized on the basis of structural similarity. One subfamily consists of receptors for thyroid hormone and vitamin D. A second subfamily consists of glucocorticoid, progesterone, androgen, and estrogen receptors. Other subfamilies contain “orphan receptors” for which natural ligands have not as yet been identified.

Activated nuclear receptors act by binding to deoxyribonucleic acid (DNA) response elements in the promoter sites where gene transcription is initiated. These DNA-binding elements, which are termed hormone response elements, then activate or suppress intracellular mechanisms such as gene activity, with the subsequent production or inhibition of mRNA and protein synthesis. The importance of the nuclear effects of thyroid and steroid hormones is illustrated by the fact that each regulates protein synthesis. Proteins whose synthesis is regulated up or down by these hormones may be enzymes, structural proteins, receptor proteins, or transcriptional proteins that regulate the expression of other genes, or proteins that are exported from the cell.

Some nuclear receptors are regulated by intracellular metabolites rather than secreted signal molecules. The peroxisome proliferator-activated receptors (PPARs), for example, bind intracellular lipid metabolites and regulate the transcription of genes involved in lipid metabolism and adipose tissue metabolism. The thiazolidinedione medications, which are used in the treatment of type 2 diabetes mellitus, act at the level of nuclear PPAR-γ receptors to promote glucose uptake and utilization by adipose tissue cells (see Chapter 33).

**Regulation of Hormone Levels**

Hormone secretion varies widely over a 24-hour period. Some hormones, such as growth hormone (GH) and adrenocorticotropic hormone (ACTH), have diurnal fluctuations that vary with the sleep–wake cycle. Others, such as the female sex hormones, are secreted in a complicated cyclic manner. The levels of hormones such as insulin and antidiuretic hormone (ADH) are regulated by feedback mechanisms that monitor substances such as glucose (insulin) and water (ADH) in the body. The levels of many of the hormones are regulated by feedback mechanisms that involve the hypothalamic-pituitary–target cell system.

**Hypothalamic-Pituitary Regulation**

The hypothalamus and pituitary gland, also known as the hypophysis, form a unit that exerts control over many functions of several endocrine glands as well as a wide range of other physiologic functions. These two structures are connected by blood flow in the hypophysial portal system, which begins in the hypothalamus and drains into the anterior pituitary gland, and by the nerve axons that connect the supraoptic and paraventricular nuclei of the hypothalamus with the posterior pituitary gland (Fig. 31-4).

**Hypothalamic Hormones.** The synthesis and release of anterior pituitary hormones are largely regulated by the action of releasing or inhibiting hormones from the hypothalamus, which is the coordinating center of the brain for endocrine, behavioral, and autonomic nervous system function. It is at the level of the hypothalamus that emotion, pain, body temperature, and other neural input are communicated to the endocrine system. The posterior pituitary hormones, ADH and oxytocin, are synthesized in the cell bodies of neurons in the hypothalamus that have axons that travel to the posterior pituitary.

The hypothalamic hormones that regulate the secretion of anterior pituitary hormones include GH-releasing hormone (GHRH), somatostatin, dopamine, TRH, corticotropin-releasing hormone (CRH), and gonadotropin-releasing hormone (GnRH). With the exception of GH and prolactin, most of the pituitary hormones are regulated by hypothalamic stimulatory hormones. GH secretion is stimulated by GHRH; thyroid-stimulating hormone (TSH) by TRH; adrenocorticotropic hormone (ACTH) by CRH; and luteinizing hormone (LH) and follicle-stimulating hormone (FSH) by GnRH. The secretion of prolactin, which is also produced by cells in the anterior pituitary gland, is inhibited by dopamine from the hypothalamus. Drugs that interfere with the synthesis or action of dopamine, such as some of the antipsychotic medications, increase prolactin secretion.

The activity of the hypothalamus is regulated by both hormonally mediated signals (e.g., negative feedback signals) and by neuronal input from a number of sources. Neuronal signals are mediated by neurotransmitters such as acetylcholine, dopamine, norepinephrine, serotonin, γ-aminobutyric acid (GABA), and opioids. Cytokines that are involved in immune and inflammatory responses, such as the interleukins, also are involved in the regulation of hypothalamic function (see Chapter 15). This is particularly true of the hormones involved in the hypothalamic-pituitary-adrenal axis. Thus, the hypothalamus can be viewed as a bridge by which signals from multiple systems are relayed to the pituitary gland.

(text continues on page 761)
Hormones bring about their effects on cell activity by binding to specific cell receptors. There are two general types of receptors: (1) cell surface receptors that exert their actions through cytoplasmic second messenger systems, and (2) intracellular nuclear receptors that modulate gene expression by binding to DNA or promoters of target genes.

**Cell Surface Receptors.** Water-soluble peptide hormones, such as parathyroid hormone and glucagon, which cannot penetrate the lipid layer of the cell plasma membrane, exert their effects through intracellular second messengers. They bind to a portion of a membrane receptor that protrudes through the surface of the cell. This produces a structural change in the receptor molecule itself, causing activation of a hormone-regulated signal system located on the inner aspect of the cell membrane. This system allows the cell to sense extracellular events and pass this information to the intracellular environment. There are several types of cell surface receptors, including G-protein–coupled receptors that mediate the actions of catecholamines, prostaglandins, thyroid-stimulating hormone, and others. Binding of the hormone to the receptor activates a G protein, which in turn acts on an effector (such as adenyl cyclase) to generate a second messenger (such as cyclic adenosine monophosphate, cAMP). The second messenger, in turn, activates other enzymes that participate in cellular secretion, gene activation, or other target cell responses.
Nuclear Receptors. Steroid hormones, vitamin D, thyroid hormones, and other lipid-soluble hormones diffuse across the cell membrane into the cytoplasm of the target cell. Once inside, they bind to an intracellular receptor that is activated by the interaction. The activated hormone-receptor complex then moves to the nucleus, where the hormone binds to a hormone response element (HRE) in the promoters on a target gene or to another transcription factor. Attachment to the HRE results in transcription of a specific messenger RNA (mRNA). The mRNA then moves into the cytoplasm, where the “transcribed message” is translated and used by cytoplasmic ribosomes to produce new cellular proteins or changes in the production of existing proteins. These proteins promote a specific cellular response or, in some cases, the synthesis of a structural protein that is exported from the cell.

Pituitary Hormones. The pituitary is a pea-sized endocrine gland that is located at the base of the brain, where it lies in a saddle-shaped depression in the sphenoid bone called the sella turcica. The pituitary gland has two functional units: an anterior lobe, or adenohypophysis, and a posterior lobe, or neurohypophysis. Embryologically, the anterior lobe of the pituitary gland develops from glandular tissue and the posterior lobe from neural tissue.

The pituitary gland has been called the master gland because its hormones control the functions of many target glands and cells. The anterior pituitary gland contains five cell types: (1) thyrotrophs, which produce thyrotropin, also called TSH; (2) corticotrophs, which produce corticotropin, also called ACTH; (3) gonadotrophs, which produce the gonadotropins, LH, and FSH; (4) somatotrophs, which produce GH; and (5) lactotrophs, which produce prolactin. The posterior pituitary gland stores and releases antidiuretic hormone (ADH) and oxytocin, which are synthesized in the hypothalamus. Hormones produced by the anterior pituitary control body growth and metabolism (GH), function of the thyroid gland (TSH), glucocorticoid hormone levels (ACTH), function of the gonads (FSH and LH), and breast growth and milk production (prolactin). Melanocyte-stimulating hormone (MSH), which is involved in the control of pigmentation of the skin, is produced by the pars intermedia (the region between the two lobes of the pituitary gland). The functions of many of these hormones are discussed in other parts of this book (e.g., thyroid hormone, GH, and the corticosteroids in Chapter 32; the sex hormones in Chapters 39 and 40; and ADH from the posterior pituitary in Chapter 8).
Feedback Regulation

The level of many of the hormones in the body is regulated by negative feedback mechanisms (Fig. 31-5). The function of this type of system is similar to that of the thermostat in a heating system. In the endocrine system, sensors detect a change in the hormone level and adjust hormone secretion so that blood levels are maintained within an appropriate range. When the sensors detect a decrease in blood levels, they initiate changes that cause an increase in hormone production; when blood levels rise above the set point of the system, the sensors cause hormone production and release to decrease. For example, an increase in thyroid hormone is detected by sensors in the hypothalamus or anterior pituitary gland, and this causes a reduction in the secretion of TSH, with a subsequent decrease in the output of thyroid hormone from the thyroid gland. The feedback loops for the hypothalamic-pituitary feedback mechanisms are illustrated in Figure 31-6.

Exogenous forms of hormones (given as drug preparations) can influence the normal feedback control of hormone production and release. One of the most common examples of this influence occurs with the administration of the corticosteroid hormones, which causes suppression of the hypothalamic-pituitary-target cell system that regulates the production of these hormones.

Although the blood levels of most hormones are regulated by negative feedback mechanisms, a small number are under positive feedback control, in which rising levels of a hormone cause another gland to release a hormone that is stimulating to the first. There must, however, be a mechanism for shutting off the release of the first hormone, or its production would continue unabated. An example of such a system is that of the female ovarian hormone estradiol. Increased estradiol production during the follicular stage of the menstrual cycle causes increased gonadotropin (FSH) production by the anterior pituitary gland. This stimulates further increases in estradiol levels until the demise of the follicle, which is the source of estradiol, results in a fall in gonadotropin levels.

In addition to positive and negative feedback mechanisms that monitor changes in hormone levels, some hormones are regulated by the level of the substance they regulate. For example, insulin levels normally are regulated in response to blood glucose levels, and those of aldosterone in response to blood levels of sodium and potassium. Other factors such as stress, environmental temperature, and nutritional status can alter feedback regulation of hormone levels.
Diagnostic Tests

Several techniques are available for assessing endocrine function and hormone levels. One technique measures the effect of a hormone on body function. Measurement of blood glucose, for example, is an indirect method of assessing insulin levels. However, insulin action (i.e., insulin activity) is also important in relation to glucose levels as hyperglycemia could occur if marked insulin resistance is present, despite the presence of a compensatory increase in insulin levels (i.e., hyperinsulinemia). This situation is common in type 2 diabetes (see Chapter 33). Thus, the most common method is to measure hormone levels directly.

Blood Tests

Hormones circulating in the plasma were first detected by bioassays using an intact animal or a portion of tissue from the animal. However, most bioassays lack the precision, sensitivity, and specificity to measure low concentrations of hormones in plasma, and they are inconvenient to perform.

Blood tests provide information about hormone levels at a specific time. For example, blood insulin levels can be measured along with blood glucose after administration of a challenge dose of glucose to measure the time course of change in blood insulin levels.
Real progress in measuring plasma hormone levels came more than 40 years ago with the use of competitive binding and the development of radioimmunoassay (RIA) methods. This method uses a radiolabeled form of the hormone and a hormone antibody that has been prepared by injecting an appropriate animal with a purified form of the hormone. The unlabeled hormone in the sample being tested competes with the radiolabeled hormone for attachment to the binding sites of the antibody. Measurement of the radiolabeled hormone–antibody complex then provides a means of arriving at a measure of the hormone level in the sample. Because hormone binding is competitive, the amount of radiolabeled hormone–antibody complex that is formed decreases as the amount of unlabeled hormone in the sample is increased. Newer techniques of RIA have been introduced, including the immunoradiometric assay (IRMA). IRMA uses two antibodies instead of one. These two antibodies are directed against two different parts of the molecule, and therefore IRMA assays are more specific. RIA has several disadvantages, including limited shelf life of the radiolabeled hormone and the cost for the disposal of radioactive waste.

Nonradiolabeled methods have been developed in which the antigen of the hormone being measured is linked to an enzyme-activated label (e.g., fluorescent label, chemiluminescent label) or latex particles that can be agglutinated with an antigen and measured. The enzyme-linked immunosorbent assays (ELISAs) use antibody-coated plates and an enzyme-labeled reporter antibody. Binding of the hormone to the enzyme-labeled reporter antibody produces a colored reaction that can be measured using a spectrophotometer.

In many situations, immunoassays are unreliable or unavailable. For some steroid or peptide hormones, mass spectrometry is becoming increasingly useful and can be combined with other analytical techniques, such as liquid chromatography. These approaches provide definitive identification of the relevant hormone or compound according to its chemical or physical characteristics (e.g., unequivocal detection of performance-enhancing agents in sports).

Other blood tests that are routinely used in endocrine disorders include various autoantibodies. For example, antithyroid peroxidase (anti-TPO) antibodies are measured during the initial diagnostic workup and subsequent follow-up of patients with Hashimoto thyroiditis. Other endocrine disorders that use autoantibody testing include type 1 diabetes, Graves disease, autoimmune hypoparathyroidism, and autoimmune Addison disease.

**Urine Tests**

Measurements of urinary hormone or hormone metabolites often are done on a 24-hour urine sample and provide a better measure of hormone levels during that period than hormones measured in an isolated blood sample. The advantages of a urine test include the relative ease of obtaining urine samples and the fact that blood sampling is not required. The disadvantage is that reliably timed urine collections often are difficult to obtain. For example, a person may be unable to urinate at specific timed intervals, and urine samples may be accidentally discarded or inaccurately preserved. Because many urine tests involve the measurement of a hormone metabolite rather than the hormone itself, drugs or disease states that alter hormone metabolism may interfere with the test result. Some urinary hormone metabolite measurements include hormones from more than one source and are of little value in measuring hormone secretion from a specific source. For example, urinary 17-ketosteroids are a measure of both adrenal and gonadal androgens.

**Stimulation and Suppression Tests**

Stimulation tests are used when hypofunction of an endocrine organ is suspected. A tropic or stimulating hormone can be administered to test the capacity of an endocrine organ to increase hormone production. The capacity of the target gland to respond is measured by an increase in the appropriate hormone. For example, the function of the hypothalamic-pituitary-adrenal system can be evaluated through stimulation tests using ACTH and measuring the cortisol response. Failure to increase cortisol levels after a ACTH stimulation test suggests an inadequate capacity to produce cortisol by the adrenals (i.e., the adrenal is dysfunctional in some way).

Suppression tests are used when hyperfunction of an endocrine organ is suspected. When an organ or tissue is functioning autonomously (i.e., is not responding to the normal negative feedback control mechanisms and continuously secretes excessive amounts of hormone), a suppression test may be useful to confirm the situation. For example, when a GH-secreting tumor is suspected, the GH response to a glucose load is measured as part of the diagnostic workup (see Chapter 32). Normally, a glucose load would suppress GH levels. However, in adults with GH-secreting tumors (a condition known as acromegaly), GH levels are not suppressed (and paradoxically increase in 50% of cases).

**Genetic Tests**

The diagnosis of genetic diseases using DNA analysis is rapidly becoming a routine part of endocrine practice. Completion of the human genome sequence has revealed the presence of about 30,000 genes. The considerable interest in the field of genomics (i.e., examination of the DNA) and transcriptomics (i.e., examination of the mRNA) has been complemented by advances in proteomics (i.e., examination of the proteome, which is all of the proteins expressed by a cell or tissue type). It is proposed that compared with the size of the genome, the proteome is far larger, with several hundred thousand to several million different protein forms possible. Analysis of the proteins produced by normal and abnormal endocrine cells, tissues, and organs will lead to a better understanding of the pathophysiologic processes of endocrine conditions. This may also lead to selective targeting for new drug development.
The cloning of many endocrine system genes has had an enormous impact on everyday clinical practice. For example, identification of a gene for a given disorder (e.g., the RET proto-oncogene in certain multiple endocrine neoplasia syndromes) means that faster diagnosis and more appropriate management for the affected individual can occur, but also that screening of family members for kindred harboring a known mutation can be undertaken.

**Imaging Techniques**

Imaging studies are important in the diagnosis and follow-up of endocrine disorders. Imaging modalities related to endocrinology can be divided into isotopic and nonisotopic types. Isotopic imaging includes radioactive scanning of the thyroid (e.g., using radioiodine) and parathyroids (e.g., using sestamibi). Nonisotopic imaging includes magnetic resonance imaging (MRI), which is the preferred choice for pituitary and hypothalamic imaging, and computed tomography (CT) scanning, which is preferred for adrenal lesions and abdominal endocrine lesions. Ultrasonographic scanning provides excellent and reproducible anatomic images for the thyroid, parathyroids, and neighboring structures. Thyroid ultrasonography is recommended for managing thyroid nodules and can aid in visualization of the nodule for biopsy (fine needle aspiration), which is necessary to help distinguish benign from malignant etiology. Selective venography is usually accompanied by venous sampling to determine hormonal output from a gland or organ (e.g., adrenal, pituitary, and kidney). Positron emission tomography (PET) scanning is being used more widely for evaluation of endocrine tumors. Dual electron x-ray absorptiometry (DEXA) is used routinely for the diagnosis and monitoring of osteoporosis and metabolic bone diseases.

**SUMMARY CONCEPTS**

- The endocrine system acts as a communication system that uses hormones as chemical messengers. Hormones travel through the blood to distant target sites of action, or act locally as paracrine or autocrine messengers to incite more local effects.

- Hormones exert their effects by interacting with high-affinity receptors, which in turn are linked to one or more effector systems in the cell. Some hormone receptors are located on the surface of the cell and act through second messenger mechanisms, and others are located in the cell, where they modulate the synthesis of enzymes, transport proteins, or structural proteins. Other hormones bind to nuclear receptors and act by directly regulating gene transcription.

- Many of the endocrine glands are under the regulatory control of other parts of the endocrine and nervous systems. The hypothalamus and the pituitary gland form a complex integrative network that joins the nervous system and the endocrine system; this central network controls the output from many of the other glands in the body.

- Many hormones are controlled by negative feedback loops that adjust their level and confer stability to the many functions of the endocrine system.

- Endocrine function can be assessed directly by measuring blood hormone levels or indirectly by assessing the effects that a hormone has on the body (e.g., assessment of insulin function through blood glucose). Imaging techniques are increasingly used to visualize endocrine structures, and genetic techniques are used to determine the presence of genes that contribute to the development of endocrine disorders.

**REVIEW EXERCISES**

1. Vitamin D is often considered a hormone rather than a vitamin.  
   A. Explain.

2. Thyroid hormones are transported in the serum bound to transport proteins such as thyroid-binding globulin and albumin.  
   A. Explain why free thyroxine (T₄) levels are usually used to assess thyroid function rather than total T₄ levels.

3. People who are being treated with exogenous forms of corticosteroid hormones often experience diminished levels of ACTH and exogenously produced cortisol.  
   A. Explain using information regarding the hypothalamic-pituitary feedback control of cortisol production by the adrenal cortex.

**BIBLIOGRAPHY**

The endocrine system, in concert with the nervous system, serves to regulate and integrate the functioning of the body's many cells and organ systems. Disorders of the endocrine system can affect many aspects of body functioning, including growth and development, energy metabolism, muscle and adipose tissue distribution, sexual development, fluid and electrolyte balance, and inflammatory and immune responses.

This chapter focuses on disorders of the anterior pituitary gland, growth and growth hormone, thyroid gland, and adrenocortical hormones. Disorders of the parathyroid hormone are discussed in Chapter 8, insulin in Chapter 33, and the male and female gonadal hormones in Chapters 39 and 40.

Disorders of Endocrine Control of Growth and Metabolism

T
gland or the absence of an enzyme needed for hormone synthesis. The gland may be destroyed by a disruption in blood flow, infection, inflammation, autoimmune responses, or neoplastic growth. There may be a decline in function with aging, or the gland may atrophy as the result of drug therapy or for unknown reasons. Some endocrine-deficient states are associated with receptor defects: hormone receptors may be absent, the receptor binding of hormones may be defective, or the cellular responsiveness to the hormone may be impaired. It is suspected that in some cases a gland may produce a biologically inactive hormone or that an active hormone may be destroyed by circulating antibodies before it can exert its action.

*Hyperfunction* usually is associated with excessive hormone production. This can result from excessive stimulation and hyperplasia of an endocrine gland or from a hormone-producing tumor. Hyperfunction symptoms may also be paraneoplastic, meaning they are caused by hormones secreted by tumors of nonendocrine tissue (see Chapter 7). In addition to excessive endogenous hormone production, syndromes of hormone excess may result from deliberate or inadvertent administration of exogenous hormones. For example, administration of glucocorticoid drugs to suppress the inflammatory response may lead to Cushing syndrome, or androgen excess with suppression of pituitary gonadotropins may occur in athletes who take androgens to improve their performance.

### Primary, Secondary, and Tertiary Disorders

Endocrine disorders in general can be divided into primary, secondary, and tertiary disorders. *Primary* disorders originate in the target gland responsible for producing the hormone. In *secondary disorders* of endocrine function, the target gland is essentially normal, but its function is altered by defective levels of stimulating hormones or releasing hormones from the pituitary gland. For example, total thyroidectomy produces a primary deficiency of thyroid hormones. Removal or destruction of the pituitary gland eliminates thyroid-stimulating hormone stimulation of the thyroid and brings about a secondary deficiency. A *tertiary disorder* results from hypothalamic dysfunction (as may occur with craniopharyngiomas or cerebral irradiation); thus, both the pituitary and target glands are understimulated.

**SUMMARY CONCEPTS**

- Disorders of the endocrine system, which provides the chemical messengers that serve to integrate the many functions of the body, can result from either a hypofunction or hyperfunction of an endocrine gland.

---

**Anterior Pituitary and Growth Hormone Disorders**

The pituitary gland, also known as the *hypophysis*, is a pea-sized gland located at the base of the brain, where it lies in a saddle-shaped depression in the sphenoid bone called the *sella turcica*. A short funnel-shaped stalk, the *infundibulum*, connects the pituitary gland with the hypothalamus. The pituitary gland has two components: a posterior lobe (neurohypophysis) or neural component, which stores and releases the oxytocin and the antidiuretic hormone (discussed in Chapter 8), and an anterior lobe (adenohypophysis) or glandular component (see Chapter 31, Fig. 31-3).

**Control of Anterior Pituitary Function**

The anterior lobe of the pituitary gland produces adrenocorticotropic hormone (ACTH), thyroid-stimulating hormone (TSH), growth hormone (GH), the gonadotropic hormones (follicle-stimulating hormone [FSH] and luteinizing hormone [LH]), and prolactin. The release of these hormones is in turn under the control of hormones produced in the hypothalamus (see Chapter 31). All of the anterior pituitary hormones, except for GH, exert their primary effects by controlling the biosynthesis and secretion of hormones from other target endocrine glands. ACTH controls the release of cortisol from the adrenal gland, TSH controls the secretion of thyroid hormone from the thyroid gland, and LH and FSH control sex hormone production and fertility.

**Clinical Manifestations of Hypothalamic-Pituitary Disorders**

Diseases of the pituitary are uncommon but may present with a variety of manifestations including pituitary hormone hypersecretion, hyposecretion, and/or the localized mass effect that causes compression of the optic chiasm or basal portion of the brain. In adults, the most common cause of hypothalamic-pituitary dysfunction is a pituitary adenoma. In children, pituitary adenomas are uncommon; the most common cause of pituitary dysfunction is hypothalamic tumors, of which craniopharyngiomas (neoplasms arising from cells of an embryonic hypophysial structure) are the most common. These tumors usually manifest with signs of pituitary hyposecretion (e.g., short stature due to low GH levels and delayed puberty due to gonadotropin...
deficiency) prior to development of headache, visual loss, and other neurologic symptoms due to the mass effect of the expanding tumor.

Assessment of Hypothalamic-Pituitary Function

The precise assessment of hypothalamic-pituitary function has been made possible by radioimmunoassay of the anterior pituitary hormones and their specific target gland hormones. Magnetic resonance imaging (MRI) is used for imaging the hypothalamus and pituitary. It has largely replaced the use of computed tomography (CT) because it allows better visualization of normal structures and has better resolution in defining tumors. When further information regarding pituitary function is required, combined hypothalamic-pituitary function tests (e.g., rapid ACTH stimulation test or GH suppression test) may be undertaken.

Pituitary Adenomas and Hyperpituitarism

The most common cause of hyperpituitarism is a pituitary adenoma, or a benign tumor arising from the anterior pituitary. Other, less common causes of hyperpituitarism are hyperplasia and carcinoma of the anterior pituitary, secretion of hormones by extrapituitary tumors, and certain hypothalamic lesions. Clinically diagnosed pituitary adenomas are responsible for about 10% of intracranial neoplasms. They are discovered incidentally in as many as 25% of routine autopsies and are increasingly being detected as incidental findings on MRI and CT scans of the head performed for other reasons.

The usual pituitary adenoma is a well-circumscribed lesion that can range in size from small lesions that do not enlarge the gland (microadenomas, <1 cm) to large, expansive tumors (macroadenomas, >1 cm) that erode the sella turcica and impinge on surrounding cranial structures. The adenomas can be divided into nonfunctional tumors and functional tumors that secrete pituitary hormones.

The signs and symptoms of pituitary adenomas include endocrine abnormalities related specifically to functional hormone-secreting adenomas and to the local mass effects of the expanding tumor. Lactotrophic adenomas are the most frequent type of hyperfunctioning pituitary adenoma, accounting for about 30% of all diagnosed cases. Lactotrophic adenomas are usually small, benign tumors composed of prolactin-secreting cells. Hyperprolactinemia inhibits the pulsatile secretion of LH, which is essential for normal ovulation in women. Thus, the manifestations of hyperprolactinemia are most easily recognized in women of reproductive age and include amenorrhea (lack of menstruation), galactorrhea (spontaneous milk secretion unrelated to pregnancy), and infertility. In males, the symptoms of hyperprolactinemia are vague and may include erectile dysfunction and loss of libido.

Because of the close proximity of the sella turcica to the optic nerves and chiasm, expanding pituitary lesions often compress the decussating fibers of the optic chiasm, giving rise to visual field abnormalities. Cranial nerve deficits, which are much less common, can result in blurred or double vision or, very rarely, paresthesia (abnormal nonpainful burning or prickling sensation) on one side of the face. As in the case of any expanding intracranial mass, pituitary adenomas may produce signs and symptoms of increased intracranial pressure, including headache, nausea, and vomiting. In some cases, pituitary adenomas may extend beyond the sella turcica into the base of the brain, producing seizures and obstructive hydrocephalus. On occasion, acute hemorrhage into an adenoma may occur, producing rapid enlargement of the pituitary. The condition, termed pituitary apoplexy, is accompanied by a combination of acute nerve palsies, severe headache, and systemic symptoms related to ACTH deficiency.

Hypopituitarism

Hypopituitarism is characterized by a decreased secretion of pituitary hormones that causes hypofunction of the secondary organs that depend on trophic stimuli from the pituitary. It may selectively involve one subset of pituitary cells (e.g., somatotropes that produce growth hormone) or all of the pituitary cells, in which case it is referred to as panhypopituitarism. Typically, 70% to 90% of the anterior pituitary must be destroyed before hypopituitarism becomes clinically evident. The cause may be congenital, or result from a variety of acquired abnormalities that cause destruction of the anterior pituitary, or from a secondary phenomenon resulting from a deficiency of hypothalamic hormones that normally act on the pituitary. Space-occupying lesions cause hypopituitarism by destroying the pituitary gland or hypothalamic nuclei or by disrupting the hypothalamic-hypophysial portal system.

Anterior pituitary hormone loss is usually gradual, especially with progressive loss of pituitary reserve due to tumors or previous pituitary radiation therapy (which may take 10 to 20 years to produce hypopituitarism). The loss of pituitary function tends to follow a classic course beginning with the loss of GH, LH, and FSH secretion followed by deficiencies in TSH, then ACTH, and finally prolactin. Impairment of GH secretion causes decreased growth in children but may be clinically unapparent in adults. Hypogonadism, manifested by amenorrhea in women and decreased libido and erectile function in men, may precede the clinical appearance of other manifestations. The manifestations of hypothyroidism caused by TSH deficiency (e.g., cold intolerance, dry skin, mental dullness) are similar to those observed in primary thyroid failure but less severe. Adrenocorticotropic hormone deficiency is the most serious endocrine deficiency. It causes secondary adrenal insufficiency, leading to weakness, nausea, anorexia, fever, and postural hypotension.
Treatment of hypopituitarism includes treating any identified underlying cause. Hormone deficiencies require replacement therapy with appropriate hormones. Cortisol replacement is started when ACTH deficiency is present, thyroid replacement when TSH deficiency is detected, and sex hormone replacement when LH and FSH are deficient. Growth hormone replacement is indicated for pediatric GH deficiency and is being increasingly used to treat GH deficiency in adults. Growth and Growth Hormone Disorders

Several hormones are essential for normal body growth and maturation, including growth hormone, insulin, thyroid hormone, and androgens. Insulin, for example, plays an essential role in growth processes, in addition to its actions on carbohydrate and fat metabolism. Children with diabetes, particularly those with poor control, often fail to grow normally even though GH levels are normal. When levels of thyroid hormone are lower than normal, bone growth and epiphyseal closure are delayed. Androgens such as testosterone and dihydrotestosterone exert anabolic growth effects through their actions on protein synthesis. Glucocorticoids at excessive levels inhibit growth, apparently because of their antagonistic effect on GH secretion.

Growth Hormone

Growth hormone, also called somatotropin, is a 191-amino-acid polypeptide hormone synthesized and secreted by special cells in the anterior pituitary called somatotropes. For many years, it was thought that GH was produced primarily during periods of growth. However, this has proved to be incorrect because the rate of GH production in adults is almost as great as in children.

Growth hormone is necessary for growth and contributes to the regulation of metabolic functions (Fig. 32-1). All aspects of cartilage growth are stimulated by GH; one of the most striking effects of GH is on linear bone growth, resulting from its action on the epiphyseal growth plates of long bones. The width of bone also increases because of enhanced periosteal growth. Visceral and endocrine organs, skeletal and cardiac muscle, skin, and connective tissue all undergo increased growth in response to GH. In many instances, the increased growth of visceral and endocrine organs is accompanied by enhanced functional capacity. For example, increased growth of cardiac muscle is accompanied by an increase in cardiac output.

**FIGURE 32-1.** Growth-promoting and anti-insulin effects of growth hormone. FFA, free fatty acids; IGF-1, insulin-like growth factor-1.
In addition to its effects on growth, GH increases the rate of protein synthesis by all of the cells of the body, enhances fatty acid mobilization and increases the use of fatty acids for fuel, and maintains or increases blood glucose levels by decreasing the use of glucose for fuel. Growth hormone has an initial effect of increasing insulin levels. However, the predominant effect of prolonged GH excess is to increase blood glucose levels despite an insulin increase. This is because GH induces a resistance to insulin in the peripheral tissues, inhibiting the uptake of glucose by muscle and adipose tissues.2

Many of the effects of GH are mediated by insulin-like growth factors (IGFs), which are produced mainly by the liver.9 Growth hormone cannot directly produce bone growth; instead, it acts indirectly by causing the liver to produce IGFs. These peptides act on cartilage and bone to promote their growth. Several IGFs have been identified; of these, IGF-1 (previously known as somatomedin C) appears to be the more important in terms of growth, and it is the one that usually is measured in laboratory tests. The IGFs have been sequenced and found to have structures that are similar to those of proinsulin. This undoubtedly explains the insulin-like activity of the IGFs and the weak action of insulin on growth. Insulin-like growth factor levels are themselves influenced by a family of at least six binding factors called IGF-binding proteins (IGFBPs).

Growth hormone is carried unbound in the plasma and has a half-life of approximately 20 to 50 minutes. The secretion of GH is regulated by two hypothalamic hormones: GH-releasing hormone (GHRH), which increases GH release, and somatostatin, which inhibits GH release. A third hormone, the recently identified ghrelin, also may be important (see Chapter 28). The hypothalamic influences of GHRH and somatostatin are tightly regulated by neural and metabolic influences. The secretion of GH fluctuates over a 24-hour period, with peak levels occurring 1 to 4 hours after onset of sleep. The nocturnal sleep bursts, which account for 70% of daily GH secretion, are greater in children than in adults.

Growth hormone secretion is stimulated by hypoglycemia, fasting, starvation, increased blood levels of amino acids (particularly arginine), and stress conditions such as excitement, emotional stress, heavy exercise, and trauma. Growth hormone is inhibited by increased glucose levels, free fatty acid release, cortisol, and obesity. Emotional disturbances can lead to functional endocrine disorders, causing psychosocial dwarfism. The causes of short stature are summarized in Chart 32-1.

Accurate measurement of height is an extremely important part of the physical examination of children. Completion of the developmental history and growth charts is essential.10,11 Growth curves and growth velocity studies also are needed. The Centers for Disease Control and Prevention (CDC) growth charts are available at http://www.cdc.gov/growthcharts. Diagnosis of short stature is not made on a single measurement, but is based on sequential height measurements and on velocity of growth and parental height.9

The diagnostic procedures for short stature include tests to exclude nonendocrine causes. If the cause is hormonal, extensive hormonal testing procedures are initiated. Usually, GH and IGF-1 levels are determined (IGFBP-3 levels also are useful). Tests can be performed using insulin (to induce hypoglycemia), GHRH, levodopa, and arginine, all of which stimulate GH secretion so that GH reserve can be evaluated.9 Because administration of pharmacologic agents can result in false-negative responses, two or more tests usually are performed. If a prompt rise in GH is realized, the child is considered normal. Physiologic tests of GH reserve (e.g., GH response to exercise) also can be performed. Levels of IGF-1 usually reflect those of GH and may be used to indicate GH deficiency. Radiologic films are used to assess bone age, which most often is delayed. Magnetic resonance imaging of the hypothalamic-pituitary area is recommended if a

![Chart 32-1 Causes of Short Stature](http://www.cdc.gov/growthcharts)

**Short Stature in Children**

Short stature is a condition in which the attained height is well below the third percentile or linear growth is below normal for age and gender. Short stature, or growth retardation, has a variety of causes, including chromosomal abnormalities such as Turner syndrome (see Chapter 6), GH deficiency, hypothyroidism, and panhypopituitarism.9 Other conditions known to cause short stature include protein-calorie malnutrition, chronic diseases such as chronic kidney disease and poorly controlled diabetes mellitus, malabsorption syndromes such as celiac disease, and certain therapies such as excessive glucocorticoid administration.
lesion is clinically suspected. After the cause of short stature has been determined, treatment can be initiated.

**Idiopathic Short Stature.** Idiopathic short stature, also referred to as normal-variant short stature, is short stature of undefined cause. It has been defined as a condition in which the height of an individual is more than 2 standard deviations below the corresponding mean height for a given age, sex, and population group without evidence of systemic, endocrine, nutritional, or chromosomal abnormalities. This definition includes children with familial short stature and constitutional delay in growth and puberty. Children with familial short stature tend to be well proportioned and to have a height close to the midparental height of their parents. The midparental height for boys can be calculated by adding 13 cm (5 inches) to the height of the mother, adding the father's height, and dividing the total by two. For girls, 13 cm (5 inches) is subtracted from the father's height, the result is added to the mother's height, and the total is divided by two. Ninety-five percent of normal children are within 8 cm (i.e., ±2 standard deviations) of the midparental height.

**Constitutional delay in growth and puberty** describes children (particularly boys) who have moderately short stature, thin build, delayed skeletal and sexual maturation, and absence of other causes of decreased growth. **Catch-up growth** is a term used to describe an abnormally high growth rate that occurs as a child approaches normal height for age. It also occurs after the initiation of therapy for GH deficiency and hypothyroidism and the correction of chronic diseases.

**Psychosocial Dwarfism.** Psychosocial dwarfism involves a functional hypopituitarism and is seen in some emotionally deprived children. These children usually present with poor growth, potbelly, and poor eating and drinking habits. Typically, there is a history of disturbed family relationships in which the child has been severely neglected or disciplined. Often, the neglect is confined to one child in the family. Growth hormone function usually returns to normal after the child is removed from the constraining environment. The prognosis depends on improvement in behavior and catch-up growth. Family therapy usually is indicated, and foster care may be necessary.

**Growth Hormone and Insulin-Like Growth Factor Deficiencies in Children.** There are several forms of GH deficiency that present in childhood. Children with idiopathic GH deficiency lack the hypothalamic GHRH but have adequate somatotropes, whereas children with pituitary tumors or agenesis of the pituitary lack somatotropes. Congenital GH deficiency is associated with a shorter than normal birth length, followed by a decrease in growth rate that can be identified by careful measurement during the first year and that becomes obvious by 1 to 2 years of age. Children with classic GH deficiency have normal intelligence, short stature, obesity with immature facial features, and some delay in skeletal maturation (Fig. 32-2). Puberty often is delayed, and males with the disorder have microphallus (abnormally small penis), especially if the condition is accompanied by gonadotropin-releasing hormone (GnRH) deficiency. In the neonate, GH deficiency can lead to hypoglycemia and seizures; if ACTH deficiency also is present, the hypoglycemia often is more severe. Acquired GH deficiency develops in later childhood. It may be caused by a hypothalamic-pituitary tumor, particularly if it is accompanied by other pituitary hormone deficiencies.

When short stature is caused by a GH deficiency, GH replacement therapy is the treatment of choice. Growth hormone is species specific, and only human GH is effective in humans. Human GH is now produced by recombinant deoxyribonucleic acid (DNA) technology, and is available in adequate supply. The hormone is administered daily by subcutaneous injection during the period of active growth and can be continued into adulthood. Children with short stature due to Turner syndrome and chronic renal insufficiency also are treated with GH. Growth hormone therapy may also be considered for children with idiopathic short stature.

In a rare condition called *Laron-type dwarfism* there is an extreme resistance to GH due to abnormalities in the growth hormone receptor. Affected persons tend to be obese and have high levels of GH and low levels of IGF-1. The condition is seen predominantly in people of Mediterranean descent, especially Sephardic Jews.
The same pathology is responsible for dwarfism of the African pygmies. IGF-1 is now produced by recombinant DNA technology. Since GH produces its effects by promoting IGF-1 secretion, IGF-1 is an effective replacement therapy for Laron dwarfism, mimicking most of the effects ascribed to GH.9

**Growth Hormone Deficiency in Adults**

There are two categories of GH deficiency in adults: GH deficiency that was present in childhood, and GH deficiency that developed during adulthood, mainly as the result of hypopituitarism resulting from a pituitary tumor or its treatment.15 Growth hormone levels also can decline with aging (described as the somatopause), and there has been interest in the effects of declining GH levels in the elderly.16 Growth hormone replacement obviously is important in the growing child; however, the role in adults (especially for the somatopause) is being assessed.

The clinical features of adult GH deficiency include changes in body composition, such as a decrease in lean body mass and an increase in fat mass, hyperlipidemia, decreased bone mineral density, and reduced exercise capacity, and diminished sense of well-being. Growth hormone deficiency is associated with a cluster of cardiovascular risk factors including central adiposity (associated with increased visceral fat), insulin resistance, and dyslipidemia.15 These features also are associated with the metabolic syndrome (see Chapter 33). In addition to these so-called traditional cardiovascular risk factors, nontraditional cardiovascular risk factors (e.g., C-reactive protein [CRP], which is a marker of the inflammatory pathway) are also elevated.17

Several recombinant human GH preparations have been approved for treatment of adults with diagnosed GH deficiency. The most common side effects of GH treatment in adults with hypopituitarism are peripheral edema, arthralgias and myalgias, carpal tunnel syndrome, paresthesias, and decreased glucose tolerance.15 Side effects appear to be more common in people who are older, have greater weight, and are overtreated as determined by high serum IGF-1 levels during therapy.

**Tall Stature and Growth Hormone Excess in Children**

Just as there are children who are short for their age and gender, there also are children who are tall for their age and gender.9,18 Normal variants of tall stature include genetic tall stature and constitutional tall stature. Children with exceptionally tall parents tend to be taller than children with shorter parents. The term constitutional tall stature is used to describe a child who is taller than his or her peers and is growing at a velocity that is within the normal range for bone age. Other causes of tall stature are genetic or chromosomal disorders such as Marfan syndrome or XYY syndrome (see Chapter 6). Endocrine causes of tall stature include sexual precocity because of early onset of estrogen and androgen secretion and excessive GH.

Exceptionally tall children (i.e., genetic tall stature and constitutional tall stature) can be treated with sex hormones—estrogens in girls and testosterone in boys—to effect early epiphyseal closure. Such treatment is undertaken only after full consideration of the risks involved. To be effective, such treatment must be instituted 3 to 4 years before expected epiphyseal fusion.9,18

Growth hormone excess occurring before puberty and the fusion of the epiphyses of the long bones results in gigantism19 (Fig. 32-3). It usually develops when excessive secretion of GH by somatotrope adenomas leads to high levels of IGF-1, the mediator of excessive skeletal growth. Fortunately, the condition is rare because of early recognition and treatment of the adenoma.

**Growth Hormone Excess in Adults**

When GH excess occurs in adulthood or after the epiphyses of the long bones have fused, it causes a condition called acromegaly (from the Greek words acros, meaning “end portion,” and megalos, meaning “large”),
which represents an exaggerated growth of the ends of the extremities (fingers, hands, and toes). The annual incidence of acromegaly is 3 to 4 cases per 1 million people, with a mean age at the time of diagnosis of 40 to 45 years.\textsuperscript{2,20,21}

The most common cause of acromegaly is GH-secreting adenomas, most of which are benign.\textsuperscript{21} The disorder usually has an insidious onset, and symptoms often are present for a considerable period before a diagnosis is made. When the production of excessive GH occurs after the epiphyses of the long bones have closed, as in the adult, the person cannot grow taller, but the soft tissues continue to grow. Enlargement of the small bones of the hands and feet and of the membranous bones of the face and skull results in a pronounced enlargement of the hands and feet, a broad and bulbous nose, a protruding jaw, and a slanting forehead (Fig. 32-4). The teeth become splayed, causing a disturbed bite and difficulty in chewing. The cartilaginous structures in the larynx and respiratory tract also become enlarged, resulting in a deepening of the voice and tendency to develop bronchitis. Vertebral changes often lead to kyphosis, or hunchback. Bone overgrowth often leads to arthralgias and degenerative arthritis of the spine, hips, and knees. Virtually every organ of the body is increased in size. Enlargement of the heart and accelerated atherosclerosis may lead to an early death.

The metabolic effects of excess levels of GH include disorders of fat and carbohydrate metabolism. Growth hormone causes increased release of free fatty acids from adipose tissue, leading to increased concentration of free fatty acids in body fluids. In addition, GH exerts multiple effects on carbohydrate metabolism, including decreased glucose uptake by tissues such as skeletal muscle and adipose tissue, increased glucose production by the liver, and increased insulin secretion. Each of these changes results in GH-induced insulin resistance (see Chapter 33). Impaired glucose tolerance occurs in as many as 50\% to 70\% of persons with acromegaly; overt diabetes mellitus subsequently can result.

Other manifestations of acromegaly include excessive sweating with an unpleasant odor, oily skin, heat intolerance, moderate weight gain, muscle weakness and fatigue, menstrual irregularities, and decreased libido. Hypertension is relatively common. Sleep apnea syndrome is present in up to 90\% of patients. The pathogenesis of the sleep apnea syndrome is obstructive in the majority of patients, due to increased pharyngeal soft tissue accumulation. Paresthesias may develop because of nerve entrapment and compression caused by excess soft tissue and accumulation of subcutaneous fluid (especially carpal tunnel syndrome). Headaches are frequent. Temporal hemianopia (loss of vision for one half of the visual field) may occur as a result of the optic chiasm being impinged by a suprasellar growth of the tumor.

The treatment goals for acromegaly focus on the correction of metabolic abnormalities and include normalization of the GH response to an oral glucose load; normalization of IGF-1 levels to age- and sex-matched control levels; removal or reduction of the tumor mass; relieving the central mass effects; and improvement of adverse clinical features.\textsuperscript{2} Pituitary tumors can be removed surgically using the transsphenoidal approach or, if that is not possible, a transfrontal craniotomy. Radiation therapy may be used, but remission (reduction in GH levels) may not occur for several years after therapy.

Somatostatin analogs (especially long-acting formulations of octreotide or lanreotide) produce feedback inhibition of GH and are effective in the medical management of acromegaly. Dopamine agonists also reduce GH levels and have been used with some success.\textsuperscript{2} Growth hormone analogs (e.g., pegvisomant) antagonize the actions of GH by binding to GH receptors on the cell surfaces. These analogs produce symptom relief and normalize serum IGF-1 levels in most individuals with acromegaly.\textsuperscript{2}
Precocious Puberty

Precocious puberty is defined as early activation of the hypothalamic-pituitary-gonadal axis, resulting in the development of secondary sexual characteristics and fertility. Classically, sexual development was considered precocious and warranting investigation when it occurred before 8 years of age for girls and before 9 years of age for boys. However, these criteria were revised based on an office pediatric study of more than 17,000 American girls. Precocious puberty is now defined as the appearance of secondary sexual development before the age of 7 years in white girls and 6 years in African American girls. In boys of both races, the lower age limit remains 9 years; however, it is recognized that puberty can develop earlier in boys with obesity (an increasingly common problem). Precocious sexual development may be idopathic or may be caused by gonadal, adrenal, or hypothalamic disorders. Benign and malignant tumors of the central nervous system (CNS) can cause precocious puberty. These tumors are thought to remove the inhibitory influences normally exerted on the hypothalamus during childhood. Central nervous system tumors are found more often in boys with precocious puberty than in girls. In girls, most cases are idiopathic.

Diagnosis of precocious puberty in girls is based on physical findings of early thelarche (i.e., beginning of breast development), adrenarche (i.e., beginning of augmented adrenal androgen production), and menarche (i.e., beginning of menstrual function) in girls. The most common sign in boys is early genital enlargement. Radiologic findings may indicate advanced bone age. Persons with precocious puberty usually are tall for their age as children but short as adults because of the early closure of the epiphyses. MRI or CT should be used to exclude intracranial lesions.

Depending on the cause of precocious puberty, the treatment may involve surgery, medication, or no treatment. The administration of a long-acting GnRH agonist results in a decrease in pituitary responsiveness to GnRH, leading to decreased secretion of gonadotropic hormones and sex steroids (i.e., due to down-regulation of GnRH receptors). Parents often need education, support, and anticipatory guidance in dealing with their feelings and the child’s physical needs and in relating to a child who appears older than his or her years.

Thyroid Hormone Disorders

The thyroid gland, which is the body’s largest single organ specialized for hormone production, plays a major role in the processes of almost all body cells.

Structure and Function of the Thyroid Gland

The thyroid gland is a shield-shaped structure located immediately below the larynx in the anterior middle portion of the neck (Fig. 32-5A). It is composed of...
a large number of tiny, saclike structures called **follicles** (Fig. 32-5B). These are the functional units of the thyroid. Each follicle is formed by a single layer of epithelial (follicular) cells and is filled with a secretory substance called **colloid**, which consists largely of a glycoprotein–tyrosine complex called **thyroglobulin** that contains 140 tyrosine amino acids. In the process of thyroid hormone synthesis, iodide is attached to these tyrosine molecules. Both thyroglobulin and iodide are secreted into the colloid of the follicle by the follicular cells.

The thyroid is remarkably efficient in its use of iodide. A daily absorption of 150 to 200 µg of dietary iodide is sufficient to form normal quantities of thyroid hormone. In the process of removing it from the blood and storing it for future use, iodide (I\(^{-}\)) is pumped into the follicular cells against a concentration gradient by an intrinsic membrane protein called the **Na\(^{+}/I\)** symporter (NIS). At the apical border, a second transport protein called **pendrin** moves iodide into the colloid, where it is involved in hormone production. The NIS is stimulated by both TSH and the TSH receptor–stimulating antibody found in Graves' disease (to be discussed). Mutations in the pendrin gene (**PDS**) have been found in persons with goiter and congenital deafness (Pendred syndrome).

### Synthesis of Thyroid Hormones

Once inside the follicle, most of the iodide is oxidized by the enzyme thyroid peroxidase (TPO) in a reaction that facilitates combination with a tyrosine molecule to form monooiodotyrosine (MIT), and a second iodide is then attached to make diiodotyrosine (DIT). Two diiodotyrosine molecules are coupled to form thyroxine (T\(_4\)), or a monooiodotyrosine and a diiodotyrosine are coupled to form triiodothyronine (T\(_3\)). Only T\(_4\) (90%) and T\(_3\) (10%) are released into the circulation (Fig. 32-5C).
There is evidence that T₃ is the active form of the hormone and that T₄ is converted to T₃ before it can act physiologically.

Thyroid hormones are bound to thyroxine-binding globulin (TBG) and other plasma proteins, mainly transthyretin and albumin, for transport in the blood. Only the free hormone enters cells and regulates the pituitary feedback mechanism. Protein-bound thyroid hormone forms a large reservoir that is slowly drawn on as free thyroid hormone is needed. More than 99% of T₄ and T₃ is carried in the bound form.²⁵,Thyroid hormones affect the function of many other organ systems, such as the central nervous system; mental development and attainment of sexual maturity; the cardiovascular system, which regulates the body levels of thyroid hormone.

Regulation of Thyroid Hormone Secretion

The secretion of thyroid hormone is regulated by the hypothalamic-pituitary-thyroid feedback system (Fig. 32-6). In this system, thyrotropin-releasing hormone (TRH), which is produced by the hypothalamus, increases the release of TSH from the anterior pituitary gland. Thyroid stimulating hormone, in turn, binds to the TSH receptor on thyroid epithelial cells stimulating essentially every aspect of thyroid function, including promoting the release of thyroid hormones from the thyroid follicles into the bloodstream, and increasing the activity of the iodide pump and iodination of tyrosine to increase production of the thyroid hormones. Thyroid stimulating hormone also has a strong tropic effect, stimulating hypertrophy, hyperplasia, and survival of thyroid epithelial cells.

Increased levels of thyroid hormone act in the feedback inhibition of TRH or TSH. High levels of iodide (e.g., from iodide-containing cough syrup or kelp tablets) also cause a temporary decrease in thyroid activity that lasts for several weeks, probably through a direct inhibition of TSH on the thyroid. Cold exposure is one of the strongest stimuli for increased thyroid hormone production and probably is mediated through TRH from the hypothalamus. Various emotional reactions also can affect the output of TRH and TSH and therefore indirectly affect secretion of thyroid hormones.

Actions of Thyroid Hormone

Most of the major organs in the body are affected by altered levels of thyroid hormone. Thyroid hormone increases metabolism and protein synthesis; it is necessary for growth and development in children, including mental development and attainment of sexual maturity; and it affects the function of many other organ systems in the body. These actions are mainly mediated by T₃.

Metabolic Rate. Thyroid hormone increases the metabolism of all body tissues except the retinas, spleen, testes, and lungs. Thyroid hormone increases the rate of oxygen consumption and production of metabolic end products, with an accompanying increase in vasodilation. Blood flow to the skin, in particular, is augmented as a means of dissipating the body heat that

Cardiorespiratory Function. Cardiovascular and respiratory functions are strongly affected by thyroid function. With an increase in metabolism, there is a rise in oxygen consumption and production of metabolic end products, with an accompanying increase in vasodilation. Blood flow to the skin, in particular, is augmented as a means of dissipating the body heat that
results from the higher metabolic rate. Blood volume, cardiac output, and ventilation are increased as a means of maintaining blood flow and oxygen delivery to body tissues. Heart rate and cardiac contractility are increased as a means of maintaining the needed cardiac output, whereas there is little change in blood pressure because the increase in vasodilation tends to offset the increase in cardiac output.

**Gastrointestinal Function.** Thyroid hormone enhances gastrointestinal function, causing an increase in motility and production of gastrointestinal secretions that often results in diarrhea. An increase in appetite and food intake accompanies the higher metabolic rate that occurs with increased thyroid hormone levels. At the same time, weight loss occurs because of the increased use of calories.

**Neuromuscular Effects.** Thyroid hormone has marked effects on neural control of muscle function and tone. Slight elevations in hormone levels cause skeletal muscles to react more vigorously, and a drop in hormone levels causes muscles to react more sluggishly. In the hyperthyroid state, a fine muscle tremor is present. The cause of this tremor is unknown, but it may represent an increased sensitivity of the neural synapses in the spinal cord that control muscle tone. In the infant, thyroid hormone is necessary for normal brain development. The hormone enhances cerebration; in the hyperthyroid state, it causes extreme nervousness, anxiety, and difficulty in sleeping.

Evidence suggests a strong interaction between thyroid hormone and the sympathetic nervous system. Many of the signs and symptoms of hyperthyroidism suggest overactivity of the sympathetic division of the autonomic nervous system, such as tachycardia, palpitations, and sweating. Tremor, restlessness, anxiety, and diarrhea also may reflect autonomic nervous system imbalances. Drugs that block sympathetic activity have proved to be valuable adjuncts in the treatment of hyperthyroidism because of their ability to relieve some of these undesirable symptoms.

### Tests of Thyroid Function

Various tests aid in the diagnosis of thyroid disorders. Measures of $T_3$, $T_4$, and TSH have been made available through immunoassay methods. The free $T_4$ test measures the unbound portion of $T_4$ that is free to enter cells to produce its effects. TSH levels are used to differentiate between primary and secondary thyroid disorders. $T_3$, $T_4$, and free $T_4$ levels are low in primary hypothyroidism, and the TSH level is elevated. The assessment of thyroid autoantibodies (e.g., anti-TPO antibodies in Hashimoto thyroiditis) is important in the diagnostic workup and consequent follow-up of patients with thyroid disorders.

The radioiodine ($^{123}$I) uptake test measures the ability of the thyroid gland to remove and concentrate iodine from the blood. Thyroid scans ($^{123}$I, $^{99m}$Tc-pertechnetate) can be used to detect thyroid nodules and determine the functional activity of the thyroid gland. Ultrasonography can be used to differentiate cystic from solid thyroid lesions, and CT and MRI scans are used to demonstrate tracheal compression or impingement on other neighboring structures. Fine needle aspiration biopsy of a thyroid nodule has proved to be the best method for differentiation of benign from malignant thyroid disease.

### Thyroid Disorders

An alteration in thyroid function can present as a hypofunctional or a hyperfunctional state. The manifestations of these two altered states are summarized in Table 32-1. Disorders of the thyroid may be due to a

congenital defect in thyroid development, or they may develop later in life, with a gradual or sudden onset.

Goiter is an increase in the size of the thyroid gland. It can occur in hypothyroid, euthyroid, and hyperthyroid states. Goiters may be toxic, producing signs of extreme hyperthyroidism or thyrotoxicosis, or they may be nontoxic. Goiters may be diffuse, involving the entire gland without evidence of nodularity, or they may contain nodules. Diffuse goiters usually become nodular.

Diffuse nontoxic and multinodular goiters are the result of compensatory hypertrophy and hyperplasia of follicular epithelium from some derangement that impairs thyroid hormone output. The degree of thyroid enlargement usually is proportional to the extent and duration of thyroid deficiency. Multinodular goiters produce the largest thyroid enlargements (Fig. 32-7). When sufficiently enlarged, they may compress the esophagus and trachea, causing difficulty in swallowing, a choking sensation, and inspiratory stridor. Such lesions also may compress the superior vena cava, producing distention of the veins of the neck and upper extremities, edema of the eyelids and conjunctiva, and syncope with coughing.

**Hypothyroidism**

Hypothyroidism can occur as a congenital or an acquired defect. Congenital hypothyroidism develops prenatally and is present at birth. Acquired hypothyroidism develops later in life because of primary disease of the thyroid gland or secondary to disorders of hypothalamic or pituitary origin.

**Congenital Hypothyroidism.** Thyroid hormone is essential for normal growth and brain development, almost half of which occurs during the first 6 months of life. If hypothyroidism in an infant may result from a congenital lack of the thyroid gland or from abnormal biosynthesis of thyroid hormone or deficient TSH secretion.25 If untreated, congenital hypothyroidism causes mental retardation and impairs physical growth.

With congenital lack of the thyroid gland, the infant usually appears normal and functions normally at birth because of hormones supplied in utero by the mother. Prolongation of physiologic jaundice, caused by delayed maturation of the hepatic system for conjugating bilirubin, may be the first sign26 (Fig. 32-8). There may be respiratory difficulties and a hoarse cry, due in part to the enlarged tongue; feeding difficulties, especially sluggishness, lack of interest, somnolence, and choking during nursing; an enlarged abdomen; and an umbilical hernia. The manifestations of untreated congenital
hypothyroidism are referred to as **cretinism**. However, the term does not apply to the normally developing infant in whom replacement thyroid hormone therapy was instituted shortly after birth.

Long-term studies have shown that closely monitored \( T_4 \) supplementation begun in the first 6 weeks of life results in normal intelligence. Fortunately, developed countries throughout the world now routinely screen newborns for hypothyroidism, providing the means for early diagnosis and treatment. The screening test involves taking a drop of blood from the infant’s heel and sending it to a central laboratory, where it is analyzed for \( T_4 \) or \( TSH \).\(^{25}\) Screening is done 24 to 48 hours after birth, usually in the hospital nursery.

Congenital hypothyroidism is treated by hormone replacement. Evidence indicates that it is important to normalize \( T_4 \) levels as rapidly as possible because a delay is accompanied by poorer psychomotor and mental development. Dosage levels are adjusted as the child grows.

Transient congenital hypothyroidism has been recognized more frequently since the introduction of neonatal screening. It is characterized by high \( TSH \) levels and low or normal thyroid hormone levels. The fetal and infant thyroids are sensitive to iodine excess. Iodine crosses the placenta and mammary glands and is readily absorbed by infant skin.\(^{25}\) Transient hypothyroidism may be caused by maternal or infant exposure to substances such as povidone-iodine used as a disinfectant (i.e., vaginal douche or skin disinfectant in the nursery). Antithyroid drugs such as propylthiouracil and methimazole can cross the placenta and in large doses will impair fetal thyroid function. Infants with transient hypothyroidism usually can have the replacement therapy withdrawn at 6 to 12 months. When early and adequate treatment regimens are followed, the risk of mental retardation in infants detected by screening programs essentially is nonexistent.

**Acquired Hypothyroidism**. Hypothyroidism in older children and adults causes a general slowing down of metabolic processes and myxedema.\(^{25}\) Myxedema implies the presence of a nonpituitary mucous type of edema caused by an accumulation of a hydrophilic mucopolysaccharide substance in the connective tissues throughout the body. The hypothyroid state may be mild, with only a few signs and symptoms, or it may progress to a life-threatening condition called **myxedematous coma**. It can result from destruction or dysfunction of the thyroid gland (i.e., primary hypothyroidism), as a secondary disorder caused by impaired pituitary function, or as a tertiary disorder caused by a hypothalamic dysfunction.

Primary hypothyroidism is much more common than secondary (and tertiary) hypothyroidism. It may result from thyroidectomy (i.e., surgical removal) or ablation of the gland with radiation. Certain goitrogenic agents, such as lithium carbonate (used in the treatment of bipolar disorders), and the antithyroid drugs propylthiouracil and methimazole in continuous dosage can block hormone synthesis and produce hypothyroidism with goiter. Large amounts of iodine (i.e., ingestion of kelp tablets or iodide-containing cough syrups, or administration of iodide-containing radiographic contrast media or the cardiac drug amiodarone, which contains 75 mg of iodine per 200-mg tablet) also can block thyroid hormone production and cause goiter, particularly in persons with autoimmune thyroid disease. Iodine deficiency, which can cause goiter and hypothyroidism, is rare in the United States because of the widespread use of iodized salt and other iodide sources.

The most common cause of hypothyroidism is **Hashimoto thyroiditis**, an autoimmune disorder in which the thyroid gland may be totally destroyed by an immunologic process.\(^{25,29}\) It is the major cause of goiter and hypothyroidism in children and adults. Hashimoto thyroiditis is predominantly a disease of women, with a female-to-male ratio of 5:1. The course of the disease varies. At the onset, only a goiter may be present. In time, hypothyroidism usually becomes evident. Although the disorder usually causes hypothyroidism, a hyperthyroid state may develop midcourse in the disease. The transient hyperthyroid state is caused by leakage of preformed thyroid hormone from damaged cells of the thyroid gland. Subacute thyroiditis, which can occur in up to 10% of pregnancies postpartum (postpartum thyroiditis), also can result in hypothyroidism.

Hypothyroidism may affect almost all body functions (see Table 32-1).\(^{25,29,30}\) The manifestations of the disorder are related largely to two factors: the hypometabolic state resulting from thyroid hormone deficiency, and myxedematous involvement of body tissues. The hypometabolic state associated with hypothyroidism is characterized by a gradual onset of weakness and fatigue, a tendency to gain weight despite a loss of appetite, and cold intolerance (Fig. 32-9). As the condition progresses, the skin becomes dry and rough and the hair becomes coarse and brittle. Reduced conversion of carotene to vitamin A and increased blood levels of carotene may give the skin a yellowish color. The face becomes puffy with edematous eyelids, and there is thinning of the outer third of the eyebrows. Fluid may collect in almost any serious cavity and in the middle ear, giving rise to conductive deafness. Gastrointestinal motility is decreased, producing constipation, flatulence, and abdominal distention. Delayed relaxation of deep tendon reflexes and bradycardia are sometimes noted. Central nervous system involvement is manifested in mental dullness, lethargy, and impaired memory.

Although the myxedematous fluid is usually most obvious in the face, it can collect in the interstitial spaces of almost any body structure and is responsible for many of the manifestations of the severe hypothyroid state. The tongue is often enlarged, and the voice becomes hoarse and husky. Carpal tunnel and other entrapment syndromes are common, as is impairment of muscle function with stiffness, cramps, and pain. Pericardial or pleural effusion may develop. Mucopolysaccharide deposits in the heart cause generalized cardiac dilation, bradycardia, and other signs of altered cardiac function.

Diagnosis of hypothyroidism is based on history, physical examination, and laboratory tests. A low
serum T₄ and elevated TSH levels are characteristic of primary hypothyroidism. The tests for antithyroid antibodies should be done when Hashimoto thyroiditis is suspected (anti-TPO antibody titer is the preferred test).

Hypothyroidism is treated by replacement therapy with synthetic preparations of T₃ or T₄. Most people are treated with T₄. Serum TSH levels are used to estimate the adequacy of T₄ replacement therapy. When the TSH level is normalized, the T₄ dosage is considered satisfactory (for primary hypothyroidism only). A “go low and go slow” approach should be considered in the treatment of elderly persons with hypothyroidism because of the risk of inducing acute coronary syndromes in susceptible individuals.

Myxedematous Coma. Myxedematous coma is a life-threatening, end-stage expression of hypothyroidism. It is characterized by coma, hypothermia, cardiovascular collapse, hypoventilation, and severe metabolic disorders including hyponatremia, hypoglycemia, and lactic acidosis. The pathophysiology of myxedema coma involves three major aspects: (1) carbon dioxide retention and hypoxemia, (2) fluid and electrolyte imbalance, and (3) hypothermia. It occurs most often in elderly women who have chronic hypothyroidism from a spectrum of causes. The fact that it occurs more frequently in winter months suggests that cold exposure may be a precipitating factor. The severely hypothyroid person is unable to metabolize sedatives, analgesics, and anesthetic drugs, and buildup of these agents may precipitate coma.

Treatment includes aggressive management of precipitating factors; supportive therapy such as management of cardiorespiratory status, hyponatremia, and hypoglycemia; and thyroid replacement therapy. If hypothermia is present (a low-reading thermometer should be used), active rewarming of the body is contraindicated because it may induce vasodilation and vascular collapse. Prevention is preferable to treatment and entails special attention to high-risk populations, such as women with a history of Hashimoto thyroiditis. These persons should be informed about the signs and symptoms of severe hypothyroidism and the need for early medical treatment.

Hyperthyroidism

Hyperthyroidism is the clinical syndrome that results when tissues are exposed to high levels of circulating thyroid hormone. In most instances, hyperthyroidism is due to hyperactivity of the thyroid gland. The most common causes of hyperthyroidism are Graves’ disease (to be discussed) and diffuse goiter. Other causes of hyperthyroidism are multinodular goiter, adenoma of the thyroid, and thyroiditis. Iodine-containing agents can induce hyperthyroidism as well as hypothyroidism. Thyroid crisis, or storm, is an acutely exaggerated manifestation of the thyrotoxic state.

Many of the manifestations of hyperthyroidism are related to the increase in oxygen consumption and use of metabolic fuels associated with the hypermetabolic state, as well as to the increase in sympathetic nervous system activity that occurs (see Table 32-1). The fact that many of the signs and symptoms of hyperthyroidism resemble those of excessive sympathetic nervous system activity suggests that thyroid hormone may heighten the sensitivity of the body to the catecholamines or that it may act as a pseudo catecholamine. With the hypermetabolic state, there are frequent complaints of nervousness, irritability, and fatigue. Other manifestations include tachycardia, palpitations, shortness of breath, excessive sweating, muscle cramps, and heat intolerance. The person appears restless and has a fine muscle tremor. Even in persons without exophthalmos (i.e., bulging of the eyeballs seen in Graves’ disease), there is an abnormal retraction of the eyelids and infrequent blinking such that they appear to be staring. The hair and skin usually are thin and have a silky appearance. About 15%
The treatment of hyperthyroidism is directed toward reducing the level of thyroid hormone. This can be accomplished with eradication of the thyroid gland with radioactive iodine, through surgical removal of part or all of the gland, or with the use of drugs that decrease thyroid function and thereby the effect of thyroid hormone on the peripheral tissues. Eradication of the thyroid with radioactive iodine is used more frequently than surgery. The β-adrenergic blocking drugs (e.g., propranolol, metoprolol, atenolol, nadolol) are administered to block the effects of the hyperthyroid state on sympathetic nervous system function. They are given in conjunction with antithyroid drugs (e.g., propylthiouracil and methimazole) that act by inhibiting the thyroid gland from using iodine in thyroid hormone synthesis and by blocking the conversion of T₄ to T₃ in the tissues (propylthiouracil only).

**Graves’ Disease.** Graves’ disease is an autoimmune disorder characterized by abnormal stimulation of the thyroid gland by thyroid-stimulating antibodies (TSH-receptor antibodies) that act through the normal TSH receptors. Identified by Irish surgeon Robert James Graves, it may be associated with other autoimmune disorders such as myasthenia gravis and pernicious anemia. The disease is associated with human leukocyte antigen (HLA)-DR3 and HLA-B8, and a familial tendency is evident. The onset usually is between the ages of 20 and 40 years, and women are five times more likely to develop the disease than men.

Graves’ disease is characterized by a triad of hyperthyroidism, goiter, ophthalmopathy (exophthalmos), or less commonly, dermopathy (pretibial edema due to accumulation of fluid and glycosaminoglycans). The ophthalmopathy, which occurs in up to one third of persons with Graves’ disease (Fig. 32-11), is thought to result from a cytokine-mediated activation of fibroblasts in orbital tissue behind the eyeball. Humoral autoimmunity also is important; an ophthalmic immunoglobulin may exacerbate lymphocytic infiltration of the extraocular muscles. The ophthalmopathy of Graves’ disease can cause severe eye problems, including abnormal positioning of the extraocular muscles resulting in diplopia; involvement of the optic nerve, with some visual loss; and corneal ulceration because the lids do not close over the protruding eyeball (due to the exophthalmos). The ophthalmopathy usually tends to stabilize after treatment of the hyperthyroidism. Since the ophthalmopathy can worsen acutely...
Thyroid Storm. Thyroid storm, or crisis, is an extreme and life-threatening form of thyrotoxicosis, rarely seen today because of improved diagnosis and treatment methods.\(^{25,38}\) When it does occur, it is seen most often in undiagnosed cases or in persons with hyperthyroidism who have not been adequately treated. It often is precipitated by stress such as an infection (usually respiratory), diabetic ketoacidosis, physical or emotional trauma, or manipulation of a hyperactive thyroid gland during thyroidectomy. Thyroid storm is manifested by a very high fever, extreme cardiovascular effects (i.e., tachycardia, congestive failure, and angina), and severe CNS effects (i.e., agitation, restlessness, and delirium). The mortality rate is high.

Thyroid storm requires rapid diagnosis and implementation of treatment. Peripheral cooling is initiated with cold packs and a cooling mattress. For cooling to be effective, the shivering response must be prevented. General supportive measures to replace fluids, glucose, and electrolytes are essential during the hypermetabolic state. A \(\beta\)-adrenergic blocking drug, such as propranolol, is used to block the undesirable effects of \(T_3\) on cardiovascular function. Glucocorticoids are used to correct the relative adrenal insufficiency resulting from the stress imposed by the hyperthyroid state and to inhibit the peripheral conversion of \(T_3\) to \(T_2\). Propylthiouracil or methimazole may be given to block thyroid synthesis. Aspirin increases the level of free thyroid hormones by displacing the hormones from their protein carriers and should not be used during thyroid storm.

Adrenal Cortical Hormone Disorders

The adrenal glands are small, bilateral structures that weigh approximately 5 g each and lie retroperitoneally at the apex of each kidney (Fig. 32-12A). The medulla or inner portion of the gland (which constitutes approximately 10% of each adrenal) secretes epinephrine and norepinephrine and is part of the sympathetic nervous system. The cortex forms the bulk of the adrenal gland (approximately 90%) and is responsible for secreting three types of hormones: glucocorticoids, mineralocorticoids, and adrenal androgens.\(^{26,39}\) Because the sympathetic nervous system also secretes the neurotransmitters epinephrine and norepinephrine, adrenal medullary function is not essential for life, but adrenal cortical function is. If untreated, the total loss of adrenal cortical function is fatal in 4 to 14 days.
Adrenal Cortical Hormones

More than 30 hormones are produced by the adrenal cortex. Of these hormones, aldosterone is the principal mineralocorticoid, cortisol (hydrocortisone) is the major glucocorticoid, and androgens are the main sex hormones. All of the adrenal cortical hormones have a similar structure in that all are steroids and are synthesized from acetate and cholesterol. Each of the steps involved in the synthesis of the various hormones requires a specific enzyme (Fig. 32-12B). The secretion of both the glucocorticoids and adrenal androgens is controlled by ACTH secreted by the anterior pituitary gland.

Cortisol, aldosterone, and the adrenal androgens are secreted in an unbound state and bind to plasma proteins for transport in the circulatory system. Cortisol binds largely to corticosteroid-binding globulin and to a lesser extent to albumin. Aldosterone and androgens circulate mainly bound to albumin. It has been suggested that the pool of protein-bound hormones may extend the duration of their action by delaying metabolic clearance.

The main site for metabolism of the adrenal cortical hormones is the liver, where they undergo a number of metabolic conversions before being conjugated and made water soluble. They are then eliminated in either the urine or the bile.

Mineralocorticoid Hormones

The mineralocorticoids play an essential role in regulating potassium and sodium levels and water balance. They are produced in the zona glomerulosa or the outer layer of cells of the adrenal cortex. Aldosterone secretion is regulated by the renin-angiotensin mechanism and by blood levels of potassium. Increased levels of aldosterone promote sodium retention by the distal tubules of the kidney while increasing urinary losses of potassium. The influence of aldosterone on fluid and electrolyte balance is discussed in Chapter 8.

Glucocorticoid Hormones

The glucocorticoid hormones, mainly cortisol, are synthesized in the zona fasciculata and the zona reticularis of the adrenal cortex. The blood levels of these hormones are regulated by negative feedback mechanisms of the hypothalamic-pituitary-adrenal (HPA) system (Fig. 32-13). Just as other hormones from the hypothalamus control the release of their target pituitary hormones, corticotropin-releasing hormone (CRH) controls the release of ACTH. In turn, ACTH controls the release of cortisol. Levels of cortisol increase as ACTH levels rise and decrease as ACTH levels fall. There is considerable diurnal variation in ACTH levels, which reach their peak in the early morning (around 6 to 8 AM) and decline as the day progresses. This appears to be due to rhythmic activity in the CNS, which causes bursts of CRH secretion and, in turn, ACTH secretion. This diurnal pattern is reversed in people who work during the night and sleep during the day. The rhythm also may be changed by physical and psychological stresses, endogenous depression, and liver disease or other conditions that affect cortisol metabolism. One of the earliest signs of Cushing syndrome, a disorder of glucocorticoid excess, is the loss of diurnal variation in CRH and ACTH secretion.

The glucocorticoids perform a necessary function in response to stress and are essential for survival. When produced as part of the stress response, these hormones aid in regulating the metabolic functions of the body and in controlling the inflammatory response. The actions of cortisol are summarized in Table 32-2. Many of the anti-inflammatory actions attributed to cortisol result from the administration of pharmacologic levels of the hormone.

By far the best-known metabolic effect of cortisol and other glucocorticoids is their ability to stimulate gluconeogenesis (glucose production) by the liver. In the process, body proteins are broken down and their amino acids are mobilized and transported to the liver, where they are used in the production of glucose. In much the same manner that cortisol promotes amino acid mobilization from muscle, it promotes mobilization of fatty acids from adipose tissue. This increased mobilization of fats by cortisol converts cell metabolism from the use of glucose for energy to the use of fats.
fatty acids. As glucose production by the liver rises and peripheral glucose use falls, a moderate resistance to insulin develops. In persons with diabetes and those who are diabetes prone, this has the effect of raising the blood glucose level.

Cortisol also influences multiple aspects of immunologic function and inflammatory responsiveness. Large quantities of cortisol are required for an effective anti-inflammatory action. This is achieved by the administration of pharmacologic rather than physiologic doses of cortisol. The increased cortisol blocks inflammation at an early stage by decreasing capillary permeability and stabilizing the lysosomal membranes so that inflammatory mediators are not released. Cortisol suppresses the immune response by reducing humoral and cell-mediated immunity. During the healing phase, cortisol suppresses fibroblast activity and thereby lessens scar formation. Cortisol also inhibits prostaglandin synthesis, which may account in large part for its anti-inflammatory actions.

The glucocorticoid hormones also appear to be involved directly or indirectly in emotional behavior. Receptors for these hormones have been identified in brain tissue, which suggests that they play a role in the regulation of behavior. Persons treated with adrenal cortical hormones have been known to display behavior ranging from mildly aberrant to psychotic.

**Adrenal Androgen Hormones**

The adrenal androgens are synthesized primarily by the zona reticularis and the zona fasciculata of the adrenal cortex (see Fig. 32-12A). These sex hormones probably exert little effect on normal sexual function. There is evidence, however, that the adrenal androgens (the most important of which is dehydroepiandrosterone [DHEA] and its sulfate conjugate [DHEAS]) contribute to the pubertal growth of body hair, particularly pubic and axillary hair in women. They also may play a role in the steroid hormone economy of the pregnant woman and the fetal-placental unit. In women, DHEAS is increasingly being used in the treatment of both Addison disease (to be discussed) and those who have decreased levels of DHEAS. Because the testes produce these hormones, there is no rationale for using it in men. The levels of DHEAS decline to approximately one-sixth the...
levels of a 20-year-old by 60 years of age (the adrenopause). The value of routine replacement of DHEAS in the adrenopause is largely unproven, but replacement may improve general well-being and sexuality and have other important effects in women.

**Pharmacologic Suppression of Adrenal Function**

A highly significant aspect of long-term therapy with pharmacologic preparations of the glucocorticoids is adrenal insufficiency upon withdrawal of the drugs. The deficiency results from suppression of the HPA system. Chronic suppression causes atrophy of the adrenal gland, and the abrupt withdrawal of drugs can cause acute adrenal insufficiency. Recovery to a state of normal adrenal function may be prolonged, requiring up to 12 months or more.

**Tests of Adrenal Function**

Several diagnostic tests can be used to evaluate adrenal cortical function and the HPA system. Blood levels of cortisol, aldosterone, and ACTH can be measured using immunoassay methods. A 24-hour urine specimen measuring the excretion of various metabolic end products of the adrenal hormones provides information about alterations in the biosynthesis of the adrenal cortical hormones. The 24-hour urinary free cortisol, late-night (between 11 PM and midnight) serum or salivary cortisol levels, and the overnight 1-mg dexamethasone suppression test (see later) are excellent screening tests for Cushing syndrome.

Suppression and stimulation tests afford a means of assessing the state of the HPA feedback system. For example, a test dose of ACTH can be given to assess the response of the adrenal cortex to stimulation. Similarly, administration of dexamethasone, a synthetic glucocorticoid drug, provides a means of measuring negative feedback suppression of ACTH. The insulin-induced hypoglycemic test, which is the gold standard for assessing the function of the HPA axis, induces a central nervous system stress response, increases CRH release, and in this way increases ACTH and cortisol secretion. It therefore measures the integrity of the axis and its ability to respond to stress.

**Adrenal Cortical Disorders**

Disorders of the adrenal cortex include disorders of adrenocortical hormone insufficiency or excess. They can be congenital or acquired and can occur as the result of primary disorders of the adrenal cortex or secondary to altered ACTH secretion.

**Congenital Adrenal Hyperplasia**

Congenital adrenal hyperplasia (CAH), or the adrenogenital syndrome, describes a congenital disorder caused by an autosomal recessive trait in which there is a deficiency of any of the enzymes necessary for the synthesis of cortisol. A common characteristic of all types of CAH is a defect in the synthesis of cortisol that results in increased levels of ACTH and adrenal hyperplasia. The increased levels of ACTH overstimulate the pathways for production of adrenal androgens. Mineralocorticoids may be produced in excessive or insufficient amounts, depending on the precise enzyme deficiency. Infants of both sexes are affected. Boys seldom are diagnosed at birth unless they have enlarged genitalia or lose salt and manifest adrenal crisis. In female infants, an increase in androgens is responsible for creating the virilization syndrome of ambiguous genitalia with an enlarged clitoris, fused labia, and urogenital sinus (Fig. 32-14). In male and female children, other secondary sex characteristics are normal, and fertility is unaffected if appropriate therapy is instituted.

The two enzymes most commonly deficient are 21-hydroxylase (accounting for >90% of cases) and 11-β-hydroxylase. A spectrum of 21-hydroxylase deficiency states exists, ranging from simple virilizing CAH to a complete salt-losing enzyme deficiency. Simple virilizing CAH impairs the synthesis of cortisol, and steroid synthesis is shunted to androgen production. Children with these deficiencies usually produce sufficient aldosterone or aldosterone intermediates to prevent signs and symptoms of mineralocorticoid deficiency. The salt-losing form is accompanied by deficient production of aldosterone and its intermediates. This results in fluid and electrolyte disorders after the 5th day of life (including hyponatremia, hyperkalemia, vomiting, dehydration, and shock). The 11-β-hydroxylase deficiency is rare and is manifested by a spectrum of severity. Affected children have excessive androgen production and impaired conversion of 11-deoxycorticosterone to corticosterone. The overproduction of 11-deoxycorticosterone, which has mineralocorticoid activity, is responsible for the hypertension that accompanies this deficiency.

Diagnosis of CAH depends on the precise biochemical evaluation of metabolites in the cortisol pathway.

and on clinical signs and symptoms. Genetic testing is also invaluable; however, correlation between the phenotype and genotype is not always straightforward.

Medical treatment of CAH includes oral or parenteral glucocorticoid replacement. Fludrocortisone acetate, a mineralocorticoid, also may be given to children who are salt losers. Depending on the degree of virilization, reconstructive surgery during the first 2 years of life is indicated to reduce the size of the clitoris, separate the labia, and exteriorize the vagina. Advances in surgical techniques have led to earlier use of single-stage surgery—between 2 and 6 months of life in girls with 21-hydroxylase deficiency, a time when the tissues are maximally pliable and psychological trauma to the child is minimized. Surgery has provided excellent results and does not usually impair sexual function.

**Adrenal Cortical Insufficiency**

There are two forms of adrenal insufficiency: primary and secondary (Table 32-3). Primary adrenal insufficiency, or Addison disease, is caused by destruction of the adrenal gland. Secondary adrenal insufficiency results from a disorder of the HPA system.

**Primary Adrenal Cortical Insufficiency.** In 1855, Thomas Addison, an English physician, provided the first detailed clinical description of primary adrenal insufficiency, now called Addison disease. The use of this term is reserved for primary adrenal insufficiency, in which adrenal cortical hormones are deficient and ACTH levels are elevated because of the lack of feedback inhibition.

Addison disease is a relatively rare disorder in which all the layers of the adrenal cortex are destroyed. Autoimmune destruction is the most common cause of Addison disease in the United States. Before 1950, tuberculosis was the major cause of Addison disease in the United States and Canada, and it continues to be a major cause of the disease in countries where the infection is more prevalent. Rare causes include metastatic carcinoma, fungal infection (particularly histoplasmosis), cytomegalovirus infection, amyloid disease, and hemochromatosis. Bilateral adrenal hemorrhage may occur in persons taking anticoagulants, during open heart surgery, and during birth or major trauma. Adrenal insufficiency can be caused by acquired immunodeficiency syndrome (AIDS), in which the adrenal gland is destroyed by a variety of opportunistic infectious agents. Drugs (e.g., ketoconazole) that inhibit synthesis or cause excessive breakdown of glucocorticoids can also result in adrenal insufficiency.

Addison disease, like type 1 diabetes mellitus, is a chronic metabolic disorder that requires lifetime hormone replacement therapy. The adrenal cortex has a large reserve capacity, and the manifestations of adrenal insufficiency usually do not become apparent until approximately 90% of the gland has been destroyed. These manifestations are related primarily to mineralocorticoid deficiency, glucocorticoid deficiency, and hyperpigmentation resulting from elevated ACTH levels. Although lack of the adrenal androgens (i.e., DHEAS) exerts few effects in men because the testes produce these hormones, women have sparse axillary and pubic hair.

Mineralocorticoid deficiency causes increased urinary losses of sodium, chloride, and water, along with decreased excretion of potassium (Fig. 32-15). The result is hyponatremia, loss of extracellular fluid, decreased cardiac output, and hyperkalemia. There may be an abnormal appetite for salt. Orthostatic hypotension is common. Dehydration, weakness, and fatigue are common early symptoms. If loss of sodium and water is extreme, cardiovascular collapse and shock ensue. Because of a lack of glucocorticoids, the person with Addison disease has poor tolerance to stress. This deficiency causes hypoglycemia, lethargy, weakness, fever, and gastrointestinal symptoms such as anorexia, nausea, vomiting, and weight loss.

Hyperpigmentation results from elevated levels of ACTH. The skin looks bronzed or suntanned in exposed and unexposed areas, and the normal creases and pressure points tend to become especially dark. The gums and oral mucous membranes may become bluish-black. The amino acid sequence of ACTH is strikingly similar to that of melanocyte-stimulating hormone; hyperpigmentation occurs in greater than 90% of persons with Addison disease and is helpful

in distinguishing the primary and secondary forms of adrenal insufficiency.

The daily regulation of the chronic phase of Addison disease usually is accomplished with oral replacement therapy, with higher doses being given during periods of stress. The pharmacologic agent that is used should have both glucocorticoid and mineralocorticoid activity. Mineralocorticoids are needed only in primary adrenal insufficiency. Hydrocortisone usually is the drug of choice. In mild cases, hydrocortisone alone may be adequate. Fludrocortisone (a mineralocorticoid) is used for persons who do not obtain a sufficient salt-retaining effect from hydrocortisone. DHEAS replacement also may be helpful in the female patient. Because persons with the disorder are likely to have episodes of hypotension and hypoglycemia, they need to have a regular schedule for meals and exercise. Persons with Addison disease also have limited ability to respond to infections, trauma, and other stresses. Such situations require immediate medical attention and treatment. All persons with Addison disease should be advised to wear a medical alert bracelet or medal.

Secondary Adrenal Cortical Insufficiency. Secondary adrenal insufficiency can occur as the result of hypopituitarism or because the pituitary gland has been surgically removed. Tertiary adrenal insufficiency results from a hypothalamic defect. However, a far more common cause than either of these is the rapid withdrawal of glucocorticoids that have been administered therapeutically. These drugs suppress the HPA system, with resulting adrenal cortical atrophy and loss of cortisol production. This suppression continues long after drug therapy has been discontinued and can be critical during periods of stress or when surgery is performed.

Acute Adrenal Crisis. Acute adrenal crisis is a life-threatening situation. If Addison disease is the underlying problem, exposure to even a minor illness or stress can precipitate nausea, vomiting, muscular weakness, hypotension, dehydration, and vascular collapse. The onset of adrenal crisis may be sudden, or it may progress over a period of several days. The symptoms may occur suddenly in children with salt-losing forms of CAH. Massive bilateral adrenal hemorrhage causes an acute fulminating form of adrenal insufficiency. Hemorrhage can be caused by meningococcal septicemia (i.e., Waterhouse-Friderichsen syndrome), adrenal trauma, anticoagulant therapy, adrenal vein thrombosis, or adrenal metastases.

Acute adrenal crisis is treated with extracellular fluid restoration and glucocorticosteroid replacement therapy. Extracellular fluid volume should be restored with several liters of 0.9% saline and 5% dextrose. Oral hydrocortisone replacement therapy can be resumed once the saline infusion has been discontinued and the person is taking food and fluids by mouth. Mineralocorticoid therapy is not required when large amounts of hydrocortisone are being given, but as the dose is reduced it usually is necessary to add fludrocortisone. Glucocorticoid and mineralocorticoid replacement therapy is monitored using heart rate and blood pressure measurements, serum electrolyte values, and titration of plasma renin activity into the upper-normal range. Since bacterial infection frequently precipitates acute adrenal crisis, broad-spectrum antibiotic therapy may be needed.

Glucocorticoid Hormone Excess

The term Cushing syndrome refers to the manifestations of hypercortisolism from any cause. Three important forms of Cushing syndrome result from excess glucocorticoid production by the body. One is a pituitary form, which results from excessive production of ACTH by a tumor of the pituitary gland. This form of the disease was the one originally described by Cushing; therefore, it is called Cushing disease. The second form
is the adrenal form, caused by a benign or malignant adrenal tumor. The third form is ectopic Cushing syndrome, caused by a nonpituitary ACTH-secreting tumor. Certain extrapituitary malignant tumors such as small cell carcinoma of the lung may secrete ACTH or, rarely, CRH and produce Cushing syndrome. Cushing syndrome also can result from long-term therapy with one of the potent pharmacologic preparations of glucocorticoids; this form is called iatrogenic Cushing syndrome.

The major manifestations of Cushing syndrome represent an exaggeration of the many actions of cortisol. Altered fat metabolism causes a peculiar deposition of fat characterized by a protruding abdomen; subclavicular fat pads or “buffalo hump” on the back; and a round, plethoric “moon face” (Fig. 32-16). There is muscle weakness, and the extremities are thin because of protein breakdown and muscle wasting. In advanced cases, the skin over the forearms and legs becomes thin, having the appearance of parchment. Purple striae, or stretch marks, from stretching of the catabolically weakened skin and subcutaneous tissues are distributed over the breast, thighs, and abdomen. Osteoporosis may develop because of destruction of bone proteins and alterations in calcium metabolism, resulting in back pain, compression fractures of the vertebrae, and rib fractures. As calcium is mobilized from bone, renal calculi may develop.

Derangements in glucose metabolism are found in approximately 75% of patients, with clinically overt diabetes mellitus occurring in approximately 20%. The glucocorticoids possess mineralocorticoid properties; this causes hypokalemia as a result of excessive potassium excretion and hypertension resulting from sodium retention. Inflammatory and immune responses are inhibited, resulting in increased susceptibility to infection. Cortisol increases gastric acid secretion, which may provoke gastric ulceration and bleeding. An accompanying increase in androgen levels causes hirsutism (facial hair), mild acne, and thinning of the hair, along with menstrual irregularities in women (Fig. 32-17). Excess levels of the glucocorticoids may give rise to extreme emotional lability, ranging from mild euphoria and absence of normal fatigue to grossly psychotic behavior.

Diagnosis of Cushing syndrome depends on the finding of cortisol hypersecretion. The determination of 24-hour excretion of cortisol in urine provides a reliable and practical index of cortisol secretions. One of the prominent features of Cushing syndrome is loss of the diurnal pattern of cortisol secretion. This is why late-night (between 11 PM and midnight) serum or salivary cortisol levels can be inappropriately elevated, aiding in the diagnosis of Cushing syndrome. The overnight dexamethasone suppression test is also used as a screening tool for Cushing syndrome.

**FIGURE 32-16.** Clinical features of Cushing syndrome.

Other tests include measurement of the plasma levels of ACTH. Adrenocorticotropic hormone levels should be normal or elevated in ACTH-dependent Cushing syndrome (Cushing disease and ectopic ACTH), and low in non-ACTH-dependent Cushing syndrome (adrenal tumors). Various suppression or stimulation tests of the HPA system are performed to delineate the cause further. MRI or CT scans afford a means for locating adrenal or pituitary tumors.

Untreated, Cushing syndrome produces serious morbidity and even death. The choice of surgery, irradiation, or pharmacologic treatment is determined largely by the cause of the hypercortisolism. The goal of treatment for Cushing syndrome is to remove or correct the source of hypercortisolism without causing permanent pituitary or adrenal damage. Transphenoidal removal of a pituitary adenoma or a hemihypophysectomy is the preferred method of treatment for Cushing disease. This allows removal of only the tumor rather than the entire pituitary gland. After successful removal, the person must receive cortisol replacement therapy for 6 to 12 months or until adrenal function returns. Pituitary radiation therapy may also be used, but the full effects of treatment may not be realized for 3 to 12 months. Unilateral or bilateral adrenalectomy may be done in the case of adrenal adenoma. When possible, ectopic ACTH-producing tumors are removed. Pharmacologic agents that block steroid synthesis (i.e., mitotane, ketoconazole, and metyrapone) may be used to treat persons with ectopic tumors or adrenal carcinomas that cannot be resected. Many of these patients also require Pneumocystis jiroveci (formerly known as Pneumocystis carinii) pneumonia prophylaxis because of the profound immunosuppression caused by the excessive glucocorticoid levels.

Incidental Adrenal Mass

An incidentaloma is a mass lesion found unexpectedly in an adrenal gland by an imaging procedure (done for other reasons), most commonly CT (but also MRI and ultrasonography). It has been increasingly recognized since the early 1980s. The prevalence of adrenal incidentalomas at autopsy is approximately 10 to 100 per 1000. In CT series, 0.6% to 4.4% are the usual figures published. Incidentalomas also can occur in other organs (e.g., pituitary, thyroid). The two most important questions are (1) is the mass malignant, and (2) is the mass hormonally active (i.e., is it functioning)?

Primary adrenal carcinoma is quite rare, but other cancers, particularly lung cancers, commonly metastasize to the adrenal gland (other cancers include breast, stomach, pancreas, colon, kidney, melanomas, and lymphomas). The size and imaging characteristics of the mass may help determine whether the tumor is benign or malignant. The risk of cancer is high in adrenal masses larger than 6 cm. Many experts recommend surgical removal of masses larger than 4 cm, particularly in younger patients. Appropriate screening to exclude a hormonally active lesion includes tests to rule out pheochromocytoma, Cushing syndrome, and Conn syndrome (mineralocorticoid excess).
1. A 59-year-old man was referred to a neurologist for evaluation of headaches. Subsequent MRI studies revealed a large suprasellar mass (2.5 x 2.4 cm), consistent with a pituitary tumor. His history is positive for hypertension and, on direct inquiry, he believes that his hands are slightly larger than previously, with increased sweating. Family history is negative, as are weight change, polyuria and polydipsia, visual disturbance, and erectile dysfunction. Subsequent laboratory findings reveal a baseline serum GH of 8.7 ng/mL (normal is 0 to 5 ng/mL), which is unsuppressed after oral glucose tolerance testing; glucose intolerance; and increased IGF-1 on two occasions (1044 and 1145 µg/L [upper limit of normal is 480 µg/L]). Other indices of pituitary function are within the normal range.

A. What diagnosis would this man’s clinical features, MRI, and laboratory findings suggest?

B. What is the reason for asking the patient about weight change, polyuria and polydipsia, visual disturbance, and erectile dysfunction?

C. How would you explain his impaired glucose tolerance?

D. What are the possible local effects of a large pituitary tumor?

2. A 76-year-old woman presents with weight gain, subjective memory loss, dry skin, and cold intolerance. On examination she is found to have a multinodular goiter. Laboratory findings reveal a low serum T₄ and elevated TSH.

A. What diagnosis would this woman’s history, physical, and laboratory tests suggest?

B. Explain the possible relationship between the diagnosis and her weight gain, dry skin, cold intolerance, and subjective memory loss.

C. What type of treatment would be indicated?

3. A 45-year-old woman presents with a history of progressive weakness, fatigue, weight loss, nausea, and increased skin pigmentation (especially of creases, pressure areas, and nipples). Her blood pressure is 120/78 mm Hg when supine and 105/52 mm Hg when standing. Laboratory findings reveal a serum sodium of 120 mEq/L (normal is 135 to 145 mEq/L), potassium level of 5.9 mEq/L (normal is 3.5 to 5 mEq/L), and low plasma cortisol and high ACTH levels.

A. What diagnosis would this woman’s clinical features and laboratory findings suggest?

B. Would her diagnosis be classified as a primary or secondary endocrine disorder?

C. What is the significance of her darkened skin?

D. What type of treatment would be indicated?

Diabetes Mellitus is an abnormality in blood glucose regulation and nutrient storage related to an absolute or relative deficiency of insulin and/or resistance to the actions of insulin. In the United States alone, diabetes mellitus affects 25.8 million people, or approximately 8.3% of the population. Type 1 diabetes, which is caused by an absolute deficiency of insulin, accounts for 1 million of these people with the remainder having type 2 diabetes. In addition, another 79 million people have been categorized as having “prediabetes.” Globally, the prevalence of prediabetes and type 2 diabetes is increasing at an alarming rate.

Hormonal Control of Nutrient Metabolism and Storage

The body uses glucose, fatty acids, and other substrates as fuel to satisfy its energy needs. Although the respiratory and circulatory systems combine efforts to furnish the body with the oxygen needed for metabolic purposes, it is the liver, in concert with insulin and other hormones, that controls the storage and mobilization of the body’s fuel supply.
Glucose Metabolism and Storage

Glucose, a six-carbon molecule, is an efficient fuel that, when metabolized in the presence of oxygen, breaks down to form carbon dioxide and water. Although many tissues and organ systems are able to use other forms of fuel, such as fatty acids and ketones, the brain and nervous system rely almost exclusively on glucose as a fuel source. Because the brain cannot use glucose effectively, it cannot be converted to fatty acids by the liver and then stored as triglycerides in the fat cells of adipose tissue.

When blood glucose levels fall below normal, as they do between meals, the liver converts stored glycogen back to glucose in a process called glycogenolysis. The glucose is then released into the bloodstream, maintaining the blood glucose within its normal range. Although skeletal muscle has glycogen stores, it lacks the enzyme glucokinase that allows glucose to be broken down sufficiently to pass through the cell membrane and enter the bloodstream, limiting its usefulness to the muscle cell.

In addition to mobilizing its glycogen stores, the liver synthesizes glucose from amino acids, glycerol, and lactate in a process called gluconeogenesis. This glucose may be released directly into the circulation or stored as glycogen.

Fat Metabolism and Storage

Fat is the most efficient form of fuel storage, providing 9 kcal/g of stored energy, compared with the 4 kcal/g provided by carbohydrates and proteins. About 40% of the calories in the normal American diet are obtained from fats, which is about equal to the amount obtained from carbohydrates. Fats are a major energy source for the body during rest as well as physical activity; in fact, the body’s use of fats for energy is as important as its use of carbohydrates. In addition, dietary carbohydrates and proteins consumed in excess of body needs are converted to triglycerides for storage in adipose tissue.

A triglyceride contains three fatty acids linked by a glycerol molecule. The mobilization of fatty acids for use as an energy source is facilitated by the action of enzymes (lipases) that break triglycerides into their glycerol and fatty acid components. The glycerol molecule can enter the glycolytic pathway and be used along with glucose to produce energy, or it can be used to produce glucose. The fatty acids are transported to tissues where they are metabolized for energy. Almost all body cells, with the exception of the brain, nervous tissue, and red blood cells, can use fatty acids interchangeably with glucose for energy. Although many cells use fatty acids as a fuel source, fatty acids cannot be converted to the glucose needed by the brain for energy.

A large share of the initial degradation of fatty acids occurs in the liver, especially when excessive amounts of fatty acids are being used for energy. The liver uses only a small amount of the fatty acids for its own energy needs; it converts the rest into ketones and releases them into the blood. In situations that favor fat breakdown, such as fasting, large amounts of ketones are released into the bloodstream. Because ketones are organic acids, release of excessive amounts, as can occur in diabetes mellitus, can prompt ketoacidosis, an acute complication of diabetes.

Protein Metabolism and Storage

Proteins are essential for the formation of all body structures, including genes, enzymes, contractile structures in muscle, matrix of bone, and hemoglobin of red blood cells. Amino acids are the building blocks of proteins. Unlike glucose and fatty acids, there is only a limited facility for the storage of excess amino acids in the body. Most of the stored amino acids are contained in body proteins. Amino acids in excess of those needed for protein synthesis are converted to fatty acids, ketones, or glucose and then stored or used as metabolic fuel. Because fatty acids cannot be converted to glucose, the body must break down proteins and use the amino acids as a major substrate for gluconeogenesis during periods when metabolic needs exceed food intake.

Glucose-Regulating Hormones

The hormonal control of blood glucose resides largely within the endocrine pancreas. The pancreas is made up of two major tissue types: the acini and the islets of Langerhans (Fig. 33-1). The acini secrete digestive juices into the duodenum, whereas the islets of Langerhans, which account for only about 1% to 2% of the volume of the pancreas, secrete hormones into the blood. Each islet is composed of beta cells that secrete insulin and amylin, alpha cells that secrete glucagon, and delta cells that secrete somatostatin. In addition, at least one other cell type, the F (or PP) cell, is present in small numbers in the islets and secretes a hormone of uncertain function called pancreatic polypeptide. Blood glucose regulation is also influenced by several gut-derived hormones that increase insulin release after nutrient intake and by counterregulatory hormones that help to maintain blood glucose levels during periods of limited glucose intake or excessive glucose use.
In insulin

Although several hormones are known to increase blood glucose levels, insulin is the only hormone known to have a direct effect in lowering blood glucose levels. The actions of insulin are threefold: (1) it promotes glucose uptake by target cells and provides for glucose storage as glycogen, (2) it prevents fat and glycogen breakdown, and (3) it inhibits gluconeogenesis and increases protein synthesis (Table 33-1). Insulin acts to promote fat storage by increasing the transport of glucose into fat cells (Fig. 33-2). It also facilitates triglyceride synthesis from glucose in fat cells and inhibits the intracellular breakdown of stored triglycerides. Insulin also inhibits protein breakdown and increases protein synthesis by increasing the active transport of amino acids into body cells, and it inhibits gluconeogenesis, or the building of glucose from new sources, mainly amino acids. When sufficient glucose and insulin are present, protein breakdown is minimal because the body is able to use glucose and fatty acids as a fuel source. In children and adolescents, insulin is needed for normal growth and development.

The active form of insulin is composed of two polypeptide chains—an A chain and a B chain (Fig. 33-3). Active insulin is formed in the beta cells from a larger molecule called proinsulin. In converting proinsulin to insulin, enzymes in the beta cell cleave proinsulin at specific sites to form two separate substances: active insulin and a biologically inactive C-peptide (connecting peptide) chain that joined the A and B chains before they were separated. Active insulin and the inactive C-peptide chain are packaged into secretory granules and released simultaneously from the beta cell. The C-peptide chains can be measured clinically, and this measurement can be used to study beta cell function (i.e., persons with

**FIGURE 33-1.** Islet of Langerhans in the pancreas.
type 2 diabetes with very little or no remaining beta cell function will have very low or nonexistent levels of C-peptide in their blood, and thus will likely need insulin replacement for treatment.

The release of insulin from the pancreatic beta cells is regulated by blood glucose levels, increasing as blood glucose levels rise and decreasing when blood glucose levels decline. Secretion of insulin occurs in a pulsatile fashion. After exposure to glucose, which is a nutrient secretagogue (a substance that prompts secretion of another substance), a first-phase release of stored preformed insulin occurs, followed by a second-phase release of newly synthesized insulin (Fig. 33-4). Diabetes may result from dysregulation or deficiency in any of the steps involved in this process (e.g., impaired sensing of blood glucose levels and defects in insulin release or synthesis). Serum insulin levels begin to rise within minutes after a meal, reach a peak in approximately 3 to 5 minutes, and then return to baseline levels within 2 to 3 hours.

Insulin secreted by the beta cells enters the portal circulation and travels directly to the liver, where approximately 50% is used or degraded. Insulin, which is rapidly bound to peripheral tissues or destroyed by the liver or kidneys, has a half-life of approximately 5 to 10 minutes once it is released into the general circulation. To initiate its effects on target cells, insulin binds to a membrane receptor. The insulin receptor consists of four subunits—two larger α subunits that extend outside the cell membrane and are involved in insulin
binding, and two smaller β subunits that are predominantly located inside the cell membrane and contain a kinase enzyme that becomes activated during insulin binding (Fig. 33-5). Activation of the kinase enzyme results in autophosphorylation of the β subunit itself. Phosphorylation of the β subunit in turn activates some enzymes and inactivates others; thereby, directing the desired intracellular effect of insulin on glucose, fat, and protein metabolism.

Because cell membranes are impermeable to glucose, they require a special carrier, called a glucose transporter, to move glucose from the blood into the cell. These transporters move glucose across the cell membrane at a faster rate than would occur by diffusion alone. Considerable research has revealed a family of glucose transporters termed GLUT-1, GLUT-2, and so forth. GLUT-4 is the insulin-dependent glucose transporter for skeletal muscle and adipose tissue (Fig. 33-6). It is sequestered inside the membrane of these cells and thus is unable to function as a glucose transporter until a signal from insulin causes it to move from its inactive site into the cell membrane, where it facilitates glucose entry. GLUT-2 is the major transporter of glucose into beta cells and liver cells. It has a low affinity for glucose and acts as a transporter only when plasma glucose levels are relatively high, such as after a meal. GLUT-1 is present in all tissues. It does not require the actions of insulin and is important in tissues with a high demand for glucose such as the brain.

Another distinct group of glucose transporters have recently been identified. The sodium glucose cotransporters (SGLTs) are responsible for transporting glucose from the lumen of the intestine across the brush border of the enterocytes and from the glomerular filtrate into the proximal tubules of the kidney. SGLT1 predominantly enables the small intestine to absorb glucose. In comparison, SGLT2 is mainly responsible for reabsorption of most (>90%) of the glucose filtered by the kidney. Pharmacologic inhibitors with varying specificities for these transporters (e.g., canagliflozin) can slow the rate of intestinal glucose absorption and increase the renal elimination of glucose into the urine. This new

**Figure 33-5.** Insulin receptor. Insulin binds to α subunits of the insulin receptor, which increases glucose and amino acid transport and causes autophosphorylation of the β subunit of the receptor, which induces tyrosine kinase activity. Tyrosine phosphorylation, in turn, activates a cascade of intracellular signaling proteins that mediate the effects of insulin on glucose, fat, and protein metabolism.

**Figure 33-6.** Insulin-dependent glucose transporter (GLUT-4). (1) Binding of insulin to insulin receptor on the surface of the cell membrane, (2) generation of intracellular signal, (3) insertion of GLUT-4 receptor from its inactive site into the cell membrane, and (4) transport of glucose across the cell membrane.
class of drugs has been shown to reduce hyperglycemia in patients with diabetes.  

**Glucagon**

Glucagon, a polypeptide molecule produced by the alpha cells of the islets of Langerhans, helps to maintain blood glucose between meals and during periods of fasting. Like insulin, glucagon travels through the portal vein to the liver, where it exerts its main action, which is to increase blood glucose (Table 33-1). The most dramatic effect of glucagon is its ability to initiate glycogenolysis (the breakdown of glycogen) as a means of raising blood glucose, usually within a matter of minutes. Glucagon also increases the transport of amino acids into the liver and stimulates their conversion into glucose through the process of gluconeogenesis. Because liver glycogen stores are limited, gluconeogenesis is important in maintaining blood glucose levels over time. Other actions of glucagon occur only when the hormone is present in high concentrations, usually well above those normally present in the blood. At high concentrations, glucagon activates adipose cell lipase, making fatty acids available for use as energy.

Glucagon secretion is regulated by blood glucose. A decrease in blood glucose concentration produces an immediate increase in glucagon secretion, and an increase produces a decrease in glucagon secretion. High concentrations of amino acids, as occur after a protein meal, also can stimulate glucagon secretion. In this way, glucagon increases the conversion of amino acids to glucose as a means of maintaining the body’s glucose levels. Glucagon levels also increase during strenuous exercise as a means of preventing a decrease in blood glucose.

**Amylin, Somatostatin, and Gut-Derived Hormones**

Islet amyloid polypeptide, or amylin, was originally identified as a major constituent of pancreatic amyloid deposits in persons with type 2 diabetes and subsequently shown to be a polypeptide that is cosecreted with insulin from the beta cells in the pancreas. Plasma levels of amylin increase in response to nutritional stimuli to produce inhibition of gastric emptying and glucagon secretion. As with insulin, the active form of amylin is derived from a larger proamylin precursor. Although the active form of amylin is soluble and acts as a hormone, there has been renewed interest in the less soluble and insoluble forms, which may cause degeneration of the beta cells and contribute to the pathogenesis of overt diabetes.

Somatostatin is a polypeptide hormone containing only 14 amino acids that has an extremely short half-life. Somatostatin secreted by the delta cells acts locally in the islets of Langerhans to inhibit the release of insulin and glucagon. It also decreases gastrointestinal activity after ingestion of food. Almost all factors related to ingestion of food stimulate somatostatin secretion. By decreasing gastrointestinal activity, somatostatin is thought to extend the time during which food is absorbed into the blood, and by inhibiting insulin and glucagon, it is thought to extend the use of absorbed nutrients by the tissues.

Several gut-derived hormones have been identified as having what is termed an incretin effect, meaning that they increase insulin release after an oral nutrient load (see Chapter 28). This suggests that gut-derived factors can stimulate insulin secretion after a predominantly carbohydrate meal. The two hormones that account for about 90% of the incretin effect are glucagon-like peptide-1, which is released from L cells in the distal small intestine, and glucose-dependent insulinotropic polypeptide, which is released by K cells more proximally (mainly in the jejunum).

**Counterregulatory Hormones**

Other hormones that can affect blood glucose include the catecholamines, growth hormone, and the glucocorticoids. These hormones, along with glucagon, are sometimes called counterregulatory hormones because they counteract the storage functions of insulin in regulating blood glucose levels during periods of fasting, exercise, and other situations that either limit glucose intake or deplete glucose stores.

**Epinephrine**. Epinephrine, a catecholamine, helps to maintain blood glucose levels during periods of stress. Epinephrine has the potent effect of stimulating glycoegenolysis in the liver, thus causing large quantities of glucose to be released into the blood. It also inhibits insulin release from the beta cells and thereby decreases the movement of glucose into muscle cells, while at the same time increasing the breakdown of muscle glycogen stores. Although the glucose that is released from muscle glycogen cannot be released into the blood, the mobilization of these stores for muscle use conserves blood glucose for use by other tissues such as the brain and nervous system. Epinephrine also has a direct lipolytic effect on adipose cells, thereby increasing the mobilization of fatty acids for use as an energy source. The blood glucose–elevating effect of epinephrine is an important homeostatic mechanism during periods of hypoglycemia.

**Growth Hormone**. Growth hormone has many metabolic effects. It increases protein synthesis in all cells of the body, mobilizes fatty acids from adipose tissue, and antagonizes the effects of insulin. Growth hormone decreases cellular uptake and use of glucose, thereby increasing the level of blood glucose. The increased blood glucose level stimulates further insulin secretion by the beta cells. The secretion of growth hormone normally is inhibited by insulin and increased levels of blood glucose. During periods of fasting, when both blood glucose levels and insulin secretion fall, growth hormone levels increase. Exercise, such as running and cycling, and various stresses, including anesthesia, fever, and trauma, also increase growth hormone levels.

Chronic hypersecretion of growth hormone, such as occurs in acromegaly (see Chapter 32), can lead to glucose intolerance and the development of diabetes mellitus. In people who already have diabetes, moderate elevations in
growth hormone levels that occur during periods of stress and periods of growth in children can produce the entire spectrum of metabolic abnormalities associated with poor regulation, despite optimized insulin treatment.

Glucocorticoid Hormones. The glucocorticoid hormones, which are synthesized in the adrenal cortex along with other corticosteroid hormones, are critical to survival during periods of fasting and starvation. They stimulate gluconeogenesis by the liver, sometimes producing a 6- to 10-fold increase in hepatic glucose production. These hormones also moderately decrease tissue use of glucose.

There are several steroid hormones with glucocorticoid activity; the most important of these is cortisol, which accounts for approximately 95% of all glucocorticoid activity (see Chapter 32). Almost any type of stress, whether physical or emotional, causes an immediate increase in adrenocorticotropic hormone (ACTH) secretion by the anterior pituitary gland, followed within minutes by greatly increased secretion of cortisol by the adrenal gland. Hypoglycemia is a potent stimulus for cortisol secretion. In predisposed persons, the prolonged elevation of glucocorticoid hormones can lead to hyperglycemia and the development of diabetes mellitus. In people with diabetes, even transient increases in cortisol can complicate control.

SUMMARY CONCEPTS

- The body predominantly metabolizes glucose and fatty acids for energy. The brain depends exclusively on glucose for its energy. Body tissues obtain glucose from the blood. The liver stores excess glucose as glycogen and it uses gluconeogenesis to convert amino acids, lactate, and glycerol into glucose during fasting or when glucose intake does not keep pace with demand.
- Blood glucose levels reflect the difference between the amount of glucose released into the circulation by the liver and the amount of glucose removed from the blood by body tissues. Fats, which serve as an efficient source of fuel for the body, are stored in adipose tissue as triglycerides, which consist of three fatty acids linked to a glycerol molecule. In situations that favor fat breakdown, such as fasting or diabetes mellitus, the triglycerides in adipose tissue are broken down and the fatty acids are used as fuel or transported to the liver, where they are converted to ketones.
- Proteins, which are made up of amino acids, are essential for the formation of all body structures. Unlike glucose and fatty acids, there is only a limited facility for storage of excess amino acids in the body. Because fatty acids cannot be converted to glucose, the body must break down proteins and use the amino acids for gluconeogenesis.
- Energy metabolism is controlled by a number of hormones, including insulin, glucagon, epinephrine, growth hormone, and the glucocorticoids. Of these hormones, only insulin has the effect of lowering the blood glucose level. It does this by facilitating the transport of glucose into body cells and decreasing the liver’s production and release of glucose into the bloodstream. Insulin also has the effect of decreasing lipolysis and the use of fats as a fuel source.
- Other hormones—glucagon, epinephrine, growth hormone, and the glucocorticoids—maintain or increase blood glucose concentrations. Glucagon and epinephrine promote glycogenolysis, and glucagon and the glucocorticoids increase gluconeogenesis. Epinephrine and glucagon also increase the use of fat for energy by increasing the release of fatty acids from adipose tissue cells. Growth hormone decreases the peripheral utilization of glucose.

Diabetes Mellitus

The term diabetes is derived from a Greek word meaning “going through,” and mellitus from the Latin word for “honey” or “sweet.” Reports of the disorder can be traced back to the first century AD, when Aretaeus the Cappadocian described the disorder as a chronic affliction characterized by intense thirst and voluminous, honey-sweet urine: “the melting down of flesh into urine.” It was the discovery of insulin by Banting and Best in 1922 that transformed the once-fatal disease into a manageable chronic health problem.

Diabetes is a disorder of carbohydrate, protein, and fat metabolism resulting from a lack of insulin availability or a reduction in the biologic effects of insulin. It can represent an absolute insulin deficiency, impaired release of insulin by the pancreatic beta cells, inadequate or defective insulin receptors or postreceptor regulation, or the production of inactive insulin or insulin that is destroyed before it can carry out its action.

Classification and Etiology

Although diabetes mellitus clearly is a disorder of insulin availability, it is not a single disease. A revised classification system, which was developed in 1997 by the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus, divides diabetes into four clinical...
classes (Table 33-2). Included are the categories of type 1 diabetes (i.e., diabetes resulting from beta cell destruction and an absolute insulin deficiency); type 2 diabetes (i.e., diabetes due to insulin resistance and a relative insulin deficiency); gestational diabetes mellitus (i.e., glucose intolerance that develops during pregnancy that is not clearly overt diabetes [either type 1 or type 2]); and other specific types of diabetes, many of which occur secondary to other conditions (e.g., Cushing syndrome, acromegaly, and pancreatitis).

Categories of Risk for Diabetes
The revised classification system also includes a system for diagnosing diabetes according to stages of glucose intolerance.8-11 The system relies on two tests: (1) a fasting plasma glucose (FPG) test, which measures plasma glucose levels after food has been withheld for at least 8 hours, and (2) an oral glucose tolerance test (OGTT), which measures the body’s ability to remove glucose from the blood within 2 hours of consuming 75 g of glucose in 300 mL of water.

A FPG below 100 mg/dL or an OGTT less than 140 mg/dL is considered normal (Table 33-3). Persons whose glucose levels, although not meeting the criteria for diabetes, are too high to be considered normal are classified as having impaired fasting plasma glucose (IFG) and/or impaired glucose tolerance (IGT). Impaired fasting glucose is defined by an elevated FPG of 100 to 125 mg/dL and IGT as plasma glucose levels of 140 to 199 mg/dL with an OGTT (see Table 33-3).

Persons with IFG and/or IGT are often referred to as having pre diabetes, meaning they are at relatively high risk for the future development of diabetes as well as cardiovascular disease.10,11 Thus, calorie restriction and weight reduction (even 5% to 10%) are important in overweight people with prediabetes.

Person with a FPG greater than or equal to 126 mg/dL (7.0 mmol/L) or an OGTT 2-hour glucose level greater than or equal to 200 mg/dL (11.1 mmol/L) are considered to have have diabetes.10,11 The criteria in Table 33-3 are used to confirm the diagnosis. Glycosylated hemoglobin (i.e., HbA1c [A1C]) is a widely used marker for chronic hyperglycemia, reflecting average blood glucose levels over a 2- to 3-month period of time (to be discussed). The A1C, which plays a critical role in the management of persons with diabetes, is now recommended for use in the diagnosis of diabetes, with a threshold of greater than 6.5%.10,11 The test can also be used to identify persons at higher risk for developing diabetes (see Table 33-3).

Type 1 Diabetes Mellitus
Type 1 diabetes mellitus, which is characterized by destruction of the pancreatic beta cells and accounts for 5% to 10% of those with diabetes, is subdivided into type 1A immune-mediated diabetes and type 1B idiopathic (non–immune-related) diabetes.10 In the United States and Europe, approximately 90% to 95% of people with type 1 diabetes mellitus have type 1A immune-mediated diabetes. The rate of beta cell destruction is

Type 1A Immune-Mediated Diabetes. Type 1A diabetes, commonly referred to as type 1 diabetes, is characterized by immune-mediated destruction of beta cells. This type of diabetes, formerly called juvenile diabetes, occurs more commonly in children and adolescents. In fact, three quarters of all cases of type 1 diabetes occur in individuals younger than 18 years of age.

Type 1A diabetes is an autoimmune disorder that is thought to result from a genetic predisposition (i.e., diabetogenic genes); an environmental triggering event, such as an infection; and a T-lymphocyte–mediated hypersensitivity reaction against some beta cell antigens. Much evidence has focused on the inherited major histocompatibility complex (MHC) genes on chromosome 6 that encode human leukocyte antigen (HLA)-DQ and HLA-DR, especially DR-3 and DR-4. \(^1\) In addition to the MHC susceptibility genes on chromosome 6, an insulin gene regulating beta cell replication and function has been identified on chromosome 11.

Type 1A diabetes–associated autoantibodies may exist for years before the onset of hyperglycemia. There are two main types of autoantibodies: insulin autoantibodies (IAAs) and islet cell autoantibodies, including antibodies directed at other islet autoantigens, including glutamic acid decarboxylase (GAD) and the protein tyrosine phosphatase IA-2. \(^3\) Testing for antibodies to GAD or IA-2 and for IAAs using sensitive assays can be used to identify new cases of type 1 diabetes when diagnostic confusion between type 1 and type 2 diabetes occurs or there is future risk of type 1 diabetes (e.g., in siblings of a person with type 1). \(^1\) These persons also have increased predisposition to other autoimmune disorders such as Graves disease, rheumatoid arthritis, and Addison disease.

The fact that type 1 diabetes is thought to result from an interaction between genetic and environmental factors led to research into methods directed at prevention and early control of the disease. These methods include the identification of genetically susceptible persons and early intervention in newly diagnosed persons with type 1 diabetes. After the diagnosis of type 1 diabetes,
there often is a short period of improved beta cell function, during which symptoms of diabetes disappear and insulin injections are reduced or not needed. This is sometimes called the *honeymoon period.* Immune interventions (immunomodulation) designed to interrupt the destruction of beta cells before development of type 1 diabetes are being investigated in various trials. Unfortunately, none of the interventions studied to date has shown real clinical utility.

**Idiopathic Type 1B Diabetes.** The term *idiopathic type 1B diabetes* is used to describe those cases of beta cell destruction in which no evidence of autoimmunity is present. Only a small number of people with type 1 diabetes fall into this category; most are of African or Asian descent. Type 1B diabetes is strongly inherited. People with the disorder have episodic DKA due to varying degrees of insulin deficiency with periods of absolute insulin deficiency that may come and go.

**Type 2 Diabetes Mellitus and the Metabolic Syndrome**

Type 2 diabetes mellitus, previously described as *non–insulin-dependent diabetes,* is a condition of hyperglycemia that accompanies a relative rather than an absolute insulin deficiency (although insulin therapy may be still be required for glycemic control).\(^5,10,11\) It currently accounts for about 90% to 95% of the cases of diabetes. Most people with type 2 diabetes are overweight and older. Recently, however, type 2 diabetes has become a more common occurrence in obese children and adolescents.\(^12,13\) Although type 1 diabetes remains the main form of diabetes in children worldwide, it seems likely that type 2 diabetes will become the predominant form within 10 years in some ethnic groups.\(^13\)

**Metabolic Abnormalities Involved in Type 2 Diabetes.** The metabolic abnormalities involved in type 2 diabetes include (1) insulin resistance, (2) increased glucose production by the liver, and (3) impaired secretion of insulin by the pancreatic beta cells.\(^14,16\) (Fig. 33-7).

Insulin resistance, which can be defined as the failure of target tissues to respond to insulin, predates the development of hyperglycemia. That is, in the early stages of the evolution of type 2 diabetes, insulin resistance is usually accompanied by compensatory beta cell hyperfunction and hyperinsulinemia.

In skeletal muscle, insulin resistance prompts decreased uptake of glucose. Although muscle glucose uptake is slightly increased after a meal, the efficiency with which it is taken up (glucose clearance) is diminished, resulting in an increase in *postprandial* (following a meal) blood glucose levels.\(^16\)

In contrast, in the liver, insulin resistance leads to impaired suppression of glucose production with an overproduction of glucose despite a fasting hyperinsulinemia. In fact, the excessive rate of hepatic glucose production is the primary determinant of elevated FPG in persons with type 2 diabetes.\(^15,16\)

Several mechanisms can lead to impaired secretion of insulin by the pancreatic beta cells. These include an initial decrease in beta cell mass related to genetic or epigenetic factors, increased apoptosis or decreased regeneration of beta cells, or beta cell exhaustion due to long-standing insulin resistance.\(^15\) According to one study, beta cell function was reduced by an average of 50% at the time of diagnosis in type 2 diabetes, and

![FIGURE 33-7. Pathogenesis of type 2 diabetes mellitus.](image-url)
progressively decreased (by an average of approximately 4% per year), resulting in worsening hyperglycemia even when the degree of insulin resistance remained Stable.\textsuperscript{17}

**Pathogenesis.** The pathogenesis of type 2 diabetes involves genetic, epigenetic, behavioral, and environmentally mediated factors. A positive family history confers a twofold to fourfold increased risk for type 2 diabetes, and 15% to 25% of first-degree relatives of persons with type 2 diabetes develop impaired glucose tolerance or diabetes.\textsuperscript{14} Despite the strong familial predisposition, the genetics of type 2 diabetes is poorly defined. This is probably because of the heterogeneous nature of the disorder as well as the difficulty in sorting out the contribution of acquired factors affecting insulin action and glycemic control.\textsuperscript{15} However, so far more than 60 genetic loci associated with type 2 diabetes have been identified. Unfortunately, when all these loci are added together they still only account for approximately 10% of the apparent genetic causes (i.e., heritability) of type 2 diabetes. Regardless, most cases of type 2 diabetes develop in obese individuals who have a genetic predisposition to beta-cell dysfunction and failure.

Among the acquired factors that predispose to type 2 diabetes, obesity and physical inactivity are paramount.\textsuperscript{14,15,18} As the body mass index (BMI) increases, the risk of developing diabetes increases, and approximately 90% of persons with type 2 diabetes are overweight. Obesity has profound effects on sensitivity of tissues to insulin, and as a consequence, on glucose homeostasis. Not only the absolute amount of body fat, but also its distribution has an effect on insulin resistance. People with upper body (or central) obesity who have increased stores of visceral (intra-abdominal) fat are at greater risk for developing type 2 diabetes and metabolic disturbances than persons with lower body (or peripheral) obesity (see Chapter 10). Waist circumference and waist–hip ratio, which are both surrogate measures of central obesity, have been shown to correlate well with insulin resistance. Thus, measures such as diet and exercise that reduce visceral adiposity are important in the management of type 2 diabetes. Other acquired factors include the patient’s microbiome (i.e., the bacteria that live in or on us) related metabolic factors and inflammatory effects.

**Role of Adipose Tissue in Type 2 Diabetes.** Although many details of the relationship between adipose tissue, insulin resistance, and increased glucose production in obese people with type 2 diabetes remain to be elucidated, several pathways have been proposed. Primary among these is the role of an increased concentration of free fatty acids (FFAs).\textsuperscript{15,19} Visceral obesity is accompanied by an increase in postprandial FFA concentrations and subsequent triglyceride storage, including in sites that do not normally store fat such as the liver, skeletal muscle, heart, and pancreatic beta cells.\textsuperscript{20,21} This has several consequences. First, excessive and chronic elevation of FFAs can directly cause pancreatic beta cell dysfunction (lipotoxicity). Second, at the level of the peripheral tissues, FFAs inhibit glucose uptake and glycogen storage. Third, the accumulation of FFAs and triglycerides reduces hepatic insulin sensitivity, leading to increased hepatic glucose production and hyperglycemia, especially in the fasting state. In the liver, the uptake of FFAs from the portal blood can lead to hepatic triglyceride accumulation and nonalcoholic fatty liver disease (see Chapter 30).

In addition to the metabolic effects of visceral obesity, adipocytes are the source of a number of important factors (e.g., adiponectin, leptin, FFAs) involved in a wide range of other processes, including glucose and lipid metabolism, inflammation, and thrombosis.\textsuperscript{15,20–23} In obesity and type 2 diabetes, there is a reduction in the production of some factors that are normally synthesized by adipocytes (i.e., adiponectin), whereas there is an accelerated release of other factors such as angiotensinogen, plasminogen activator inhibitor-1, leptin, and proinflammatory cytokines (e.g., tumor necrosis factor-\(\alpha\)). Adiponectin, which is secreted by adipocytes and circulates in the blood, is the only known adipocyte-secreted factor that increases tissue sensitivity to insulin.\textsuperscript{23} It has been shown that decreased levels of adiponectin coincide with insulin resistance in persons with obesity and type 2 diabetes. In skeletal muscle, adiponectin has been shown to decrease tissue triglyceride content by increasing the use of fatty acids as a fuel source. Adiponectin also appears to have antidiabetes, anti-inflammatory, and antiatherogenic effects.

**Insulin Resistance and the Metabolic Syndrome.** There is increasing evidence to suggest that when people with type 2 diabetes present predominantly with insulin resistance, the diabetes may represent only one aspect of a syndrome of metabolic disorders.\textsuperscript{24} Hyperglycemia in these people is frequently associated with intra-abdominal obesity, high levels of plasma triglycerides and low levels of high-density lipoproteins (HDLs), hypertension, systemic inflammation (as detected by C-reactive protein [CRP] and other mediators), abnormal fibrinolysis, abnormal function of the vascular endothelium, and macrovascular disease (coronary artery, cerebrovascular, and peripheral arterial disease). This constellation of abnormalities often is referred to as the insulin resistance syndrome, syndrome X, or, the preferred term, metabolic syndrome.\textsuperscript{21} In clinical practice, the definition of metabolic syndrome given in the Third Report of the National Cholesterol Education Program (NCEP III) is widely used\textsuperscript{20} (Chart 33-1).

**Other Specific Types of Diabetes**

The category of other specific types of diabetes, formerly known as secondary diabetes, includes diabetes that is associated with certain other conditions and syndromes. Such diabetes can occur with pancreatic disease...
ticoids (which can increase insulin resistance) and cer-
tents. Several drugs are thought to be important in the
organ transplant and occurs in 15% to 30% of recipi-
tal nutrition (i.e., hyperalimentation). Drug-related
contraceptives, antipsychotic agents, and total paren-
sium loss, which is thought to impair beta cell release
hyperglycemia do so by increasing the hepatic produc-
tion of glucose or decreasing the cellular use of glucose.
Several specific types of diabetes are associated with
single gene defects in beta cell function. These specific
types of diabetes, which resemble type 2 diabetes but
occur at an earlier age (usually before 25 years of age),
were formerly referred to as maturity-onset diabetes of
the young (MODY).3 Cystic fibrosis–related diabetes (CFRD)
is now recognized as the most common comp-
lication of cystic fibrosis. Glucose abnormalities are
especially common in children younger than 10 years
old. The pathophysiology of CFRD is poorly under-
stood, but insulin deficiency is the major factor (possibly
related to pancreatic scarring).11
Several diuretics—thiazide and loop diuretics—can
elevate blood glucose. These diuretics increase potas-
sium loss, which is thought to impair beta cell release
of insulin. Other drugs and therapies known to cause
hyperglycemia include diazoxide, glucocorticoids, oral
sulfonylureas, and antiglucagon. In addition, thiazide
and loop diuretics may cause hyperglycemia in some
individuals.11

In addition, changes in fat distribution (peripheral
lipodystrophy and visceral obesity), sometimes referred
to as lipodystrophy, often occur (see Chapter 16). These
people should be aggressively treated to prevent
biochemical complications resulting from the abnor-
mal risk factors.

**Gestational Diabetes**

Gestational diabetes mellitus (GDM) is defined as glu-
cose intolerance that develops during pregnancy and is
not clearly overt diabetes (either type 1 or type 2).11
It occurs in 3% to 7% of pregnancies in the United
States and is growing in prevalence.26,27 The hyperglyce-
mia varies in severity from glucose concentrations that
would be diagnostic of diabetes apart from pregnancy to
concentrations that are asymptomatic and only slightly
above normal.27 Factors that indicate a high risk for
GDM include glycosuria, strong family history of type 2
diabetes, severe obesity, polycystic ovary disease, and
prior history of GDM or delivery of a previous large-
for-gestational-age infant.

All pregnant women should undergo risk assessment
for diabetes during their first prenatal visit to determine
the need for additional screening tests. Women who
are younger than 25 years of age; were of normal body
weight before pregnancy; have no family history of dia-
abetes, prior history of GDM or large-for-gestational age
infant, or presence of glycosuria; and are not members
of a high-risk ethnic/racial group (e.g., Hispanic, Native
American, Asian, African American) may not need to
be screened.11,26,27 Women at high risk for GDM should
undergo glucose testing as soon as possible. An FPG
greater than or equal to 126 mg/dL; or a casual plasma
glucose greater than or equal to 200 mg/dL; or a 1 A1C
greater or equal to 6.5% meets the threshold for diag-
nosis of diabetes mellitus and should be confirmed on
a subsequent day as soon as possible.11 Women of average
or low risk, including those not found to have diabetes
early in pregnancy, should undergo GDM testing at 24 to
28 weeks of gestation using a 50-g OGTT. This screen-
ing test consists of 50 g of glucose given without regard
to the last meal, followed in 1 hour by a venous blood
sample for glucose concentration. If the plasma glucose
level is greater than 140 mg/dL (7.8 mmol/L), a 100-g
3-hour OGTT is indicated to establish the diagnosis of
GDM.27 If the plasma glucose measured 3 hours after
the test is greater or equal to 140 mg/dL (7.8 mmol/L), a
diagnosis of GDM is made.27

Diagnosis and careful medical management are essential
because women with GDM are at higher risk for com-
plications of pregnancy, mortality, and fetal abnor-
malities.11 Fetal abnormalities include macrosomia (i.e.,
large body size), hypoglycemia, hypocalcemia, polycy-
themias, and hyperbilirubinemia. Treatment of GDM
includes close observation of the mother and fetus because even mild hyperglycemia has
been shown to be detrimental to the fetus.26,27 Maternal
fasting and postprandial blood glucose levels should be
measured regularly. The mother’s diet should provide
the necessary nutrients for maternal and fetal health,
result in normoglycemia and proper weight gain, and prevent ketosis. If dietary management alone does not achieve a capillary blood glucose of 90 to 99 mg/dL or a 2-hour postprandial blood glucose less than 120 mg/dL, the Fifth International Workshop on GDM recommends therapy with insulin. More recently, several oral agents have also been used for the treatment of GDM, including glyburide and metformin. Self-monitoring of blood glucose levels is essential.

Approximately 50% of women with GDM will develop type 2 diabetes within 5 to 10 years. Women in whom GDM is diagnosed should be followed after delivery to detect diabetes early in its course. These women should be evaluated during their first postpartum visit with a 2-hour OGTT with a 75-g glucose load.

Clinical Manifestations of Diabetes

Diabetes mellitus may have a rapid or an insidious onset. In type 1 diabetes, signs and symptoms often arise suddenly. Type 2 diabetes usually develops more insidiously; its presence may be detected during a routine medical examination or when a patient seeks medical care for other reasons.

The most commonly identified signs and symptoms of diabetes are often referred to as the three polys: (1) polyuria (i.e., excessive urination), (2) polydipsia (i.e., excessive thirst), and (3) polyphagia (i.e., excessive hunger). These three symptoms are closely related to the hyperglycemia and glycosuria of diabetes. Glucose is a small, osmotically active molecule. When blood glucose levels are sufficiently elevated, the amount of glucose filtered by the glomeruli of the kidney exceeds the amount that can be reabsorbed by the renal tubules; this results in glycosuria accompanied by large losses of water in the urine. Thirst results from the intracellular dehydration that occurs as blood glucose levels rise and water is pulled out of body cells, including those in the hypothalamic thirst center. This early symptom may be easily overlooked in people with type 2 diabetes, particularly in those who have had a gradual increase in blood glucose levels. Polyphagia usually is not present in people with type 2 diabetes. In type 1 diabetes, it probably results from cellular starvation and the depletion of cellular stores of carbohydrates, fats, and proteins.

Weight loss despite normal or increased appetite is a common occurrence in people with uncontrolled type 1 diabetes. The cause of weight loss is twofold. First, loss of body fluids results from osmotic diuresis. Vomiting may exaggerate the fluid loss in ketoacidosis. Second, body tissue is lost because the lack of insulin forces the body to use its fat stores and cellular proteins as sources of energy. In terms of weight loss, there often is a marked difference between type 2 diabetes and type 1 diabetes. Many people with uncomplicated type 2 diabetes often have problems with obesity.

Other signs and symptoms of hyperglycemia include recurrent blurred vision, fatigue, paresthesias, and skin infections. In type 2 diabetes, these often are the symptoms that prompt a person to seek medical treatment. Blurred vision develops as the lens and retina are exposed to hyperosmolar fluids. Lowered plasma volume produces weakness and fatigue. Paresthesias reflect a temporary dysfunction of the peripheral sensory nerves. Chronic skin infections can occur and are more common in people with type 2 diabetes. Hyperglycemia and glycosuria favor the growth of yeast organisms. Pruritus and vulvovaginitis due to Candida infections are common initial complaints in women with diabetes. Balanitis secondary to Candida infections can occur in men.

Diagnostic Tests

The diagnosis of diabetes mellitus is confirmed through the use of laboratory tests that measure blood glucose levels. Testing for diabetes should be considered in all individuals 45 years of age and older. Diabetes screening should be considered at a younger age in people who are obese, have a first-degree relative with diabetes, are members of a high-risk group, have delivered an infant weighing more than 9 pounds or been diagnosed with GDM, have hypertension or hyperlipidemia, or have met the criteria (IFG, IGT, elevated A1C) for increased risk of diabetes on previous testing.

Blood Tests

Blood glucose measurements are used in both the diagnosis and management of diabetes. Diagnostic tests include the FPG, casual plasma glucose, the glucose tolerance test, and glycosylated hemoglobin (i.e., A1C). Laboratory and capillary or finger-stick glucose tests are used for glucose management in people with diagnosed diabetes.

Fasting Plasma Glucose. The FPG represents plasma glucose levels after food has been withheld for at least 8 hours. Advantages of the FPG are convenience, patient acceptability, and cost. An FPG level below 100 mg/dL (5.6 mmol/L) is considered normal (see Table 33-3).

Casual Blood Glucose Test. A casual (or random) plasma glucose one that is done without regard to the time of the last meal. A casual plasma glucose concentration that is unequivocally elevated (≥200 mg/dL [11.1 mmol/L]) in the presence of classic symptoms of diabetes such as polydipsia, polyphagia, polyuria, and blurred vision is diagnostic of diabetes mellitus at any age.

Oral Glucose Tolerance Test. The OGTT is an important screening test for diabetes. The test measures the body’s ability to store glucose by removing it from the blood. In men and women, the test measures the plasma glucose response to 75 g of concentrated glucose solution at selected intervals, usually 1 and 2 hours. In people with normal glucose tolerance, blood glucose levels return to normal within 2 to 3 hours after ingestion of a glucose load. Because people with diabetes lack the ability to respond to an increase in blood glucose by
releasing adequate insulin to facilitate storage, their blood glucose levels rise above those observed in normal people and remain elevated for longer periods.

**Capillary Blood Glucose Monitoring.** Technological advances have provided the means for monitoring blood glucose levels by using a drop of capillary blood. This procedure has provided health professionals with a rapid and economical means for monitoring blood glucose and has given people with diabetes a way of maintaining near-normal blood glucose levels through self-monitoring of blood glucose. These methods use a drop of capillary blood obtained by pricking the finger or forearm with a special needle or small lancet. Small trigger devices make use of the lancet virtually painless. The drop of capillary blood is placed on or absorbed by a reagent strip, and glucose levels are determined electronically using a glucose meter.

Laboratory tests that use plasma for measurement of blood glucose give results that are 10% to 15% higher than the finger-stick method, which uses whole blood. Many blood glucose monitors approved for home use and some test strips now calibrate blood glucose readings to plasma values. It is important that people with diabetes know whether their monitors or glucose strips provide whole-blood or plasma test results.

Continuous glucose monitoring (CGM) systems are becoming available to fine-tune glucose management. The various systems have small catheters implanted in the subcutaneous tissue to provide frequent samples. The variety and accuracy of these systems are continuously improving. Finger-stick glucose monitoring remains the standard of care, but does not provide as much information regarding the glycemic profile as CGM (especially during the overnight period).

**Glycosylated Hemoglobin.** Glycosylated hemoglobin, hemoglobin A1c (HbA1c), and A1C are terms used to describe hemoglobin into which glucose has been incorporated. Hemoglobin normally does not contain glucose when it is released from the bone marrow. During its 120-day life span in the red blood cell, hemoglobin becomes glycosylated to form HbA1. The major form of HbA1 is HbA1c, which makes up 2% to 6% of total hemoglobin. Because glucose entry into red blood cells is not insulin dependent, the rate at which glucose becomes attached to the hemoglobin molecule depends on blood glucose levels. Glycosylation is essentially irreversible, and the level of A1C present in the blood provides an index of blood glucose levels over the previous 6 to 12 weeks. In uncontrolled diabetes or diabetes with hyperglycemia, there is an increase in the level of A1C. The American Diabetes Association (ADA) recommends initiating corrective measures for A1C levels greater than an individualized goal. For example, the presence of several factors including advanced age, history of severe hypoglycemic episodes, and presence of cardiovascular disease might suggest a glycemic goal of 7.5% to 8%, whereas the absence of these and other worrying factors may mean that a target goal of 6.5% or less is warranted as long as this can be achieved safely. The A1C may overestimate glycemic burden in certain individuals and ethnic groups (such as African Americans). In addition, A1C can be misleading in persons with certain forms of anemia and hemoglobin disorders, and in pregnant women. For these populations, the diagnosis of diabetes must use glucose criteria exclusively. Also, the A1C may not be significantly elevated in rapidly evolving diabetes, such as the development of type 1 diabetes in children.

**Urine Tests**

The ease, accuracy, and convenience of self-administered blood glucose monitoring techniques have made urine testing for glucose obsolete for most people with diabetes. These tests only reflect urine glucose levels and are influenced by such factors as the renal threshold for glucose, fluid intake and urine concentration, urine testing methodologies, and some drugs. It is recommended that all people with diabetes self-monitor their blood glucose. Urine ketone determinations remain an important part of monitoring diabetic control, particularly in people with type 1 diabetes who are at risk for development of ketoacidosis, and in pregnant diabetic women to check the adequacy of nutrition and glycemic control.

**Diabetes Management**

The desired outcome of glycemic control in both type 1 and type 2 diabetes is normalization of blood glucose as a means of preventing short- and long-term complications. Treatment plans involve dietary management (medical nutrition therapy), exercise, and antidiabetic agents. People with type 1 diabetes require insulin therapy from the time of diagnosis. Weight loss and dietary management may be sufficient to control blood glucose levels in people with type 2 diabetes. However, they require follow-up care because insulin secretion from the beta cells may decrease or insulin resistance may persist or worsen, in which case non-insulin agents are prescribed.

Among the methods used to achieve these treatment goals are education in self-management and problem solving. Individual treatment goals should take into account the person’s age and other disease conditions, the person’s capacity to understand and carry out the treatment regimen, and socioeconomic factors that might influence compliance with the treatment plan. Optimal control of both type 1 and type 2 diabetes is associated with prevention or delay of chronic diabetes complications.

**Dietary Management**

Dietary management usually is individualized to meet the specific needs of each person with diabetes. Therapy goals include maintenance of near-normal blood glucose levels, achievement of optimal lipid levels, adequate calories to attain and maintain a reasonable weight, prevention and treatment of chronic diabetes complications, and improvement of overall health through optimal nutrition.
The diabetic diet has undergone marked changes over the years, particularly in the recommendations for distribution of calories among carbohydrates, proteins, and fats. There no longer is a generic diabetic or ADA diet, but rather an individualized dietary prescription based on metabolic parameters, medical history of factors such as renal impairment and gastrointestinal autonomic neuropathy, and treatment goals. For a person with type 1 diabetes, eating consistent amounts and types of food at specific and routine times is encouraged. Home blood glucose monitoring is used to fine-tune the plan. Most people with type 2 diabetes are overweight; thus nutrition therapy focuses on achieving glucose, lipid, and blood pressure goals, and weight loss if indicated. Mild to moderate weight loss (5% to 10% of total body weight) has been shown to improve diabetes control, even if desirable weight is not achieved.

**Exercise**

The benefits of exercise for anyone include increased cardiovascular fitness and psychological well-being. For people with type 1 diabetes, the benefits of exercise include a decrease in body fat, better weight control, and improvement in insulin sensitivity. Exercise is so important in diabetes management that an individualized program of regular exercise usually is considered an integral part of the therapeutic regimen for every diabetic. In general, sporadic exercise has only transient benefits; a regular program is necessary for cardiovascular conditioning and to maintain a muscle–fat ratio that enhances peripheral insulin receptivity.

In people with diabetes, the beneficial effects of exercise are accompanied by an increased risk of hypoglycemia. Although muscle uptake of glucose increases significantly, the ability to maintain blood glucose levels is hampered by failure to suppress the absorption of injected insulin and activate the counterregulatory mechanisms that maintain blood glucose. Not only is there an inability to suppress insulin levels, but insulin absorption may also increase. This increased absorption is more pronounced when insulin is injected into the subcutaneous tissue of the exercised muscle, but it occurs even when insulin is injected into other body areas. Even after exercise ceases, insulin’s lowering effect on blood glucose continues. In some people with type 1 diabetes, the symptoms of hypoglycemia occur several hours after cessation of exercise, perhaps because subsequent insulin doses (in people using multiple daily insulin injections) are not adjusted to accommodate the exercise-induced decrease in blood glucose. The cause of hypoglycemia in people who do not administer a subsequent insulin dose is unclear. It may be related to the fact that the liver and skeletal muscles increase their uptake of glucose after exercise as a means of replenishing their glycogen stores, or that the liver and skeletal muscles are more sensitive to insulin during this time. People with diabetes should be aware that delayed hypoglycemia can occur after exercise and that they may need to alter their diabetes medication dose, their carbohydrate intake, or both.

Although of benefit to people with diabetes, exercise must be weighed on the risk–benefit scale. Before beginning an exercise program, persons with diabetes should undergo an appropriate evaluation for macrovascular and microvascular disease. The goal of exercise is safe participation in activities consistent with an individual’s lifestyle. As with nutrition guidelines, exercise recommendations need to be individualized. Considerations include the potential for hypoglycemia, hyperglycemia, ketosis, cardiovascular ischemia and arrhythmias (particularly silent ischemic heart disease), exacerbation of proliferative retinopathy, and lower extremity injury. For those with chronic diabetes, the complications of vigorous exercise can be harmful and cause eye hemorrhage and other problems.

**Oral and Injectable Antidiabetic Agents**

Historically, two categories of antidiabetic agents existed: insulin injections and oral medications. However, this classification has been set aside since the introduction of new injectable non-insulin antidiabetic agents. Because people with type 1 diabetes are deficient in insulin, they are in need of exogenous insulin replacement therapy from the start. People with type 2 diabetes can have increased hepatic glucose production, decreased peripheral utilization of glucose, decreased utilization of ingested carbohydrates, and, over time, impaired insulin secretion and excessive glucagon secretion from the pancreas (Fig. 33-8). The antidiabetic (non-insulin) agents used in the treatment of type 2 diabetes (insulin secretagogues, biguanides, α-glucosidase inhibitors, thiazolidinediones, SGLT2 inhibitors, and incretin-based agents) attack each one of these areas and sometimes all. If good glycemic control cannot be achieved with one or a combination of non-insulin agents, insulin can be added or used by itself.

**Insulin Secretagogues.** The insulin secretagogues act at the level of the pancreatic beta cells to stimulate insulin secretion. There are two general classes of insulin secretagogues: (1) sulfonylureas and (2) meglitinides. Both types require the presence of functioning beta cells, are used only in the treatment of type 2 diabetes, and have the potential for producing hypoglycemia.

The control of insulin release from the pancreatic beta cells by glucose or the sulfonylurea drugs requires the generation of adenosine triphosphate (ATP), closing of an ATP-gated potassium channel, and opening of a transmembrane calcium channel. The sulfonylureas (e.g., glipizide, glyburide, glimepiride) act by binding to a high-affinity sulfonylurea receptor on the beta cell that is linked to an ATP-sensitive potassium channel (Fig. 33-9). Binding of a sulfonylurea closes the channel, resulting in a coupled reaction that leads to an influx of calcium ions and insulin secretion. Because the sulfonylureas increase insulin levels and the rate at which glucose is removed from the blood, it is important to recognize that they can cause hypoglycemic reactions. This problem is more common in elderly people with
impaired hepatic and renal function who are taking the longer-acting sulfonylureas.

The meglitinides (repaglinide) and related drugs (nateglinide) are shorter-acting insulin secretagogues (termed glinides) that target post-prandial glucose elevation. These agents, which are rapidly absorbed from the gastrointestinal tract, are taken shortly before meals. Both drugs can produce hypoglycemia; thus, proper timing of meals in relation to drug administration is essential.

**Biguanides.** Metformin, the only currently available biguanide, inhibits hepatic glucose production and increases the sensitivity of peripheral tissues to the actions of insulin. Secondary benefits of metformin therapy include weight loss and improved lipid profiles. This medication does not stimulate insulin secretion; therefore, it does not produce hypoglycemia. However, it confers an increased risk for lactic acidosis, and is contraindicated in people with elevated serum creatinine levels, clinical and laboratory evidence of severe liver disease, or conditions associated with hypoxemia or dehydration.32

**α-Glucosidase Inhibitors.** The α-glucosidase inhibitors (acarbose, miglitol) block the action of intestinal brush border enzymes that break down complex carbohydrates.32 By delaying the breakdown of complex carbohydrates, the α-glucosidase inhibitors delay the absorption of carbohydrates from the gut and blunt the postprandial increase in plasma glucose and insulin levels. Although not a problem with monotherapy or combination therapy with a biguanide, hypoglycemia may occur with concurrent sulfonylurea treatment. If hypoglycemia does occur, it should be treated with glucose (dextrose) and not

**FIGURE 33-8. (A) Mechanisms of elevated blood glucose in type 2 diabetes mellitus. (B) Action sites of hypoglycemic agents and mechanisms of lowering blood glucose in type 2 diabetes. The incretins are the dipeptidyl peptidase-4 (DPP-4) inhibitors and glucagon-like peptide-1 (GLP-1) agonists.**
FIGURE 33-9. One model of control of release of insulin by the pancreatic beta cells and the action of the sulfonylurea agents. In the resting beta cell with low adenosine triphosphate (ATP) levels, potassium diffuses through the ATP-gated channels, maintaining the resting membrane potential. As blood glucose rises and is transported into the beta cell by the glucose transporter, ATP rises, causing the potassium channels to close and depolarization to occur. Depolarization results in opening of the voltage-gated calcium channels, which leads to insulin secretion. (Modified from Karam JH. Type II diabetes and syndrome X. Endocrinol Metab Clin North Am. 1992;21(2):329–350.)

sucrose (table sugar), whose breakdown may be blocked by the action of the α-glucosidase inhibitors.

Thiazolidinediones. The thiazolidinediones (TZDs) or glitazones (e.g., pioglitazone, rosiglitazone) are the only class of drugs that directly target insulin resistance. They do this by increasing insulin sensitivity in the insulin-responsive tissues—liver, skeletal muscle, and fat—allowing the tissues to respond to endogenous insulin more efficiently without increased output from already dysfunctional beta cells. Because of the previous problem with liver toxicity in this class of drugs, liver enzymes should be monitored before starting therapy according to guidelines. Both agents can cause fluid accumulation and are therefore contraindicated in patients with stage III and IV heart failure (see Chapter 20, Table 20-1). Other potential adverse effects include an increased risk of bone fractures and of bladder cancer.

Incretin-Based Agents. Incretins are hormones released into the circulation by the gastrointestinal tract after a meal, especially one high in carbohydrates, that amplify the glucose-induced release of insulin (see Chapter 28). The main incretins secreted are glucagon-like peptide 1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP). Both GLP-1 and GIP are rapidly degraded by the enzyme dipeptidyl peptidase-4 (DPP-4). DPP-4 enzyme inhibitors work by inhibiting the DPP-4 enzyme and increasing GLP-1 and GIP levels, which then increase insulin release. Glucagon-like peptide 1 also helps to suppress glucagon release.

Exenatide, a synthetic analog of GLP-1 that is resistant to DPP-4 degradation, is approved as an injectable adjunctive therapy for people with type 2 diabetes. The drug has been shown to have multiple actions such as potentiation of glucose-mediated insulin release, slowed gastric emptying, and a central loss of appetite. Although exenatide was the first GLP-1 agonist to be developed and approved, other agents and formulations have also been approved.

Many other novel classes of antidiabetes agents are also approved for type 2 diabetes including the SGLT2 inhibitor, canagliflozin. This agent, which works by inhibiting glucose reabsorption from the kidney, results in about 70 g (approximately 300 Kcal) glucose loss per day. The adverse effects are understandable, including polyuria due to osmotic diuresis and increased urinary tract infections and genitourinary Candida infections.

Insulin

Type 1 diabetes mellitus always requires treatment with insulin, and many people with type 2 diabetes eventually require insulin therapy. Insulin is destroyed in the gastrointestinal tract and must be administered by injection or inhalation. An inhaled form of insulin (Exubera) was on the market for a short time in the United States but was withdrawn for commercial reasons. Other inhaled insulin formulations are in clinical development.

Human insulin has become widely available, providing an alternative to forms of insulin obtained from bovine and porcine sources. Its manufacture uses recombinant deoxyribonucleic acid (DNA) technology. More recently, analogs to human insulin have become available that offer even better and more reproducible release characteristics.

Four insulin types are classified by length and peaking of action: short acting, rapid acting, intermediate acting, and long acting. Short-acting insulin (regular) is a soluble crystalline insulin whose effects begin within 30 minutes after subcutaneous injection and generally last for 5 to 8 hours. The rapid-acting insulins (lispro, aspart, glulisine) are produced by recombinant technology and have a more rapid onset, peak, and duration of action than short-acting regular insulin. The rapid-acting...
insulins, which are used in combination with intermediate- or long-acting insulins, are usually administered immediately before a meal. Intermediate- to long-acting insulins (neutral protamine Hagedorn [NPH], glargine, and detemir) have slower onsets and a longer duration of action. They require several hours to reach therapeutic levels, so their use in type 1 diabetes requires supplementation with rapid- or short-acting insulin. All forms of insulin have the potential to produce hypoglycemia or “insulin reaction” as a side effect (to be discussed).

Two intensive treatment regimens—multiple daily injections and continuous subcutaneous infusion of insulin—closely simulate the normal pattern of insulin secretion by the body. With each method, a basal insulin level is maintained, and bolus doses of short- or rapid-acting insulin are delivered before meals. The choice of management is determined by the person with diabetes in collaboration with the health care team.

With multiple daily injections (MDIs), the basal insulin requirements are met by an intermediate- or long-acting insulin administered once or twice daily. Boluses of rapid- or short-acting insulin are used before meals. The development of convenient injection devices (e.g., pen injectors) has made it easier for people with diabetes to comply with algorithms for these insulins that are administered before meals.

The continuous subcutaneous insulin infusion (CSII) method uses an insulin pump. With this method, the basal insulin requirements are met by continuous infusion of subcutaneous insulin, the rate of which can be varied to accommodate diurnal variations. The computer-operated pump then delivers one or more set basal amounts of insulin. In addition to the basal amount delivered by the pump, a bolus amount of insulin may be delivered when needed (e.g., before a meal) by pushing a button. Although the pump’s safety has been proven, strict attention must be paid to signs of hyperglycemia. Self-monitoring of blood glucose levels is a necessity when using the CSII method of management. Hyperglycemia and ketotic episodes caused by pump failure, catheter clogging, and infections at the needle site also are possible complications. Candidate selection is crucial to the successful use of the insulin pump. Only people who are highly motivated to do frequent blood glucose tests and make daily insulin adjustments are candidates for this method of treatment.

**Pancreas or Islet Cell Transplantation**

Pancreas or islet cell transplantation is not a lifesaving procedure. It does, however, afford the potential for significantly improving the quality of life. The most serious problems are the requirement for immunosuppression and the need for diagnosis and treatment of rejection. Investigators are looking for methods of transplanting islet cells and protecting the cells from destruction without the use of immunosuppressive drugs.

**Management of Diabetes in Children**

Children with diabetes have traditionally been diagnosed with type 1 diabetes. However, health care providers are finding more children with type 2 diabetes, a disease that has usually been diagnosed in adults aged 40 years or older. The epidemics of obesity and the low level of physical activity among young people, as well as exposure to diabetes in utero (resulting in epigenetic changes), may be major contributors to the increase in type 2 diabetes during childhood and adolescence.

Children with diabetes differ from adults in many respects, including changes in insulin sensitivity related to sexual maturity and physical growth, their ability to provide self-care and their need for supervision in child care and school, and vulnerability to hypoglycemia and diabetic ketoacidosis. While current standards of care for diabetes management reflect the need to maintain glucose levels as near normal as possible, glycemic goals need to take into account that children younger than 6 or 7 years of age have a form of “hypoglycemic unawareness.” Their counterregulatory mechanisms are immature and they lack the cognitive capacity to recognize and respond to hypoglycemic symptoms, placing them at greater risk for hypoglycemia and its sequelae. Also, unlike adults, young children under 5 years of age are at risk for permanent cognitive impairment after episodes of severe hypoglycemia. Thus, the glycemic goals for children must consider the benefits of long-term health outcomes against the risks of hypoglycemia and the difficulties in achieving normoglycemia in children. Additional concerns include the effects of drugs developed and tested primarily for adults on growth and brain development in children.

**Acute Complications**

The three major acute complications of impaired blood glucose regulation are diabetic ketoacidosis (DKA), hyperglycemic hyperosmolar state (HHS), and hypoglycemia. All are life-threatening conditions that demand immediate recognition and treatment. The Somogyi effect and dawn phenomenon, which result from the mobilization of counterregulatory hormones, contribute to difficulties with diabetic control.

**Diabetic Ketoacidosis**

Diabetic ketoacidosis, characterized by hyperglycemia, ketosis, and metabolic acidosis, is an acute life-threatening complication of uncontrolled diabetes. Diabetic ketoacidosis primarily affects persons with type 1 diabetes, but may also occur in persons with type 2 diabetes when severe stress such as sepsis or trauma is present. It may be an initial manifestation of previously undiagnosed type 1 diabetes or may result from increased insulin requirements in type 1 diabetes during stress situations, such as infection or trauma, that increase the release of stress hormones. For example, a mother may bring a child into the clinic or emergency department with reports of lethargy, vomiting, and abdominal pain, unaware that the child has diabetes. In clinical practice, ketoacidosis also occurs with the omission or inadequate use of insulin.

Ketoacidosis reflects the effect of insulin deficiency at multiple sites (Fig. 33-10). A lack of insulin results in the
rapid breakdown of energy stores from muscle and fat deposits, leading to increased movement of amino acids to the liver for conversion to glucose and of fatty acids for conversion to ketones. In the presence of ketosis, the levels of glucagon and counterregulatory hormones (i.e., glucocorticosteroids, epinephrine, and growth hormone) are consistently increased. Furthermore, in the absence of insulin, peripheral utilization of glucose and ketones is reduced. Metabolic acidosis is caused by the excess ketoacids that require buffering by bicarbonate ions; this leads to a marked decrease in serum bicarbonate levels.

The definitive diagnosis of DKA consists of hyperglycemia (blood glucose levels >250 mg/dL [13.8 mmol/L]), low serum bicarbonate, low arterial pH, and positive urine and serum ketones. It can be further subdivided into mild DKA (serum bicarbonate of 15 to 18 mEq/dL [15 to 18 mmol/L], pH 7.25 to 7.30); moderate DKA (serum bicarbonate 10 to <15 mEq/dL [10 to <15 mmol/L], pH 7.00 to 7.24); and severe DKA (serum bicarbonate <10 mEq/dL [<10 mmol/L], pH <7.00). Hyperglycemia leads to osmotic diuresis, dehydration, and a critical loss of electrolytes. Hyperosmolality of extracellular fluids from hyperglycemia leads to a shift of water and potassium from the intracellular to the extracellular compartment. Extracellular sodium concentration frequently is low or normal despite enteric water losses because of an intracellular–extracellular fluid shift. This dilutional effect is referred to as pseudohyponatremia. Serum potassium levels may also be normal or elevated, despite total potassium depletion resulting from protracted polyuria and vomiting.

The development of DKA is commonly preceded by a day or more of polyuria, polydipsia, nausea, vomiting, and marked fatigue, with eventual stupor that can progress to coma. Abdominal pain and tenderness may be experienced without abdominal disease. The breath has a characteristic fruity smell because of the presence of volatile ketoacids. Hypotension and tachycardia may be present because of a decrease in blood volume. A number of the signs and symptoms that occur in DKA are related to compensatory mechanisms. The heart rate increases as the body compensates for a decrease in blood volume, and the rate and depth of respiration increase (i.e., Kussmaul respiration) as the body attempts to prevent further decreases in pH. Metabolic acidosis is discussed further in Chapter 8.

The goals in treating DKA are to improve circulatory volume and tissue perfusion, decrease blood glucose, and correct the acidosis and electrolyte imbalances. These objectives usually are accomplished through the
administration of insulin and intravenous fluid and electrolyte replacement solutions. Because insulin resistance accompanies severe acidosis, low-dose insulin therapy is used. An initial loading dose of short-acting (i.e., regular) or rapid-acting insulin often is given intravenously, followed by continuous low-dose short-acting insulin infusion. Frequent laboratory tests are used to monitor blood glucose and serum electrolyte levels and to guide fluid and electrolyte replacement. It is important to replace fluid and electrolytes and correct pH while bringing the blood glucose concentration to a normal level. Too rapid a drop in blood glucose may cause hypoglycemia. A sudden change in the osmolality of extracellular fluid can also occur when blood glucose levels are lowered too rapidly, and this can cause cerebral edema. Cerebral and other autoregulatory mechanisms may not be as well developed in younger children, placing them at particular risk for development of cerebral edema. Serum potassium levels often fall as acidosis is corrected and potassium moves from the extracellular into the intracellular compartment. Thus, it may be necessary to add potassium to the intravenous infusion. Identification and treatment of the underlying cause, such as infection, also are important.

Hyperglycemic Hyperosmolar State

The hyperglycemic hyperosmolar state (HHS) is characterized by hyperglycemia (blood glucose >600 mg/dL [33.3 mmol/L]), hyperosmolarity (plasma osmolarity >320 mOsm/L) and dehydration, the absence of ketoacidosis, and depression of the sensorium. Hyperglycemic hyperosmolar state may occur in various conditions, including type 2 diabetes, acute pancreatitis, severe infection, myocardial infarction, and treatment with oral or parenteral nutrition solutions. It is seen most frequently in people with type 2 diabetes. A partial or relative insulin deficiency may initiate the syndrome by reducing glucose utilization while inducing a glucagon-stimulated increase in hepatic glucose output. With massive glycosuria, obligatory water loss occurs. If the person is unable to maintain adequate fluid intake because of associated acute or chronic illness or has excessive fluid loss, dehydration develops. As the plasma volume contracts, renal insufficiency develops and the resultant limitation of renal glucose losses leads to increasingly higher blood glucose levels and an increase in severity of the hyperosmolar state.

In hyperosmolar states, the increased serum osmolality has the effect of pulling water out of body cells, including brain cells. The condition may be complicated by thromboembolic events arising because of the high serum osmolality. The most prominent manifestations are weakness, dehydration, polyuria, neurologic signs and symptoms, and excessive thirst. The neurologic signs include hemiparesis, Babinski reflex, aphasia, muscle fasciculations, hyperthermia, hemianopia, nystagmus, visual hallucinations, seizures, and coma. The onset of HHS often is insidious, and because it occurs most frequently in older people, it may be mistaken for a stroke.

The treatment of HHS requires judicious medical observation and care as water moves back into brain cells, posing a threat of cerebral edema. Extensive potassium losses that also have occurred during the diuretic phase of the disorder require correction. Because of the problems encountered in the treatment and the serious nature of the disease conditions that cause HHS, the prognosis for this disorder is less favorable than that for ketoacidosis.

Hypoglycemia

Hypoglycemia, or an insulin reaction, occurs from a relative excess of insulin in the blood and is characterized by below-normal blood glucose levels. It occurs most commonly in people treated with insulin injections, but prolonged hypoglycemia also can result from some oral hypoglycemic agents (i.e., sulfonylurea). There are many factors that can precipitate an insulin reaction in a person with type 1 or type 2 diabetes, including error in insulin dose, failure to eat, increased exercise, decreased insulin need after removal of a stress situation, medication changes, and a change in insulin injection site. Alcohol decreases liver gluconeogenesis, and people with diabetes need to be cautioned about its potential for causing hypoglycemia, especially if it is consumed in large amounts or on an empty stomach.

Hypoglycemia usually has a rapid onset and progression of symptoms. The signs and symptoms of hypoglycemia can be divided into two categories: (1) those caused by altered cerebral function and (2) those related to activation of the autonomic nervous system. Because the brain relies on blood glucose as its main energy source, hypoglycemia produces behaviors related to altered cerebral function. Headache, difficulty in problem solving, disturbed or altered behavior, coma, and seizures may occur. At the onset of the hypoglycemic episode, activation of the parasympathetic nervous system often causes hunger. The initial parasympathetic response is followed by activation of the sympathetic nervous system; which causes anxiety, tachycardia, sweating, and a cool and clammy skin due to constriction of the skin vessels.

The signs and symptoms of hypoglycemia are highly variable, especially in children and the elderly, and not everyone manifests all or even most of the symptoms. Elderly people may not display the typical autonomic responses, but typically do display signs of altered cerebral function, including mental confusion. Also, some medications, such as β-adrenergic blocking drugs, interfere with the autonomic response normally seen in hypoglycemia. Some people develop hypoglycemic unawareness; that is, they do not report symptoms when their blood glucose concentrations are less than 50 to 60 mg/dL (2.8 to 3.3 mmol/L). This occurs most commonly in people who have a longer duration of diabetes and A1C levels within the normal range.

The most effective treatment of an insulin reaction is the immediate administration of 15 g of glucose in a concentrated carbohydrate source. According to the so-called rule of 15, this 15 g of glucose can be repeated
every 15 minutes for up to 3 doses. Monosaccharides such as glucose, which can be absorbed directly into the bloodstream, work best. Complex carbohydrates can be administered after the acute reaction has been controlled to sustain blood glucose levels. It is important not to overtreat hypoglycemia and cause rebound hyperglycemia. Alternative methods for increasing blood glucose may be required when the person having the reaction is unconscious or unable to swallow. Glucagon may be given intramuscularly or subcutaneously. Glucagon acts by hepatic glycogenolysis to raise blood glucose. Because the liver contains only a limited amount of glycogen (approximately 75 g), glucagon is ineffective in people whose glycogen stores have been depleted. In situations of severe or life-threatening hypoglycemia, it may be necessary to administer glucose (20 to 50 mL of a 50% solution) intravenously. If hypoglycemia occurs with α-glucosidase inhibitors, it should be treated with glucose (dextrose) and not sucrose (table sugar), whose breakdown may be blocked by the action of the α-glucosidase inhibitors.

The Somogyi Effect and Dawn Phenomenon

The Somogyi effect describes a cycle of insulin-induced posthypoglycemic episodes. In 1924, Joslin and associates noticed that hypoglycemia was associated with alternate episodes of hyperglycemia. It was not until 1959 that Somogyi presented the results of his 20 years of studies, which confirmed the observation that “hypoglycemia begets hyperglycemia.” In people with diabetes, insulin-induced hypoglycemia produces a compensatory increase in blood levels of catecholamines, glucagon, cortisol, and growth hormone. These counterregulatory hormones cause blood glucose to become elevated and produce some degree of insulin resistance. The cycle begins when the increase in blood glucose and insulin resistance is treated with larger insulin doses. The hypoglycemic episode often occurs during the night or at a time when it is not recognized, rendering the diagnosis of the phenomenon more difficult.

Research suggests that even mild insulin-associated hypoglycemia, which may be asymptomatic, can cause hyperglycemia in people with type 1 diabetes through the recruitment of counterregulatory mechanisms, although the insulin action does not wane. A waning of insulin’s effects when it occurs (i.e., end of the duration of action) causes an exacerbation of the posthypoglycemic hyperglycemia that occurs and accelerates its development. These findings may explain the labile nature of the disease in some people with diabetes. Measures to prevent hypoglycemia and the subsequent activation of counterregulatory mechanisms include a redistribution of dietary carbohydrates and an alteration in insulin dose or time of administration.

The dawn phenomenon is characterized by increased levels of fasting blood glucose, or insulin requirements, or both, between 5 AM and 9 AM without antecedent hypoglycemia. It occurs in people with type 1 or type 2 diabetes. It has been suggested that a change in the normal circadian rhythm for glucose tolerance, which usually is higher during the latter part of the morning, is altered in people with diabetes. Growth hormone has been suggested as a possible factor. When the dawn phenomenon occurs alone, it may produce only mild hyperglycemia, but when it is combined with the Somogyi effect, it may produce profound hyperglycemia.

Chronic Complications

The chronic complications of diabetes include disorders of the microvasculature (i.e., neuropathies, nephropathies, and retinopathies), macrovascular complications (i.e., coronary artery, cerebrovascular, and peripheral arterial disease), and foot ulcers (Fig. 33-11). The level of chronic complications is determined by the degree of hyperglycemia, duration of diabetes, and ability to control the disease. Chronic complications include disorders of the nervous system, cardiovascular system, eye, foot ulcers, and genitourinary tract.

hyperglycemia is the best-established concomitant factor associated with diabetic complications. The Diabetes Control and Complications Trial (DCCT) and its ongoing long-term observational study, the Epidemiology of Diabetes Interventions and Complications Study (EDIC) conducted in 1441 patients with type 1 diabetes, demonstrated that the incidence of retinopathy, nephropathy, and neuropathy can be reduced by intensive glycemic control. Similar results have been demonstrated by the United Kingdom Prospective Diabetes Study (UKPDS) in 5000 patients with type 2 diabetes. 

Theories of Pathogenesis

The interest among researchers in explaining the causes and development of chronic lesions in a person with diabetes has led to a number of theories. At least three distinct metabolic pathways have been proposed in long-term complications of diabetes: intracellular hyperglycemia and disturbance in polyol pathways, formation of advanced glycation end products, and activation of protein kinase C.

Polyol Pathway. A polyol is an organic compound that contains three or more hydroxyl (OH) groups. The polyol pathway refers to the intracellular mechanisms responsible for changing the number of hydroxyl units on a glucose molecule. In the sorbitol pathway, glucose is transformed first to sorbitol and then to fructose. This process is activated by the enzyme aldose reductase. Although glucose is converted readily to sorbitol, the rate at which sorbitol can be converted to fructose and then metabolized is limited. Sorbitol is osmotically active, and it has been hypothesized that the presence of excess intracellular amounts may alter cell function in the tissues that use this pathway (e.g., lens, kidneys, nerves, blood vessels). In the lens, for example, the osmotic effects of sorbitol cause swelling and opacity. Increased sorbitol also is associated with a decrease in myo-inositol and reduced ATP activity. The reduction of these compounds may contribute to the pathogenesis of neuropathies caused by Schwann cell damage. Aldose reductase inhibitors have been tested with the aim of reducing complications resulting from this pathway; however, to date none of them has been successful.

Formation of Advanced Glycation End Products. Glycoproteins, or what could be called glucose proteins, are normal components of the basement membrane in smaller blood vessels and capillaries. These glycoproteins are also termed advanced glycation end products (AGEs). It has been suggested that the increased intracellular concentration of glucose associated with uncontrolled blood glucose levels in diabetes favors the formation of AGEs. These abnormal glycoproteins are thought to produce structural defects in the basement membrane of the microcirculation and to contribute to eye, kidney, and vascular complications. Some of the altered cellular functions resulting from AGEs are due to binding to specific receptors for AGEs (RAGEs).

Protein Kinase C. Diacylglycerol (DAG) and protein kinase C (PKC) are critical intracellular signaling molecules that can regulate many vascular functions, including permeability, vasodilator release, endothelial activation, and growth factor signaling. Levels of DAG and PKC are elevated in diabetes. Activation of PKC in blood vessels of the retina, kidney, and nerves can produce vascular damage. A PKC inhibitor was previously studied for the treatment of diabetic retinopathy and neuropathy, but showed variable results and is not marketed.

Diabetic Neuropathies

Although the incidence of neuropathies is high among people with diabetes (approximately 50% compared with 2% in the general population and approximately 15% when age >40 years), it is difficult to document exactly how many people are affected by these disorders because of the diversity in clinical manifestations and because the condition often is far advanced before it is recognized. Results of the DCCT study showed that intensive diabetic therapy can reduce the incidence of clinical neuropathy by 60% compared with conventional therapy.

Several types of pathologic changes have been observed in connection with diabetic neuropathies. These include thickening of the walls of the nutrient vessels that supply the nerve, leading to the assumption that vessel ischemia plays a major role in the development of these neural changes. Another finding is a segmental demyelination process that affects the Schwann cell. This demyelination process is accompanied by a slowing of nerve conduction.

Although there are several methods for classifying the diabetic peripheral neuropathies, a simplified system divides them into the somatic and autonomic nervous system neuropathies (Chart 33-2).

Somatic Neuropathy. A distal symmetric polyneuropathy, in which loss of function typically occurs in a stocking-glove pattern, is the most common form of peripheral neuropathy. Somatic sensory involvement usually occurs first, often is bilateral and symmetric, and is associated with diminished perception of vibration, pain, and temperature, particularly in the lower extremities. In addition to the discomforts associated with the loss of sensory or motor function, lesions in the peripheral nervous system predispose a person with diabetes to other complications. The loss of feeling, touch, and position sense increases the risk of falling. Impairment of temperature and pain sensation increases the risk of serious burns and injuries to the feet. Denervation of the small muscles of the foot result in clawing of the toes and displacement of the submetatarsal fat pad anteriorly. These changes, together with joint and connective tissue changes, alter the biomechanics of the foot, increasing plantar pressure and predisposing to development of foot trauma and ulcers.

Painful diabetic neuropathy involves the somatosensory neurons that carry pain impulses. This disorder, which causes hypersensitivity to light touch and
Diabetes Mellitus and the Metabolic Syndrome

CHART 33-2  Classification of Diabetic Neuropathies

Somatic
- Polyneuropathies (bilateral sensory)
  - Paresthesias, including numbness and tingling
  - Impaired pain, temperature, light touch, two-point discrimination, and vibratory sensation
  - Decreased ankle and knee-jerk reflexes
- Mononeuropathies
  - Involvement of a mixed nerve trunk that includes loss of sensation, pain, and motor weakness
- Amyotrophy
  - Associated with muscle weakness, wasting, and severe pain of muscles in the pelvic girdle and thigh

Autonomic
- Impaired vasomotor function
  - Postural hypotension
- Impaired gastrointestinal function
  - Gastric atony
  - Diarrhea, often postprandial and nocturnal
- Impaired genitourinary function
  - Paralytic bladder
  - Incomplete voiding
  - Erectile dysfunction
  - Retrograde ejaculation
- Cranial nerve involvement
  - Extraocular nerve paralysis
  - Impaired pupillary responses
  - Impaired special senses

Diabetic Nephropathies

Diabetic nephropathy, a term used to describe the combination of lesions that occur concurrently in the diabetic kidney, is the leading cause of chronic kidney disease (CKD) in persons starting renal replacement therapy (see Chapter 26).57 Not all people with diabetes develop clinically significant nephropathy; for this reason, attention is focused on risk factors for the development of this complication. Among the suggested risk factors are genetic and familial predisposition, elevated blood pressure, poor glycemic control, smoking, hyperlipidemia, and increased albumin excretion.11,58 Diabetic nephropathy occurs in family clusters, suggesting a familial predisposition, although this does not exclude the possibility of environmental factors shared by siblings. The risk for development of kidney disease is greater among Native Americans, Hispanic Americans (especially Mexican Americans), and African Americans,51,58 The most common kidney lesions in people with diabetes are those that affect the glomeruli. These include capillary basement membrane thickening, diffuse glomerular sclerosis, and nodular glomerulosclerosis, in which the development of nodular lesions in the glomerular capillaries causes impaired blood flow with progressive loss of kidney function and, eventually, renal failure (see Chapter 25). Nodular glomerulosclerosis is thought to occur only in people with diabetes. Changes in the basement membrane in diffuse nodular glomerulosclerosis allow plasma proteins to escape in the urine, causing albuminuria, hypoalbuminemia, edema, and other signs of impaired kidney function.

Kidney enlargement, nephron hypertrophy, and hyperfiltration are early accompaniments of diabetes, reflecting the increased work performed by the kidneys in reabsorbing excessive amounts of glucose. One of the first manifestations of diabetic nephropathy is an increase in urinary albumin excretion, which is defined as a urine protein loss greater or equal to 30 mg/day or an albumin-to-creatinine ratio (A/C ratio) greater or equal to 30 µg/mg (normal <30 µg/mg) from a spot urine collection.58 It is recommended that the A/C ratio be the preferred screen for increased urinary albumin excretion. Both systolic and diastolic forms of hypertension accelerate the progression of diabetic nephropathy. Even moderate lowering of blood pressure can decrease the risk of CKD.11 The estimated glomerular filtration rate (eGFR) should also be monitored on a regular basis.

Measures to prevent diabetic nephropathy or its progression in persons with diabetes include achievement of

occasionally severe “burning pain,” particularly at night, can become physically and emotionally disabling.53

Autonomic Neuropathy. The autonomic neuropathies involve disorders of sympathetic and parasympathetic nervous system function. There may be disorders of vasomotor function, decreased cardiac responses, inability to empty the bladder, gastrointestinal motility problems, and sexual dysfunction.54 Defects in vasomotor reflexes can lead to dizziness and syncope due to postural hypotension when the person moves from the supine to the standing position (see Chapter 18). Incomplete emptying of the bladder predisposes to urinary stasis and bladder infection and increases the risk of renal complications.

Gastrointestinal motility disorders are common in persons with long-standing diabetes. The symptoms vary in severity and include gastroparesis, constipation, diarrhea, and fecal incontinence. Gastroparesis (delayed emptying of stomach) is commonly seen in persons with diabetes.55 The disorder is characterized by complaints of epigastric discomfort, nausea, postprandial vomiting, bloating, and early satiety. Abnormal gastric emptying also jeopardizes the regulation of the blood glucose level. Diarrhea is another common symptom seen mostly in persons with poorly controlled type 1 diabetes and autonomic neuropathy.56 The pathogenesis is thought to be multifactorial. Diabetic diarrhea is typically intermittent, watery, painful, and nocturnal and may be associated with fecal incontinence.

In the male, disruption of sensory and autonomic nervous system function may cause sexual dysfunction (see Chapter 39). Diabetes is the leading pathophysiological cause of erectile dysfunction (ED), and it occurs in both type 1 and type 2 diabetes. Of the 13 million men with diabetes in the United States, 30% to 60% have ED.54
glycemic control, maintenance of blood pressure control (<140/80 mm Hg), prevention or reduction in the level of proteinuria (using angiotensin-converting enzyme inhibitors or angiotensin receptor blockers, or protein restriction in selected patients), treatment of hyperlipidemia, and smoking cessation in people who smoke. 11,15 Smoking increases the risk of CKD in both persons with and without diabetes. People with type 2 diabetes who smoke have a greater risk of increased urinary albumin excretion, and their rate of progression to CKD is approximately twice as rapid as in those who do not smoke. 11

**Diabetic Retinopathies**

Diabetes is the leading cause of acquired blindness in the United States. 38,59 Although people with diabetes are at increased risk for development of cataracts and glaucoma, retinopathy is the most common pattern of eye disease. Diabetic retinopathy is estimated to be the most frequent cause of newly diagnosed blindness among Americans between the ages of 20 and 74 years. 39

Diabetic retinopathy is characterized by abnormal retinal vascular permeability, microaneurysm formation, neovascularization and associated hemorrhage, scarring, diabetic macular edema, and retinal detachment 39 (see Chapter 38). Twenty years after the onset of diabetes, nearly all people with type 1 diabetes and more than 60% of people with type 2 diabetes have some degree of retinopathy. Pregnancy, puberty, and cataract surgery can accelerate these changes. 59 Risk factors associated with diabetic retinopathy are similar to those for other complications. Among the suggested risk factors associated with diabetic retinopathy are poor glycemic control, elevated blood pressure, dyslipidemia, and smoking. The strongest case for control of blood glucose comes from the DCCT/EDIC and UKPDS studies, which demonstrated a reduction in retinopathy with improved glucose control. 49,50

Because of the risk of retinopathy, it is important that people with diabetes have regular dilated eye examinations. The recommendation for follow-up examinations is based on the type of examination that was done and the findings of that examination. People with persistently elevated glucose levels or proteinuria should be examined yearly. 59 Women who are planning a pregnancy should be counseled on the risk of development or progression of diabetic retinopathy. Women with diabetes who become pregnant should be followed closely throughout pregnancy. This does not apply to women in whom GDM develops because such women are not at risk for development of diabetic retinopathy.

People with macular edema, moderate to severe non-proliferative retinopathy, or any proliferative retinopathy should receive the care of an ophthalmologist who is knowledgeable and experienced in the management and treatment of diabetic retinopathy. Methods used in the treatment of diabetic retinopathy include the destruction and scarring of the proliferative lesions with laser photocoagulation. The use of antagonists to growth factors (e.g., vascular endothelial growth factor) administered by intra-vitreal injections also play an important role in the management of diabetic retinopathy, and are considered the gold-standard therapy in diabetic macular edema.

**Macrovascular Complications**

Diabetes mellitus is a major risk factor for atherosclerotic coronary artery disease, cerebrovascular disease, and peripheral vascular disease. The prevalence of these macrovascular complications is increased two- to fourfold in people with diabetes.

Multiple risk factors for macrovascular disease, including obesity, hypertension, hyperglycemia, hyperinsulinemia, hyperlipidemia, altered platelet function, endothelial dysfunction, systemic inflammation (as evidenced by increased CRP), and elevated fibrinogen levels, frequently are found in people with diabetes. There appear to be differences between type 1 and type 2 diabetes in terms of duration and development of macrovascular disease, with type 2 diabetics more commonly manifesting macrovascular disease at the time of diagnosis. This greater prevalence has been attributed to the associated cardiovascular risk factors that are part of the metabolic syndrome and which may have been present for many years before the diagnosis of type 2 diabetes. 19,20

Aggressive management of cardiovascular risk factors should include smoking cessation, lifestyle changes including weight loss, and measures to control blood lipids, hypertension, and blood glucose, as appropriate. 19 Antiplatelet agents (aspirin or clopidogrel) may be prescribed to reduce the threat of blood clots. If treatment is warranted for peripheral arterial disease, the peroneal arteries between the knees and ankles commonly are involved in diabetes, making revascularization difficult.

**Diabetic Foot Ulcers**

Foot problems are common among people with diabetes and may become severe enough to cause ulceration, infection, and, eventually, the need for amputation. 60,61 Foot problems have been reported as the most common complication leading to hospitalization among people with diabetes. They represent the effects of neuropathy and vascular insufficiency. Approximately 60% to 70% of people with diabetic foot ulcers have neuropathy without vascular disease, 15% to 20% have vascular disease, and 15% to 20% have neuropathy and vascular disease. 60

Distal symmetric neuropathy is a major risk factor for foot ulcers. People with sensory neuropathies have impaired pain sensation and often are unaware of the constant trauma to the feet caused by poorly fitting shoes, improper weight bearing, hard objects or pebbles in the shoes, or infections such as athlete’s foot. Neuropathy may prevent people from detecting pain; they are unable to adjust their gait to avoid walking on an area of the foot where pressure is causing trauma and necrosis. Motor neuropathy with weakness of the intrinsic muscles of the foot may result in foot deformities, which lead to focal areas of high pressure. When
the abnormal focus of pressure is coupled with loss of sensation, a foot ulcer can occur. Common sites of trauma are the back of the heel, the plantar metatarsal area, or the great toe, where weight is borne during walking (Fig. 33-12).

All persons with diabetes should receive a full foot examination at least once a year. This examination should include assessment of protective sensation, foot structure and biomechanics, vascular status, and skin integrity.\(^6\) Evaluation should include a somatosensory test using the Semmes-Weinstein monofilament, a simple, inexpensive device for testing loss of protective sensation (Fig. 33-13). The monofilament is held in the hand or attached to a handle at one end. When the unattached or unsupported end of the monofilament is pressed against the skin until it buckles or bends slightly, it delivers 10 g of pressure at the point of contact.\(^6\) The person tested reports when he or she is being touched by the monofilament. Usually four sites per foot are touched. An incorrect response at even one site indicates loss of protective sensation and increased risk of ulceration.

Because of the constant risk of foot problems, it is important that people with diabetes wear shoes that have been fitted correctly and inspect their feet daily, looking for blisters, open sores, and fungal infection (e.g., athlete's foot) between the toes. If their eyesight is poor, a family member should do this for them. In the event a lesion is detected, prompt medical attention is needed to prevent serious complications. Specially designed shoes have been demonstrated to be effective in preventing relapses in people with previous ulcerations.\(^6\) Because cold produces vasoconstriction, appropriate foot coverings should be used to keep the feet warm and dry. Toenails should be cut straight across to prevent ingrown toenails. The toenails often are thickened and deformed, requiring the services of a podiatrist. Smoking should be avoided because it causes vasoconstriction and contributes to vascular disease.

Cardiovascular risk factors should be addressed in patients with diabetic foot ulcers and peripheral arterial disease. Ulcers that are resistant to standard therapy may respond to application of growth factors. Growth factors provide a means by which cells communicate with each other and can have profound effects on cell proliferation, migration, and extracellular matrix synthesis. For example, becaplermin, a topical preparation of recombinant human platelet-derived growth factor, is used in the treatment of neuropathic lower extremity ulcers.

**Infections**

Although not specifically an acute or a chronic complication, infections are a common concern of people with diabetes. Certain types of infections occur with increased frequency in people with diabetes: soft tissue infections of the extremities, osteomyelitis, urinary tract infections and pyelonephritis, candidal infections of the skin and mucous surfaces, dental caries and periodontal disease, and tuberculosis.\(^62,63\) Moreover, infections often are more serious in people with diabetes.

Suboptimal response to infection in a person with diabetes is caused by the presence of chronic complications, such as vascular disease and neuropathies, and by the presence of hyperglycemia and altered neutrophil function. Sensory deficits may cause a person with diabetes to ignore minor trauma and infection, and vascular disease may impair circulation and delivery of blood cells and other substances needed to produce an adequate inflammatory response and effect healing. Pyelonephritis and urinary tract infections are relatively common in persons with diabetes, and it has been suggested that these infections may bear some relation to the presence of a neurogenic bladder or nephrosclerotic changes in the kidneys. Hyperglycemia and glycosuria (including treatment with SGLT2 inhibitors) may influence the growth of microorganisms and increase the severity of the infection. Diabetes and elevated

**FIGURE 33-12.** Neuropathic ulcers occur on pressure points in areas with diminished sensation in diabetic polyneuropathy. Pain is absent (and therefore the ulcer may go unnoticed). (From Bates BB. A Guide to Physical Examination and History Taking. 6th ed. Philadelphia, PA: J.B. Lippincott; 1995.)

**FIGURE 33-13.** Use of a monofilament in testing for impaired sensation in the foot of a person with diabetes.
blood glucose levels also may impair host defenses such as the function of neutrophils and immune cells. Polymorphonuclear leukocyte function, particularly adherence, chemotaxis, and phagocytosis, is depressed in persons with diabetes, particularly those with poor glycemic control.

**SUMMARY CONCEPTS**

- Diabetes mellitus is a disorder of carbohydrate, protein, and fat metabolism resulting from an imbalance between insulin availability and insulin need. In type 1 diabetes, there is destruction of beta cells and an absolute insulin deficiency. Type 2 diabetes is characterized by a lack of insulin availability or effectiveness. Diabetes can also occur secondary to some other condition that destroys beta cells (e.g., pancreatic disorders) or endocrine diseases that cause increased production of glucose by the liver and decreased use of glucose by the tissues (e.g., Cushing syndrome). Gestational diabetes develops during pregnancy.

- The metabolic syndrome represents a constellation of metabolic abnormalities characterized by obesity, insulin resistance, high triglyceride levels and low HDL levels, hypertension, cardiovascular disease, and increased risk for development of type 2 diabetes.

- The most commonly identified symptoms of type 1 diabetes are polyuria, polydipsia, polyphagia, and weight loss despite normal or increased appetite. Although persons with type 2 diabetes may present with one or more of these symptoms, they are often asymptomatic initially. The diagnosis of diabetes mellitus is based on clinical signs of the disease, fasting blood glucose levels, random plasma glucose measurements, and results of the glucose tolerance test. Glycosylation involves the irreversible attachment of glucose to the hemoglobin molecule; the measurement of glycated hemoglobin (A1C) provides an index of blood glucose levels over several months. Self-monitoring of capillary blood glucose provides a means of maintaining near-normal blood glucose levels through adjustment of insulin dosage.

- Dietary management of diabetes focuses on maintaining a well-balanced diet, controlling calories to achieve and maintain an optimum weight, and regulating the distribution of carbohydrates, proteins, and fats.

- Pharmacologic agents used in the management of diabetes include injectable insulin, injectable non-insulin agents including amylin and GLP-1 analogs, and oral diabetic drugs. Type 1 diabetes (and sometimes type 2 diabetes) requires treatment with injectable insulin. Oral antidiabetic drugs include the insulin secretagogues, biguanides, α-glucosidase inhibitors, thiazolidinediones, and incretin-based therapies. These drugs require a functioning pancreas and may be used in the treatment of type 2 diabetes.

- The metabolic disturbances associated with diabetes affect almost every bodily system. The acute complications of diabetes include diabetic ketoacidosis, hyperglycemic hyperosmolar state, and hypoglycemia in people with insulin-treated diabetes. The chronic complications of diabetes affect the microvascular system (including the retina, kidneys, and peripheral nervous system) and the macrovascular system (coronary, cerebrovascular, and peripheral arteries). The diabetic foot is usually a combination of both microvascular and macrovascular dysfunction. Infection is also a frequent occurrence and is more likely to be severe in the diabetic patient.

**REVIEW EXERCISES**

1. A 6-year-old boy is admitted to the emergency department with nausea, vomiting, and abdominal pain. He is very lethargic; his skin is warm, dry, and flushed; his pulse is rapid; and he has a sweet smell to his breath. His parents relate that he has been very thirsty during the past several weeks, his appetite has been poor, and he has been urinating frequently. His initial plasma glucose is 420 mg/dL (23.1 mmol/L), and a urine test for ketones is strongly positive.

   **A.** What is the most likely cause of this boy’s elevated blood glucose and ketonuria?

   **B.** Explain his presenting signs and symptoms in terms of the elevated blood glucose and metabolic acidosis.

   **C.** What type of treatment will this boy require?

2. A 53-year-old accountant presents for his routine yearly examination. His history indicates that on two prior occasions he had a fasting plasma glucose of 120 mg/dL (6.7 mmol/L). Currently he is asymptomatic. He has no other medical problems and does not use any medications. He neither smokes nor drinks alcohol. His father was diagnosed with type 2 diabetes at age 60 years. His physical examination reveals a blood pressure of 125/80 mm Hg.
BMI of 32 kg/m², and waist circumference of 45 inches (114 cm). Complete blood count (CBC), thyroid-stimulating hormone (TSH), and alanine aminotransferase (ALT) are within normal limits. The lipid panel shows that his HDL cholesterol (30 mg/dL [0.8 mmol/L]) and LDL cholesterol (136 mg/dL [3.5 mmol/L]) are within the normal range, and triglycerides are elevated (290 mg/dL [2.3 mmol/L]); normal is <165 mg/dL [1.9 mmol/L]).

A. What is this man’s probable diagnosis?
B. Based on this man’s blood glucose level and the ADA diabetes classification system, what glucose intolerance status would you place this man in? Does he need a 75-g OGTT for further assessment of his IFG?
C. His OGTT test result reveals a 2-hour glucose value of 175 mg/dL (9.6 mmol/L). What is the diagnosis? What type of treatment would be appropriate for this man?

REFERENCES

The nervous system, in coordination with the endocrine system, provides the means by which cell and tissue functions are integrated into an independent, living organism. It controls skeletal muscle movement and helps to regulate cardiac and visceral smooth muscle activity; it enables the reception, integration, and perception of sensory information; it provides the substratum necessary for intelligence, anticipation, and judgment; and it facilitates adjustment to an ever-changing external environment.

**Nervous Tissue Cells**

Anatomically, the nervous system can be divided into two basic components: the central and peripheral nervous systems. The *central nervous system* (CNS) consists of the brain and spinal cord, which are protected by the skull and vertebral column. The *peripheral nervous system* (PNS) includes the neurons outside the CNS (cranial nerves and their ganglia, and spinal nerves and their ganglia), which connect the brain and spinal cord with peripheral structures. Inherent in the basic design of the nervous system is the provision for the concentration of computational and control functions in the CNS, with the PNS relaying somatic and visceral sensory (afferent) input to the CNS for processing and transmitting efferent or motor output from the CNS to effector organs throughout the body (Fig. 34-1).
Functionally, the nervous system is divided into two systems: the somatic and autonomic nervous systems. The somatic (Greek soma, “body”) nervous system provides sensory and motor innervation for all parts of the CNS and PNS except viscera, smooth muscle, and glands. The autonomic nervous system (ANS) provides efferent innervation to smooth muscle in blood vessels and visceral structures, the conduction system of the heart, the sweat glands, and the exocrine glands of the gastrointestinal tract.

Nervous tissue consists of two principal types of cells—neurons and neuroglia or supporting cells. The neurons are the functional cells of the nervous system. They exhibit membrane excitability and conductivity and secrete neurotransmitters (signal-transmitting chemicals) and hormones, such as epinephrine and antidiuretic hormone (ADH). The neuroglial cells, such as the Schwann cells in the PNS and the oligodendrocytes in the CNS, protect the nervous system and provide metabolic support for the neurons.

**Neurons**

A typical neuron has three distinct parts: a cell body, dendrites, and an axon. The axonal and dendritic processes form the functional connections, or synapses, with other nerve cells, receptor cells, or effector cells. Afferent, or sensory, neurons of the PNS transmit information to the CNS (see Fig. 34-1A), whereas efferent, or motor, neurons carry information away from the CNS (see Fig. 34-1B). Interspersed between the afferent and efferent neurons is a network of interconnecting neurons (also called interneurons or internuncial neurons) that modulate and control the body’s response to changes in the internal and external environments.

The cell body of a neuron, also known as the soma, contains a large vesicular nucleus with one or more distinct nucleoli and a well-developed rough endoplasmic reticulum. A neuron’s nucleus has the same deoxyribonucleic acid (DNA) and genetic information that is present in other cells of the body, and its nucleolus produces the ribonucleic acid (RNA) associated with protein synthesis. The cytoplasm contains large masses of ribosomes that are prominent in most neurons. These RNA masses, which are involved in protein synthesis, stain as dark Nissl bodies (see Fig. 34-1B). The Nissl bodies and free ribosomes extend into the dendrites, but not into the axon. The area of the cell body, called the axon hillock, is free of large cytoplasmic organelles and serves as a landmark to distinguish between axons and dendrites in microscopic preparations.

The dendrites (from the Greek dendron, “tree”) are multiple, branched extensions of the nerve cell body; they conduct information toward the cell body and are the main source of information for the neuron. The dendrites and cell body are studded with synaptic terminals that communicate with axons and dendrites of other neurons (see Fig. 34-1A).

Axons are long efferent processes that project from the cell body and carry impulses away from the cell. Most neurons have only one axon; however, axons may exhibit multiple branching that results in many axonal terminals. The cytoplasm of the cell body extends to fill
the dendrites and the axon. The proteins and other materials used by the axon are synthesized in the cell body and then flow down the axon through its cytoplasm.

The cell body of the neuron is equipped for a high level of metabolic activity. This is necessary because the cell body must synthesize the cytoplasmic and membrane constituents required to maintain the function of the axon and its terminals. Some of these axons extend for a distance of 1 to 1.5 m and have a volume that is 200 to 500 times greater than the cell body itself. Two axonal transport systems, one slow and one rapid, move molecules from the cell body through the cytoplasm of the axon to its terminals. Replacement proteins and nutrients slowly diffuse from the cell body, where they are transported down the axon, moving at the rate of approximately 1 mm/day. Other molecules, such as neurosecretory granules (e.g., neurotransmitters and neurohormones) or their precursors, are conveyed by a rapid, energy-dependent active transport system, moving at the rate of approximately 400 mm/day. For example, antidiuretic hormone (ADH) and oxytocin, which are synthesized by neurons in the hypothalamus, are carried by rapid axonal transport to the posterior pituitary, where the hormones are released into the bloodstream. A reverse (retrograde) axonal transport is responsible for moving molecules destined for degradation from the axon back to the cell body, where they are broken down.

**Neuroglial Cells**

The neuroglial, or supporting cells, which outnumber neurons 10 to 1, provide support and protection for neurons in both CNS and PNS. Although they do not participate directly in the short-term communication of information through the nervous system, the supporting cells segregate the neurons into isolated metabolic compartments, which are required for normal neural function.

The neuroglial cells in the PNS include the Schwann cells and satellite cells. The CNS has four types of glial cells: astrocytes, oligodendrocytes (oligodendroglia), microglia, and ependymal cells. Two of these cell types share a similar function: The Schwann cells of the PNS and the oligodendrocyte of the CNS wrap nerve axons in multiple layers, producing myelin sheaths that serve to increase the velocity of nerve impulse conduction in axons (see Fig. 34-1B, inset). Myelin has a high lipid content, which gives it a whitish color, and hence the name white matter is given to the masses of myelinated axons of the spinal cord and brain. Besides its role in increasing conduction velocity, the myelin sheath is essential for the survival of larger neuronal processes, perhaps by secreting neurotrophic compounds. In some pathologic conditions, such as multiple sclerosis in the CNS and Guillain-Barré syndrome involving the PNS, the myelin may degenerate or be destroyed, leaving a section of the axonal process without myelin while leaving the nearby Schwann or oligodendroglial cells intact. Unless remyelination takes place, the axon eventually dies.

**Neuroglial Cells of the Peripheral Nervous System**

The Schwann cells and satellite cells provide support and protection for the PNS. Schwann cells produce the myelin sheath that isolates nerve axons in the PNS from the surrounding extracellular compartment, ensuring rapid conduction of nerve impulses. They also aid in cleaning up PNS debris and guide the regrowth of PNS nerve fibers. During the process of myelination, the Schwann cell wraps around each nerve fiber several times in a "jelly roll" fashion (Fig. 34-2). Successive Schwann cells are separated by short extracellular fluid-filled gaps, called the nodes of Ranvier, where the myelin is missing and voltage-gated sodium channels are concentrated. The nodes of Ranvier increase the speed of nerve conduction by allowing the impulse to jump from node to node through the extracellular fluid in a process called saltatory conduction. In this way, the impulse can travel more rapidly than it could if it was required to move systematically along the entire nerve fiber. This increased conduction velocity greatly reduces reaction time, or time between the application of a stimulus and the subsequent motor response. The short reaction time is especially important in peripheral nerves with long distances for conduction between the CNS and distal effector organs.
Each of the Schwann cells along a peripheral nerve fiber is encased in a continuous tube of basement membrane, which in turn is surrounded by a multilayered sheath of loose connective tissue known as the endoneurium (see Fig. 34-2). The endoneurial sheath, which is essential to the regeneration of peripheral nerves, provides a collagenous tube through which a regenerating axon can again reach its former target. The endoneurial sheath does not penetrate the CNS. The absence of the endoneurial sheaths is thought to be a major factor in the limited axonal regeneration of CNS nerves compared with those of the PNS.

The endoneurial sheaths are bundled with blood vessels into small clusters of nerves called fascicles. In the nerve, fascicles consisting of bundles of nerve fibers are surrounded by another protective covering called the perineurium. Usually, several fascicles are further surrounded by the heavy, protective epineurial sheath of the peripheral nerve. The protective layers that surround the peripheral nerve processes are continuous with the connective tissue capsule of the sensory nerve endings and the connective tissue that surrounds the effector structures, such as the skeletal muscle cell. Centrally, the connective tissue layers continue along the dorsal and ventral roots of the nerve and fuse with the meninges that surround the spinal cord and brain.

Satellite cells are a type of neuroglial cell that surround the cell body of neurons in the PNS, including those with ganglia. They have been found to serve a variety of roles, including control over the microenvironment of sympathetic ganglia. Satellite cells are thought to have a role similar to that of astrocytes in the CNS. They supply nutrients to the surrounding neurons, and they also act as protective, cushioning cells.

**Neuroglial Cells of the Central Nervous System**

The neuroglial cells of the CNS consists of four types of cells: oligodendrocytes, astrocytes, microglia, and ependymal cells (Fig. 34-3). The oligodendrocytes form the myelin in the CNS. Instead of forming a myelin covering for a single axon, these cells reach out with several processes, each wrapping around and forming a multilayered myelin segment around several different axons. As within the PNS, the covering of axons in the CNS increases the velocity of nerve conduction.

**Astrocytes** are the largest and most numerous of neuroglia and are particularly prominent in the gray matter of the CNS. They form a network within the CNS and communicate with neurons to support and modulate their activities. Astrocytes have many processes, some stretching their processes from blood vessels to neurons and others filling most of the intercellular space within the CNS. It is now thought that astrocytes play an important role in the movement of metabolites and wastes to and from neurons and regulate ionic concentrations in the intercellular compartment. In addition, astrocytes take up neurotransmitters from synaptic zones after their release and thereby help regulate synaptic activity. They also have a role in maintaining the tight junctions of capillaries that form the blood-brain barrier. Astrocytes are also the principal cells responsible for repair and scar formation in the brain. They can fill their cytoplasm with microfibrils (i.e., fibrous astrocytes), and masses of these cells form the special type of scar tissue that develops in the CNS when tissue is destroyed, a process called gliosis.

A third type of neuroglia, the microglia, are the resident macrophages of the central nervous system. They are available for cleaning up debris after cellular damage, infection, or cell death. The fourth type
of cell, the ependymal cell, forms the lining of the neural tube cavity, the ventricular system. In some areas, these cells combine with a rich vascular network to form the choroid plexus, where production of the cerebrospinal fluid (CSF) takes place.

Metabolic Requirements of Nervous Tissue

Nervous tissue has a high rate of metabolism. Although the brain makes up only 2% of the body's weight, it receives approximately 15% of the resting cardiac output and consumes 20% of its oxygen. Despite its substantial metabolic requirements, the brain can neither store oxygen nor engage in anaerobic metabolism. An interruption in the blood or oxygen supply to the brain rapidly leads to clinically observable signs and symptoms. Without oxygen, brain cells continue to function for approximately 10 seconds. Unconsciousness occurs almost simultaneously with cardiac arrest, and the death of brain cells begins within 4 to 6 minutes. Interruption of blood flow also leads to the accumulation of metabolic by-products that are toxic to neural tissue.

Glucose is the major fuel source for the nervous system. Unlike muscle cells, neurons have no glycogen stores and must rely on glucose from the blood or the glycogen stores of supporting glial cells to meet their energy needs. Persons receiving insulin for diabetes may experience signs of neural dysfunction and unconsciousness (i.e., insulin reaction or shock) when blood glucose drops because of insulin excess (see Chapter 33).

SUMMARY CONCEPTS

- Anatomically, the nervous system can be divided into two basic components: the central nervous system (CNS), consisting of the brain and spinal cord; and the peripheral nervous system (PNS), which relays afferent or sensory input to the CNS for processing and transmitting efferent or motor output from the CNS to effector organs throughout the body.
- The nervous system contains two major types of cells: neurons, which are functioning cells of the nervous system, and neuroglial cells, which protect the nervous system and supply metabolic support.
- Neurons (nerve cells), which are the functional components of the nervous system, are composed of three parts: a cell body, which controls cell activity; dendrites, which conduct information toward the cell body; and an axon, which carries impulses from the cell body.
- The neuroglial cells that provide support and protection for the neurons consist of the Schwann and satellite cells of the PNS and the oligodendrocytes, astrocytes, microglial cells, and ependymal cells of the CNS. The Schwann cells of the PNS and the oligodendrocytes of the CNS form the myelin sheath that allows for rapid conduction of impulses.
- The nervous system has a high level of metabolic activity, requiring a continuous supply of oxygen and glucose. Although the brain makes up only 2% of the body's weight, it receives approximately 15% of the resting cardiac output and consumes 20% of its oxygen.

Nerve Cell Communication

Neurons are characterized by their ability to communicate with other neurons and body cells through electrical impulses or action potentials, which are abrupt, pulsatile changes in the membrane potential that last a few ten thousandths to a few thousandths of a second. The frequency and pattern of action potentials constitute the code used by neurons to transfer information from one location to another.

Action Potentials

The cell membranes of excitable tissue, including those of nerve and muscle cells, contain ion channels that are responsible for generating action potentials (see Chapter 1, Understanding Membrane Potentials). These ion channels are guarded by voltage-dependent gates that open and close with changes in the membrane potential. Separate voltage-gated channels exist for the sodium, potassium, and calcium ions. Each type of ion channel has a characteristic membrane potential that opens and closes its channels. Also present are ligand-gated channels that respond to chemical messengers such as neurotransmitters, mechanically gated channels that respond to physical changes in the cell membrane, and light-gated channels that respond to fluctuations in light levels.

Action potentials can be divided into three phases: the resting or polarized state, depolarization, and repolarization (Fig. 34-4). The resting membrane potential (approximately −90 mV for large nerve fibers) is the undisturbed period of the action potential during which the nerve is not transmitting impulses. During this period, the membrane is said to be “polarized” because of the −90 mV negative membrane potential (i.e., positive on the outside and negative on the inside) that is present. The resting phase of the membrane potential continues until some event causes the membrane to increase its permeability to sodium. A threshold potential
**Synaptic Transmission**

Neurons communicate with each other through structures known as synapses. There are two types of synapses in the nervous system: electrical and chemical. Electrical synapses permit the passage of current-carrying ions through small openings called gap junctions that penetrate the cell junction of adjoining cells. Although not important in synaptic transmission in the nervous system, gap junctions are important in cell-to-cell communication in smooth and cardiac muscle.

Chemical synapses, which are the more common type of synapse, involve special presynaptic and postsynaptic membrane structures, separated by a synaptic cleft. The presynaptic terminal secretes one and often several chemical transmitter molecules (e.g., neurotransmitters, neuromodulators). The secreted neurotransmitters diffuse into the synaptic cleft and bind to receptors on the postsynaptic membrane. In contrast to an electrical synapse, a chemical synapse permits only one-way communication. Chemical synapses are divided into two types: excitatory and inhibitory. In excitatory synapses, binding of the neurotransmitter to the receptor produces depolarization of the postsynaptic membrane; and in inhibitory synapses it reduces the postsynaptic neuron’s ability to generate an action potential.

The process of neurotransmission involves the synthesis, storage, and release of a neurotransmitter; the reaction of the neurotransmitter with a receptor; and termination of the receptor action. Neurotransmitters are synthesized in the cytoplasm of the axon terminal. The synthesis of transmitters may require one or more enzyme-catalyzed steps (e.g., one for acetylcholine and three for norepinephrine). Each neuron generally produces only one type of neurotransmitter. After synthesis, the neurotransmitter molecules are stored in the axon terminal in tiny, membrane-bound sacs called synaptic vesicles.
These vesicles protect the neurotransmitters from enzyme destruction in the nerve terminal. There may be thousands of vesicles in a single terminal, each containing 10,000 to 100,000 transmitter molecules. Membrane depolarization due to arrival of an action potential causes the vesicles to move to the cell membrane and release their neurotransmitter molecules by fusion of the vesicular membrane with the outer cell membrane.

Once a neurotransmitter has exerted its effects on the postsynaptic membrane, its rapid removal is necessary to maintain precise control of neural transmission. A released transmitter can: (1) be broken down into inactive substances by enzymes, (2) be taken back up into the presynaptic neuron in a process called reuptake, or (3) diffuse away into the intercellular fluid until its concentration is too low to influence postsynaptic excitability. For example, acetylcholine is rapidly broken down by acetylcholinesterase into acetic acid and choline, with the choline being taken back into the presynaptic neuron for reuse in acetylcholine synthesis. The catecholamines are largely taken back into the neuron in an unchanged form for reuse. Catecholamines also can be degraded by enzymes, such as catechol-O-methyltransferase (COMT) in the synaptic space or monoamine oxidase (MAO) in the nerve terminals. Catechol-O-methyltransferase inhibitors and MAO inhibitors are used in the treatments of various conditions, such as Parkinson disease, major depression, and anxiety (see the Autonomic Neurotransmission section for detail).

**Postsynaptic Potentials**

A neuron’s cell body and dendrites are covered by thousands of synapses, any or many of which can be active at any moment. Because of the interaction of this rich synaptic input, each neuron resembles a little computer, in which circuits of many neurons interact with one another. It is the complexity of these interactions and the subtle integrations involved in excitatory and inhibitory responses that give rise to the nervous system’s intelligence.

Neurotransmitters exert their actions through specific proteins, called receptors, embedded in the postsynaptic membrane. These receptors are tailored precisely to match the size and shape of the transmitter. In each case, the interaction between a neurotransmitter and receptor causes the opening or closing of ion channels in the postsynaptic membrane, resulting in a transient, local change in the polarization of the postsynaptic membrane, called a postsynaptic potential. There are two types of postsynaptic potentials: excitatory and inhibitory. If opening of the ion channel results in a net gain of positive charge across the membrane, causing the potential to move close to zero, the membrane is said to be depolarized. This is called an excitatory postsynaptic potential, since it brings the resting potential closer to its firing threshold. If, on the other hand, opening of the ion channel results in a net gain of negative charge causing the potential to move further from zero, the membrane is said to be hyperpolarized. This is called an inhibitory postsynaptic potential, since it causes the resting membrane potential to move further from threshold.

**Chemical Synaptic Transmission**

The function of the nervous system relies on chemical substances that serve as synaptic messengers. These messengers include neurotransmitters, neuromodulators, and neurotrophic or nerve growth factors.

**Neurotransmitters.** Neurotransmitters are endogenous chemicals that facilitate the transmission of signals from one neuron to the next across synapses. There are many different ways to classify neurotransmitters, including by whether they produce excitatory or inhibitory effects on postsynaptic membranes and by their chemical structure. A neurotransmitter is classified as excitatory if it activates a receptor; for example, glutamate, the most common excitatory neurotransmitter in the brain, increases the probability that the target cell will fire an action potential. A neurotransmitter is classified as inhibitory if it inhibits a receptor; gamma aminobutyric acid (GABA) is the brain’s main inhibitory neurotransmitter. There are, however, other neurotransmitters for which both excitatory and inhibitory receptors exist; for example, acetylcholine is excitatory when it binds to a receptor at a myoneural junction, and it is inhibitory when it binds to a receptor at the sinoatrial node in the heart. Finally, some types of receptors activate complex metabolic pathways in the postsynaptic cell to produce effects that cannot appropriately be called either excitatory or inhibitory. Receptors are named according to the type of neurotransmitter with which they interact. For example, a cholinergic receptor is a receptor that binds acetylcholine.

In addition to function, neurotransmitters can be broadly categorized into three groups according to their chemical structure: (1) amino acids, (2) peptides, and (3) monoamines. Amino acids, such as glutamine, glycine, and GABA, serve as neurotransmitters at most CNS synapses. GABA mediates most synaptic inhibition in the CNS. Drugs such as the benzodiazepines (e.g., the tranquilizer diazepam) and the barbiturates exert their action by binding to their own distinct receptor on a GABA-operated ion channel. The drugs by themselves do not open the channel, but they change the effect that GABA has when it binds to the channel at the same time as the drug. Peptides are low–molecular-weight molecules that are made up of two or more amino acids. Neuropeptides are peptides used by neurons to communicate with each other. They include somatostatin, substance P, and opioid peptides such as endorphins and enkephalins, which are involved in pain sensation and perception (see Chapter 35). A monoamine is an amine molecule containing one amino group (–NH₂ group). All monoamines are derived from aromatic amino acids like phenylalanine, tyrosine, and tryptophan. Serotonin, dopamine, norepinephrine, and epinephrine are examples in this category.

**Neuromodulators.** Another class of messenger molecules, known as neuromodulators, also may be released from axon terminals. In contrast to neurotransmitters, neuromodulators do not directly activate ion-channel
Neurons communicate with each other through chemical synapses and the use of neurotransmitters. Chemical synapses consist of a presynaptic neuron, a synaptic cleft, and a postsynaptic neuron. The communication process relies on (1) synthesis and release of the neurotransmitter from a presynaptic neuron, (2) binding of the neurotransmitter to receptors in the postsynaptic neuron, and (3) removal of the neurotransmitter from the receptor site.

**1 Neurotransmitter Synthesis and Release.** Neurotransmitters are synthesized in the presynaptic neuron, then stored in synaptic vesicles. Communication between the two neurons begins with a nerve impulse that stimulates the presynaptic neuron, followed by movement of the synaptic vesicles to the cell membrane and release of neurotransmitter into the synaptic cleft.

**2 Receptor Binding.** Once released from the presynaptic neuron, the neurotransmitter moves across the synaptic cleft and binds to receptors on the postsynaptic neuron. The action of a neurotransmitter is determined by the type of receptor (excitatory or inhibitory) to which it binds. Binding of a neurotransmitter to a receptor with an excitatory function often results in the opening of an ion channel, such as the sodium channel. Many presynaptic neurons also have receptors to which a neurotransmitter binds. The presynaptic receptors function in a negative feedback manner to inhibit further release of the neurotransmitter.
Neurotransmitter Removal. Precise control of synaptic function relies on the rapid removal of the neurotransmitter from the receptor site. A released neurotransmitter can (1) be taken back up into the neuron through reuptake, (2) diffuse out of the synaptic cleft, or (3) be broken down by enzymes into inactive substances or metabolites. The action of norepinephrine is largely terminated by the reuptake process, in which the neurotransmitter is taken back into the neuron in an unchanged form and reused. It can also be broken down by enzymes in the synaptic cleft or in the nerve terminals. The neurotransmitter acetylcholine is rapidly broken down by the enzyme acetylcholinesterase.

(text continued from page 827)

receptors, but bring about long-term changes that subtly enhance or depress the action of the receptors. Neuromodulators, such as dopamine, serotonin, acetylcholine, histamine, and others, may act at either presynaptic or postsynaptic sites. They may act on postsynaptic receptors to produce slower and longer-lasting changes in membrane excitability, by enhancing or decreasing the action of faster-acting neurotransmitter molecules. By combining with autoreceptors on its own presynaptic membrane, a transmitter can act as a neuromodulator by augmenting or inhibiting further nerve activity. In some nerves, such as the peripheral sympathetic nerves, a messenger molecule can have both transmitter and modulator functions. For example, norepinephrine can activate an $\alpha_1$-adrenergic postsynaptic receptor to produce vasoconstriction or stimulate an $\alpha_2$-adrenergic presynaptic receptor to inhibit further norepinephrine release.

Neurotrophic Factors. Neurotrophic factors, also known as neurotrophins, are a family of polypeptide growth factors that influence the proliferation, differentiation, and survival of neuronal and nonneuronal cells. Neurotrophins are secreted by axon terminals independent of action potentials. Examples include neuron-to-neuron trophic factors in the sequential synapses of CNS sensory neurons. Trophic factors from target cells that enter the axon and are necessary for the long-term survival of presynaptic neurons also have been demonstrated. Alterations in neurotrophin levels have been implicated in neurodegenerative disorders such as Alzheimer disease and Huntington disease, as well as psychiatric disorders such as depression and substance abuse.

SUMMARY CONCEPTS

- Neurons communicate with other neurons and body cells through electrical signals in their membrane called action potentials. Action potentials are divided into three parts: (1) the resting membrane potential, during which the membrane is polarized (positively charged on the outside of the membrane and negatively charged on the inside); (2) the depolarization phase, during which sodium channels open, allowing rapid inflow of the charged sodium ions that generate the electrical impulse; and (3) the repolarization phase, during which the outflow of potassium ions returns the membrane to its resting potential.
- Neurotransmission or communication relies on chemical messengers or neurotransmitters, released from the presynaptic neuron, that cross the synaptic cleft and then interact with receptors on the postsynaptic neuron.

(continued)
SUMMARY CONCEPTS (continued)

- Neurotransmitters can produce either excitatory or inhibitory effects and can be broadly categorized into three groups based on their chemical structure: (1) amino acids (e.g., glutamic acid, glycine, and GABA) that serve as neurotransmitters at most CNS synapses; (2) peptide neurotransmitters (e.g., endorphins and enkephalins) that are involved in pain perception and sensation; and (3) monoamines (e.g., epinephrine and norepinephrine) that serve as neurotransmitters for the ANS.

- Neuromodulators bring about long-term changes that subtly enhance or depress the action of target receptors. Neurotrophic factors are polypeptides that influence the proliferation, differentiation, and survival of neuronal and nonneuronal cells. They are secreted by axon terminals.

Developmental Organization of the Nervous System

The organization of the nervous system can be understood in terms of its embryonic development, in which newer functions and greater complexity result from the modification and enlargement of earlier developed structures. Thus, the rostral or front end of the CNS, which is the last to develop, is more specialized in its functions than the caudal or tail end structures, namely the brain stem and spinal cord, which are the first to develop. The dominance of the rostral end of the CNS is reflected in what has been termed a hierarchy of control, with the forebrain having control over the brain stem and the brain stem having control over the spinal cord. In the developmental process, newer functions were added to the surface of earlier developed systems. As newer functions were added to the surface of earlier developed systems and became concentrated at the rostral end of the CNS, they also became more vulnerable to injury. Nothing exemplifies this principle better than the persistent vegetative state (discussed in Chapter 37) that occurs when severe brain injury causes irreversible damage to higher cortical centers, while lower brain stem centers such as those that control breathing remain functional.

Embryonic Development

The nervous system appears very early in embryonic development (22 to 23 days). This early development is essential because it influences the development and organization of many other body systems, including the axial skeleton, skeletal muscles, and sensory organs such as the eyes and ears. Throughout life, the organization of the nervous system retains many patterns that were established during embryonic life.

During the 2nd week of development, embryonic tissue consists of two layers, the endoderm and the ectoderm. At the beginning of week 3, the ectoderm begins to invaginate and migrates between the two layers, forming a third layer called the mesoderm (Fig. 34-5). Mesoderm along the entire midline of the embryo forms a specialized rod of embryonic tissue called the notochord. The notochord and adjacent mesoderm provide the necessary induction signal for the overlying neuroectoderm to differentiate and form a thickened structure called the neural plate. Within the neural plate a groove develops and sinks into the underlying mesoderm. Its walls fuse across the top, forming an ectodermal tube called the neural tube. The neuroectoderm of the neural plate gives rise to the brain and spinal cord of the CNS, while the notochord becomes the foundation around which the vertebral column develops. The surface ectoderm separates from the neural tube and fuses over the top to become the outer layer of skin.

This process involved in the formation of the neural plate and neural folds and closure of the folds begins at the cervical and high thoracic levels and zippers both rostrally and caudally. Complete closure occurs at the rostral-most end of the brain around day 25 and at about day 27 in the lumbosacral region. Most congenital defects, such as spina bifida, result from failure of fusion of one or more neural arches of the developing vertebral column during the fourth week of embryonic development.

As the neural tube closes, ectodermal cells called neural crest cells migrate away from the dorsal surface of the neural tube to become the progenitors or parent cells of the neurons and neuralgial cells of the PNS. Some of these cells gather into clusters to form the dorsal root ganglia at the sides of each spinal cord segment and the cranial ganglia that are present in most brain segments. Neurons of these ganglia become the afferent or sensory neurons of the PNS. Other neural crest cells become the pigment cells of the skin or contribute to the formation of many structures of the face, certain cells of the autonomic nervous system, and other structures.

During development, the more rostral (toward the head) portions of the embryonic neural tube—approximately 10 segments—undergo extensive modification and enlargement to form the brain (Fig. 34-6). In the early embryo, 3 swellings, or primary vesicles, develop, subdividing these 10 segments into the forebrain, containing the first 2 segments; the midbrain, which develops from segment 3; and the hindbrain, which develops from segments 4 to 10. In the prosencephalon or forebrain, two pairs of lateral outpouchings develop: the optic cup, which becomes the optic nerve and retina, and the telencephalic vesicles, which become the cerebral hemispheres. Within the prosencephalon, the hollow central canal expands to become enlarged...
CSF-filled cavities, the first and second (lateral) ventricles. The remaining diencephalic portion of the neural tube develops into the thalamus and hypothalamus. The neurohypophysis (posterior pituitary) grows as a midline ventral outgrowth at the junctions of segments 1 and 2. A dorsal outgrowth, the pineal body, develops between segments 2 and 3.

Segmental Organization

Developmentally, the basic organizational pattern of the nervous system is that of a longitudinal series of segments, each repeating the same fundamental pattern that is retained in postnatal life. The CNS and its associated peripheral nerves consist of approximately 43 segments,
is a later development that has not occurred in the

branches containing a grouping of component axons.

vous system in which each segment has multiple paired

portion of the basic segmental organization of the ner-

roots of each segment contain bers supplying skeletal

horn of its respective CNS segment. The paired ventral

dorsal roots connecting a pair of dorsal root ganglia and their corresponding CNS segment. The dor-

ventral roots entering the dorsal lateral surface of the cord. The dorsal

root ganglion contains dorsal root ganglion cells, whose axons

bifurcate: one process enters the spinal cord in the dorsal

root, and the other extends peripherally to supply the skin and

muscle of the body. The ventral root is formed by axons from

motor neurons in the spinal cord. IA, input association.

33 of which form the spinal cord and spinal nerves, and

10 of which form the brain and its cranial nerves.

The basic pattern of the CNS is that seen in the spi-

cord—a central cavity surrounded by an inner core of

gray matter and a superficial layer of white matter

(Fig. 34-7). The brain retains this organization, but it

also contains additional regions of gray matter that are

not evident in the spinal cord. The gray matter is func-
tionally divided into longitudinal columns of nerve cell

bodies called the cell columns. The superficial white

matter region contains the longitudinal tract systems of

the CNS. The dorsal half or dorsal horn of the gray mat-

ter contains afferent neurons. The ventral portion, or

ventral horn, contains efferent neurons that communi-
cate by way of the ventral roots with effector cells of the

body segment. Many CNS neurons develop axons that

grow longitudinally as tract systems that communicate

between neighboring and distal segments of the neural

tube.

Each segment of the CNS is accompanied by two

pairs of bundled nerve roots—a dorsal and ventral pair.
The paired dorsal roots connect a pair of dorsal root

ganglia and their corresponding CNS segment. The dor-
sal root ganglia contain many afferent nerve cell bodies,
each having two axonlike processes—one that ends in

a peripheral receptor and another that enters the dorsal

horn of its respective CNS segment. The paired ventral

roots of each segment contain fibers supplying skeletal

muscles and visceral structures of the body segment.

All brain segments, except segment 2, retain some

portion of the basic segmental organization of the ner-

vous system in which each segment has multiple paired

branches containing a grouping of component axons.
The classic pattern of spinal nerve organization, which

consists of a pair of dorsal and a pair of ventral roots, is a later development that has not occurred in the

cranial nerves. Consequently, the cranial nerves, which

are arbitrarily numbered 1 through 12, retain the early

pattern of development, with more than one cranial

nerve branching from a single segment. The truly seg-

mental nerve pattern of the cranial nerves is altered

because all branches from segment 2 and most of the

branches from segment 1 are missing. Cranial nerve 2,

also called the optic nerve, is not a segmental nerve, but

a brain tract connecting the retina (modified brain) with

the first forebrain segment from which it developed.

Cell Columns

Anatomically, the body is organized into soma (e.g.,

skin, muscles, and skeletal structures of the body wall)

and viscera (internal organs). The organizational struc-
ture of the nervous system can be best explained and

simplified as a pattern in which functionally specific

PNS and CNS afferent and efferent somatic and visceral

neurons are repeated as parallel cell columns running

lengthwise along the nervous system. In this organiza-
tional pattern, afferent neurons, dorsal horn cells, and

ventral horn cells are organized as a bilateral series of

11 cell columns.

The cell columns on each side can be further grouped

according to their location in the PNS: four in the dorsal

root ganglia that contain sensory neurons, four in the

dorsal horn that contain sensory input association (IA)

interneurons, and three in the ventral horn that contain

motor neurons (Fig. 34-8). The processes of sensory

neurons that enter the dorsal horn communicate with IA

neurons, which then distributes the afferent information

to local reflex circuitry and to more rostral segments of

the CNS. The ventral horns contain output association

(OA) interneurons and lower motor neurons, which

project to the effector muscles. The afferent and efferent

cell columns of the PNS and CNS, their projections, and

the type of information they transmit are summarized in

Table 34-1.

Between the IA neurons and the OA neurons are

networks of small interconnecting neurons arranged in

complex circuits that provide the discreetness, appropri-
ateness, and intelligence of responses to stimuli. Most

of the billions of CNS cells in the spinal cord and brain

gray matter are interconnecting neurons.

Dorsal Horn Cell Columns. Four columns of affer-

tent (sensory) neurons in the dorsal root ganglia directly

innervate four corresponding columns of IA neurons

in the dorsal horn (see Fig. 34-8). These are the special

somatic and special visceral afferents and the general

somatic and general visceral afferents.

The special somatic afferent (SSA) neurons are con-

cerned with internal sensory information such as joint

and tendon sensation. They relay information to local

reflexes concerned with posture and movement, as well

as to the cerebellum, contributing to coordination of

movement, and to the forebrain, contributing to expe-

rience. Afferents innervating the vestibular system of

the inner ear also belong to the special somatic afferent

category.
Special visceral afferent (SVA) neurons innervate specialized gut-related visceral receptors, such as the taste buds and receptors of the olfactory mucosa. They communicate with neurons involved in salivation, chewing, swallowing, and sensations of taste (i.e., gustation) and smell (i.e., olfaction).

General somatic afferent (GSA) neurons innervate the skin and other somatic structures, responding to stimuli such as those that produce pressure or pain.

General visceral afferent (GVA) fibers innervate visceral structures such as the gastrointestinal tract, urinary bladder, and heart and great vessels; they communicate with neurons that send information to the forebrain regarding visceral sensations such as stomach fullness and bladder pressure.

Ventral Horn Cell Columns. The ventral horn contains three longitudinal cell columns: the general visceral efferent (GVE), pharyngeal efferent (PE), and general somatic efferent (GSE) neurons and their output association (OA) neurons.

![Figure 34-8](image)

**FIGURE 34-8.** (A) Cell columns of the central nervous system. The cell columns in the dorsal horn contain input association (IA) neurons for the general visceral afferent (GVA), special visceral afferent (SVA), special sensory afferent (SSA), and general somatic afferent (GSA) neurons with cell bodies in the dorsal root ganglion. The cell columns in the ventral horn contain the general visceral efferent (GVE), pharyngeal efferent (PE), and general somatic efferent (GSE) neurons and their output association (OA) neurons.

Afferent (sensory) components: SSA, special somatic afferent; GSA, general somatic afferent; SVA, special visceral afferent; GVA, general visceral afferent.

Efferent (motor) components: GVE, general visceral efferent (autonomic nervous system); PE, pharyngeal efferent; GSE, general somatic efferent; DTRs, deep tendon reflexes.
The general visceral efferent (GVE) neurons are structurally and functionally divided between either the sympathetic or the parasympathetic nervous systems of the ANS (discussed later in this chapter). Their axons project through the segmental ventral roots to innervate smooth and cardiac muscle and glandular cells of the body, most of which are in the viscera.

The general somatic efferent (GSE) neurons supply skeletal muscles of the body and head, including those of the trunk, limbs, and tongue and the extrinsic eye muscles. Because they transmit the commands of the CNS to peripheral effectors, the skeletal muscles, they are considered the "final common pathway neurons" in the sequence leading to motor activity. They are often called lower motor neurons (LMNs) because they are under the control of upper motor neurons (UMNs) that have their origin in the CNS.

The pharyngeal efferent (PE) neurons innervate the muscles of mastication and facial expression, as well as the muscles of the pharynx and larynx. Pharyngeal efferent neurons also innervate the muscles responsible for moving the head.

**Longitudinal Tracts**

The gray matter of the cell columns in the CNS is surrounded by bundles of myelinated axons (i.e., white matter) and unmyelinated axons that travel longitudinally along the length of the neural axis. This white matter can be divided into three layers: inner, middle, and outer (Fig. 34-9). The inner layer contains short fibers that project for a maximum of approximately five segments before reentering the gray matter. The fibers of the middle layer project to six or more segments. The outer layer contains large-diameter axons that can travel the entire length of the nervous system (Table 34-2). Suprasegmental is a term that refers to higher levels of the CNS, such as the brain stem and cerebrum and structures above a given CNS segment. The middle and outer layer fibers have suprasegmental projections.

The longitudinal layers are arranged in bundles, or fiber tracts, that contain axons that have the same destination, origin, or function (Fig. 34-10). These longitudinal tracts are named systematically to reflect their origin and destination; the origin is named first, and the destination is named second. For example, the spinothalamic tract originates in the spinal cord and terminates in the thalamus and the corticospinal tract originates in the cerebral cortex and ends in the spinal cord.

**The Inner Layer.** The inner or archi layer of white matter contains the axons of neurons that connect neighboring segments of the nervous system. Axons of this layer permit the pool of motor neurons of several segments to work together as a functional unit. They also allow the afferent neurons of one segment to trigger reflexes that activate motor units in the same or a neighboring segment. The inner layer is the first of the longitudinal layers to become functional, and is the most primitive. Its circuitry may be limited to reflex movements, such as those of the fetus (i.e., quickening) that begin during the fifth month of intrauterine life.

The inner layer of the white matter differs from the other two layers in one important aspect. Many neurons in the embryonic gray matter migrate out into this layer, resulting in a rich mixture of neurons and local fibers called the reticular formation. The circuitry of most reflexes is contained in the reticular formation. In the brain stem, the reticular formation becomes quite large and acts in vital reflexes controlling respiration, cardiovascular function, swallowing, and vomiting. A functional system called the reticular activating system (RAS)
operates in the lateral portions of the reticular formation of the medulla, pons, and especially the midbrain.

The RAS has descending and ascending portions. The descending portion communicates with and serves to facilitate many cord-level reflexes. For example, it speeds reaction time and stabilizes postural reflexes. The ascending portion accelerates brain activity, particularly thalamic and cortical activity.

The Middle Layer. The middle or paleolayer layer of the white matter contains most of the major fiber tract systems required for sensation and movement. It contains the ascending spinoreticular and spinothalamic tracts. This layer consists of larger-diameter and longer suprasegmental fibers, which ascend to the brain stem and are largely functional at birth. It facilitates many primitive functions, such as the auditory startle reflex, which occurs in response to loud noises. This reflex consists of turning the head and body toward the sound, dilating the pupils of the eyes, catching of the breath, and quickening of the pulse.

The Outer Layer. The outer or neolayer layer of the tract systems develops after the other two layers. This pathway, which becomes functional at about 2 years of age, contains the pathways needed for bladder training. Myelination of these suprasegmental tracts, which include many pathways required for delicate and highly coordinated skills, is not complete until approximately the fifth year of life. This includes the development of tracts needed for fine manipulative skills, such as the finger–thumb coordination required for using tools and the toe movements needed for acrobatics. Being the last to be most developed and more superficial, the neolayer tracts are the most vulnerable to injury.

Collateral Communication Pathways. Axons in the inner and middle layer tracts characteristically possess many collateral branches that move into the gray cell columns or synapse with fibers of the reticular formation as the axon passes each succeeding CNS segment. Should a major axon be destroyed at some point along its course, these collaterals provide multisynaptic alternative pathways that bypass the local damage. Damage usually is followed by slow return of function, presumably through the collateral connections.

The outer layer tracts do not possess these collaterals but instead project mainly to the target neurons with which they communicate. When tracts in this layer are damaged, tracts in the middle and inner layers often remain functional, and rehabilitation methods can result in effective use of the older systems. Delicacy and refinement of motor movement may be lost, but basic function remains. For example, when the corticospinal system, an important outer layer system that permits the fine manipulative control required for writing, is damaged, the remaining middle systems, if intact, permit the grasping and holding of objects. The hand can still be used to perform its basic function, but the individual manipulation of the fingers is permanently lost.

**SUMMARY CONCEPTS**

- The organization of the nervous system can be described in terms of its embryonic development, in which newer and more complex functions result from modification and enlargement of earlier developed structures. The dominance of the rostral end of the nervous system reflects a hierarchy of control, with the forebrain having control over the brain stem and the brain stem having control over the spinal cord.
In terms of organization, the nervous system retains many early patterns of segmental development that were established during early embryonic life, with a longitudinal series of segments, each repeating the same fundamental pattern of a central cavity surrounded by an inner core of gray matter made up of nerve cells and a superficial layer of white matter containing axons of the longitudinal tract systems. Each of the body segments is connected to their corresponding central nervous system (CNS) segments by afferent sensory and efferent motor neurons of the peripheral nervous system (PNS).

There are four types of afferent neurons that carry sensory information to the CNS through the dorsal root ganglia: general somatic afferents that carry sensory information from the skin and other somatic structures, special somatic afferents that are concerned with internal sensory information such as joint and tendon sensation, general visceral afferents that innervate visceral structures such as the gastrointestinal and genitourinary systems, and special visceral afferents that innervate gut-related visceral receptors such as taste buds and olfactory receptors.

There are three types of efferent neurons in the ventral horn that synapse with lower motor neurons that exit the CNS in the ventral roots: general somatic efferent neurons that innervate skeletal muscles, general visceral efferent neurons that supply visceral structures innervated by the autonomic nervous system, and the pharyngeal efferent neurons that innervate pharyngeal muscles.

Communication between longitudinal segments is provided by tracts that are arranged in three layers: an inner, a middle, and an outer layer. The inner layer of white matter contains the axons of neurons that connect neighboring segments of the nervous system. It contains a mixture of nerve cells and axons called the reticular formation and is the site of many important spinal cord and brain stem reflex circuits. The middle layer provides for longitudinal communication between the more distant segments of the nervous system; it contains most of the major fiber tract systems required for sensation and movement. The outer layer contains large-diameter axons that travel the entire length of the nervous system; it includes tracts needed for fine manipulative skills.

Spinal Cord and Brain

The central nervous system, which consists of the spinal cord and brain, gathers information about the environment from the peripheral nervous system, processes this information, perceives part of it, and organizes reflexes and other behavioral responses.

The Spinal Cord

In the adult, the spinal cord is found in the upper two thirds of the spinal canal of the vertebral column (Fig. 34-11A). It extends from the foramen magnum at the base of the skull to a cone-shaped termination, the conus medullaris, usually located at the level of the first or second lumbar vertebra (L1 or L2) in the adult. The dorsal and ventral roots of the more caudal portions of the cord elongate during development and angle downward from the cord, forming what is called the cauda equina (from the Latin for “horse’s tail”). The filum terminale, which is composed of nonneural tissues and the pia mater, continues caudally and attaches to the second sacral vertebra (S2).

Cross-Sectional Anatomy of the Spinal Cord

The spinal cord is somewhat oval on transverse section, with the gray matter that forms the dorsal and ventral horns having the appearance of a butterfly or the letter “H” (see Fig. 34-11B). The central portion of the cord, which connects the dorsal and ventral horns, is called the intermediate gray matter. The intermediate gray matter surrounds the central canal. In the thoracic area, the small, slender projections that emerge from the intermediate gray matter are called the intermediolateral columns of the horns. These columns contain the visceral output association neurons and the efferent neurons of the sympathetic nervous system.

The gray matter is proportional to the amount of tissue innervated by a given segment of the cord (see Fig. 34-11B). Larger amounts of gray matter are present in the lower lumbar and upper sacral segments, which supply the lower extremities, and in the fifth cervical segment to the first thoracic segment, which supply the upper limbs. The white matter in the spinal cord also increases progressively toward the brain because ever more ascending fibers are added and the number of descending axons is greater.

The spinal cord and the dorsal and ventral roots are covered by a connective tissue sheath, the pia mater, which also contains the blood vessels that supply the white and gray matter of the cord (Fig. 34-12). On the lateral sides of the spinal cord, extensions of the pia mater, the denticulate ligaments, attach the sides of the spinal cord to the bony walls of the spinal canal. Thus, the cord is suspended by both the denticulate ligaments and the segmental nerves. A fat- and vessel-filled epidural space intervenes between the spinal dura mater and the inner wall of the spinal canal.
Protection of the Spinal Cord

The spinal cord, spinal nerves, and their supporting structures are protected by the bony structures of the vertebral column. The vertebral body is the anterior, more massive part of the bone that gives strength to the vertebral column and supports body weight. Each vertebral body has two pedicles that extend posteriorly and support the laterally oriented transverse processes of the laminae, which arch medially and fuse to continue as the spinal processes. The vertebral arch and posterior surface of the vertebral body form the wall of the vertebral foramen which is formed by the union of the vertebral arch with the vertebral body. The succession of vertebral foramina in the articulated spinal column forms the vertebral canal (spinal canal), which contains the spinal cord, meninges, fat, and spinal nerve roots. The spaces between the vertebral bodies are filled with fibrocartilaginous discs and stabilized with tough ligaments. A gap, the intervertebral foramen, occurs between each two succeeding pedicles, allowing for the exit of the segmental nerves and passage of blood.
vessels. Supporting structures of the spinal cord are discussed further in Chapter 36.

Early in fetal life, the spinal cord extends the entire length of the vertebral column and the spinal nerves exit through the intervertebral foramina (openings) near their level of origin. Because the vertebral column and spinal dura grow at a faster rate than the spinal cord, a disparity develops between each succeeding cord segment and the exit of its dorsal and ventral nerve roots through the corresponding intervertebral foramina. In the newborn, the cord terminates at the level of L2 or L3. In the adult, the cord usually terminates in the inferior border of L1, and the arachnoid mater and its enclosed subarachnoid space, which is filled with CSF, do not close down on the filum terminale until they reach the level of S2. This results in the formation of a pocket of CSF, the dural cisterna spinalis, which extends from approximately L2 to S2. Because this area contains an abundant supply of CSF and the spinal cord does not extend this far, the area is often used for sampling the CSF. A procedure called a spinal tap, or puncture, can be done by inserting a special needle into the dural sac at L3 or L4. The spinal roots, which are covered with pia mater, are in little danger of trauma from the needle used for this purpose.

**Spinal Nerves**

The peripheral nerves that carry information to and from the spinal cord are called spinal nerves. There are 31 left-right pairs of spinal nerves (8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal); each pair is named for the segment of the spinal cord from which it exits. Because the first cervical spinal nerve exits the spinal cord just above the first cervical vertebra (C1), this nerve is given the number of the bony vertebra just below it (see Fig. 34-11A). However, the numbering is changed for all lower levels. An extra cervical nerve, the C8 nerve, exits above the T1 vertebra, and each of the subsequent nerves is numbered for the vertebra just above its point of exit.

Each spinal cord segment communicates with its corresponding body segment through the paired segmental spinal nerves. Each spinal nerve, accompanied by the blood vessels supplying the spinal cord, enters the spinal canal through an intervertebral foramen, where it divides into two branches, or roots. One branch enters the dorsolateral surface of the cord (i.e., dorsal root), carrying the axons of afferent neurons into the CNS. The other branch leaves the ventrolateral surface of the cord (i.e., ventral root), carrying the axons of efferent neurons into the periphery. These two branches or roots fuse at the intervertebral foramen, forming the mixed spinal nerve—“mixed” because it has both afferent and efferent axons.

After emerging from the vertebral column, the spinal nerve divides into two branches or rami (singular, ramus): a small dorsal primary ramus and a larger ventral primary ramus (Fig. 34-13). The thoracic and upper lumbar spinal nerves also lead to a third branch, the ramus communicans, which contains sympathetic axons supplying the blood vessels, the genitourinary system, and the gastrointestinal system. The dorsal ramus contains sensory fibers from the skin and motor fibers to muscles of the back. The ventral primary ramus contains motor fibers that innervate the skeletal muscles of the anterior body wall and the legs and arms.

Spinal nerves do not go directly to skin and muscle fibers; instead, they form complicated nerve networks called plexuses (see Fig. 34-11A). A plexus is a site of intermixing nerve branches. Many spinal nerves enter a plexus and connect with other spinal nerves before exiting from the plexus. Nerves emerging from a plexus form progressively smaller branches that supply the skin and muscles of the various parts of the body. The PNS contains four major plexuses: the cervical, brachial, lumbar, and sacral plexuses.

**Spinal Reflexes**

A reflex is a highly predictable relationship between a stimulus and a motor response. A spinal reflex is a response mediated by cells in the spinal cord, bypassing any conscious effort from the brain. A reflex may involve neurons at a single spinal cord segment (i.e., segmental reflexes), several or many reflexes (i.e., segmental reflexes), or structures in the brain (i.e., suprasegmental reflexes).

A spinal reflex involves a sensory receptor, an afferent pathway, an integrating center in the spinal cord, an efferent pathway, and an effector muscle or gland. A classic example is the knee-jerk or patellar reflex, in which the leg jerks when the kneecap is briskly tapped with a reflex hammer. The reflex reaction is initiated by sensory receptors at the site of the stimulus, and relayed to the spinal cord via afferent sensory neurons. This happens in a fraction of a second, allowing people to jerk away before the brain is even aware of a problem. The integrating center in the spinal cord, in turn,
sends a signal via an efferent motor pathway, signaling an effector response. A signal is also sent to the brain, alerting it to the sensation and response. This happens so quickly that people may experience the sensation of pain almost simultaneously with the development of the reflex, even though the brain is aware of the situation.

The withdrawal reflex is initiated by a painful (nociceptive) stimulus and quickly moves the body part away from the offending stimulus, usually by flexing a limb part. The withdrawal reflex is powerful, taking precedence over other reflexes associated with locomotion. All the joints of an extremity (e.g., finger, wrist, elbow, shoulder) typically are involved. This complex, polysynaptic reflex also shifts postural support to the opposite side of the body with a crossed extensor reflex and simultaneously alerts the forebrain to the offending stimulus event. The withdrawal reflex also can produce contraction of muscles other than the extremities. For example, irritation of the abdominal viscera may cause contraction of the abdominal muscles.

The Brain

The brain is divided into three regions, the hindbrain, the midbrain, and the forebrain (Fig. 34-14). The hindbrain includes the medulla oblongata, the pons, and its dorsal outgrowth, the cerebellum. Midbrain structures include two pairs of dorsal enlargements, the superior and inferior colliculi (not shown). The forebrain, which consists of two hemispheres covered by the cerebral cortex, contains central masses of gray matter, the basal ganglia (discussed in Chapter 36), and the rostral end of the neural tube, the diencephalon with its adult derivatives—the thalamus and hypothalamus. The olfactory and optic nerves are also considered part of the forebrain. In contrast, the motor and sensory nuclei of the 3rd to 12th cranial nerves are located in the midbrain and hindbrain.

An important concept is that the more rostral or recently developed parts of the neural tube gain dominance or control over regions and functions at lower levels. They do not replace the earlier developed circuitry but merely dominate it. After damage to the more vulnerable parts of the forebrain, as occurs with severe brain injury, a brain stem–controlled organism remains that is capable of breathing and may survive if the environmental temperature is regulated and nutrition and other aspects of care are provided. However, all aspects of intellectual function, experience, perception, and memory usually are permanently lost.

Hindbrain

During embryonic development, the hindbrain becomes subdivided into the cerebellum, the medulla oblongata—also referred to as the medulla—and the pons. The CSF-filled tube becomes the fourth ventricle, which is continuous with the cerebral aqueduct of the midbrain (see Fig. 34-14).

The cerebellum, the “little brain,” is an important movement control center (see Chapter 36). It receives massive axonal inputs from the spinal cord and pons. Neurons in the spinal cord provide information about the body’s position in space, and those in the pons relay information from the cerebral cortex specifying the goals of the intended movements.

Brain Stem. The brain stem is the region of the brain that connects the cerebrum with the spinal cord. It consists of the midbrain, medulla oblongata, and the pons. In the brain stem, the reticular formation has been greatly expanded. Certain groups of neurons termed vital centers are located in the reticular formation of the pons and medulla. These centers include the respiratory, cardiovascular, and vasomotor centers. Still other centers in the brain stem are concerned with swallowing, intestinal movements, control of micturition, and a variety of more specific functions such as salivation and pupillary diameter.
The medulla represents the five caudal segments of the brain part of the neural tube; the cranial nerve branches entering and leaving it have functions similar to the spinal segmental nerves. Although the ventral horn areas in the medulla are quite small, the dorsal horn areas are enlarged, processing the large amount of information pouring through cranial nerves XII (hypoglossal), X (vagus), and IX (glossopharyngeal) (see Table 34-1).

The pons, which develops from the fifth neural tube segment, is located between the medulla and the midbrain. As the name implies (pons, Latin for “bridge”), the pons is composed chiefly of conduction fibers. The enlarged area on the ventral surface of the pons contains the pontine nuclei, which receive information from all parts of the cerebral cortex. The axons of these neurons form a massive bundle that enters the cerebellum. In the pons, the reticular formation is large and contains the circuitry for manipulating the jaws during chewing and speech. Cranial nerves VIII, VII, and VI have their origin in the pons (see Table 34-1).

**Midbrain**

The midbrain develops from the fourth segment of the neural tube, and its organization is similar to that of a spinal segment. Two prominent bundles of nerve fibers, the cerebral peduncles, pass along the ventral surface of the midbrain. These fibers include the corticospinal tracts and are the main motor pathways between the forebrain and the pons. On the dorsal surface, four “little hills,” the superior and inferior colliculi, are areas of cortical formation. The inferior colliculus is involved in directional head turning and, to some extent, in experiencing the direction of sound sources. The superior colliculi are essential to the reflex mechanisms that coordinate eye movements when the visual environment is surveyed. Two cranial nerves, the oculomotor nerve (CN III) and the trochlear nerve (CN IV), exit the midbrain (see Table 34-1).

**Forebrain**

The most rostral part of the brain, the forebrain consists of the diencephalon, or “between brain,” and the telencephalon, or “end brain.” The diencephalon forms the core of the forebrain, and the telencephalon forms the cerebral hemispheres.

**Diencephalon.** Three of the most forward brain segments form an enlarged dorsal horn and ventral horn with a narrow, CSF-filled central canal—the third ventricle—separating the two sides. This region is called the diencephalon. The dorsal horn part of the diencephalon is the thalamus and subthalamus, and the ventral horn part is the hypothalamus (Fig. 34-15). The optic nerve, or cranial nerve II, and retina are outgrowths of the diencephalon.

The thalamus consists of two large, egg-shaped masses, one on either side of the third ventricle. The thalamus is divided into several major parts, and each part is divided into distinct nuclei, which are the major relay stations for information going to and from the cerebral cortex. All sensory pathways have direct projections to thalamic nuclei, which convey the information to restricted areas of the sensory cortex. Coordination and integration of peripheral sensory stimuli occur in the thalamus, along with some crude interpretation of highly emotion-laden auditory experiences that not only occur but can be remembered. For example, a person can recover from a deep coma in which cerebral cortex activity was minimal and remember some of what was said at the bedside.

The thalamus also plays a role in relaying critical information regarding motor activities to and from

---

**FIGURE 34-15.** Frontal section of the brain passing through the third ventricle, showing the thalamus, subthalamus, hypothalamus, internal capsule, corpus callosum, basal ganglia (caudate nucleus, lentiform nucleus), amygdaloid complex, insula, and parietal cortex.
selected areas of the motor cortex. Two neuronal circuits are significant in this regard. One is the pathway from the cerebral cortex to the pons and cerebellum and then, by way of the thalamus, back to the motor cortex. The second is the feedback circuit that travels from the cortex to the basal ganglia, then to the thalamus, and from the thalamus back to the cortex. The subthalamus also contains movement control systems related to the basal ganglia.

Through its connections with the ascending reticular activating system, the thalamus processes neural influences that are basic to cortical excitatory rhythms (i.e., those recorded on the electroencephalogram), to essential sleep–wake cycles, and to the process of attending to stimuli. Besides their cortical connections, the thalamic nuclei have connections with each other and with neighboring nonthalamic brain structures such as the limbic system. Through their connections with the limbic system, some thalamic nuclei are involved in relating stimuli with the emotional responses they evoke.

The ventral horn portion of the diencephalon is the hypothalamus, which borders the third ventricle and includes a ventral extension, the posterior pituitary gland or neurohypophysis. The hypothalamus is the area of master-level integration of homeostatic control of the body’s internal environment. Maintenance of blood gas concentration, water balance, food consumption, and major aspects of endocrine and ANS control require hypothalamic function.

The internal capsule is a broad band of projection fibers that lies between the thalamus medially and the basal ganglia laterally (see Fig. 34-15). It contains all of the fibers that connect the cerebral cortex with deeper structures, including the basal ganglia, thalamus, midbrain, pons, medulla, and spinal cord.

Cerebral Hemispheres. The two cerebral hemispheres are lateral outgrowths of the diencephalon. The cerebral hemispheres contain the CSF-filled lateral ventricles, which are connected with the third ventricle of the diencephalon by a small opening called the interventricular foramen (see Fig. 34-14). Axons of the olfactory nerve, or cranial nerve I, terminate in the most primitive portion of the cerebrum—the olfactory bulb, where initial processing of olfactory information occurs.

The corpus callosum is a massive commissure, or bridge, of myelinated axons that connects the cerebral cortex of the two sides of the brain (see Fig. 34-15). Two smaller commissures, the anterior and posterior commissures, connect the two sides of the more specialized regions of the cerebrum and diencephalon.

The surface of the hemispheres, which contains the six-layered neocortex, can be described as lateral (side), medial (area between the two sides of the brain), and basal (ventral). The surface of the hemispheres contains many ridges and grooves. A gyrus is the ridge between two grooves, and the groove is called a sulcus or fissure. The cerebral cortex is arbitrarily divided into lobes named after the bones that cover them: the frontal, parietal, temporal, and occipital lobes (Fig. 34-16A).

Frontal Lobe. The frontal lobe extends from the frontal pole to the central sulcus and is separated from the temporal lobe by the lateral sulcus. The frontal lobe can be subdivided rostrally into the frontal pole and laterally into the superior, middle, and inferior gyri, which continue on the undersurface over the eyes as the orbital cortex. These areas are associated with the medial thalamic nuclei, which also are related to the limbic system. In terms of function, the prefrontal cortex is thought to be involved in anticipation and prediction of consequences of behavior.

The precentral gyrus (area 4), next to the central sulcus, is the primary motor cortex (see Fig. 34-16B). This area of the cortex provides precise movement control for distal flexor muscles of the hands and feet and the phonation apparatus required for speech. Just rostral to the precentral gyrus is a region of the frontal cortex called the premotor or motor association cortex. This region (area 8 and rostral area 6) is involved in the planning of complex learned movement patterns. The primary motor cortex and the association motor cortex are connected with lateral thalamic nuclei, through which they receive feedback information from the basal ganglia and cerebellum. On the medial surface of the hemisphere, the premotor area includes a supplementary motor cortex involved in the control of bilateral movement patterns requiring great dexterity.

Parietal Lobe. The parietal lobe of the cerebrum lies behind the central sulcus and above the lateral sulcus. The strip of cortex bordering the central sulcus is called the primary somatosensory cortex (areas 1, 2, and 3) because it receives very discrete sensory information from the lateral nuclei of the thalamus. Just behind the primary sensory cortex is the somatosensory association cortex (areas 5 and 7), which is connected with the thalamic nuclei and the primary sensory cortex. This region is necessary for perceiving the meaningfulness of integrated sensory information from various sensory systems, especially the perception of “where” the stimulus is in space and in relation to body parts. Localized lesions of this region can result in the inability to recognize the meaningfulness of an object (i.e., agnosia). With the person’s eyes closed, a screwdriver can be felt and described as to shape and texture. Nevertheless, the person cannot integrate the sensory information required to identify it as a screwdriver.

Temporal Lobe. The temporal lobe lies below the lateral sulcus and merges with the parietal and occipital lobes. The primary auditory cortex (area 41) is important in discrimination of sounds entering opposite ears. It receives auditory input projections by way of the inferior colliculus of the midbrain and a ventrolateral thalamic nucleus. The auditory association area (area 22) functions in the recognition of certain sound patterns and their meaning. The remaining portion of the temporal cortex is less defined functionally but apparently is important in long-term memory recall. This is particularly true with respect to perception and memory of complex sensory patterns, such as geometric figures and faces (i.e., recognition of “what” or “who” the stimulus is).
Irritation or stimulation can result in vivid hallucinations of long-past events.

**Occipital Lobe.** The occipital lobe lies posterior to the temporal and parietal lobes. It contains the primary visual cortex (area 17), stimulation of which causes the experience of bright lights called phosphenes in the visual field. Just superior and inferior is the visual association cortex (areas 18 and 19), which is required for gnostic visual function, by which the meaningfulness of visual experience, including experiences of color, motion, depth perception, pattern, form, and location in space, occurs.

The neocortical areas of the parietal lobe, between the somatosensory and the visual cortices, have a function in relating the texture, or “feel,” and location of an object with its visual image. Between the auditory and visual association areas, the parieto-occipital region is necessary for relating the meaningfulness of a sound and image to an object or person.

**Limbic System.** The medial aspect of the cerebrum is organized into concentric bands of cortex, the limbic system (from the Latin *limbus*, “border”), which surrounds the connection between the lateral and third ventricles. The innermost band just above and below the cut surface of the corpus callosum is folded out of sight but is a three-layered cortex ending as the hippocampus in the temporal lobe. Just outside the folded area is a band of transitional cortex, which includes the cingulate and the parahippocampal gyri (Fig. 34-17). The limbic lobe has reciprocal connections with the medial and the intralaminar nuclei of the thalamus, with the deep nuclei of the cerebrum, and with the hypothalamus. Overall, this region of the brain is involved in emotional experience and in the control of emotion-related behavior. Stimulation of specific areas in this system can lead to feelings of dread, high anxiety, or exquisite pleasure. It also can result in violent behaviors, including attack, defense, or explosive and emotional speech.
Meninges

Inside the skull and vertebral column, the brain and spinal cord are loosely suspended and protected by several connective tissue sheaths called the meninges (Fig. 34-18). The surfaces of the spinal cord, brain, and segmental nerves are covered with a delicate connective tissue layer called the pia mater (Latin for "delicate mother"). The surface blood vessels and those that penetrate the brain and spinal cord are encased in this protective tissue layer. A second, very delicate, non-vascular, and waterproof layer, called the arachnoid mater, encloses the entire CNS. The arachnoid layer is named for its spider-web appearance. The CSF is contained in the subarachnoid space. Immediately outside the arachnoid mater is a continuous sheath of strong connective tissue, the dura mater (Latin for "tough mother"), which provides the major protection for the brain and spinal cord. The cranial dura often splits into two layers, with the outer layer serving as the periosteum of the inner surface of the skull.

The inner layer of the dura forms two major folds. The first, a longitudinal fold called the falx cerebri separates the cerebral hemispheres and fuses with a second transverse fold, the tentorium cerebelli (Fig. 34-19). The tentorium cerebelli separates the anterior and middle depression in the skull (cranial fossae), which contains the cerebral hemispheres, from the posterior fossa, found interiorly and containing the brain stem and cerebellum.

Ventricular System and Cerebrospinal Fluid

The ventricular system is a set of structures containing cerebrospinal fluid (CSF) in the brain (Fig. 34-20). The system comprises four ventricles: right and left lateral ventricles (the first and second ventricles), third ventricle, and fourth ventricle. Cerebrospinal fluid is a clear, colorless ultrafiltrate of blood plasma, composed of 99% water with other constituents, making it close to the composition of the brain extracellular fluid. The total volume of CSF is 135 to 150 mL. The daily production is about 500 to 600 mL/day, so the CSF turns over about 4 times per day.

The CSF provides a supporting and protective fluid in which the brain and spinal cord float, and it helps to maintain a constant ionic environment that serves as a medium for diffusion of nutrients, electrolytes, and metabolic end products into the extracellular fluid surrounding CNS neurons and glia. Filling the ventricles, the CSF supports the mass of the brain. Because it fills the subarachnoid space surrounding the CNS, a physical force delivered to either the skull or spine is to some extent diffused and cushioned.

The CSF is produced by tiny reddish masses of specialized capillaries from the pia mater, called the choroid plexus, which projects into the ventricles. Once produced, the CSF flows freely through the ventricles (Fig. 34-20B). Three openings, or foramina, allow the CSF to pass into

FIGURE 34-17. The limbic system includes the limbic cortex (cingulate gyrus, parahippocampal gyrus, uncus) and associated subcortical structures (mammillary body, amygdala).

FIGURE 34-18. The cranial meninges. Arachnoid villi, shown within the superior sagittal sinus, are one site of cerebrospinal fluid absorption into the blood.

FIGURE 34-19. Cranial dura mater. The skull is open to show the falx cerebri and the right and left portions of the tentorium cerebelli, as well as some of the cranial venous sinuses.
the subarachnoid space. Two of these, the foramina of Luschka, are located at the lateral corners of the fourth ventricle. The third, the median foramen of Magendie, is in the midline at the caudal end of the fourth ventricle (see Fig. 34-20A). Approximately 30% of the CSF passes down into the subarachnoid space that surrounds the spinal cord, mainly on its dorsal surface, and moves back up to the cranial cavity along its ventral surface.

Reabsorption of CSF into the vascular system occurs along the sides of the superior sagittal sinus in the anterior and middle fossa. Here, the waterproof arachnoid mater has protuberances, the arachnoid villi, which penetrates the inner dura and venous walls of the superior sagittal sinus (see Fig. 34-20A). The arachnoid villi function as one-way valves, permitting CSF outflow into the blood but not allowing blood to pass into the arachnoid spaces.

**Blood–Brain and Cerebrospinal Fluid–Brain Barriers**

Maintenance of a chemically stable environment is essential to the function of the brain. In most regions of the body, extracellular fluid undergoes small fluctuations in pH and concentrations of hormones, amino acids, and potassium ions during routine daily activities such as eating and exercising. If the brain were to undergo these fluctuations, the result would be uncontrolled neural activity because some substances, such as amino acids, act as neurotransmitters, and ions such as potassium influence the threshold for neural firing. Two barriers, the blood–brain barrier and the CSF-brain barrier, provide the means for maintaining the stable chemical environment of the brain. Only water, carbon...
junctions that join the overlapping capillary endothelial cells. In addition, most brain capillaries are completely surrounded by a basement membrane and by the processes of previously described supporting astrocyte cells of the brain (Fig. 34-21). The blood–brain barrier permits passage of essential substances while excluding unwanted materials. Reverse transport systems remove materials from the brain. Large molecules such as proteins and peptides are largely prevented from crossing the blood–brain barrier. Acute cerebral lesions, such as trauma and infection, increase the permeability of the blood–brain barrier and alter brain concentrations of proteins, water, and electrolytes.

The blood–brain barrier prevents many drugs from entering the brain. Most highly water-soluble compounds are excluded from the brain, especially molecules with high ionic charge, such as many of the catecholamines. In contrast, many lipid-soluble molecules cross the lipid layers of the blood–brain barrier with ease. Alcohol, nicotine, and heroin are very lipid soluble and rapidly enter the brain. Some substances that enter the capillary endothelium are converted by metabolic processes to a chemical form incapable of moving into the brain.

The cerebral capillaries are much more permeable at birth than in adulthood, and the blood–brain barrier develops during the early years of life. In severely jaundiced infants, bilirubin can cross the immature blood–brain barrier, producing kernicterus and brain damage (see Chapter 13). In adults, the mature blood-brain barrier prevents bilirubin from entering the brain, and the nervous system is not affected.

Cerebrospinal Fluid–Brain Barrier. The ependymal cells covering the choroid plexus are linked together by tight junctions, forming a blood-CSF barrier to diffusion of many molecules from the blood plasma of choroid plexus capillaries to the CSF. Water is transported through the choroid epithelial cells by osmosis. Oxygen and carbon dioxide move into the CSF by diffusion, resulting in partial pressures roughly equal to those of plasma. The high sodium and low potassium contents of the CSF are actively regulated and kept relatively constant. Lipids and nonpeptide hormones diffuse through the barrier rather easily, but most large molecules, such as proteins, peptides, many antibiotics, and other medications, do not normally get through. Many substances, including proteins, sodium ions, and a number of micronutrients such as vitamins C, B₆ (pyridoxine), and folate are actively secreted into the CSF by the choroid epithelium. Because the brain and spinal cord have no lymphatic channels, the CSF serves this function.

There are several specific areas of the brain where the blood-CSF barrier does not exist. One area is at the caudal end of the fourth ventricle, where specialized receptors for the carbon dioxide level of the CSF influence respiratory function. Another area consists of the walls of the third ventricle, which permit hypothalamic neurons to monitor blood glucose levels. This mechanism permits hypothalamic centers to respond to these blood glucose levels, contributing to hunger and eating behaviors.

**SUMMARY CONCEPTS**

- In the adult, the spinal cord is in the upper two thirds of the spinal canal of the vertebral column. On transverse section, the spinal cord has an oval shape, and the internal gray matter has the appearance of a butterfly or letter “H.” The dorsal horns contain the input association (IA) neurons and receive afferent information from dorsal root and other connecting neurons. The ventral horns contain the output association neurons and lower motor neurons that leave the cord by the ventral roots.

- There are 31 pairs of spinal nerves (8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal), each communicating with its corresponding body segments. Each spinal nerve is formed by the combination of nerve fibers from the dorsal and ventral roots of the spinal cord. The dorsal roots carry afferent sensory axons entering the dorsal horn of the gray matter, while the ventral roots carry efferent motor axons from the central nervous system.
carry efferent axons from motor neurons located within the ventral horn of the gray matter. At its distal end, the ventral root joins with the dorsal root to form a mixed spinal nerve.

- The brain can be divided into three regions: the hindbrain, the midbrain, and the forebrain. The hindbrain, consisting of the medulla oblongata, pons, and cerebellum, contains the neuronal circuits for the eating, breathing, and locomotive functions required for survival and cranial nerves V through XII. The midbrain contains cranial nerves IV and III. The forebrain consists of the diencephalon, which forms the core of the forebrain; and the telencephalon, which forms the cerebral hemispheres.

- The diencephalon contains the thalamus and hypothalamus. All sensory pathways have direct projections to the thalamic nuclei, which convey the information to restricted parts of the sensory cortex. The hypothalamus functions in the homeostatic control of the internal environment.

- The cerebral hemispheres, which are the lateral outgrowths of the diencephalon, are divided into four lobes—the frontal, parietal, temporal, and occipital lobes. The premotor area and primary motor cortex are located in the frontal lobe; the primary sensory cortex and somatosensory association area are in the parietal cortex; the primary auditory cortex and the auditory association area are in the temporal lobe; and the primary visual cortex and association visual cortex are in the occipital lobe.

- The brain is enclosed and protected by connective tissue sheaths called the meninges, which consist of three layers: the dura mater, arachnoid mater, and pia mater. The CSF, in which the brain and spinal cord float, is secreted into the ventricles by the choroid plexus, circulates through the ventricular system, passes outside to surround the brain, and is reabsorbed into the venous system through the arachnoid villi. The blood-brain barrier and CSF-brain barrier protect the brain from substances in the blood that would disrupt brain function.

## The Autonomic Nervous System

The autonomic nervous system (ANS), in contrast to the previously discussed somatic nervous system, provides a person with the ability to maintain internal physiologic homeostasis and perform the activities of daily living in an ever-changing physical environment. The term “autonomic” (self-governing) reflects the independent nature of this part of the nervous system or functioning largely below the level of consciousness. The ANS is involved in regulating, adjusting, and coordinating vital visceral functions such as heart rate and blood pressure. It is strongly affected by emotional influences and is involved in many of the expressive aspects of behavior, including blushing, pallor, palpitations, clammy hands, and dry mouth.

As with the somatic nervous system, the ANS is represented in both the CNS and the PNS. Traditionally, the ANS has been defined as a general efferent system innervating visceral organs. The efferent outflow from the ANS has two divisions: the sympathetic nervous system and the parasympathetic nervous system. The efferent input to the ANS is provided by visceral afferent neurons, usually not considered part of the ANS.

The functions of the sympathetic nervous system include maintaining body temperature, respiration, digestion, elimination, and adjusting blood flow and blood pressure to meet the changing needs of the body. The sympathoadrenal system also can discharge as a unit when there is a critical threat to the integrity of the individual—the so-called fight-or-flight response. During a stress situation, the heart rate accelerates, the blood pressure rises, blood flow shifts from the skin and gastrointestinal tract to the skeletal muscles and brain, blood sugar increases, the bronchioles and pupils dilate, the spincters of the stomach and intestine and the internal sphincters of the urethra constrict, and the rate of secretion of exocrine glands that are involved in digestion diminishes. Emergency situations often require vasoconstriction and shunting of blood away from the skin and into the muscles and brain, a mechanism that, should a wound occur, would provide for a reduction in blood flow and preservation of vital functions needed for survival.

In contrast to the sympathetic nervous system, the functions of the parasympathetic nervous system are concerned with conservation of energy, resource replenishment and storage, and maintenance of organ function during periods of minimal activity. The parasympathetic nervous system slows heart rate, stimulates gastrointestinal function and related glandular secretion, promotes bowel and bladder elimination, and contracts the pupil, protecting the retina from excessive light during periods when visual function is not vital to survival.

The two divisions of the ANS usually are viewed as having opposite and antagonistic actions (i.e., if one activates, the other inhibits a function). Exceptions are functions, such as sweating and regulation of arteriolar blood vessel diameter, that are controlled by a single division of the ANS, in this case the sympathetic nervous system.

The sympathetic and parasympathetic nervous systems are continually active. The effect of this continual or basal (baseline) activity is referred to as tone. The tone of an effector organ or system can be increased or decreased and usually is regulated by a single division of the ANS. For example, vascular smooth muscle tone is controlled by the sympathetic nervous system. Increased sympathetic activity produces local vasoconstriction from increased vascular smooth muscle tone,
and decreased activity results in vasodilatation caused by decreased tone. In structures such as the sinoatrial node and atrioventricular node of the heart, which are innervated by both divisions of the ANS, one division predominates in controlling tone. In this case, the tonically active parasympathetic nervous system exerts a constraining or braking effect on heart rate, and when parasympathetic outflow is withdrawn, similar to releasing a brake, the heart rate increases. The increase in heart rate that occurs with vagal withdrawal can be further augmented by sympathetic stimulation.

**Autonomic Efferent Pathways**

The outflow of both divisions of the ANS follows a two-neuron efferent pathway (Fig. 34-22). The cell body of the first motor neuron, called the preganglionic neuron, lies in the brain stem or the spinal cord. The second motor neuron, called the postganglionic neuron, synapses with a preganglionic neuron in an autonomic ganglion located in the PNS. The two divisions of the ANS differ in terms of location of preganglionic cell bodies, relative length of preganglionic fibers, general function, nature of peripheral responses, and preganglionic and postganglionic neurotransmitters and their postsynaptic receptors (Table 34-3).

Most visceral organs are innervated by both sympathetic and parasympathetic fibers. Exceptions include structures such as blood vessels and sweat glands that have input from only sympathetic division of the ANS. The fibers of the sympathetic nervous system are distributed to effectors throughout the body, and as a result, sympathetic actions tend to be more diffuse than those of the parasympathetic nervous system, in which there is a more localized distribution of fibers. The preganglionic fibers of the sympathetic nervous system may traverse a considerable distance and pass through several ganglia before synapsing with postganglionic neurons, and their terminals make contact with a large number of postganglionic fibers. In some ganglia, the ratio of preganglionic to postganglionic cells may be 1:20; because of this, the effects of sympathetic stimulation are diffuse. There is considerable overlap, and one ganglion cell may be supplied by several preganglionic fibers. In contrast to the sympathetic nervous system, the parasympathetic nervous system has its postganglionic neurons located very near or in the organ of innervation. Because the ratio of preganglionic to postganglionic communication often is 1:1, the effects of the parasympathetic nervous system are much more circumscribed.

**Sympathetic Nervous System**

The preganglionic neurons of the sympathetic nervous system are located primarily in the thoracic and upper lumbar segments (T1 to L2) of the spinal cord; thus, the

sympathetic nervous system often is referred to as the thoracolumbar division of the ANS. These preganglionic neurons have axons that are largely myelinated and relatively short. The postganglionic neurons of the sympathetic nervous system are located in the paravertebral ganglia of the sympathetic chain that lie on either side of the vertebral column, or in prevertebral sympathetic ganglia such as the celiac ganglia, the branches of which innervate the liver, stomach, and other visceral organs (Fig. 34-23). Besides postganglionic efferent neurons, the sympathetic ganglia contain interconnecting neurons similar to those associated with complex circuitry in the brain and spinal cord, many of which inhibit modulation preganglionic-to-postganglionic transmission.

sympathetic nervous system often is referred to as the thoracolumbar division of the ANS. These preganglionic neurons have axons that are largely myelinated and relatively short. The postganglionic neurons of the sympathetic nervous system are located in the paravertebral ganglia of the sympathetic chain that lie on either side of the vertebral column, or in prevertebral sympathetic ganglia such as the celiac ganglia, the branches of which innervate the liver, stomach, and other visceral organs (Fig. 34-23). Besides postganglionic efferent neurons, the sympathetic ganglia contain interconnecting neurons similar to those associated with complex circuitry in the brain and spinal cord, many of which inhibit modulation preganglionic-to-postganglionic transmission.

FIGURE 34-23. Sympathetic pathways. Sympathetic preganglionic fibers (blue) leave the spinal cord by way of the ventral root of the spinal nerves, enter the ventral primary rami, and pass through the white rami to the prevertebral or paravertebral ganglia of the sympathetic chain, where they synapse with postganglionic neurons (black). Other preganglionic neurons (red dotted lines) travel directly to their destination in the various effector organs.
The axons of the preganglionic neurons leave the spinal cord through the ventral root of the spinal nerves (T1 to L2), enter the ventral primary rami (i.e., nerve divisions) and leave the spinal nerve through white rami of the rami communicantes to reach the paravertebral ganglionic chain (see Fig. 34-23). In the sympathetic chain of ganglia, preganglionic fibers may synapse with neurons of the ganglion they enter, pass up or down the chain and synapse with one or more ganglia, or pass through the chain and move outward through a splanchnic nerve to terminate in one of the prevertebral ganglia (i.e., celiac, superior mesenteric, or inferior mesenteric) that are scattered along the dorsal aorta and its branches. The adrenal medulla, which is part of the sympathetic nervous system, contains postganglionic sympathetic neurons that secrete sympathetic neurotransmitters directly into the bloodstream.

**Parasympathetic Nervous System**

As is true in the sympathetic nervous system, efferent parasympathetic nerve signals are carried from the central nervous system to their targets by a two-neuron pathway. The preganglionic fibers of the parasympathetic nervous system, also referred to as the craniosacral division of the ANS, originate in some segments of the brain stem and sacral segments of the spinal cord (see Fig. 34-22). The central regions of origin are the midbrain, pons, medulla oblongata, and sacral part of the spinal cord. The outflow from the midbrain passes through the oculomotor nerve (cranial nerve III) to supply the pupillary sphincter muscle of each eye and the ciliary muscles that control lens thickness for accommodation. Caudal pontine outflow comes from branches of the facial nerve (cranial nerve VII) that supply the lacrimal and nasal glands. The medullary outflow develops from cranial nerves VII, IX, and X. Fibers in the glossopharyngeal nerve (cranial nerve IX) supply the parotid salivary glands. Approximately 75% of parasympathetic efferent fibers are carried in the vagus nerve (cranial nerve X). The vagus nerve provides parasympathetic innervation for the heart, trachea, lungs, esophagus, stomach, small intestine, proximal half of the colon, liver, gallbladder, pancreas, kidneys, and upper portions of the ureters.

Sacral preganglionic axons leave the S2 to S4 segmental nerves by gathering into the pelvic nerves. The pelvic nerves leave the sacral plexus on each side of the cord and distribute their peripheral fibers to the bladder, uterus, urethra, prostate, distal portion of the transverse colon, descending colon, and rectum. The sacral parasympathetic fibers also supply the venous outflow from the external genitalia to facilitate erectile function.

With the exception of cranial nerves III, VII, and IX, which synapse in discrete ganglia, the long parasympathetic preganglionic fibers pass uninterrupted to short postganglionic fibers located in the organ wall. In the walls of these organs, postganglionic neurons send axons to smooth muscle and glandular cells that modulate their functions.

**Central Integrative Pathways**

General visceral afferent fibers accompany the sympathetic and parasympathetic output into the spinal and cranial nerves, bringing chemoreceptor, pressure, and nociceptive (pain) information from organs of the viscera to the brain stem, thoracolumbar cord, and sacral cord. Local reflex circuits relating visceral afferent and autonomic efferent activity are integrated into a hierarchical control system in the spinal cord and brain stem. Progressively greater complexity in the responses and greater precision in their control occur at each higher level of the nervous system. Most visceral reflexes receive input from the lower motor neurons that innervate skeletal muscles as part of their response patterns.

For most autonomic-mediated functions, the hypothalamus serves as the major control center. The hypothalamus, which has connections with the cerebral cortex, the limbic system, and the pituitary gland, is in a prime position to receive, integrate, and transmit information to other areas of the nervous system. The neurons concerned with thermoregulation, thirst, and feeding behaviors are found in the hypothalamus. The hypothalamus also is the site for integrating neuroendocrine function. Hypothalamic releasing and inhibiting hormones control the secretion of the anterior pituitary hormones (see Chapter 31).

The organization of many life-support reflexes occurs in the reticular formation of the medulla and pons. These areas of reflex circuitry, often called centers, produce complex combinations of autonomic and somatic efferent functions required for the cough, sneeze, swallow, and vomit reflexes, as well as for the more purely autonomic control of the cardiovascular system. One of the striking features of ANS function is the rapidity and intensity with which it can change visceral function. Within 3 to 5 seconds, it can increase heart rate to approximately twice its resting level. Bronchial smooth muscle tone is largely controlled by parasympathetic fibers carried in the vagus nerve. These nerves produce mild to moderate constriction of the bronchioles.

Other important ANS reflexes are located at the level of the spinal cord. As with other spinal reflexes, these are modulated by input from higher centers. When there is loss of communication between the higher centers and the spinal reflexes, as occurs in spinal cord injury, these reflexes function in an unregulated manner (see Chapter 36).

**Autonomic Neurotransmission**

The generation and transmission of impulses in the ANS occur in the same manner as in the CNS. There are self-propagating action potentials with transmission of impulses across synapses and other tissue junctions by way of neurohumoral transmitters. The postganglionic fibers of the ANS form a diffuse neural plexus at the site of innervation. The membranes of the cells of many smooth muscle fibers are connected by gap junctions that permit rapid conduction of impulses through whole sheets of smooth muscle, often in repeating waves of contraction. Autonomic neurotransmitters released near a limited portion of these fibers provide a modulating function extending to a large number of effector cells, such as those of the muscle layers of the gut and of the bladder. The main neurotransmitters of the ANS are acetylcholine and the catecholamines, epinephrine and norepinephrine.
Acetylcholine and Cholinergic Receptors

Acetylcholine (ACh) is the preganglionic neurotransmitter in autonomic ganglia of both the sympathetic and parasympathetic nerve fibers as well as the postganglionic neurotransmitter in parasympathetic nerve endings. It also is released at sympathetic nerve endings that innervate the sweat glands and cholinergic vasodilator fibers found in skeletal muscle. Acetylcholine is synthesized in cholinergic neurons from choline and acetyl coenzyme A (acetyl CoA) by a single step reaction catalyzed by the biosynthetic enzyme choline acetyltransferase (Fig. 34-24A). Once synthesized, ACh is transported from the cytoplasm into vesicles that are concentrated on the inner surface of the presynaptic neuron. Activation of the postsynaptic receptors occurs with action potential-mediated release of ACh from the presynaptic vesicles. Following dissociation from the postsynaptic receptors, ACh is rapidly hydrolyzed by the enzyme acetylcholinesterase (AChE) into acetate and choline in the synaptic cleft. The choline molecule is transported back into the nerve ending, where it is used again in the synthesis of ACh.

Cell membrane receptors that respond to acetylcholine are called cholinergic receptors. There are two types of cholinergic receptors: nicotinic and muscarinic. Nicotinic ACh receptors are of two types: muscle type receptor (N\(_M\) or N\(_1\)) and neuronal type receptor (N\(_N\) or N\(_2\)). N\(_M\) receptor is located in the neuromuscular junction, which causes the contraction of skeletal muscles by way of end-plate potential. N\(_N\) receptor causes depolarization in autonomic ganglia resulting in postganglionic impulse. Some skeletal muscle relaxants, such as succinylcholine and tubocurarine, can be used to induce muscle relaxation and short-term paralysis in anesthesia by blocking N\(_M\) receptors at the neuromuscular junction. Muscarinic acetylcholine receptors are present on the innervational targets of postganglionic fibers of the parasympathetic nervous system and the sweat glands, which are innervated by the sympathetic nervous system. The drug atropine is a competitive antagonist for the muscarinic acetylcholine receptor that prevents the action of acetylcholine at excitatory and inhibitory muscarinic receptor sites. Because it is a muscarinic-blocking drug, it exerts little effect at nicotinic receptor sites.
Catecholamines and Adrenergic Receptors

The catecholamines constitute a class of neurotransmitters and hormones that occupy key positions in the regulation of physiological processes and the development of neurological, psychiatric, endocrine, and cardiovascular diseases. Catecholamines are characterized by a catechol group (a benzene ring with two hydroxyl groups) to which is attached an amine (nitrogen-containing) group. Among the catecholamines are norepinephrine, epinephrine, and dopamine. Norepinephrine is released at most sympathetic nerve endings. The adrenal medulla, which is a modified neural crest tissue, produces epinephrine along with small amounts of norepinephrine. Dopamine, which is an intermediate compound in the synthesis of norepinephrine, also acts as a neurotransmitter. It is the principal inhibitory transmitter of interconnecting neurons in the sympathetic ganglia. It also has vasodilator effects on renal, splanchnic, and coronary blood vessels when given intravenously and is sometimes used in the treatment of shock (see Chapter 20).

All catecholamines are synthesized in the brain, the adrenal medulla, and by some sympathetic nerve fibers. Synthesis of dopamine and norepinephrine begins in the axoplasm of sympathetic nerve terminals from the amino acid tyrosine according to the following sequence: tyrosine →dopa →dopamine →norepinephrine (Fig. 34-24B). In the adrenal gland, an additional step takes place during which approximately 80% of the norepinephrine is transformed into epinephrine.

Each of the steps in sympathetic neurotransmitter synthesis requires a different enzyme, and the type of neurotransmitter that is produced depends on the types of enzymes that are available in a nerve terminal. For example, the postganglionic sympathetic neurons that supply blood vessels have the needed enzymes for the synthesis of norepinephrine, whereas those in the adrenal medulla have the enzymes needed to convert norepinephrine into epinephrine. As the catecholamines are synthesized, they are stored in vesicles. The final step of norepinephrine synthesis occurs in these vesicles. When an action potential reaches an axon terminal, the neurotransmitter molecules are released from the storage vesicles. The storage vesicles provide a means for concentrated storage of the catecholamines and protect them from the cytoplasmic enzymes that degrade the neurotransmitters.

In addition to neuronal synthesis, there is a second major mechanism for replenishment of norepinephrine in sympathetic nerve terminals. This mechanism consists of the active reuptake of the released neurotransmitter into the nerve terminal. Between 50% and 80% of the norepinephrine that is released during an action potential is removed from the synaptic area by an active reuptake process. This process terminates the action of the neurotransmitter and allows it to be reused by the neuron. The remainder of the released catecholamines diffuses into the surrounding tissue fluids or is degraded by two special enzymes: catechol-O-methyltransferase, which is diffusely present in all tissues, and monoamine oxidase (MAO), which is found in the nerve endings themselves.

Catecholamines can cause excitation or inhibition of smooth muscle contraction, depending on the site, dose, and type of receptor present. The excitatory or inhibitory responses of organs to sympathetic neurotransmitters are mediated by interaction with cell membrane receptors. There are two types of sympathetic receptors: α-adrenergic and β-adrenergic receptors. The α-adrenergic receptors have been further subdivided into α₁ and α₂ receptors, and β-adrenergic receptors into β₁, β₂, and β₃ receptors. The α₁ receptors are primarily found in postsynaptic effector sites; they mediate responses in vascular smooth muscle. It causes vasoconstriction in many blood vessels, including those of the skin, gastrointestinal tract, kidney, and brain. The α₂ receptors are mainly located presynaptically and can inhibit the release of norepinephrine from sympathetic nerve terminals. The α₂ receptors are abundant in the CNS and are thought to influence the central control of blood pressure. The β₁ receptors are primarily found in the heart; they mediate an increase in cardiac output by increasing heart rate (positive chronotropic effect), conduction velocity (positive dromotropic effect), and stroke volume (by enhancing contractility—positive inotropic effect). It can be selectively blocked by β₁-receptor–blocking drugs, such as atenolol. The β₂ receptors are found in the bronchioles and in other sites, such as visceral smooth muscle of the GI tract, uterus, and urinary bladder. Actions of the β₂ receptor by smooth muscle relaxation facilitate respiration, inhibit GI tract motility, inhibit labor, and delay need of micturition. The β₃ receptor is located mainly in adipose tissue and is involved in the regulation of lipolysis and thermogenesis.

**SUMMARY CONCEPTS**

- The autonomic nervous system (ANS) functions at the subconscious level and is responsible for maintaining the visceral functions of the body. The two divisions of the ANS are the sympathetic and parasympathetic nervous systems. Although these divisions function in concert, they are generally viewed as having opposite and antagonistic actions. The sympathetic division maintains vital functions and responds when there is a critical threat to the integrity of the individual—the “fight-or-flight” response. The parasympathetic nervous system is concerned with conservation of energy, resource replenishment, and maintenance of organ function during periods of minimal activity.
- The outflow of both divisions of the ANS consists of a two-neuron efferent pathway: a preganglionic and a postganglionic neuron. Acetylcholine is the neurotransmitter for the preganglionic neurons for both ANS divisions, as well as the postganglionic neurons of the parasympathetic nervous system. The catecholamines, including dopamine, norepinephrine, and epinephrine, are the neurotransmitters for most sympathetic postganglionic neurons.
REVIEW EXERCISES

1. An event such as cardiac arrest, which produces global ischemia of the brain, can result in a selective loss of recent memory and cognitive skills, while the more vegetative and life-sustaining functions such as breathing are preserved.
   A. Use principles related to the development of the nervous system and hierarchy of control to explain why.

2. Usually spinal cord injury or disease produces both sensory and motor deficits. An exception is infection by the poliomyelitis virus, which produces muscle weakness and paralysis without loss of sensation in the affected extremities.
   A. Explain using information on the cell column organization of the spinal cord.

3. The functions of the sympathetic nervous system are often described in relation to the “fight-or-flight” response. Using this description, explain the physiologic advantage for the following distribution of sympathetic nervous system receptors:
   A. The presence of \( \beta_2 \) receptors on the blood vessels that provide blood flow to the skeletal muscles during “fight or flight,” and the presence of \( \alpha_1 \) receptors on the resistance vessels that control blood pressure.
   B. The presence of acetylcholine receptors on the sweat glands that allow for evaporative loss of body heat during “fight or flight,” and the presence of \( \alpha_1 \) receptors that constrict the skin vessels that control blood flow to the skin.
   C. The presence of \( \beta_2 \) receptors that produce relaxation in the detrusor muscle of the bladder during “fight or flight,” and the presence of \( \alpha_1 \) receptors that produce contraction of the smooth muscle in the internal sphincter of the bladder.

BIBLIOGRAPHY

Sensory mechanisms provide individuals with a continuous stream of information about their bodies, the outside world, and the interactions between the two. The somatosensory component of the nervous system provides an awareness of pain, touch, temperature, and position, as compared to the specialized senses of sight and hearing (discussed in Chapter 38). Between 2 and 3 million nerve endings in the skin and deep body tissues provide a steady stream of encoded somatosensory information to the central nervous system. Only a small portion of this information reaches awareness; most of which provides input essential for the myriad of reflexes and automatic mechanisms that keep us functioning.

This chapter is organized into two distinct parts. The first part describes the organization and control of somatosensory function, and the second focuses on pain as a somatosensory modality.

Organization and Control of Somatosensory Function

The somatosensory system provides the central nervous system (CNS) with information related to deep and superficial body structures. It includes three types of neurons that vary in terms of distribution and type of sensation that is detected—general somatic, special somatic, and general visceral. General somatic afferent neurons have branches with widespread distribution throughout the body and with many distinct types of receptors that result in sensations such as pain, touch, and temperature. Special somatic afferent neurons have receptors located primarily in muscles, tendons, and joints. These receptors sense position and movement of the body. General visceral afferent neurons have receptors in various visceral structures that sense fullness and discomfort.

Somatosensory Systems

Sensory systems can be conceptualized as a series of first-order, second-order, and third-order neurons. First-order neurons transmit sensory information from the
periphery to the CNS. Second-order neurons communicate with various reflex networks and sensory pathways in the spinal cord and travel directly to the thalamus. Third-order neurons relay information from the thalamus to the cerebral cortex (Fig. 35-1).

This organizing framework corresponds with the three primary levels of neural integration in the somatosensory system: the sensory units, which contain the sensory receptors; the ascending pathways; and the central processing centers in the thalamus and cerebral cortex. Sensory information usually is relayed and processed in a cephalad (toward the head) direction by the three orders of neurons. Many interneurons process and modify the sensory information at the level of the second- and third-order neurons, and many more participate before coordinated and appropriate learned-movement responses occur. The number of participating neurons increases exponentially from the first-order through third-order levels.

The Sensory Unit

The somatosensory experience arises from information provided by a variety of receptors distributed throughout the body. These receptors monitor four major types or modalities of sensation: discriminative touch, which is required to identify the size and shape of objects and their movement across the skin; temperature sensation; sense of movement of the limbs and joints of the body; and nociception, or pain.

Each of these somatosensory modalities is mediated by a distinct system of receptors and pathways to the brain. However, all somatosensory information from the limbs and trunk shares a common class of first-order neurons called dorsal root ganglion neurons, and all somatosensory information from the face and cranial structures is transmitted by trigeminal sensory neurons, which function in the same manner as the dorsal root ganglion neurons. The cell body of the dorsal root ganglion neuron, its peripheral branch (which innervates a small area of periphery), and its central axon (which projects to the CNS) form a sensory unit.

The fibers of different dorsal root ganglion neurons conduct impulses at varying rates, ranging from 0.5 to 120 m/second. This rate depends on the diameter of the nerve fiber. There are three types of nerve fibers that transmit somatosensory information: A, B, and C. Type A fibers, which are myelinated, have the fastest rate of conduction. Type B fibers convey cutaneous pressure and touch sensation, cold sensation, mechanical pain, and heat pain. Type C fibers, which also are myelinated, transmit information from cutaneous and subcutaneous mechanoreceptors. The unmyelinated type C fibers have the smallest diameter and the slowest rate of conduction. They convey warm–hot sensation and mechanical and chemical as well as heat- and cold-induced pain sensation.

Dermatomal Pattern of Innervation

The somatosensory innervation of the body, including the head, retains a basic segmental pattern that was established during embryonic development. Thirty-three paired spinal (i.e., segmental) nerves provide sensory and motor innervation of the body wall, the limbs, and the viscera (see Chapter 34, Fig. 34-12). Sensory input to each spinal cord segment is provided by sensory neurons with cell bodies in the dorsal root ganglia. The head and face are innervated by the three branches of the trigeminal cranial nerve (CN V).

The region of the body wall that is supplied by a single pair of dorsal root ganglia is called a dermatome. These dorsal root ganglion–innervated strips occur in a regular sequence moving upward from the second coccygeal segment through the cervical segments, reflecting the basic segmental organization of the body and the nervous system (Fig. 35-2). Branches of the trigeminal nerve innervate the head, sending their axons to the equivalent nuclei in the brain stem. Neighboring dermatomes overlap one another sufficiently so that a loss of one dorsal root or root ganglion results in reduced but not total loss of sensory innervation of a dermatome (Fig. 35-3). Dermatome maps are helpful in interpreting the level and extent of sensory deficits that are the result of segmental nerve and spinal cord damage. For example, on the basis of the dermatomal map we can predict that sensory changes limited to the distal forearm and fourth and fifth fingers are the result of injury to the cervical (C) 8 and thoracic (T) 1 dorsal roots.

Spinal Circuitry and Ascending Neural Pathways

On entry into the spinal cord, the central axons of the somatosensory neurons branch extensively and project to neurons in the spinal cord gray matter. Some branches become involved in local spinal cord reflexes and directly initiate motor reflexes (e.g., flexor-withdrawal reflex). Two parallel pathways, the discriminative pathway and the anterolateral pathway, carry the information from the spinal cord to the thalamic level of sensation, each taking a different route through the CNS.1,2 Having a
two-pathway system has several advantages. It adds richness to the sensory input by allowing sensory information to be handled in two different ways, and it ensures that if one pathway is damaged, the other still can provide input.

**Discriminative Pathway.** The discriminative pathway is used for the rapid transmission of sensory information, such as discriminative touch. It uses only three types of neurons to transmit information from a sensory receptor to the somatosensory cortex on the opposite side of the brain: (1) the dorsal root ganglion neurons, which project their central axons to the dorsal horn in the spinal cord; (2) the dorsal column nuclei, which send their axons upward and across the midline of the medulla where they form a band of white matter called the *medial lemniscus* that passes upward to the thalamus; and (3) the thalamic neurons, which project to the primary sensory cortex (Fig. 35-4A). As the fibers in the medial lemniscus ascend through the brain stem, they are joined by sensory fibers from the trigeminal nerve that supplies the head and face. Sensory information arriving at the sensory cortex by this route can be discretely localized and discriminated in terms of intensity.

One of the distinct features of the discriminative pathway is that it relays precise information regarding spatial orientation. This is the only pathway taken by the sensations of muscle and joint movement, vibration, and delicate discriminative touch, which is required to correctly differentiate the location of touch on the skin at two neighboring points (i.e., two-point discrimination). One of the important functions of the discriminative pathway is to integrate the input from multiple receptors. The sense of shape and size of an object in the absence of visualization, called *stereognosis*, is based on precise afferent information from muscle, tendon, and joint receptors. For example, a screwdriver is perceived as being different from a knife in terms of its texture (tactile sensibility) and shape based on the relative position of the fingers as they move over the object. This complex interpretive perception requires that both the discriminative pathway and the somatosensory association area of the cerebral cortex are functioning properly. If the discriminative
pathway is functional but the association area has been damaged, the person can correctly describe the object but does not recognize it as a screwdriver. This deficit is called **astereognosis**.

**Anterolateral Pathway.** The anterolateral pathway (anterior and lateral spinothalamic tracts) consists of bilateral, multisynaptic, slow-conducting tracts (see Chapter 34, Fig. 34-11). These tracts provide for transmission of sensory information such as pain, thermal sensations, crude touch, and pressure that does not require discrete localization of signal source or fine discrimination of intensity. The fibers of the anterolateral pathway originate in the dorsal horns at the level of the segmental nerve, where the dorsal root ganglion neurons enter the spinal cord. These spinal neurons cross in the anterior commissure, within a few segments of origin, to the anterolateral column on the opposite side of the cord, and then ascend upward toward the brain. The anterolateral tract fibers synapse with several nuclei in the thalamus, but en route they give off numerous branches that travel to the reticular activating system of the brain stem. These projections provide the basis for increased wakefulness or awareness after strong somatosensory stimulation and for the generalized startle reaction that occurs with sudden and intense stimuli. They also stimulate autonomic nervous system responses, such as a rise in heart rate and blood pressure, dilation of the pupils, and the pale, moist skin that results from constriction of the cutaneous blood vessels and activation of the sweat glands.

There are two subdivisions in the anterolateral pathway: the neospinothalamic and paleospinothalamic tracts are important in pain perception (see Fig. 35-4B). The **neospinothalamic tract** consists of a sequence of at least three neurons with long axons. It provides for relatively rapid transmission of sensory information to the thalamus. The **paleospinothalamic tract**, which is phylogenically older, consists of bilateral, multisynaptic, slow-conducting tracts that transmit sensory signals that do not require discrete localization or discrimination of fine gradations in intensity. This slower-conducting pathway also projects into the intralaminar nuclei of the thalamus, which have close connections with the limbic cortical systems. This circuitry gives touch its affective or emotional aspects, such as the particular unpleasantness of heavy pressure and the peculiar pleasantness of the tickling and gentle rubbing of the skin.
Central Processing of Somatosensory Information

Perception, or the final processing of somatosensory information, involves awareness of the stimuli, localization and discrimination of their characteristics, and interpretation of their meaning.\(^1,2\) As sensory information reaches the thalamus, it begins to enter the level of consciousness, is roughly localized, and is perceived as a crude sense. The full localization, discrimination of the intensity, and interpretation of the meaning of the stimuli require processing by the somatosensory cortex.

The somatosensory cortex is located in the parietal lobe, which lies behind the central sulcus and above the lateral sulcus (Fig. 35-5). The strip of parietal cortex that borders the central sulcus is called the primary somatosensory cortex because it receives primary sensory information by direct projections from the thalamus. Parallel to and just behind the primary somatosensory cortex (i.e., toward the occipital cortex) lies the somatosensory association area, which is required to transform the raw sensory information into a meaningful learned perception. Most of the perceptive aspects of body sensation, or somesthesia, require the function of this association area. The perceptive aspect, or meaningfulness, of a stimulus pattern—such as the perception of sitting on a soft chair rather than on a hard bicycle seat—involves the integration of present sensation with past learning.

**Somatosensory Modalities**

Earlier, we noted that somatosensory experience can be divided into modalities, qualitative distinctions between the sensations of touch, temperature, position, and pain.\(^1,2\) Somatosensory experience also involves quantitative discrimination; that is, the ability to distinguish between different intensities of sensory stimulation. Although sensory receptors can respond to many forms of sensory information at high levels, they are highly sensitive to low levels of a particular type of sensation. For example, a receptor may be particularly sensitive to a small increase in local skin temperature, yet stimulation with strong pressure also can result in receptor stimulation. Cool versus warm, sharp versus dull pain, and delicate touch versus deep pressure are all based on different populations of afferent neurons or on central integration of simultaneous input from several differently tuned afferents.

**Tactile Sensation**

The tactile system, which relays sensory information regarding touch, pressure, and vibration, is considered the basic somatosensory system. Loss of temperature or pain sensitivity leaves the person with no awareness of deficiency. If the tactile system is lost, however, total anesthesia (i.e., numbness) of the involved body part results.

Touch sensation results from stimulation of tactile receptors in the skin and in tissues immediately beneath the skin, pressure from deformation of deeper tissues, and vibration from rapidly repetitive sensory signals. There are at least six types of specialized tactile receptors in the skin and deeper structures: free nerve endings, Meissner corpuscles, Merkel disks, pacinian corpuscles, hair follicle end-organs, and Ruffini end-organs\(^1,2\) (Fig. 35-6).

Free nerve endings are found in skin and many other tissues, including the cornea. They detect touch and pressure. Meissner corpuscles are elongated, encapsulated nerve endings present in nonhairy parts of the skin. They are particularly abundant in the fingertips, lips, and other areas where the sense of touch is highly developed. Merkel disks are dome-shaped receptors found in nonhairy and hairy parts of the skin. In contrast to Meissner corpuscles, which adapt within a fraction of a second, Merkel disks transmit an initial strong signal that diminishes in strength but is slow in adapting. They are responsible for giving steady-state signals that allow for continuous sense of touch against the skin.

Pacinian corpuscles are located immediately beneath the skin and deep in the fascial tissues. They are stimulated by rapid movements of the tissues and are important in detecting tissue vibration. The hair follicle end-organs consist of afferent unmyelinated fibers entwined around most of the length of the hair follicle. These receptors, which are rapidly adapting, detect movement on the surface of the body. Ruffini end-organs are found in the skin and deeper structures, including the joint capsules. These receptors, which have multibranched encapsulated endings, have very little adaptive capacity and are important for signaling continuous states of deformation, such as heavy and continuous touch and pressure.

Almost all the specialized touch receptors, with the exception of free nerve endings, transmit their signals through large myelinated nerve fibers (i.e., types Aα, Aβ) that have transmission velocities ranging from 25 to 70 m/second. Most free nerve endings transmit signals...
by way of small myelinated fibers (i.e., type Aδ) with conduction velocities of 10 to 30 m/second.

The sensory information for tactile sensation enters the spinal cord through the dorsal roots of the spinal nerves. All tactile sensation that requires rapid transmission is conducted through the discriminative pathway to the thalamus by way of the medial lemniscus. Tactile sensation also uses the more primitive and crude anterolateral pathway. Because of these multiple routes, total destruction of the anterolateral pathway seldom occurs. The only time this crude alternative system becomes essential is when the discriminative pathway is damaged. Then, despite projection of the anterolateral system information to the somatosensory cortex, only a poorly localized, high-threshold sense of touch remains. Such persons lose all sense of joint and muscle movement, body position, and two-point discrimination.

**Thermal Sensation**

Thermal sensation is discriminated by three types of receptors: cold, warmth, and pain. The cold and warmth receptors are located immediately under the skin at discrete but separate points, each serving an area of approximately 1 mm². Different gradations of heat and cold reception result from the relative degrees of stimulation of the different types of nerve endings. Warmth receptors respond proportionately to increases in skin temperature above resting values of 34°C and cold receptors to temperatures below 34°C. The thermal pain receptors are stimulated only by extremes of temperature such as “freezing cold” (temperatures below 5°C) and “burning hot” (temperatures above 45°C) sensations. Thermal receptors respond rapidly to sudden changes in temperature and then adapt over the next few minutes. They do not adapt completely, however, but continue to respond to steady states of temperature. For example, the sensation of heat one feels on entering a tub of hot water is the initial response to a change in temperature, followed by an adaptation in which one gets accustomed to the temperature change but still feels the heat because the receptors have not adapted completely.

Thermal afferents, with receptive thermal endings in the skin, send their central axons into the segmental dorsal horn of the spinal cord. On entering the dorsal horn, thermal signals are processed by second-order input association neurons. These association neurons activate projection neurons whose axons then cross to the opposite side of the cord and ascend in the multisynaptic, slow-conducting anterolateral system to the opposite side of the brain. Thalamic and cortical somatosensory regions for temperature are mixed with those for tactile sensibility.

Conduction of thermal information through peripheral nerves is quite slow compared with the rapid conduction of tactile sensation that travels through the discriminative system. If a person places a foot in a tub of hot water, the tactile sensation occurs well in advance of the burning sensation. The foot has been removed from the hot water by the local withdrawal reflex well before the excessive heat is perceived by the forebrain. Local anesthetic agents block the small-diameter afferents that carry thermal sensory information before they block the large-diameter axons that carry discriminative touch information.

**Position Sense**

Proprioception refers to the sense or perception of limb and body movement and position without the use of vision. It is mediated by input from proprioceptive receptors (muscle spindle receptors and Golgi tendon organs) found primarily in muscles, tendons, and joint capsules (see Chapter 36). There are two submodalities of proprioception: the stationary or static component (limb position sense) and the dynamic aspects of position sense (kinesthesia). Both of these depend on constant transmission of information to the CNS regarding the degree of angulation of all joints and the rate of change in angulation. In addition, stretch-sensitive receptors in the skin (Ruffini end-organs, pacinian corpuscles, and Merkel cells) also signal postural information. Signals from these receptors are processed through the dorsal column–medial lemniscus pathway. In addition, stretch-sensitive receptors in the skin (Ruffini end-organs, pacinian corpuscles, and
Merkel cells) also signal postural information. Signals from these receptors travel through the discriminative pathway and are processed in the thalamus before reaching the cerebral cortex. Lesions affecting the posterior column of the spinal cord impair position sense. The vestibular system (see Chapter 38) also plays an essential role in position sense.

**SUMMARY CONCEPTS**

- The somatosensory component of the nervous system relays information about four major sensory modalities of touch, temperature, pain, and body position.

- Somatosensory information is sequentially transmitted over three types of neurons: first-order neurons, which transmit information from receptors in the sensory units of the system to dorsal horn neurons; second-order association neurons in the spinal cord, which communicate with various reflex circuits and transmit information to the thalamus, where it is roughly localized and perceived as a crude sense; and third-order neurons, which forward the information from the thalamus to the somatosensory cortex, where full localization, intensity discrimination, and interpretation occurs.

- The somatosensory system is organized segmentally into dermatomes, with each segment supplied by a single dorsal root ganglion that contains the neuronal cell bodies for the sensory units of the segment.

- There are two ascending pathways for transmission of somatosensory information: the discriminative and anterolateral pathways. The discriminative pathway, which crosses at the medulla, uses only three neurons to rapidly transmit information such as position sense and discriminative touch from sensory receptors to somatosensory cortex. The anterolateral pathway, which crosses within the first few segments of entering the spinal cord, consists of bilateral, multisynaptic, slow-conducting tracts that transmit information such pain, thermal sensation, crude touch, and pressure.

**Pain Sensation**

Pain is an unpleasant sensory and emotional sensation associated with actual or potential tissue damage. Unlike other somatic modalities, pain has an urgent and primitive quality, a quality responsible for the psychological, social, cultural, and cognitive aspects of the pain experience. Despite its unpleasantness, pain can serve a useful purpose in that it warns of impending tissue injury, motivating the person to seek relief. For example, an inflamed appendix could progress in severity, rupture, and even cause death were it not for the warning afforded by pain.

Pain is a common symptom that varies widely in intensity and spares no age group. It can be equally devastating for infants and children, young and middled-aged adults, and the elderly. Both acute pain and chronic pain can be major health problems. It is the most common reason for visits to health care facilities. Acute pain often results from injury, surgery, or invasive medical procedures. It also can be a presenting symptom of infections, such as otitis media. Chronic pain can be symptomatic of a wide range of health problems including arthritis, back injury, and cancer.

**Pain Theories**

Many theories, including the specific and pattern theories, have been offered to explain the physiologic basis for the pain experience. The specificity theory regards pain as a separate sensory modality evoked by the activity of specific receptors that transmit information by special nerve endings to pain centers or regions in the forebrain where pain is experienced. Pattern theory proposes that pain receptors share endings or pathways with other sensory modalities, but that different patterns of activity (i.e., spatial or temporal) of the same neurons can be used to signal painful and nonpainful stimuli. For example, light touch applied to the skin would produce the sensation of touch through low-frequency firing of the receptor; intense pressure would produce pain through high-frequency firing of the same receptor. Both of these theories focus on the neurophysiologic basis of pain, and aspects of both probably apply. Specific nociceptive afferents have been identified; however, almost all afferent stimuli, if driven at a very high frequency, can be experienced as painful.

Gate control theory, a modification of specificity theory proposed by Melzack and Wall in 1965, postulated that the presence of a neural gating mechanism at the segmental spinal cord level could block projection of pain information to the brain. According to this theory, internuncial neurons involved in the gating mechanism are activated by large-diameter, faster-propagating fibers that carry tactile information capable of blocking the transmission of impulses from small-diameter myelinated and unmyelinated pain fibers. Pain therapists have long known that pain intensity can be temporarily modified by the stimulation of other sensory fibers. For example, repeated sweeping of a soft-bristled brush on the skin (i.e., brushing) over or near a painful area may result in pain reduction for several minutes to several hours.

Pain modulation is now known to be a much more complex phenomenon than that proposed by these theories. Tactile information is transmitted by small- and large-diameter fibers. Major interactions between sensory modalities, including the so-called gating phenomenon,
occur at several levels of the CNS rostral to the input segment. Perhaps the most puzzling aspect of locally applied stimuli, such as brushing, that can block the experience of pain is the relatively long-lasting effect (minutes to hours) of such treatments. This prolonged effect has been difficult to explain on the basis of specificity theories, including the gate control theory. Other important factors include the effect of endogenous opioids and their receptors at the segmental and brain stem level, descending feedback modulation, altered sensitivity, learning, and culture.

More recently, Melzack has developed the neuromatrix theory to further address the brain’s role in pain as well as the psychological and emotional dimensions of pain. This theory proposes that the brain contains a widely distributed neural network, called the body–self neuromatrix, that has multiple somatosensory, limbic, and thalamocortical components. Genetic and sensory influences determine the architecture of each individual’s neuromatrix, which integrates multiple sources of inputs. These include somatosensory inputs; other sensory inputs affecting interpretation of the situation; inputs from the brain addressing such things as attention, expectation, culture, and personality; various components of stress regulation systems; and other sources. The neuromatrix theory of pain, which places genetic and neuroendocrine mechanisms on a level equal to that of neural transmission, has important implications for research and therapy.  

Pain Mechanisms and Pathways

Pain can be either nociceptive or neuropathic in origin. The term nociception, which means “pain sense,” comes from the Latin word nocere, “to injure.” Nociceptive pain is initiated by nociceptors that are activated by injury to peripheral tissues. Neuropathic pain, on the other hand, arises from direct injury or dysfunction of the sensory axons of peripheral or central nerves. Two aspects of pain affect an individual’s response to a painful stimulus—pain threshold and tolerance. Although the terms often are used interchangeably, they have distinct meanings. Pain threshold is closely associated with the point at which a nociceptive stimulus is perceived as painful. Pain tolerance relates more to the total pain experience; it is defined as the maximum intensity or duration of pain that a person is willing to endure before the person wants something done about the pain. Psychological, familial, cultural, and environmental factors significantly influence the amount of pain a person is willing to tolerate. The threshold for pain is fairly uniform from one person to another, whereas pain tolerance is extremely variable.

The mechanisms of pain are many and complex. As with other forms of somatosensation, the pathways are composed of first-, second-, and third-order neurons (Fig. 35-7). The first-order neurons and their receptive endings detect stimuli that threaten the integrity of innervated tissues. Second-order neurons are located in the spinal cord and process nociceptive information. Third-order neurons project pain information to the brain. The thalamus and somatosensory cortex integrate and modulate pain as well as the person’s subjective reaction to the pain experience.

Pain Receptors and Primary Afferent Pathways

Nociceptors, or pain receptors, are activated by noxious insults to peripheral tissues. Structurally, they are free nerve endings of the peripheral pain fibers. These receptive endings translate noxious stimuli into signals that are transmitted by a dorsal root ganglion to the dorsal horn of the spinal cord.

Nociceptive Simulation. Unlike other sensory receptors, nociceptors respond to several forms of stimulation, including mechanical, thermal, and chemical. Some receptors respond to a single type of stimuli (mechanical or thermal) and others, called polymodal receptors,
respond to all three types of stimuli (mechanical, thermal, and chemical). Mechanical stimuli can arise from intense pressure applied to skin or from the violent contraction or extreme stretch of a muscle. Extremes of both heat and cold can stimulate nociceptors. Chemical stimuli arise from a number of sources, including chemical mediators released from injured and inflamed tissues. These chemical mediators produce their effects by directly stimulating nociceptors or sensitizing them to the effects of nociceptive stimuli; perpetuating the inflammatory responses that lead to the release of chemical agents that act as nociceptive stimuli; or inciting neurogenic reflexes that increase the response to nociceptive stimuli. For example, bradykinin, histamine, serotonin, and potassium activate and also sensitize nociceptors, resulting in the lowering of the activation threshold. This in turn results in a transmission of afferent signals to the dorsal horn and causes neurogenic inflammation. Other chemical mediators act alone or in concert to sensitize nociceptors through other chemical agents such as prostaglandins. Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) are effective in controlling pain because they block the enzyme needed for prostaglandin synthesis.

Peripheral Pain Fibers. Two types of afferent fibers transmit pain signals from the free nerve endings into the CNS: myelinated Aδ fibers and unmyelinated C fibers.1,2 The larger Aδ fibers have considerably greater conduction velocities, transmitting impulses at a rate of 10 to 30 m/second. The C fibers are the smallest of all peripheral nerve fibers; they transmit impulses at the rate of 0.5 to 2.5 m/second. Pain conducted by Aδ fibers traditionally is called fast pain or first pain and typically is elicited by mechanical or thermal stimuli. C-fiber pain often is described as slow pain or second pain because it is slower in onset and longer in duration, continuing to elicit pain for up to 80 hours.9 It typically is incited by chemical stimuli or by persistent mechanical or thermal stimuli. The slow postexcitatory impulses generated in C fibers are now believed to be responsible for central sensitization to chronic pain.

Nociceptive stimulation that activates C fibers can cause a response known as neurogenic inflammation that produces vasodilatation and an increased release of chemical mediators to which nociceptors respond. This inflammatory process results in vasodilatation and the leakage of proteins and fluids into the extracellular space around the terminal end of the nociceptor. As a result, there is increased activity of immune cells, which further contributes to the inflammatory process.8 This mechanism is thought to be mediated by a dorsal root neuron reflex that produces retrograde transport and release of chemical mediators, which in turn causes increasing inflammation of peripheral tissues. This reflex can set up a vicious cycle, which has implications for persistent pain and hyperalgesia (excessive sensitivity to pain), a condition in which the second-order neurons are overly sensitive to low levels of noxious stimulation.

The transmission of impulses between the peripheral nociceptive neurons and dorsal horn neurons in the spinal cord is mediated by neurotransmitters released from nerve endings of the nociceptive neurons.10 Some of these neurotransmitters are amino acids (e.g., glutamate), others are amino acid derivatives (e.g., norepinephrine), and still others are low-molecular-weight peptides composed of two or more amino acids. The amino acid glutamate is a major excitatory neurotransmitter released from the central nerve endings of the nociceptive neurons. Substance P, a neuropeptide, also is released in the dorsal horn by C fibers in response to nociceptive stimulation. Substance P elicits slow excitatory potentials in dorsal horn neurons. Unlike glutamate, which confines its action to the immediate area of the synaptic terminal, some neuropeptides released in the dorsal horn can diffuse some distance because they are inactivated by reuptake mechanisms. This may help to explain the excitability and unlocalized nature of many persistently painful conditions. Neuropeptides such as substance P also appear to prolong and enhance the action of glutamate. If these neurotransmitters are released in large quantities or over extended periods, they can lead to secondary hyperalgesia.

Spinal Cord Circuitry and Ascending Pathways

On entering the spinal cord through the dorsal roots, the pain fibers bifurcate and ascend or descend one or two segments before synapsing with association neurons in the dorsal horn. From the dorsal horn, the axons of association projection neurons cross through the anterior commissure to the opposite side and then ascend upward in the previously described neospinothalamic and anterolateral pathways (Fig. 35-8).

The faster-conducting fibers in the neospinothalamic tract are associated mainly with the transmission of sharp–fast pain information to the thalamus. In the thalamus, synapses are made and the pathway continues to the contralateral parietal somatosensory area to provide the precise location of the pain. Typically, the pain is experienced as bright, sharp, or stabbing in nature.

The paleospinothalamic tract is a slower-conducting, multisynaptic tract concerned with the diffuse, dull, aching, and unpleasant sensations that commonly are associated with chronic and visceral pain. Fibers of this system also travel up the contralateral (i.e., opposite) anterolateral pathway to terminate in several thalamic regions, including the intralateral nuclei, which project to the limbic system. These projections are associated with the emotional or affective–motivational aspects of pain. Spinoreticular fibers from this pathway project bilaterally to the reticular formation of the brain stem. This component of the paleospinothalamic system facilitates avoidance reflexes at all levels. It also contributes to elevated levels of alertness and increased heart rate and blood pressure that can occur with pain.

Brain Centers and Pain Perception

Information from tissue injury is carried from the spinal cord to brain centers in the thalamus where the basic sensation of hurtfulness, or pain, occurs (see Fig. 35-8). In the neospinothalamic system, interconnections between the
lateral thalamus and the somatosensory cortex are necessary to add precision, discrimination, and meaning to the pain sensation. The paleospinothalamic system projects diffusely from the intralaminar nuclei of the thalamus to large areas of the limbic cortex. These connections probably are associated with the hurtfulness and the mood-altering and attention-narrowing effect of pain.

Recent research has demonstrated cortical representation of fast–sharp and slow–chronic types of pain sensation. In healthy adults, nociceptive A\(\delta\) afferent stimulation is related to activation in the contralateral primary somatosensory cortex in the parietal lobe, whereas C afferent stimulation is related to activation of the secondary somatosensory cortices and the anterior cingulated cortex, which is part of the limbic system. With both afferents there is activation of the bilateral secondary somatosensory cortices in the posterior parietal lobes.

**Central Pathways for Pain Modulation**

A major advance in understanding pain was the discovery of neuroanatomic pathways that arise in the midbrain and brain stem, descend to the spinal cord, and modulate ascending pain impulses. One such pathway
begins in an area of the midbrain called the periaqueductal gray (PAG) region. Opioid receptors are highly concentrated in this region of the CNS and produce analgesia (pain relief) through the release of endogenous opioids. Thus, the PAG area of the midbrain often is referred to as the endogenous analgesia center.

The PAG region receives input from widespread areas of the CNS by way of the paleospinothalamic and neospinothalamic tracts. It is intimately connected to the limbic system, which is associated with emotional experience. The neurons of the PAG have axons that descend into an area in the rostral medulla called the nucleus raphe magnus (NRM). The axons of these NRM neurons project to the dorsal horn of the spinal cord, where they terminate in the same layers as the entering primary pain fibers (see Fig. 35-1). In the spinal cord these descending pathways inhibit pain transmission by dorsal horn projection neurons. Serotonin has been identified as a neurotransmitter in the NRM medullary nuclei. Tricyclic antidepressant drugs, such as amitriptyline, which enhance the effects of serotonin by blocking its presynaptic uptake, have been found to be effective in the management of certain types of chronic pain.

Additional inhibitory spinal projections arise from noradrenergic neurons in the pons and medulla, which also receive input from the PAG.

### Endogenous Analgesic Mechanisms

There is evidence that opioid receptors and endogenously synthesized opioid peptides are found on the peripheral processes of primary afferent neurons and in many regions of the CNS. Three families of opioid peptides have been identified—the enkephalins, endorphins, and dynorphins. Although they appear to function as neurotransmitters, their full significance in pain control and other physiological functions is not completely understood. However, research into the receptors that bind these endogenous opioid peptides has increased our understanding of the actions of available opioid drugs, such as morphine, and has stimulated further research into the development of new preparations that are more effective in relieving pain, but with fewer side effects than existing drugs.

### Types of Pain

The most widely accepted classifications of pain are based on source or location (somatic or visceral), referral, and duration (acute or chronic). Classification based on associated medical diagnosis (e.g., surgery, trauma, cancer, sickle cell disease, fibromyalgia) is useful in planning appropriate interventions.

### Cutaneous and Deep Somatic Pain

Cutaneous pain arises from superficial structures, such as the skin and subcutaneous tissues. It is a sharp pain with a burning quality and may be abrupt or slow in onset. It can be localized accurately and may be distributed along the dermatomes. Because there is an overlap of nerve fiber distribution between the dermatomes, the boundaries of pain frequently are not as clear-cut as dermatome diagrams indicate.

Deep somatic pain originates in deep body structures, such as the peristemeum, muscles, tendons, joints, and blood vessels. This pain is more diffuse than cutaneous pain. Various stimuli, such as strong pressure exerted on bone, ischemia to a muscle, and tissue damage, can produce deep somatic pain. Radiation of pain from the original site of injury can occur. For example, damage to a spinal nerve root can cause a person to experience pain radiating along its fiber distribution.

### Visceral Pain

Visceral, or splanchnic, pain has its origin in the visceral organs and is one of the most common pains produced by disease. One of the most important differences between somatic and visceral pain is the type of damage that causes pain. For example, “a surgeon can cut the bowel entirely in two in a patient who is awake without causing significant pain.” In contrast, strong contractions, distention, or ischemia affecting the walls of the viscera can induce severe pain. Also, visceral pain is not evoked from all viscera (e.g., the liver or lung). Another difference is the diffuse and poorly localized nature of visceral pain—its tendency to be referred to other locations and to be accompanied by symptoms associated with autonomic reflexes (e.g., nausea). There are several explanations for this. There is a low density of nociceptors in the viscera compared with the skin. There is functional divergence of visceral input within the CNS, which occurs when many second-order neurons respond to a stimulus from a single visceral afferent. There is also convergence between somatic and visceral afferents in the spinal cord and in the supraspinal centers, and possibly also between visceral afferents (e.g., bladder, uterus, cervix, and vagina).

Visceral afferents are predominantly small, unmyelinated pain fibers that terminate in the dorsal horn of the spinal cord and express peptide neurotransmitters such as substance P. Extended visceral stimulation, such as that caused by hypoxia and inflammation, often results in sensitization of the visceral nociceptors. Once sensitized, these receptors begin to respond to otherwise innocuous stimuli (e.g., motility and secretory activity) that normally occur in the viscera. This sensitization may resolve more slowly than the initial injury, and thus visceral pain may persist longer than expected based on the initial injury.

### Referred Pain

Referred pain is pain that is perceived at a site different from its point of origin but innervated by the same spinal segment. It is hypothesized that visceral and somatic afferent neurons converge on the same dorsal horn projection neurons (Fig. 35-9). For this reason, it can be difficult for the brain to correctly identify the original source of pain. Pain that originates in the abdominal or thoracic viscera is diffuse and poorly localized and often perceived at a site far removed from the affected area. For example, the pain associated with myocardial infarction commonly is referred to the left arm, neck, and chest, which may delay diagnosis and treatment...
of a potentially life-threatening condition. Moreover, referred pain may arise alone or concurrent with pain located at the origin of the noxious stimuli.

Although the term referred usually is applied to pain that originates in the viscera and is experienced as if originating from the body wall, it also may be applied to pain that arises from somatic structures. For example, pain referred to the chest wall could be caused by nociceptive stimulation of the peripheral portion of the diaphragm, which receives somatosensory innervation from the intercostal nerves. An understanding of pain referral is of great value in diagnosing illness. The typical pattern of pain referral can be derived from understanding that the afferent neurons from visceral or deep somatic tissue enter the spinal cord at the same level as the afferent neurons from the cutaneous areas to which the pain is referred (Fig. 35-10).

The sites of referred pain are determined embryologically with the development of visceral and somatic structures that share the same site for entry of sensory information into the CNS and then move to more distant locations. For example, a person with peritonitis may complain of pain in the shoulder. Internally, there is inflammation of the peritoneum that lines the central part of the diaphragm. In the embryo, the diaphragm originates in the neck, and its central portion is innervated by the phrenic nerve, which enters the cord at the level of the third to fifth segments (C3 to C5). As the fetus develops, the diaphragm descends to its adult position between the thoracic and abdominal cavities while maintaining its embryonic pattern of innervation. Thus, fibers that enter the spinal cord at the C3 to C5 levels carry information from both the neck area and the diaphragm, and the diaphragmatic pain is interpreted by the forebrain as originating in the shoulder or neck area.

Although the visceral pleura, pericardium, and peritoneum are said to be relatively free of pain fibers, the parietal pleura, pericardium, and peritoneum do react to nociceptive stimuli. Visceral inflammation can involve parietal and somatic structures, and this may give rise to diffuse local or referred pain. For example, irritation of the parietal peritoneum resulting from appendicitis typically gives rise to pain directly over the inflamed area in the lower right quadrant, while producing referred pain in the umbilical area.

Muscle spasm, or guarding, occurs when somatic structures are involved. Guarding is a protective reflex rigidity; its purpose is to protect the affected body parts (e.g., an abscessed appendix or a sprained muscle). This protective guarding may cause blood vessel compression and give rise to the pain of muscle ischemia, causing local and referred pain.

**Acute and Chronic Pain**

It is common to classify pain according to its duration. Pain research of the last several decades has emphasized the importance of differentiating acute pain from chronic pain. The diagnosis and therapy for each is distinctive because they differ in cause, function, mechanisms, and psychological sequelae (Table 35-1).
Traditionally, the distinction between acute and chronic pain has relied on a single continuum of time with some interval (e.g., 6 months) since the onset of pain used to designate the onset of acute pain or the transition when acute pain became chronic. A more recent conceptualization includes both time and pathophysiologic dimensions. Some conditions such as osteoarthritis exhibit dimensions of both acute and chronic pain.

**Acute Pain.** Acute pain is generally of short duration and remits when the underlying pathologic process has resolved. Besides alerting the person to the existence of actual or impending tissue damage, acute pain typically prompts a search for professional help. The pain’s location, radiation, intensity, and duration, as well as those factors that aggravate or relieve it, provide essential diagnostic clues.

Acute pain is elicited by surgery or trauma to body tissues and activation of nociceptive stimuli at the site of tissue damage. This may induce an early wave of hyperexcitability of neurons within the CNS. The development of an inflammatory reaction to the tissue injury, with sensitization of peripheral receptors, often results in a second wave of longer-acting afferent input and a new increase in central hyperexcitability. The resulting hyperalgesia can lead to increased postoperative and post-traumatic pain, usually after the second or third day, and in some cases an increased likelihood of developing chronic pain. A number of chronic pain syndromes, including whiplash injury and phantom pain, develop after trauma and surgery.

Because acute pain is self-limited, in that it resolves as the injured tissues heal, long-term therapy usually is not needed. However, pain from acute illness, trauma, surgery, or medical procedures should be aggressively managed and preemptive analgesia provided before the pain becomes severe. The use of preemptive and multimodal therapy (two or more analgesics with differing analgesic mechanisms) not only allows the person to be more comfortable and active, but also helps to prevent peripheral sensitization of pain receptors and hyperexcitability of central pain centers. Usually, less medication is needed when the drug is given before the pain becomes severe and the pain pathways become sensitized. Interventions that alleviate acute pain also relieve the anxiety and musculoskeletal spasms, as well increasing mobility and respiratory movements such as deep breathing and coughing.

**Chronic Pain.** Chronic pain is pain that persists longer than might be reasonably expected after an inciting event and is sustained by factors that are both pathologically and physically remote from the originating cause. Chronic pain is highly variable. It may be unrelenting and extremely severe, as in metastatic bone pain. It can be relatively continuous with or without periods of escalation, as with some forms of back pain. Some conditions with recurring episodes of acute pain are particularly problematic because they have characteristics of both acute and chronic pain, as in sickle cell crisis or migraine headaches.

The biologic factors that contribute to chronic pain include peripheral mechanisms, peripheral–central mechanisms, and central mechanisms. Peripheral mechanisms result from persistent stimulation of nociceptors, termed peripheral sensitization. Inflammatory mediators released from injured tissues increase the sensitivity of the C fibers and lead to increased duration of pain associated with chronic musculoskeletal, visceral, and vascular disorders. Peripheral–central mechanisms involve abnormal function of the peripheral and central portions of the somatosensory system.
result from partial or complete loss of descending inhibitory pathways or spontaneous firing of regenerated nerve fibers. They include conditions such as causalgia, phantom limb pain, and postherpetic neuralgia. Central pain, which is associated with disease or injury of the CNS, is characterized by burning, aching, hyperalgesia, dysesthesia, and other abnormal sensations, and is experienced as superficial (skin) or deep (bone or muscle) pain. It is associated with conditions such as thalamic lesions, spinal cord injury, surgical interruption of pain pathways, and multiple sclerosis.

Unlike acute pain, chronic pain serves no useful purpose. It imposes physiologic, psychological, interpersonal, and economic stresses and may exhaust a person’s resources. It is often associated with loss of appetite, sleep disturbances, and depression, which commonly is relieved once the pain is removed.

Chronic pain management is complex and treatment depends on the cause of the pain, the natural history of the underlying health problem, and the life expectancy of the individual. If the organic illness causing the pain cannot be cured, then noncurative methods of pain control become the cornerstone of treatment. Chronic pain is best handled by a multidisciplinary team that includes specialists in areas such as anesthesiology, nursing, physical therapy, social services, and surgery.

Cancer is a common cause of chronic pain. The goal of chronic cancer pain management should be pain alleviation and prevention. Preemptive therapy tends to reduce sensitization of pain pathways and provides for more effective pain control. Pharmacologic and nonpharmacologic interventions are the same as those used for other types of chronic pain. Depending on the form and stage of the cancer, other treatments such as palliative radiation, antineoplastic therapies, and palliative surgery may help to control the pain. In 1986, the World Health Organization (WHO) developed a three-step ladder that assists clinicians in choosing the appropriate analgesic medications. Step 1 involves the use of nonopioid analgesics, and steps 2 and 3 involve the use of opioid analgesics.

Pain Management

Careful assessment of pain assists clinicians in diagnosing, managing, and relieving the patient’s pain. As with other disease states, eliminating the cause of the pain is preferable to simply treating the symptom.

Assessment

Assessment includes such things as the nature, severity, location, and radiation of the pain. Reports of pain are almost entirely subjective. A careful history often provides information about the triggering factors (i.e., injury, infection, or disease) and the site of nociceptive stimuli (i.e., peripheral receptor or visceral organ). A comprehensive pain history should include pain onset; description, localization, radiation, intensity, quality, and pattern of the pain; anything that relieves or exacerbates it; and the individual’s personal reaction to the pain.

The single most reliable indicator of the existence and intensity of acute pain is probably the person’s self-report. Unlike many other bodily responses, such as temperature and blood pressure, the nature, severity, and distress of pain cannot be measured objectively. To overcome this problem, various methods have been developed for quantifying pain based on the person’s report. They include numeric pain intensity, visual analog, and verbal descriptor scales. Most pain questionnaires assess a single aspect of pain such as pain intensity. For example, a numeric pain intensity scale would have patients select which number best represents the intensity of their pain, where 0 represents no pain and 10 represents the most intense pain imaginable. A visual analog scale also can be used; it is a straight line, often 10 cm in length, with a word description (e.g., “no pain” and “the most intense pain imaginable”) at each of the ends of the line representing the continuum of pain intensity.

Nonpharmacologic Interventions

A number of nonpharmacologic methods of pain control are used in pain management. These include cognitive-behavioral interventions (e.g., relaxation, distraction, imagery, and biofeedback), physical agents (e.g., heat and cold), electroanalgesia (transcutaneous electrical nerve stimulation [TENS]), and acupuncture. Often these methods are used in addition to analgesics rather than as the sole form of pain management.

Pharmacologic Treatment

Pharmacologic treatment involves the use of drugs in the management of pain. It includes the use of nonnarcotic and narcotic analgesics, as well as adjuvant medications, such as antidepressants, anticonvulsants, and muscle relaxants. Topical medications (e.g., fentanyl patch) are a new aspect of pain management, whose full potential has yet to be determined.

An analgesic drug is a medication that acts on the nervous system to decrease or eliminate pain without inducing unconsciousness. Analgesic drugs do not cure the underlying cause of the pain, but their appropriate use makes the pain more tolerable and, in the case of acute pain, may prevent it from progressing to chronic pain. The ideal analgesic would be effective and nonaddictive and produce minimal adverse effects. Although long-term treatment with opioids can result in opioid tolerance (i.e., increasingly greater drug dosages being needed to achieve the same effect) and physical dependence, this should not be confused with addiction. Long-term drug-seeking behavior is rare in persons who are treated with opioids only during the time that they require pain relief. The unique needs and circumstances presented by each person in pain must be addressed to achieve satisfactory pain management.

Nonnarcotic Analgesics. Nonnarcotic oral analgesic medications include aspirin, other NSAIDs, and acetaminophen. Aspirin (acetylsalicylic acid) acts peripherally and centrally to block the transmission of pain impulses. It also has antipyretic and anti-inflammatory properties. The action of aspirin and other NSAIDs is
through the inhibition of the cyclooxygenase (COX) enzymes, which mediate the biosynthesis of prostaglandins. Prostaglandins (particularly prostaglandin E₁) exert their effect through peripheral sensitization of nociceptors to chemical mediators such as bradykinin and histamine.²⁷ The NSAIDs also decrease the sensitivity of blood vessels to bradykinin and histamine, affect cytokine production by T lymphocytes, inhibit vasodilation, and decrease the release of inflammatory mediators from granulocytes and mast cells. Acetaminophen is an alternative to the NSAIDs. Although usually considered equivalent to aspirin as an analgesic and antipyretic agent, it lacks anti-inflammatory properties.

Opioid Analgesics. The term opioid or narcotic is used to refer to a group of medications, natural or synthetic, with morphinelike actions. The opioids (e.g., morphine, codeine, and many other semisynthetic congeners of morphine) exert their action through opioid receptors. There are three major categories of opioid receptors in the CNS, designated as mu (µ), delta (δ), and kappa (κ).²⁷ Analgesia, as well as respiratory depression, miosis (constriction of the pupil), reduced gastrointestinal motility (causing constipation), feelings of well-being or euphoria, and physical dependence, principally result from morphine and morphinelike opioid analgesics that act at the mu receptors. Part of the pain-relieving properties of exogenous opioids such as morphine involve the release of endogenous opioids.²⁷

Opioids are used in the management of acute and chronic pain. When given for temporary relief of severe pain, such as that occurring after surgery, there is much evidence that opioids given routinely before the pain starts or becomes extreme are far more effective than those administered in a sporadic manner. Persons who are treated in this manner usually require fewer doses and are able to resume regular activities sooner. Opioids also are used for persons with chronic pain such as that caused by cancer. Morphine remains the most useful strong opioid, and the WHO has recommended that oral morphine be part of the essential medication list and be made available throughout the world as the medication of choice for cancer pain.²⁴,²⁷

Adjuvant Analgesics. Adjuvant analgesics include medications such as tricyclic antidepressants, antiseizure medications, and neuroleptic anxiolytic agents.²⁸ Serotonin has been shown to play an important role in producing analgesia. In recent years the use of medications classified as serotonin norepinephrine reuptake inhibitors (SNRIs) have been shown to help with the treatment of chronic pain. The Food and Drug Administration (FDA) has approved two drugs in this class, duloxetine and milnacipran, for the treatment of chronic pain associated with fibromyalgia.²⁹ The use of these drugs has also shown potential benefit for the treatment of postherpetic neuralgia and painful diabetic neuropathy.³⁰ The tricyclic antidepressant medications that block the removal of serotonin from the synaptic cleft have been shown to produce pain relief in some persons. These medications are particularly useful in some chronic painful conditions, such as postherpetic neuralgia. Antiseizure medications that suppress spontaneous neuronal firing are particularly useful in the management of pain that occurs after nerve injury (neuropathic pain), including diabetic neuropathy and chronic regional pain syndrome. Other agents, such as the corticosteroids, may be used to decrease inflammation and the nociceptive stimuli responsible for pain.

Surgical Interventions

If surgery removes the problem causing the pain, such as a tumor pressing on a nerve or an inflamed appendix, it can be curative. In other situations, surgery is used for symptom management rather than for cure. However, with rare exceptions, noninvasive analgesic approaches for pain relief should precede invasive surgical approaches.¹⁶ Surgery for severe, intractable pain of peripheral or central origin has met with some success. It can be used to remove the cause or block the transmission of intractable pain from phantom limb pain, severe neuralgia, inoperable cancer of certain types, and other disorders.
Modulation of the pain experience occurs by way of the endogenous analgesic center in the midbrain, the pontine noradrenergic neurons, and the nucleus raphe magnus in the medulla, which sends inhibitory signals to dorsal horn neurons in the spinal cord or trigeminal nerve.

Pain can be classified according to location, referral, and duration as well as associated medical diagnoses. Pain can arise from stimulation of cutaneous, deep somatic, or visceral pain receptors. Referred pain is pain perceived at a site different from its origin. Acute pain is self-limiting pain that ends when the injured tissue heals. Chronic pain is pain that lasts much longer than the anticipated healing time for the underlying cause of the pain.

Treatment modalities for pain include the use of nonpharmacologic and pharmacologic agents either singly or in combination. Management of acute pain includes therapy directed at providing pain relief by interrupting the nociceptive stimulus. Chronic pain management is much more complex and is based on multiple considerations, including life expectancy.

Alterations in Pain Sensitivity and Special Types of Pain

Pain sensitivity and types of pain vary according to the body structures, the initiating event, and the duration of the pain. It also varies among persons and in the same person under different conditions.

Alterations in Pain Sensitivity

Sensitivity to and perception of pain varies among persons and in the same person under different conditions and in different parts of the body. Irritation, mild hypoxia, and mild compression of a peripheral nerve often result in hyperexcitability of the sensory nerve fibers or cell bodies. This is experienced as unpleasant hypersensitivity (i.e., hyperesthesia) or increased painfulness (i.e., hyperalgesia). Primary hyperalgesia describes pain sensitivity that occurs directly in damaged tissues. Secondary hyperalgesia occurs in the surrounding uninjured tissue. An example of primary hyperalgesia is the extreme sensitivity of sunburned skin, which results from sensitization of the skin pain endings by local products from the burn.

More severe pathologic processes can result in reduced or lost tactile (e.g., hypoesthesia, anesthesis), temperature (e.g., hypothermia, athermia), and pain sensation (i.e., hypoalgesia). Analgesia, in addition to meaning the relief of pain without loss of consciousness, is a pathology characterized by the absence of pain on noxious stimulation. The inability to sense pain may result in trauma, infection, and even loss of a body part or parts. It is thought to result from a peripheral nerve defect or a cortical defect, either of which disrupts the perception of pain. Whatever the cause, persons who lack the ability to perceive pain are at constant risk of tissue damage because pain cannot serve its protective function.

Alloodynia (Greek allo, “other,” and odynia, “painful”) is the puzzling phenomenon of pain that follows a non-noxious stimulus to apparently normal skin. Examples of such non-noxious stimuli are wind, touching sheets, and showering. The condition may arise when otherwise normal tissues are abnormally innervated or are referral sites. It can also result from increased responsiveness within the spinal cord (central sensitization) or a reduction in the threshold for nociceptor activation (peripheral sensitization). One type of allodynia involves trigger points, which are highly localized points on the skin or mucous membrane that can produce immediate intense pain at that site or elsewhere with light tactile stimulation.

Special Types of Pain

Neuropathic Pain

“Neuropathic pain refers to pain that originates from pathology of the nervous system.” When peripheral nerves are affected by injury or disease, it can lead to unusual and sometimes intractable sensory disturbances. The notable features that point to neuropathic processes as a cause of pain include widespread pain that is not otherwise explainable, evidence of sensory deficit (e.g., numbness, paresthesias), burning pain, pain that occurs with light stroking of the skin, and attacks of pain that occur without seeming provocation. Depending on the cause, few or many axons could be damaged and the condition could be unilateral or bilateral.

Causes of neuropathic pain can be categorized according to the extent of peripheral nerve involvement. Conditions that can lead to pain by causing damage to peripheral nerves in a single area include nerve entrapment, nerve compression from a tumor mass, and various neuralgias (e.g., trigeminal, postherpetic, and post-traumatic). Conditions that can lead to pain by causing damage to peripheral nerves in a wide area include diabetes mellitus, long-term alcohol use, hypothyroidism, renal insufficiency, and drug treatment with neurotoxic agents. Diabetes often causes a length-dependent neuropathy (meaning that the longest axons in a peripheral nerve are most vulnerable). Injury to a nerve also can lead to a multisymptom, multisystem syndrome, called complex regional pain syndrome. Nerve damage associated with amputation is believed to be a cause of phantom limb pain.

Neuropathic pain can vary with the extent and location of disease or injury. There may be allodynia or pain that is stabbing, jabbing, burning, or shooting.
The pain may be persistent or intermittent. The diagnosis depends on the mode of onset, the distribution of abnormal sensations, the quality of the pain, and other relevant medical conditions (e.g., diabetes, hypothyroidism, alcohol use, rash, or trauma). Injury to peripheral nerves sometimes results in pain that persists beyond the time required for the tissues to heal. Peripheral pathologic processes (e.g., neural degeneration, neuroma formation, and generation of abnormal spontaneous neural discharges from the injured sensory neuron) and neural plasticity (i.e., changes in CNS function) are the primary working hypotheses to explain persistent neuropathic pain.

Treatment methods include measures aimed at restoring or preventing further nerve damage (e.g., surgical resection of a tumor causing nerve compression, improving glycemic control for diabetic patients with painful neuropathies) and interventions for the palliation of pain. Although many adjuvant analgesics are used for neuropathic pain, pain control often is difficult. The initial approach in seeking adequate pain control is to try these drugs in sequence and then in combination. The adjuvant analgesics can be divided into three general classes according to the pain they are used to treat: burning, tingling, or aching pain; stabbing or shooting pain; and neurogenic pain. For pain that is burning, tingling, or aching, tricyclic antidepressants and the \( \alpha \)-adrenergic agonist clonidine frequently are used. For the stabbing or shooting pain of neuralgias, antiepileptic medications or baclofen, a drug used in the treatment of spasticity, may be used.\(^2\) Nonpharmacologic therapies such as electrical stimulation of the peripheral or spinal nerves can be used for radiculopathies and neuralgias. As a last resort, neurolysis or neurosurgical blockade sometimes is used.

**Neuralgia**

Neuralgia is characterized by severe, brief, often repetitive attacks of lightninglike or throbbing pain. It occurs along the distribution of a spinal or cranial nerve and usually is precipitated by stimulation of the cutaneous region supplied by that nerve.

**Trigeminal Neuralgia.** Trigeminal neuralgia, or tic douloureux, is one of the most common and severe neuralgias. It is manifested by facial tics or spasms and characterized by paroxysmal attacks of stabbing pain that usually are limited to the unilateral sensory distribution of one or more branches of the trigeminal cranial nerve (CN V), most often the maxillary or mandibular divisions.\(^3\) Although intermittent, the pain often is excruciating and may be triggered by light touch, movement, drafts, and eating. Considerable controversy remains regarding the pathophysiology of trigeminal neuralgia, but it is thought to be related to neurovascular compression. It also occurs secondary to major neurological diseases such as multiple sclerosis or tumor formation.\(^3\)

Treatment of trigeminal neuralgia includes pharmacologic and surgical modalities. Other interventions include avoidance of precipitating factors (e.g., stimulation of trigger spots) and eye injury due to irritation; provision for adequate nutrition; and avoidance of social isolation. Carbamazepine, an antiepileptic drug, is recognized as a first-line agent for treatment of trigeminal neuralgia. There is also some research showing the addition of lamotrigine, an anti-convulsant medication, to the treatment plan may be helpful.\(^3\) Surgical release of vessels, dural structures, or scar tissue surrounding the semilunar ganglion or root in the middle cranial fossa often eliminates the symptoms. If not, percutaneous blocking or partial destruction of peripheral branches of the trigeminal nerve with heat, glycerol, or balloon compression may be used. Gamma knife radiosurgery, one of the newest techniques, involves imaging of the trigeminal nerve root entry zone, and radiation of the trigeminal nerve. There has also been recent interest in the use of botulinum toxin as a treatment modality.\(^3\)

**Postherpetic Neuralgia.** Herpes zoster (also called shingles) is caused by the same herpes virus (varicella-zoster virus) that causes chickenpox and is thought to represent a localized recurrent infection by the varicella-zoster virus that has remained latent in the dorsal root ganglia since the initial attack of chickenpox (see Chapter 46). Reactivation of viral replication is associated with a decline in cellular immunity, such as occurs with aging. Thus, the probability of developing herpes zoster increases strikingly with aging, and most cases occur in the elderly. Impaired cellular immunity also increases the risk.

During the acute stage of herpes zoster, the reactivated virus travels from the affected sensory ganglia and peripheral nerve to the skin of the corresponding dermatomes, causing a unilateral localized vesicular eruption and hyperpathia (i.e., abnormally exaggerated subjective response to pain).

Persons with postherpetic neuralgia may suffer from constant pain (“burning, aching, throbbing”), intermittent pain (“stabbing, shooting”), and stimulus-evoked pain (allodynia). Persons with allodynia often suffer from excruciating pain after the slightest touch to affected skin by such things as cold wind or clothing. These subtypes of pain may interfere with sleep and basic activities of living, causing chronic fatigue, depression, anorexia, weight loss, and social isolation.

Early treatment of shingles with antiviral drugs such as acyclovir or valacyclovir that inhibit herpes virus deoxyribonucleic acid (DNA) replication may reduce the severity of herpes zoster. Initially, postherpetic neuralgia can be treated with a topical anesthetic agent, lidocaine-prilocaine cream or 5% lidocaine gel. A tricyclic antidepressant medication, such as amitriptyline or desipramine, may be used for pain relief. Regional nerve blockade (i.e., stellate ganglion, epidural, local infiltration, or peripheral nerve block) has been used with limited success.

A live attenuated vaccine is now available for prevention of herpes zoster in adults 60 years of age and older. The vaccine is not indicated for treatment of herpes zoster or postherpetic neuralgia.\(^3\)
Complex Regional Pain Syndrome

The complex regional pain syndrome (CRPS), formerly known as reflex sympathetic dystrophy (RSD), is a rare disorder of the extremities characterized by autonomic and vasomotor instability.\textsuperscript{36–38} There are two forms of the CRPS: CRPS I (equivalent of RSD) and CRPS II, also known as causalgia. The International Association for the Study of Pain (IASP) lists the diagnostic criteria for CRPS I as the presence of an initiating traumatic event, continuing pain, allodynia (perception of pain from a nonpainful stimulus), or hyperalgesia disproportionate to the inciting event with evidence at some time of edema, changes in skin blood flow, or abnormal sensorimotor activity in the area of pain. The diagnosis is excluded by the existence of any condition that would otherwise account for the degree of pain and dysfunction.\textsuperscript{39}

According to the IASP, CRPS II (i.e., causalgia) is diagnosed as the presence of continuing pain, allodynia, or hyperalgesia after a nerve injury, not necessarily limited to the distribution of the injured nerve, with evidence at some time of edema, changes in skin blood flow, or abnormal sensorimotor activity in the region of pain. The diagnosis is excluded by the existence of any condition that would otherwise account for the degree of pain and dysfunction. The primary difference between type I and type II is the identification of a definable nerve injury.

The hallmark of both types of CRPS is pain and mobility problems more severe than the injury warrants. Characteristically, the pain is severe and burning with or without deep aching. Usually, the pain can be elicited with the slightest movement or touch to the affected area, it increases with repetitive stimulation, and it lasts even after the stimulation has stopped. The pain can be exacerbated by emotional upsets or any increased peripheral sympathetic nerve stimulation. All the variations of CRPS include sympathetic components. These are characterized by vascular and trophic (e.g., dystrophic or atrophic) changes to the skin, soft tissue, and bone, and can include rubor or pallor, sweating or dryness, edema (often sharply demarcated), and, with time, patchy osteoporosis.

The pathophysiologic process of CRPS remains uncertain. Although abnormalities in sympathetic activity are observed, recent experimental data suggest that sensitization of small-diameter, polymodal C and A\textsubscript{\textdelta} fibers to noxious stimuli may be the basis for hyperalgesia to heat and nociceptive stimuli.\textsuperscript{39} There is also evidence that central mechanisms may play a role in sensitization of central neurons that occurs after intense peripheral mechanical stimuli or continuous activity in nociceptors. The sympathetic nervous system, either directly or indirectly through prostaglandin or \alpha\textsubscript{1}-adrenergic receptor activity, is considered to contribute to the excitation and sensitization of the nociceptive afferents. Other proposed mechanisms include neurogenic inflammation caused by the activation of neuromediators, such as substance P, calcitonin gene–related peptide, and histamine, which also mediates inflammation and vasodilation of microvessels.\textsuperscript{36} Recent research demonstrated the presence of autoantibodies against autonomic nervous system structures in patients with CRPS, especially CRPS II, suggesting that the disorder may result from dysfunction of the autonomic nervous system caused by an autoimmune attack.\textsuperscript{39}

Early mobilization after injury or surgery reduces the likelihood of developing the syndrome.\textsuperscript{38} In addition to addressing the underlying disorder, treatment is directed at restoration of function. Physical therapy is a cornerstone of therapy. Pain management involves the use of standard pharmacologic agents used in the management of neuropathic pain, namely, antidepressants (e.g., amitriptyline) and antiseizure drugs (e.g., gabapentin). Short-term corticosteroid (prednisone) treatment may be used in resistant cases. If this does not lead to improvement, treatment by sympathetic blockade may be used to provide pain relief and determine the extent to which the pain is sympathetically maintained. The latter mechanism, when present, might respond to the use of a \alpha\textsubscript{1}-adrenergic receptor antagonist (e.g., terazosin, phenoxybenzamine). Electrical neurostimulation of the spinal cord may also be considered. Neurostimulation not only may provide analgesia, but also may reduce the burning dysesthesia of which many patients complain. It may also improve circulation in the affected extremity by blocking the sympathetic efferent pathways.\textsuperscript{38}

Phantom Limb Pain

Phantom limb pain, a type of neurologic pain, follows amputation of a limb or part of a limb.\textsuperscript{40} Pain associated with the loss of a limb can fall into three categories: phantom limb pain, residual limb pain, and phantom limb sensations. It is estimated that up to 95\% of all patients who have some form of limb loss will experience sensations in one of these categories.\textsuperscript{40} The pain often begins as sensations of tingling, heat and cold, or heaviness, followed by burning, cramping, or shooting pain. It may disappear spontaneously or persist for many years and typically occurs within the first 6 months after the limb loss occurs.\textsuperscript{40} One of the more troublesome aspects of phantom limb pain is that the person may experience painful sensations that were present before the amputation, such as that of a painful ulcer or bunion.

Several theories have been proposed as to the causes of phantom limb pain.\textsuperscript{40} One theory is that the end of a regenerating nerve becomes trapped in the scar tissue of the amputation site. It is known that when a peripheral nerve is cut, the scar tissue that forms becomes a barrier to regenerating outgrowth of the axon, which often becomes trapped, forming a tangled growth (i.e., neuroma) of small-diameter axons, including nociceptive afferents and sympathetic efferents. It has been proposed that the afferents show increased sensitivity to innocuous mechanical stimuli and to sympathetic activity and circulating catecholamines. A related theory proposes that the source of phantom limb pain is in the spinal cord, suggesting that the pain is due to the spontaneous firing of spinal cord neurons that have lost their normal
sensory input from the body. Another theory proposes that the phantom limb pain may be caused by changes in the flow of signals through somatosensory areas of the brain. Treatment of phantom limb pain has been accomplished by the use of sympathetic blocks, TENS of the large myelinated afferents innervating the area, hypnosis, and relaxation training.

**SUMMARY CONCEPTS**

- Pain may occur with or without an adequate stimulus, or it may be absent in the presence of an adequate stimulus—either of which describes a pain disorder. There may be analgesia (absence of pain), hyperalgesia (increased sensitivity to pain), hypoalgesia (a decreased sensitivity to painful stimuli), hyperesthesia (an abnormal increase in sensitivity to sensation), hypoesthesia (an abnormal decrease in sensitivity to sensations), or allodynia (pain produced by stimuli that do not normally cause pain).

- Neuropathic pain may be due to trauma or disease of neurons in a focal area or in a more global distribution (e.g., from endocrine disease or neurotoxic medications). Neuralgia is characterized by severe, brief, often repetitive attacks of lightninglike or throbbing pain that occurs along the distribution of a spinal or cranial nerve and usually is precipitated by stimulation of the cutaneous region supplied by that nerve. Trigeminal neuralgia is one of the most common and severe neuralgias. It is manifested by facial tics or spasms. Postherpetic neuralgia is a chronic pain that can occur after shingles, an infection of the dorsal root ganglia and corresponding areas of innervation by the varicella-zoster virus.

- Complex regional pain syndrome (CRPS) types I and II are pain syndromes characterized by severe pain or hyperalgesia, edema, changes in skin blood flow, and abnormal sensorimotor activity that typically follow an initiating traumatic event. The primary difference between CRPS I and II is the identification of a definable nerve injury, with type I occurring in the area of an initiating injury, and type II not necessarily limited to the distribution of the injured nerve.

- Phantom limb pain follows amputation of a limb or part of a limb. The pain sensations, which may disappear spontaneously or persist for many years, can be similar to those that were present before the amputation, as though the limb were still present.

---

**Headache and Associated Pain**

Although head and facial pain have characteristics that distinguish them from other pain disorders, they also share many of the same features.

**Headache**

Headache is a common health problem, with approximately 25% of adults reporting recurrent headaches and 4% reporting daily or nearly daily headaches. Headache is caused by a number of conditions. Some headaches represent primary disorders and others occur secondary to other disease conditions in which head pain is a symptom. In 2004, the International Headache Society (IHS) published the second edition of *The International Classification of Headache Disorders* (ICHD-2). The classification system is divided into three sections: (1) primary headaches, (2) headaches secondary to other medical conditions, and (3) cranial neuralgias and facial pain. The most common types of primary or chronic headaches are migraine headache, tension-type headache, cluster headache, and chronic daily headache.

Although most causes of secondary headache are benign, some are indications of serious disorders such as meningitis, brain tumor, or cerebral aneurysm. The sudden onset of a severe, intractable headache in an otherwise healthy person is more likely to be due to a serious intracranial disorder, as are headaches that disturb sleep, headaches prompted by exertion, and headaches accompanied by neurologic symptoms such as drowsiness, visual or limb disturbances, or altered mental status. Other indications of secondary headache disorder include a fundamental change or progression in headache pattern or a new headache in individuals younger than 5 or older than 50 years of age, or in individuals with cancer, immunosuppression, or pregnancy.

The diagnosis and classification of headaches requires a comprehensive history and physical examination to exclude secondary causes. The history should include factors that precipitate headache, such as foods and food additives, missed meals, and association with the menstrual period. A careful medication history is essential because many medications can provoke or aggravate headaches. Alcohol also can cause or aggravate headache. A headache diary in which the person records his or her headaches and concurrent or antecedent events may be helpful in identifying factors that contribute to headache onset. Appropriate laboratory and imaging studies of the brain may be done to rule out secondary headaches.

**Migraine Headache**

Migraine headaches affect approximately 20 million persons in the United States. They occur in about 18% of women and 6% of men and result in considerable time lost from work and other activities. Migraine headaches tend to run in families and are thought to be inherited as an autosomal dominant trait with incomplete penetrance.
There are two major types of migraine headache—migraine without aura and migraine with aura. Migraine without aura, which accounts for approximately 85% of migraines, is a pulsatile, throbbing, unilateral headache that typically lasts 1 to 2 days and is aggravated by routine physical activity. The headache is accompanied by nausea and vomiting, which often is disabling, and sensitivity to light and sound. Visual disturbances occur quite commonly and consist of visual hallucinations such as stars, sparks, and flashes of light. Migraine with aura has similar symptoms, but is preceded by a sensory experience called an aura. It typically consists of visual symptoms, including flickering lights, spots, or loss of vision; sensory symptoms, including feeling of pins or needles, or numbness; and speech disturbances or other neurologic symptoms. These symptoms precede the headache, developing over a period of 5 to 20 minutes, and last from 5 minutes to 1 hour. Although only a small percentage of persons with migraine experience an aura before an attack, many persons without aura have prodromal symptoms, such as fatigue and irritability, that precede the attack by hours or even days.

A retinal migraine is a rare form of migraine characterized by recurrent attacks of fully reversible scintillations (visual sensation of sparks or flashes of light), scotomata (visual blind spots), or blindness affecting one eye, followed within an hour by a headache. Migraines can also be chronic, occurring on 15 or more days per month for 3 months or more, in the absence of medication overuse. Migraine headache also can present as a mixed headache, including symptoms typically associated with tension-type or sinus headaches. These are called transformed migraine and are difficult to classify.

Migraine headaches occur in children as well as adults. Before puberty, migraine headaches are equally distributed between the sexes. The essential diagnostic criterion for migraine in children is the presence of recurrent headaches separated by pain-free periods. Diagnosis is based on at least three of the following symptoms or associated findings: abdominal pain, nausea or vomiting, throbbing headache, unilateral location, associated aura (visual, sensory, motor), relief during sleep, and a positive family history. Symptoms vary widely among children, from those that interrupt activities and cause the child to seek relief in a dark environment to those detectable only by direct questioning. A common feature of migraine in children is intense nausea and vomiting. The vomiting may be associated with abdominal pain and fever; thus, migraine may be confused with other conditions such as appendicitis. More than half of children with migraine undergo spontaneous prolonged remission after their 10th birthday. Because headaches in children can be a symptom of other, more serious disorders, including intracranial lesions, it is important that other causes of headache that require immediate treatment be ruled out.

The pathophysiologic mechanisms of the pain associated with migraine headaches remain poorly understood. Although many alternative theories exist, it is well established that during a migraine the trigeminal cranial nerve (CN V) becomes activated. This may lead to the release of neuropeptides, causing painful neurogenic inflammation within the meningeal vasculature characterized by plasma protein extravasation, vasodilation, and mast cell degranulation. Another possible mechanism implicates neurogenic vasodilation of meningeal blood vessels as a key component of the inflammatory processes that occur during migraine. Supporting the neurogenic basis for migraine is the frequent presence of premonitory symptoms before the headache begins; the presence of focal neurologic disturbances, which cannot be explained in terms of cerebral blood flow; and the numerous accompanying symptoms, including those related to autonomic and somatic nervous system dysfunction.

Fluctuations in hormone levels, particularly in estrogen levels, are thought to play a role in the pattern of migraine attacks. For many women, migraine headaches coincide with their menstrual periods. Dietary substances, such as monosodium glutamate, aged cheese, and chocolate, also may precipitate migraine headaches. The actual triggers for migraine are the chemicals in the food, not allergens.

The treatment of migraine headaches includes preventive and abortive nonpharmacologic and pharmacologic treatment. Nonpharmacologic treatment includes the avoidance of migraine triggers, such as foods, that precipitate an attack. Many persons with migraines benefit from maintaining regular eating and sleeping habits. Measures to control stress, which also can precipitate an attack, also are important. During an attack, many persons find it helpful to retire to a quiet, darkened room until symptoms subside.

Pharmacologic treatment involves both abortive therapy for acute attacks and preventive therapy. A wide range of medications is used to treat the acute symptoms of migraine headache. First-line agents include aspirin and other NSAIDs (e.g., naproxen sodium, ibuprofen), combinations of acetaminophen, acetylsalicylic acid, and caffeine; serotonin (5-HT_1_) receptor agonists (e.g., sumatriptan); ergotamine derivatives (e.g., dihydroergotamine); and antiemetic medications (e.g., ondansetron, metoclopramide). Non-oral routes of administration may be preferred in individuals who develop severe pain rapidly or on awakening, or in those with severe nausea and vomiting. Both sumatriptan and dihydroergotamine have been approved for intranasal administration. For intractable migraine headache, dihydroergotamine may be administered parenterally with an antiemetic or opioid analgesic. Frequent use of abortive headache medications may cause rebound headache. Because of the risk of coronary vasospasm, the 5-HT_1_ receptor agonists should not be given to persons with coronary artery disease. Ergotamine preparations can cause uterine contractions and should not be given to pregnant women. They also can cause vasospasm and should be used with caution in persons with peripheral arterial disease.

Preventive pharmacologic treatment may be necessary if migraine headaches become disabling, if they occur more than two or three times a month, if abortive treatment is being used more than two times a week, or if the individual has hemiplegic migraine, migraine with
Tension-type headaches frequently involve daily activities. Tension-type headache usually is not sufficiently severe that it interferes with daily activities. Unlike migraine and cluster headaches, tension-type headache is not associated with nausea or vomiting. It can be infrequent, episodic, or chronic.

The exact mechanisms of tension-type headache are not known and the hypotheses of causation are contradictory. One popular theory is that it results from sustained tension of the muscles of the scalp and neck. Another theory suggests that migraine headache may be transformed gradually into chronic tension-type headache. Oromandibular dysfunction, psychogenic stress, anxiety, and depression may contribute, and overuse of analgesics or caffeine may also be involved.

Tension-type headaches often are more responsive to nonpharmacologic techniques, such as biofeedback, massage, acupuncture, relaxation, imagery, and physical therapy, than other types of headache. For persons with poor posture, a combination of range-of-motion exercises, relaxation, and posture improvement may be helpful.

The medications of choice for acute treatment of tension-type headaches are analgesics, including acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs), and caffeine. Persons with infrequent tension-type headache usually self-medicate using over-the-counter analgesics to treat the acute pain, and do not require prophylactic medication. These agents should be used cautiously because rebound headaches can develop when the medications are taken regularly. Other medications, including the entire range of migraine medications, may be tried in refractory cases.

**Cluster Headache**

Cluster headaches are relatively uncommon headaches that occur in about 1 in 1000 individuals, affecting men (80% to 85%) more frequently than women with the typical age of onset between 20 to 40 years of age. These headaches tend to occur in clusters over weeks or months, followed by a long, headache-free remission period. Cluster headache is a type of primary neurovascular headache that typically includes severe, unremitting, unilateral pain located, in order of decreasing frequency, in the orbital, retro-orbital, temporal, supraorbital, and infraorbital regions. The pain is of rapid onset, builds to a peak in approximately 10 to 15 minutes, and lasts for 15 to 180 minutes. The pain behind the eye radiates to the ipsilateral trigeminal nerve (e.g., temple, cheek, gum). The headache frequently is associated with one or more symptoms such as restlessness or agitation, conjunctival redness, lacrimation, nasal congestion, rhinorrhea, forehead and facial sweating, miosis, ptosis, and eyelid edema. Because of their location and associated symptoms, cluster headaches are often mistaken for sinus infections or dental problems.

The underlying pathophysiologic mechanisms of cluster headaches are not completely known. It is thought that heredity, through an autosomal dominant gene, plays some role in the pathogenesis of the headaches. The most likely pathophysiologic mechanisms include the interplay of vascular, neurogenic, metabolic, and humoral factors. The regulating centers in the hypothalamus are thought to play a role because of circadian biologic changes and neuroendocrine disturbances (e.g., changes in cortisol, prolactin, and testosterone) that are observed both in active periods and during clinical remission.

Because of the relatively short duration and self-limited nature of cluster headache, oral preparations typically take too long to reach therapeutic levels. The most effective treatments are those that act quickly (e.g., oxygen inhalation and subcutaneous sumatriptan). Intranasal lidocaine also may be effective. Oxygen inhalation may be indicated for home use. Prophylactic medications for cluster headaches include ergotamine derivatives, verapamil (a calcium channel blocker), corticosteroids, and valproic acid. Deep-brain surgical neurostimulation is an experimental approach beginning to show promise in the elimination of cluster headaches.

**Tension-Type Headache**

The most common type of headache is tension-type headache. Unlike migraine and cluster headaches, tension-type headache usually is not sufficiently severe that it interferes with daily activities. Tension-type headaches frequently are described as dull, aching, diffuse, nondescript headaches, occurring in a hatband distribution around the head, and not associated with nausea or vomiting or worsened by activity. They can be infrequent, episodic, or chronic.

The underlying pathophysiologic mechanisms of tension-type headache are not completely known and the hypotheses of causation are contradictory. One popular theory is that it results from sustained tension of the muscles of the scalp and neck. Another theory suggests that migraine headache may be transformed gradually into chronic tension-type headache. Oromandibular dysfunction, psychogenic stress, anxiety, and depression may contribute, and overuse of analgesics or caffeine may also be involved.

Tension-type headaches often are more responsive to nonpharmacologic techniques, such as biofeedback, massage, acupuncture, relaxation, imagery, and physical therapy, than other types of headache. For persons with poor posture, a combination of range-of-motion exercises, relaxation, and posture improvement may be helpful.

The medications of choice for acute treatment of tension-type headaches are analgesics, including acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs), and caffeine. Persons with infrequent tension-type headache usually self-medicate using over-the-counter analgesics to treat the acute pain, and do not require prophylactic medication. These agents should be used cautiously because rebound headaches can develop when the medications are taken regularly. Other medications, including the entire range of migraine medications, may be tried in refractory cases.

**Chronic Daily Headache**

The term chronic daily headache (CDH) is used to refer to headaches that occur 15 days or more a month, including those due to medication overuse. Little is known about the prevalence and incidence of CDH. Diagnostic criteria for CDH are not provided in the IHS Classification System. The cause of CDH is unknown, although there are several hypotheses. They include transformed migraine headache, evolved tension-type headache, new daily persistent headache, and post-traumatic headache. In many persons, CDH retains characteristic features of migraine, whereas in others it resembles chronic tension-type headache. Chronic daily headache may be associated with chronic episodic tension-type headache. New daily persistent headache may have a fairly rapid onset, with no history of migraine, tension-type headache, trauma, or psychologic stress. Although overuse of symptomatic medications (e.g., analgesics, ergotamine) has been related to CDH, there is a group of patients in whom CDH is unrelated to excessive use of medications.

For patients with CDH, a combination of pharmacologic and behavioral interventions may be necessary. As with tension-type headaches, nonpharmacologic techniques, such as biofeedback, massage, acupuncture, relaxation, imagery, and physical therapy, may be helpful. Measures to reduce or eliminate medication and caffeine overuse may be helpful. If the patient is abusing medications, the overuse must be managed.
before prophylactic agents will be effective. Most of the medications used for prevention of CDH have not been examined in well-designed, double-blind studies.

**Temporomandibular Joint Pain**

A common cause of head pain is temporomandibular joint (TMJ) syndrome. It usually is caused by an imbalance in joint movement because of poor bite, bruxism (i.e., teeth grinding), or joint problems such as inflammation, trauma, and degenerative changes. The pain almost always is referred and commonly presents as facial muscle pain, headache, neck ache, or earache. Referred pain is aggravated by jaw function. Headache associated with this syndrome is common in adults and children and can cause chronic pain problems.

Treatment of TMJ pain is aimed at correcting the problem, and in some cases this may be difficult. The initial therapy for TMJ pain should be directed toward relief of pain and improvement in function. Pain relief can be achieved with use of the NSAIDs. Muscle relaxants may be used when muscle spasm is a problem. In some cases, the selected application of heat or cold, or both, may provide relief. Referral to a dentist who is associated with a team of therapists, such as a psychologist, physical therapist, or pain specialist, may be indicated.

### Summary Concepts

- Headache is a common disorder that is caused by a number of conditions. Some headaches represent primary disorders and others occur secondary to another disease state in which head pain is a symptom.
- Primary headache disorders include migraine headache, tension-type headache, cluster headache, and chronic daily headache.
- Although most causes of secondary headache are benign, some are indications of serious disorders such as meningitis, brain tumor, or ruptured cerebral aneurysm.
- Temporomandibular joint (TMJ) syndrome is one of the major causes of headaches. It usually is caused by an imbalance in joint movement because of poor bite, teeth grinding, or joint problems such as inflammation, trauma, and degenerative changes.

### Pain in Children and Older Adults

Pain frequently is under-recognized and undertreated in both children and the elderly. In addition to the concern about the effects of analgesia on respiratory status and the potential for addiction to opioids, another obstacle to adequate pain management in children and the elderly is the myth that patients in these age groups feel less pain than other patients, and even if they feel significant pain, they do not remember it. Moreover, it can be extremely difficult to accurately assess the location and intensity of pain in very young children, who are cognitively immature, or in cognitively impaired elderly. Research during the past few decades has added a great deal to the body of knowledge about pain in children and the elderly.

### Pain in Children

Human responsiveness to painful stimuli begins in the neonatal period and continues through the life span. Although the specific and localized behavioral reactions are less marked in newborns, they clearly perceive and remember pain, as demonstrated by their integrated physiologic responses, including protective or withdrawal reflexes, to nociceptive stimuli. For example, newborns in the neonatal intensive care unit (NICU) demonstrate protective withdrawal responses to a heel stick after repeated episodes. In fact, a newborn’s pain may be accentuated because descending inhibitory pathways to the dorsal horn are not as well developed at birth. Furthermore, the newborn’s dorsal horn neurons have a wider receptive field and lower excitatory threshold than those of older children. The recognition that untreated pain can lead to serious consequences has resulted in a more liberal use of opioids for treatment of pain in the newborn, particularly in the NICU.

As infants and children mature cognitively and developmentally, their responses to pain become more complex. Children do feel pain and have been shown to reliably and accurately report pain at as young as 3 years of age. Like newborns, they also remember pain, as evidenced in studies of children with cancer, whose distress during painful procedures increases over time without intervention.

### Pain Assessment

To manage pain adequately, ongoing assessment of the presence of pain and response to treatment is essential. Behavior is a useful sign, but can be misleading. A toddler may scream during an ear examination because of fear rather than pain, and a child with inadequately relieved cancer pain may withdraw from his or her surroundings. Some physiologic measures, such as heart rate, are convenient to measure and respond rapidly to brief nociceptive stimuli, but they are nonspecific. Investigators have devised a range of behavioral distress scales for infants and young children, mostly emphasizing the child’s facial expressions, crying, and bodily movements.

Children 3 to 7 years of age become more articulate in describing the intensity, location, and severity of the pain. There are self-report measures for children of this age, including scales with faces of actual children or cartoon faces. With children 8 years of age or older,
Pain Management

The management of children’s pain basically falls into two categories: pharmacologic and nonpharmacologic. In terms of pharmacologic interventions, many of the analgesics used in adults can be used safely and effectively in children and adolescents. However, it is critical when using specific medications to determine that the medication has been approved for use with children and that it is dosed appropriately according to the child’s weight and level of physiologic development. Age-related differences in physiologic functioning, notably in neonates, will affect drug action. Neonates have decreased fat and muscle and increased water, which increases the duration of action for some water-soluble drugs; neonates also have decreased concentration of plasma proteins (albumin and $\alpha_1$-glycoprotein), which increases the unbound concentration of protein-bound drugs. $^{58}$ Neonates and infants also have decreased levels of the hepatic enzymes needed for metabolism of many analgesics. The levels of these hepatic enzymes quickly increase to adult levels in the first few months of life. Drug clearance in the 2- to 6-year-old age group is actually higher than adult levels because of the larger hepatic mass relative to body weight. $^{58,60}$ The renal excretion of drugs depends on renal blood flow, glomerular filtration rate, and tubular secretion, all of which are decreased in neonates, particularly premature neonates. Renal function reaches adult levels by 1 year of age. $^{58,60}$

The overriding principle in all pediatric pain management is to treat each child’s pain on an individual basis and to match the analgesic agent with the cause and intensity of pain. $^{60}$ A second principle involves maintaining the balance between the level of side effects and pain relief such that pain relief is obtained with as little opioid and sedation as possible. One strategy toward this end is to time the administration of analgesia so that a steady blood level is achieved and, as much as possible, pain is prevented. This requires that the child receive analgesia on a regular dosing schedule, not “as needed.” Also, most drugs are packaged primarily for adult use, and dose calculations and serial dilutions may predispose to medication errors. Common errors include milligram-microgram errors, decimal point errors, confusion between daily dose and fractional dose (e.g., 100 mg/kg/d divided by 6 hours versus 100 mg/kg per dose every 6 hours), and dilution errors. $^{60}$

Nonpharmacologic strategies can be very effective in reducing the overall amount of pain and amount of analgesia used. In addition, some nonpharmacologic strategies can reduce anxiety and increase the child’s level of self-control during pain. Pacifiers and sucrose are being used in the NICU. The effects of sucrose (sweet taste) are believed to be opioid mediated because its effects are reversed by naloxone (an opioid antagonist). $^{59}$ Distraction helps children of any age divert their attention away from pain and onto other activities. Common attention diverters include bubbles, music, television, conversation, and games. Relaxation techniques and massage therapy are particularly useful in children with chronic pain. Other nonpharmacologic techniques can be taught to the child to provide psychological preparation for a painful procedure or surgery. These include positive self-talk, imagery, play therapy, modeling, and rehearsal. The nonpharmacologic interventions must be developmentally appropriate and, if possible, the child and parent should be taught these techniques when the child is not in pain (e.g., before surgery or a painful procedure) so that it is easier to practice the technique.

Pain in Older Adults

Among adults, the prevalence of pain in the general population increases with age. Prevalence reports for persistent pain in older adults ranges from 25% to 80%, depending on whether the older adults are community dwelling or reside in a nursing home. $^{61}$ Among the common causes of pain in older adults are musculoskeletal disorders such as osteoarthritis and chronic low back pain; rheumatologic diseases such as rheumatoid arthritis and polymyalgia rheumatica; and neurologic conditions such as diabetic neuropathy, postherpetic neuralgia, and central post-stroke pain.

Unrelieved pain can have significant functional, cognitive, emotional, and societal effects in the elderly. $^{61,62}$ Decreased activity because of pain can lead to myofascial deconditioning and gait disturbances, which in turn can result in injuries from falls. Pain in the elderly has been associated with impaired appetite, increased sleep disturbances, and in some cases a decrease in cognitive function. These consequences can lead to less than optimal participation in rehabilitation efforts and decreased quality of life. Increased costs because of health care use have also been attributed to unrelieved pain in the elderly.

Pain Assessment

The assessment of pain in the elderly can range from relatively simple in a well-informed, alert, cognitively intact individual with pain from a single source and no comorbidities to extraordinarily difficult in a frail individual with severe dementia and many concurrent health problems. $^{61,63,64}$ When possible, a patient’s report of pain is the gold standard, but behavioral signs of pain should be considered as well. Accurately diagnosing pain when the individual has many health problems or some decline in cognitive function can be particularly challenging. In recent years, there has been increased awareness of the need to address issues of pain in individuals with dementia. The Assessment for Discomfort in Dementia Protocol is one example of the efforts to improve assessment and pain management in these individuals. It includes behavioral criteria for assessing pain and recommended interventions for pain. Its use has been shown to improve pain management. $^{65}$
Pain Management

When prescribing pharmacologic and nonpharmacologic methods of pain management for the older population, care must be taken to consider the cause of the pain, the person’s health status, concurrent therapies, and mental status. In the older population, where the risk of adverse reaction to drugs is higher, the nonpharmacologic options are usually less costly and cause fewer side effects.

Common nonpharmacologic interventions include application of cold (which suppresses the release of products from tissue damage) and heat (which promotes the release of endogenous endorphins). The role of mental focus and anxiety is important, and relaxation techniques, massage, and biofeedback may be useful. Physical therapy and occupational therapy bring a variety of modalities, including the use of braces or splints, changes in biomechanics, and exercise, all of which have been shown to promote pain relief.

Although efficacy is important when considering the use of pharmacologic agents for pain relief in the elderly, safety must also be considered. The elderly may have physiologic changes that affect the pharmacokinetics of medications prescribed for pain management. These changes include decreased blood flow to organs, delayed gastric motility, reduced kidney function, and decreased albumin related to poor nutrition. Also, the elderly often have coexisting health problems requiring medications. On average, a 70-year-old takes seven different medications. The addition of analgesics to a complex medication regimen may cause drug interactions and complicate compliance; however, these considerations should not preclude the appropriate use of analgesic drugs to achieve pain relief. Non-opioids are generally the first line of therapy for mild to moderate pain, and acetaminophen is usually the first choice because it is relatively safe for older adults. Opioids are used for more severe pain and for palliative care. As with younger persons, adjuvant analgesics are effectively used for treatment of pain in older adults. The use of some assessment tool to evaluate the level of pain and effectiveness of treatment is essential. Monitoring for side effects is also critical.

Children experience and remember pain, and even fairly young children are able to accurately and reliably report their pain. Recognition of this has changed the clinical practice of health professionals involved in the assessment of children’s pain. Pharmacologic (including opioids) and nonpharmacologic pain management interventions have been shown to be effective in children. Nonpharmacologic techniques must be based on the developmental level of the child and should be taught to both children and parents.

- Pain is a common symptom in the elderly. Assessment, diagnosis, and treatment of pain in the elderly can be complicated. The elderly may be reluctant or cognitively unable to report their pain. Diagnosis and treatment can be complicated by comorbidities and age-related changes in cognitive and physiologic function.

REVIEW EXERCISES

1. A 25-year-old man is admitted to the emergency department with acute abdominal pain that began in the epigastric area and has now shifted to the lower right quadrant of the abdomen. There is localized tenderness and guarding or spasm of the muscle over the area. His heart rate and blood pressure are elevated, and his skin is moist and cool from perspiring. He is given a tentative diagnosis of appendicitis and referred for surgical consultation.

   A. Describe the origin of the pain stimuli and the neural pathways involved in the pain that this man is experiencing.
   B. Explain the neural mechanisms involved in the spasm of the overlying abdominal muscles.
   C. What is the significance of his cool, moist skin and increased heart rate and blood pressure?

2. A 65-year-old woman with breast cancer is receiving hospice care in her home. She is currently receiving a long-acting opioid analgesic supplemented with a short-acting combination opioid and nonnarcotic medication for breakthrough pain.

   A. Explain the difference between the mechanisms and treatment of acute and chronic pain.
   B. Describe the action of opioid drugs in the treatment of pain.
   C. Define the term tolerance as it refers to the use of opioids for treatment of pain.

3. A 42-year-old woman presents with sudden, stabbing-type facial pain that arises near the right side of her mouth and then shoots toward the right ear, eye, and nostril. She is holding her hand to protect her face because the pain is “triggered by touch, movement, and drafts.” Her initial diagnosis is trigeminal neuralgia.

   A. Explain the distribution and mechanisms of the pain, particularly the triggering of the pain by stimuli applied to the skin.
   B. What are possible treatment methods for this woman?
4. A 21-year-old woman presents to the student health center with complaints of a throbbing pain on the left side of her head, nausea and vomiting, and extreme sensitivity to light, noise, and head movement. She also tells you she had a similar headache 3 months ago that lasted for 2 days, and she thinks she is developing migraine headaches like her mother. She is concerned because she has been unable to attend classes and has exams next week.

A. Are this woman’s history and symptoms consistent with migraine headaches? Explain.

B. Use the distribution of the trigeminal nerve and the concept of neurogenic inflammation to explain this woman’s symptoms.

5. A 48-year-old man presents with complaints of severe pain in his right foot after a crush injury. He reports that although he had his ankle pinned surgically, it still causes severe pain now, almost 1 year after injury. He states that he cannot stand to have the sheets touch his foot, and even wearing shoes is painful. His physician has diagnosed chronic regional pain syndrome type I.

A. Differentiate chronic regional pain syndrome type I from type II.

B. Explain the proposed theories of why this pain syndrome develops.

Chapter 36
Disorders of Neuromuscular Function

Just as our perceptual skills reflect the ability of our sensory systems to detect, analyze, and estimate the significance of our physical environment, the ability to carry out these movements requires skeletal muscles that contract and neural pathways that plan, coordinate, and execute them in a manner that provides for smooth, purposeful, and coordinated movement. In some cases, purposeless and disruptive movements can be almost as disabling as relative or complete absence of movement. This chapter provides an introduction to the organization and control of motor function, followed by a discussion of disorders of motor function, including muscular dystrophy, and disorders of the neuromuscular junction, peripheral nerves, the basal ganglia and cerebellum, and upper motor neurons.

Organization and Control of Motor Function

Motor function, whether it involves walking, running, or precise finger movements, requires movement and maintenance of posture. Posture can be described as the relative position of the various parts of the body with respect to one another (limb extension, flexion) or to the environment (standing, supine). Posture also can be described as the active muscular resistance to the displacement of the body by gravity or acceleration. The structures that control posture and movement are located throughout the neuromuscular system. The system consists of the motor unit (motor neuron and the muscle fibers it innervates); the spinal cord, which contains the basic reflex circuitry for posture and movement; and the descending pathways from brain stem circuits, the cerebellum, the basal ganglia, and the motor cortex.

Organization of Movement

As with other parts of the nervous system, the motor systems are organized in a functional hierarchy, each concerned with increased levels of complexity.
lowest level of the hierarchy occurs at the spinal cord, which contains the basic reflex circuitry needed to coordinate the function of the motor units. Above the spinal cord is the brain stem, and above the brain stem are the cerebellum and basal ganglia, structures that modulate the actions of the brain stem systems. Overseeing these supraspinal structures are the motor centers in the cerebral cortex. The highest level of function, which occurs at the level of the frontal cortex, is concerned with the purpose and planning of motor movements. The efficiency of movement depends on input from sensory systems that operate in parallel with the motor systems.

**The Spinal Cord**

The spinal cord is the lowest level of motor hierarchical organization. It contains the neuronal circuits that mediate a variety of reflexes and automatic rhythmic movements. Similar circuits governing reflex movements of the face and mouth are located in the brain stem. The simplest circuits are monosynaptic, containing only a primary motor neuron. However, most reflexes are polysynaptic, involving more than one interposed interneurons. Interneurons and motor neurons also receive input from axons descending from higher centers. These supraspinal signals can modify reflex responses to peripheral stimuli by facilitating or inhibiting different populations of interneurons. They also coordinate movements through these interneurons.

**The Brain Stem**

The next level of motor hierarchy is in the brain stem. The brain stem contains many groups of neurons that project from the spinal gray matter. These projections are grouped into two main systems—the medial and lateral brain stem systems—which receive input from the cerebral cortex and subcortical nuclei and project to the spinal cord. The medial descending systems contribute to the control of posture by integrating visual, vestibular, and somatosensory information. The lateral descending systems control more distal limb muscles and are thus more concerned with goal-directed movements, especially of the arm and hand. Brain stem circuits also control movements of the eyes and head.

**The Motor Cortex**

The motor cortex represents the highest level of motor function. Precise, skillful, and intentional movements of the distal and especially flexor muscles of the limbs and speech apparatus are initiated and controlled by the primary, premotor, and supplementary motor cortices located in the posterior part of the frontal lobe (Fig. 36-1). These motor areas receive information from the thalamus and somatosensory cortex and, indirectly, from the cerebellum and basal ganglia.

The primary motor cortex (Brodmann area 4) is located on the medial surface of the brain, and adjacent portions of the central sulcus. It controls specific muscle movement sequences and is the first level of descending control for precise motor movements. The neurons in the primary motor cortex are arranged in a somatotopic array or distorted map of the body called the motor homunculus (Fig. 36-2). The areas of the body that require the greatest dexterity have the largest cortical areas devoted to them. More than half of the primary motor cortex is concerned with controlling the muscles of the hands, of facial expression, and of speech.

The premotor cortex (areas 6 and 8), which is located just anterior to the primary motor cortex, sends some fibers into the corticospinal tract but mainly innervates the primary motor cortex. Nerve signals generated by the premotor cortex produce much more complex “patterns” of movement than the discrete patterns generated by the primary motor cortex. For example, the movement pattern to accomplish a particular objective, such as throwing a ball or picking up a fork, is programmed by the prefrontal association cortex and associated thalamic nuclei.

The supplementary motor cortex, which contains representations of all parts of the body, is located on the
complex motor control systems in the brain could not
special neuronal circuits in the spinal cord, even the most
pathway for integration of motor function.

The Motor Unit

The motor neurons in the spinal cord represent the final
pathway for integration of motor function. Without
the special neuronal circuits in the spinal cord, even the most
complex motor control systems in the brain could not
cause any purposeful muscle movement. Located in each
segment of the anterior horn of the spinal cord are sev-
eral thousand motor neurons called lower motor neurons
(LMNs). Upper motor neurons (UMNs) control LMNs.
They project from the motor strip in the cerebral cortex
to the anterior horn of spinal cord and are fully contained
in the central nervous system (CNS) (Fig. 36-3).

Motor neurons segregate into two major categories: alpha and gamma. The alpha motor neurons are large
nerve fibers that innervate the extrafusal muscle fibers
responsible for muscle contraction and force generation.
The much-smaller gamma motor neurons innervate the
intrafusal muscle fibers of the muscle spindles, which
help control basic muscle tone (to be discussed under spinal reflexes). Each alpha motor neuron undergoes
multiple branchings, making it possible for a single
alpha motor neuron to innervate a few to thousands of
muscle fibers. In general, large muscles—those containing hundreds or thousands of muscle fibers and providing
gross motor movement—have large motor units.
This contrasts sharply with those that control the hand,
tongue, and eye movements, for which the motor units
are small and permit very precise control.

The alpha motor neuron and the group of muscle
fibers it innervates is called a motor unit. When an alpha
motor neuron develops an action potential, all of the
muscle fibers in the motor unit it innervates develop
action potentials, causing them to contract simultane-
ously. Thus, a motor neuron and the muscle fibers it
innervates function as a single unit—the basic unit of
motor control.

The Cerebellum and Basal Ganglia

In addition to the brain stem and cerebral cortex, the
cerebellum and basal ganglia assist in the planning and
execution of motor movements. They provide feedback
circuits that regulate cortical and brain stem motor
areas, and they receive indirect input from various areas
of the motor cortex. The cerebellum and basal ganglia
do not send significant output directly to the spinal cord,
but act on motor neurons in the brain stem.

Although the precise contributions of the cerebellum
and basal ganglia are still unclear, both are necessary for
smooth movement and posture. The basal ganglia pro-
vide the smoothness of performance as well as the sup-
portive posture for highly skilled movements. Cerebellar
circuits are involved with the timing and coordination
of movements that are in progress and with learning
of motor skills. Damage to the cerebellum by vascular
lesions of certain familial degenerative disorders pro-
duces cerebellar ataxia, a characteristic loss of coordi-
nation and accuracy of limb movement.

Spinal Reflexes

The spinal cord contains neural reflexes or coordinated,
involuntary motor responses that are initiated by a stim-
ulus applied to peripheral receptors. Some reflexes, such as
the flexor-withdrawal reflex, initiate movements to
avoid hazardous situations, whereas others, such as
the stretch reflex or crossed-extensor reflex, serve to
integrate motor movements so they function in a coor-
dinated manner. The anatomic basis of a reflex consists
of an afferent neuron that synapses either directly with
an efferent neuron that innervates a muscle or with an
interneuron that synapses with an efferent neuron. Reflexes
are essentially “wired into” the CNS so that they are always ready to function. With training, most
reflexes can be modified to become part of more com-
plicated movements. A reflex may involve neurons in a
single cord segment (i.e., segmental reflexes), several or
many segments (i.e., intersegmental reflexes), or struc-
tures in the brain (i.e., suprasegmental reflexes).

In most cases, reflex activities go on without our con-
scious awareness. There is a significant amount of reflex
circuitry in the spinal cord for the coordinated control
of movements, particularly stereotyped movements con-
cerned with locomotion. Many of these reflexes work
equally well in decerebrate animals (those in which the
brain has been destroyed) as long as the spinal cord is
intact. Other spinal reflexes require the activity of the
brain for their successful completion.

FIGURE 36-2. Representation of the relative extent of motor
cortical area 4 devoted to muscles of the various body regions.
Medial surface is at the left, lateral surface is at the right, with
pharyngeal and laryngeal muscle representation extending
toward the insula. (From Penfield E, Rasmussen T The Cerebral
Cortex in Man: A Clinical Study of Localization of Function.
New York: Macmillan; 1968.)
If the skeletal muscles of the body are to perform normally, the brain must be continually informed of the current state of contraction, and the muscles must exhibit healthy tone (resistance to active and passive stretch at rest). The first requirement depends on the transmission of information regarding the sense of body position, movement, and muscle tone to the CNS. Information from sensory afferent neurons is relayed to the cerebellum and cerebral cortex and is experienced as proprioception or the sense of body movement and position, independent of vision. To provide this information, the muscles and their tendons are supplied with two types of receptors: muscle spindles and Golgi tendon organs. The muscle spindles consist of a group of specialized miniature skeletal muscle fibers called intrafusal fibers that are encased in a connective tissue capsule and attached to the extrafusal fibers of a skeletal muscle. In the center of the receptor area, a large sensory neuron spirals around the intrafusal fiber, forming the so-called primary or annulus spiral ending (see Understanding the Stretch Reflex and Muscle Tone).

Muscle Spindle and the Stretch Reflex. The muscle spindles consist of a group of specialized miniature skeletal muscle fibers called intrafusal fibers that are encased in a connective tissue capsule and attached to the extrafusal fibers of a skeletal muscle. In the center of the receptor area, a large sensory neuron spirals around the intrafusal fiber, forming the so-called primary or annulus spiral ending (see Understanding the Stretch Reflex and Muscle Tone).

The intrafusal muscle fibers function as stretch receptors that increase their firing when the muscle is stretched and decrease their firing when the muscle is relaxed. Axons of these spindle fiber neurons enter the spinal cord through several branches of the dorsal root. Some (text continues on page 886)
Muscle tone is controlled by the stretch reflex, which monitors changes in muscle length. The activity of the stretch reflex can be divided into three steps: (1) activation of the stretch receptors, (2) integration of the reflex in the spinal cord, and (3) regulation of reflex sensitivity by higher centers in the brain. Testing the knee-jerk reflex provides a means of assessing the stretch reflex.

1. **Stretch Reflex Receptors.** Skeletal muscle is composed of two types of muscle fibers: a large number of extrafusal fibers, which control muscle movement, and a smaller number of intrafusal fibers, which control muscle tone. The intrafusal fibers are encapsulated in sheaths, forming a muscle spindle that runs parallel to the extrafusal fibers. Each intrafusal fiber is innervated by a large Ia sensory nerve fiber, which encircles the central noncontractile portion of the fiber to form the so-called annulospiral ending. Because the spindles are oriented parallel to the extrafusal muscle fibers, stretching of the extrafusal fibers also stretches the spindle fibers and stimulates the receptive endings of the Ia afferent neuron.

2. **Spinal Reflex Centers.** Afferent impulses from the Ia sensory fiber of the muscle spindle are transmitted to the spinal cord, where they synapse with α motor neurons of the stretched muscle to form a monosynaptic reflex arc. They are "monosynaptic" because only one synapse separates the primary sensory input from the motor neuron output. The reflex muscle contraction that follows resists further stretching of the muscle. As this spinal reflex activity is occurring, impulses providing information on muscle length are transmitted to higher centers in the brain. It is the coordinated activity of all the monosynaptic reflexes supplying the extrafusal fibers in a skeletal muscle that provides the muscle tone needed for organized movement.
Brain Center Connections. Although a spinal reflex can function independently, its sensitivity is adjusted by higher centers in the brain. Both types of muscle fibers are supplied with motor neurons—the extrafusal fibers with large alpha motor neurons, which produce muscle contraction; and the intrafusal fibers with smaller gamma motor neurons, which control the sensitivity of the stretch reflex. Descending fibers of motor pathways synapse with both alpha and gamma motor neurons, and the impulses are sent simultaneously to the large extrafusal fibers and to the intrafusal fibers to maintain muscle spindle tension (and sensitivity) during muscle contraction.

The Knee-Jerk Reflex. The knee-jerk reflex that occurs when the knee is tapped with a reflex hammer tests for the intactness of the stretch reflex arc in the quadriceps muscle. Stretching of the extrafusal fibers by tapping with a reflex hammer leads to lengthening of the intrafusal fibers and increased firing of the type Ia afferent neuron. Impulses from the Ia fiber enter the dorsal horn of the spinal cord and make monosynaptic contact with the anterior horn alpha motor neuron supplying the extrafusal fibers in the quadriceps muscle. The resultant reflex contraction (shortening) of the quadriceps muscle is responsible for the knee jerk. These muscle reflexes are called deep tendon reflexes (DTRs). They can be checked at the wrists, elbows, knees, and ankles as a means of assessing the components of the stretch reflex at different spinal cord segments.
branches end in the segment of entry; others ascend to adjacent segments, influencing intersegmental reflex function; and still others ascend in the dorsal column of the cord to the brain stem. Segmental branches establish monosynaptic contact with each of the LMNs that have motor units in the muscle containing the spindle receptor. This produces an opposing muscle contraction. Another segmental branch of the same afferent neuron innervates an internuncial neuron that is inhibitory to motor units of antagonistic muscle groups. This disynaptic inhibitory pathway is the basis for the reciprocal activity of agonist and antagonist muscles (i.e., when an agonist muscle is stretched, the antagonists relax). Reciprocal innervation is useful not only for the stretch reflex, but also for voluntary movements. Relaxation of the antagonist muscle during movements enhances the speed and efficiency because the muscles that act as prime movers are not working against contraction of the opposing muscle.  

Another function of the stretch reflex is to inform the CNS of the status of muscle length. Ascending impulses from stretch receptors in the contracting muscle fibers ultimately provide information about muscle length to higher centers in the cerebellum and cerebral cortex. When a skeletal muscle lengthens or shortens against tension, a feedback mechanism needs to be available for readjustment such that the spindle apparatus remains sensitive to moment-to-moment changes in muscle stretch, even while changes in muscle length are occurring. This is accomplished by the gamma motor neurons that adjust spindle fiber length to match the length of the extrafusal muscle fiber. Descending fibers of motor pathways synapse with and simultaneously activate both the alpha motor neurons of the contracting muscle and gamma motor neurons so that the sensitivity of the spindle fibers is coordinated with muscle movement.

**Golgi Tendon Reflex.** The Golgi tendon organ helps control muscle tension. The major difference between the Golgi tendon organ versus the muscle spindle is that the muscle spindle monitors muscle length whereas the Golgi tendon organ monitors muscle tension.  

Another possible function of the Golgi tendon reflex is to equalize contractile forces of separate muscle fibers by inhibiting those fibers that exert excessive tension and permitting those that exert too little tension to become more excited by withdrawing the inhibition. This spreads the muscle load over all the muscle fibers and prevents damage to isolated areas of a muscle where small numbers of fibers might be overloaded.

**Central Control of the Spinal Reflexes.** Normal muscle tone depends on stretch reflexes initiated by the muscle spindles, which monitor changes in muscle length; and the Golgi tendon organs, which monitor muscle tension. The neural circuits responsible for stretch reflexes provide higher centers of the nervous system with a mechanism for adjusting muscle tone. Disorders of muscle tone are frequently associated with lesions of the motor system, especially those that interfere with descending pathways. Stretch reflexes are hyperactive when lesions of the corticospinal tract (e.g., stroke or spinal cord injury) reduce or disrupt the inhibitory effect of the brain on the spinal cord, and they are hypoactive or absent in cases of peripheral nerve damage or anterior spinal cord injury.

Central control over the gamma motor neurons also permits increases or decreases in muscle tone in anticipation of changes in the muscle force. Through its coordinated control of the muscle’s alpha and the spindle’s gamma motor neurons, the CNS can suppress the stretch reflex. This occurs during centrally programmed movements, such as pitching a baseball, that require a muscle to produce a full range of unopposed motion. Without this programmed adjustability of the stretch reflex, any movement is immediately opposed and prevented.

**Motor Pathways.** The primary motor cortex (Brodman area 4) is structured into six well-defined layers. Those in layers I through IV project to the premotor and somatosensory areas on the same side of the brain, the opposite side of the brain, or to subcortical structures such as the thalamus and basal ganglia. Efferent motor neurons in layers V and VI descend to the brain stem and spinal cord. The axons of these UMNss project through the subcortical white matter and internal capsule to the deep surface of the brain stem, through the ventral bulge of the pons, and on to the ventral surface of the medulla, where they form a ridge or pyramid (see Fig. 36-3). The majority of corticospinal UMNs cross the midline in the pyramidal ridge to form the lateral corticospinal tract on the opposite side of the spinal cord. The remaining UMNs do not cross to the opposite side, but pass down the ventral column of the cord, mainly to cervical levels, where they cross and innervate contralateral LMNs.

Traditionally, motor tracts have been classified as belonging to one of two motor systems: the pyramidal and extrapyramidal systems. According to this classification system, the pyramidal system consists of the motor neurons that cross the midline in the pyramidal ridge. All other descending UMNs emanating from the motor cortex and basal ganglia are generally grouped together as the extrapyramidal system. Disorders of the pyramidal tracts (e.g., stroke) are characterized by spasticity and paralysis, whereas those affecting the extrapyramidal tracts (e.g., Parkinson disease) result in involuntary movements, muscle rigidity, and immobility without paralysis. As increased knowledge regarding motor pathways has emerged, it has become evident that the extrapyramidal and pyramidal systems are extensively interconnected and cooperate in the control of movement.
Assessment of Motor Function

Disorders of the motor system produce signs and symptoms that can be used in localizing the disorder. These include changes in muscle characteristics (strength, bulk, and tone), spinal reflex activity, and motor coordination. The distinction between LMNs and UMNs is important because each class of neurons produces distinctive symptoms.

Muscle Strength, Bulk, and Tone

**Muscle Strength.** Abnormalities in any part of the motor pathway can produce impaired strength or muscle weakness. *Paralysis* refers to loss of movement, and *paresis* to weakness or incomplete loss of strength. The pattern of weakness may be helpful in the localization of the lesion. *Monoparesis* or *monoplegia* results from the destruction of pyramidal UMN innervation of one limb; *hemiparesis* or *hemiplegia*, both limbs on one side; *diparesis* or *diplegia* or *paraparesis* or *paraplegia*, both upper or lower limbs; and *tetraparesis* or *tetraplegia*, also called *quadriparesis* or *quadriplegia*, all four limbs (Fig. 36-4).

Paresis or paralysis can be further designated as of UMN or LMN origin. UMN lesions of the motor cortex or corticospinal tract typically affect the flexors in the upper extremities more than the extensors, whereas in the lower extremities, the flexors are more affected. In LMN or peripheral nerve disorders, the weakness is predominantly in the distal limb, whereas in muscle disorders, such as muscular dystrophy, proximal limb function may be affected sooner than distal limb function.

**Muscle Bulk.** The size of muscle (whether muscles are normal sized, enlarged, or atrophied) also helps localize the lesion, and sometimes provides helpful hints to the pathologic process. Muscular atrophy, or loss of muscle bulk, usually results from LMN lesions as well as diseases of the muscles themselves. Hypertrophy refers to an increase in muscle bulk with a proportionate increase in strength. Pseudohypertrophy, as occurs with Duchenne muscular dystrophy, refers to an increase in bulk without an accompanying increase in strength.

**Muscle Tone.** Muscle tone is the normal state of muscle tension. It is assessed by palpating the muscle while at rest and during passive stretching. With the person at rest, the joints are put through the normal range of motion (flexion and extension) by the examiner. Disorders of skeletal muscle tone are characteristic of many nervous system lesions. Any interruption of the myotatic or stretch reflex circuitry by peripheral nerve injury, pathologic process of the neuromuscular junction, injury to the spinal cord, or damage to the corticospinal system can result in disturbances of muscle tone.

Abnormalities of muscle tone may be described as hypotonia (less than normal), flaccidity (absent), or hypertonia, rigidity, spasticity, or tetany (all indicating higher-than-normal tone). Typically, UMN lesions produce increased tone, whereas LMN lesions produce decreased tone. Increased resistance that varies and commonly becomes worse at the extremes of the range of motion is called spasticity. Resistance that becomes worse throughout the range and in both directions is referred to as lead-pipe rigidity. Decreased resistance suggests disease of the LMNs or the acute stages of spinal cord injury. Marked flappiness indicates hypotonic or flaccid muscles.

**Fasciculations.** Fasciculations are visible squirming and twitching movements of muscle fibers that can be seen as flickers under the skin. They are caused by spontaneous...
contractions of all the muscle fibers in a motor unit due to irritation and hyperexcitability of the cell body and its motor neuron, and suggest LMN disease.

**Spinal Reflex Activity**

Testing of deep tendon reflexes (see Understanding the Stretch Reflex and Muscle Tone) can provide important information about the status of the CNS in controlling muscle function. Hyperactive reflexes are suggestive of a UMN disorder. Clonus is the rhythmic contraction and alternate relaxation of a limb that is caused by suddenly stretching a muscle and gently maintaining it in the stretched position. It is seen in the hypertonia of spasticity associated with UMN lesions, such as spinal cord injury. Hyporeflexia or areflexia suggests the presence of an LMN lesion. The distribution of abnormality in the reflexes is also helpful in determining the location of the lesion. For example, hyperreflexia in both lower extremities would suggest a lesion in the spinal cord, whereas hyperreflexia on one side of the body would suggest a lesion in the UMN along the motor pathway (e.g., in the motor cortex or internal capsule).

**Coordination of Movement**

Coordination of muscle movement requires that four areas of the nervous system function in an integrated manner—the motor system for muscle strength, the cerebellar system for rhythmic movement and steady posture, the vestibular system for posture and balance, and the sensory system for position sense.

In cerebellar disease, one movement cannot be followed quickly by its opposite movement. Movements are slow, irregular, clumsy, unsteady, and inappropriately varying in their speed, force, and direction. Dysdiadochokinesia is the failure to accurately perform rapid alternating movements. Ataxia is a term used to describe a wide-based, unsteady gait. Dysmetria is a term used to describe inaccuracies of movements leading to a failure to reach a specified target. This can be tested by having the person touch the examiner’s finger and then alternately touch his or her own finger. These movements are normally smooth and accurate. Asking the person to touch the examiner’s finger with an outstretched arm and finger, first with the eyes open and then closed, provides a test for position sense. Repetitive and consistent deviation to one side (referred to as past pointing), which is worse with the eyes closed, suggests cerebellar or vestibular disease.

Chorea (abnormal writhing movements), dystonia (abnormal simultaneous contractions of agonist and antagonist muscles, leading to abnormal postures), tremor (rhythmic movements of a particular body part), bradykinesia (slowness of movements), and myoclonus (involuntary jerking movement) indicate abnormalities in the basal ganglia, although the exact localization may be difficult to determine.

**SUMMARY CONCEPTS**

- Motor function, whether it involves walking, running, or precise finger movements, requires functioning neural pathways consisting of upper motor neurons (UMNs) that project from the motor cortex to the brain stem or spinal cord, where they innervate the lower motor neurons (LMNs) of the contracting muscles.
- Proper control of muscle function requires not only excitation of the muscle by the LMNs located in the spinal cord, but also the function of reflex circuitry that monitors the functional status of the muscle fibers on a moment-by-moment basis. The muscle spindles of the stretch reflex function to monitor and correct for changes in muscle length when extrafusal fibers are either shortened (by contraction) or lengthened (by stretch).
- Assessments of muscle strength and muscle bulk, muscle tone and motor reflexes, and patterns of motor movement and posture provide the means for determining the location of disorders of motor function. Paresis (weakness) and paralysis (loss of muscle movement) reflect a loss of muscle strength. UMN lesions tend to produce spastic paralysis, and LMN lesions flaccid paralysis. Changes in muscle bulk are characterized by a loss of muscle mass (atrophy) or an increase in muscle mass (hypertrophy). Hypotonia is a condition of less-than-normal muscle tone, and hypertonia or spasticity is a condition of excessive tone. Abnormal and uncoordinated movements and postures are suggestive of a cerebellar or basal ganglia pathologic process.

**Disorders of the Motor Unit**

Most of the diseases of the motor unit cause weakness and wasting of skeletal muscles. The distinguishing features of these diseases vary depending on which of the components of the motor unit is primarily affected—the cell body of the motor neuron, its axon, the neuromuscular junction, or the muscle fibers.7-9 Disorders affecting the nerve cell body are often referred to as LMN disorders, those affecting the nerve axon as peripheral neuropathies, and primary disorders affecting the muscle fibers as myopathies.
Skeletal Muscle Disorders

Muscle Atrophy

Maintenance of muscle strength requires relatively frequent movements against resistance. Reduced use results in muscle atrophy, which is characterized by a reduction in the diameter of the muscle fibers because of a loss of protein filaments. When a normally innervated muscle is not used for long periods, the muscle cells shrink in diameter, and although the muscle cells do not die, they lose much of their contractile proteins and become weakened. This is called disuse atrophy, and it occurs with conditions such as immobilization and chronic illness. The most extreme examples of muscle atrophy are found in persons with disorders that deprive muscles of their LMN innervation. This is called denervation atrophy.

Muscular Dystrophy

Muscular dystrophy is a term applied to a number of genetic disorders that produce progressive degeneration and necrosis of skeletal muscle fibers and eventual replacement with fat and connective tissue. They are primary diseases of muscle tissue and probably do not involve the nervous system. As the muscle undergoes necrosis, fat and connective tissue replace the muscle fibers, which increases muscle size and results in muscle weakness. The increase in muscle size resulting from connective tissue infiltration is called pseudohypertrophy. Muscle weakness is insidious in onset but continually progressive, varying with the type of disorder.

The two most common forms of muscular dystrophy are Duchenne muscular dystrophy (DMD) and Becker muscular dystrophy (BMD), both of which are inherited as an X-linked recessive trait. Duchenne muscular dystrophy is the most common and severe form, with an incidence of 1 in every 3600 to 6000 live male births. Despite the X-linked inheritance in DMD, about 30% of cases are due to new mutations and the mother is not a carrier. Female carriers are usually asymptomatic. Affected girls are occasionally encountered, but usually have much milder symptoms than boys. Becker muscular dystrophy, which shares the same genetic locus as DMD, manifests later in childhood or adolescence and has a slower and less severe course of progression.

Both DMD and BMD are caused by mutations in the dystrophin gene, located on the short arm of the X chromosome. Dystrophin is a large protein that is expressed in a variety of tissues, including all types of muscle cells. It attaches portions of the muscle sarcomere to the cell membrane, maintaining the structural integrity of skeletal and cardiac muscle cells. The role of dystrophin in transferring the force of contraction to the extracellular connective tissue matrix has been proposed as the basis for muscle cell degeneration that occurs with dystrophin defects or changes in other proteins that interact with dystrophin. The dystrophin gene is one of the largest in the human genome, spanning 2.3 million base pairs, a factor that is thought to make it particularly vulnerable to mutations. Muscle biopsy specimens from individuals with DMD show little or no dystrophin. In comparison, those with BMD, who also have mutations in the dystrophin gene, show diminished amounts of dystrophin, usually of an abnormal molecular weight, reflecting mutations that allow synthesis of an abnormal protein of smaller size.

Clinical Course. Boys with DMD are usually asymptomatic at birth and during infancy. Early gross movements such as rolling, sitting, and standing are usually achieved at the proper age. The postural muscles of the hips and shoulders are usually the first to be affected. Pseudohypertrophy of the calf muscle eventually develops (Fig. 36-5). Signs of muscle weakness usually become evident beginning at 2 to 3 years of age, when the child begins to fall frequently. Imbalances between agonist and antagonist muscles lead to abnormal postures and the development of contractures and joint immobility. Scoliosis (curvature of the spine) is common. Wheelchairs usually are needed at approximately 7 to 12 years of age. Function of the distal muscles usually is preserved well enough that the child can continue to use eating utensils and a computer keyboard. The function of the extraocular muscles also is well preserved, as is the function of the muscles controlling urination and defecation. Incontinence is an uncommon and late event. Respiratory muscle involvement results in weak and ineffective cough, frequent respiratory infections, and decreasing respiratory reserve.

Cardiomyopathy is a common feature of the disease. The severity of cardiac involvement, however, does not necessarily correlate with skeletal muscle weakness. Some persons die early as the result of severe cardiomyopathy, whereas others maintain adequate cardiac function until the terminal stages of the disease. Death from respiratory and cardiac muscle involvement usually occurs in young adulthood.

Diagnosis and Treatment. Observation of the child’s voluntary movement and a complete family history provide important diagnostic data for the disease. Serum levels of the enzyme creatine kinase (CK), which leaks out of damaged muscle fibers, suggests the presence of

FIGURE 36-5. Pseudohypertrophy of the calves exercise for a child with proximal muscle weakness caused by Duchenne muscular dystrophy.
A specific molecular genetic diagnosis is possible by demonstrating the defective dystrophin gene in a blood sample. Muscle biopsy, which shows a mixture of muscle cell degeneration and regeneration and reveals fat and scar tissue replacement, may be done to confirm the diagnosis. The same methods of genetic testing may be used on blood samples to establish carrier status in female relatives at risk, such as sisters and cousins. Prenatal diagnosis is possible as early as 12 weeks’ gestation by sampling chorionic villi for DNA analysis (see Chapter 6). Echocardiography, electrocardiography, and chest radiography are used to assess cardiac function.

Management of the disease is directed toward maintaining ambulation and preventing deformities. Passive stretching, correct or counterposturing, and splints help to prevent deformities. Precautions should be taken to avoid respiratory infections.

Glucocorticoids are the only medication currently available to slow the decline in muscle strength and function in DMD. Steroids decrease inflammation, prevent fibrosis, and improve muscle regeneration.

Disorders of the Neuromuscular Junction

The neuromuscular junction serves as a synapse between a motor neuron and a skeletal muscle fiber. It consists of the axon terminals of a motor neuron and a specialized region of the muscle membrane called the endplate. The transmission of impulses at the neuromuscular junction is mediated by the release of the neurotransmitter acetylcholine from the axon terminals. Acetylcholine binds to specific receptors in the endplate region of the muscle fiber surface to cause muscle contraction (Fig. 36-6A). Acetylcholine is active in the neuromuscular junction only for a brief period, during which an action potential is generated in the innervated muscle cell. Some of the transmitter diffuses out of the synapse, and the remaining transmitter is rapidly inactivated by an enzyme called acetylcholinesterase (see Chapter 34, Fig. 34-25A). The rapid inactivation of acetylcholine allows repeated muscle contractions and gradations of contractile force.

Drug- and Toxin-Induced Disorders

A number of drugs and agents can alter neuromuscular function by changing the release, inactivation, or receptor binding of acetylcholine. Curare acts on the postjunctional membrane of the motor endplate to prevent the depolarizing effect of the neurotransmitter. Neuromuscular transmission is blocked by curare-type drugs during many types of surgical procedures to facilitate relaxation of involved musculature. Drugs such as physostigmine and neostigmine inhibit the action of acetylcholinesterase and allow acetylcholine released from the motor neuron to accumulate. These drugs are used in the treatment of myasthenia gravis.

Neurotoxins from the botulism organism (Clostridium botulinum) produce paralysis by blocking acetylcholine release. Clostridia are anaerobic, gram-positive, spore-forming bacilli found worldwide in soils, marine and fresh water sediments, and the intestines of many animals. Classic food-borne botulism occurs through ingestion of soil-grown foods that are not properly cooked or preserved. Canned vegetables, items preserved in garlic oil, and soups are usually the cause of sporadic outbreaks. Wound botulism occurs through colonization of wounds with C. botulinum.

Pharmacologic preparations of the botulinum toxin (botulinum type A toxin [Botox] and botulinum type B toxin [Myobloc]) have become available for use in treating eyelid and eye movement disorders such as blepharospasm and strabismus. These agents also are used for treatment of spasmodic torticollis, spasmodic dysphonias (laryngeal dystonia), and other dystonias. The drug is injected into the target muscle using the electrical activity recorded from the tip of a special electromyographic injection needle to guide the injection. The treatment is not permanent and usually needs to be repeated approximately every 3 months.

![FIGURE 36-6. Neuromuscular junction. (A) Acetylcholine (ACh) released from the motor neurons in the myoneural junction crosses the synaptic space to reach receptors that are concentrated in the folds of the endplate of the muscle fiber. Once released, ACh is rapidly broken down by the enzyme acetylcholinesterase (AChesterase). (B) Decrease in ACh receptors in myasthenia gravis.](image-url)
The aminoglycoside antibiotics (e.g., gentamicin) may produce a clinical disturbance similar to botulism by preventing the release of acetylcholine from nerve endings. The symptoms usually subside rapidly once the drug is eliminated from the body. These drugs are particularly dangerous in persons with preexisting disturbances of neuromuscular transmission, such as myasthenia gravis.

The organophosphates (e.g., malathion, parathion) that are used in some insecticides bind acetylcholinesterase to prevent the breakdown of acetylcholine. They produce excessive and prolonged acetylcholine action with a depolarization block of cholinergic receptors, including those of the neuromuscular junction. The organophosphates are well absorbed from the skin, lungs, gut, and conjunctiva of the eye, making them particularly effective as insecticides but also potentially dangerous to humans. Malathion and certain other organophosphates are rapidly metabolized to inactive products in humans and are considered safe for sale to the general public. The sale of other insecticides, such as parathion, which is not effectively metabolized to inactive products, has been banned. Other organophosphate compounds (e.g., soman) were developed as “nerve gases”; if absorbed in high enough concentrations, they produce lethal effects through depolarization block and loss of respiratory muscle function.

Myasthenia Gravis

Myasthenia gravis is a disorder of the neuromuscular junction that affects impulse transmission between the motor neuron and the innervated muscle cell. Women are affected nearly three times as often as men during early adulthood (age < 40 years), whereas the incidence is roughly equal during puberty and between ages 40 and 50. After 50 years of age, the incidence is higher in men. The Lambert-Eaton myasthenic syndrome is a special type of myasthenic syndrome that develops in association with neoplasms, particularly small cell carcinoma of the lung.

Now recognized as an autoimmune disease, the disorder is caused by an antibody-mediated loss of acetylcholine receptors in the neuromuscular junction (see Fig. 36-6B). Three mechanisms are thought to underlie the loss of functional acetylcholine receptors: (1) complement-mediated injury to the postsynaptic muscle membrane, (2) accelerated acetylcholine receptor degradation by receptor-specific antibodies, and (3) blockade of the receptors by antibodies attached to the acetylcholine-binding sites. Neonatal myasthenia gravis, caused by placental transfer of the acetylcholine receptor antibody, occurs in about 10% to 15% of infants born to mothers with the disease. Spontaneous resolution of symptoms usually occurs within a few months of birth.

The trigger or inciting factor leading to the autoimmune derangement in myasthenia gravis remains unclear, but several lines of evidence implicate the thymus gland in the process. Approximately 75% of persons with myasthenia gravis also have thymic abnormalities, such as a thymoma (i.e., thymus tumor) or thymic hyperplasia (i.e., increased thymus weight from an increased number of thymus cells).

Clinical Manifestations. In persons with myasthenia gravis who have a loss of functional acetylcholine receptors, each release of acetylcholine from the presynaptic membrane results in diminished motor response. This results in both muscle weakness and fatigability with sustained effort. Most commonly affected are the eye and periorbital muscles, with ptosis (drooping of eyelids) due to eyelid weakness or diplopia (double vision) due to weakness of the extracocular muscles as an initial symptom. The disease may progress from ocular muscle weakness to generalized weakness, including respiratory muscle weakness. Chewing and swallowing may be difficult. Weakness in limb movement usually is more pronounced in the proximal rather than distal parts of the extremity, so that climbing stairs and lifting objects are difficult. As the disease progresses, the muscles of the lower face are affected, causing speech impairment. In most persons, symptoms are least evident when arising in the morning, but grow worse with effort and as the day proceeds.

Persons with myasthenia gravis may experience a sudden exacerbation of symptoms and weakness known as myasthenic crisis. Myasthenic crisis occurs when muscle weakness becomes severe enough to compromise ventilation to the extent that respiratory support and airway protection are needed. This usually occurs during a period of stress, such as infection, emotional upset, pregnancy, alcohol ingestion, cold exposure, or surgery. It also can result from inadequate or excessive doses of the anticholinesterase drugs used in treatment of the disorder.

Diagnosis and Treatment. The diagnosis of myasthenia gravis is based on history and physical examination and confirmed by the response to a short-acting anticholinesterase test. Edrophonium (Tensilon) commonly is used for the test. The drug, which is administered intravenously, decreases the breakdown of acetylcholine in the neuromuscular junction. When weakness is caused by myasthenia gravis, a dramatic transitory improvement in muscle function occurs. Electrophysiologic studies can be done to demonstrate a decremental muscle response to repetitive motor nerve stimulation. An immunoassay test can be used to detect the presence of anticholinesterase receptor antibodies circulating in the blood.

Treatment methods include the use of pharmacologic agents; immunosuppressive therapy, including corticosteroid drugs; management of myasthenic crisis; thymectomy; and plasmapheresis or intravenous immunoglobulin. Medications that may exacerbate myasthenia gravis, such as the aminoglycoside antibiotics, should be avoided. Pharmacologic treatment with reversible anticholinesterase drugs (i.e., neostigmine, pyridostigmine) inhibits the breakdown of acetylcholine. Corticosteroid drugs, which suppress the immune response, are used in cases of a poor response to anticholinesterase drugs.
and thymectomy. Immunosuppressant drugs (e.g., azathioprine, cyclosporine) also may be used, often in combination with plasmapheresis.

Plasmapheresis removes antibodies from the circulation and provides short-term clinical improvement. It is used primarily to stabilize the condition of persons in myasthenic crisis or for short-term treatment in persons undergoing thymectomy. Intravenous immunoglobulin also produces improvement in persons with myastenia gravis. Although the effect is temporary, it may last for weeks to months. Intravenous immunoglobulin therapy is very expensive, which limits its use.

Thymectomy, or surgical removal of the thymus, may be used as a treatment for myasthenia gravis. Because the mechanism whereby surgery exerts its effect is unknown, the treatment is controversial. Thymectomy may be performed in persons with thymoma, regardless of age, and in persons with generalized myasthenia gravis with onset before 50 years of age.

Peripheral Nervous System Disorders

Peripheral nervous system (PNS) disorders involve neurons that are located outside the CNS. They include disorders of the motor and sensory branches of the somatic and visceral nervous systems and the peripheral branches of the autonomic nervous system (see Chapter 34). The result usually is muscle weakness, with or without atrophy, and sensory changes.

Unlike the nerves of the CNS, peripheral nerves are fairly strong and resilient. They contain a series of connective tissue sheaths: the outer epineurium that surrounds the medium-sized to large nerves, the perineurium that invests each bundle of nerve fibers; and the endoneurium that surrounds each nerve fiber (see Chapter 34, Fig. 34-2). Inside the endoneurium are the Schwann cells that produce the myelin sheath that surrounds the peripheral nerves. Each Schwann cell can myelinate only one segment of a single axon—the one that it covers—so that myelination of an entire axon requires the participation of a long line of these cells.

Peripheral Nerve Injury and Repair

There are two main types of peripheral nerve injury based on the target of the insult: segmental demyelination involving the Schwann cell and axonal degeneration involving the neuronal cell body or its axon.

Segmental Demyelination. Segmental demyelination occurs when there is a disorder of the Schwann cell (as in hereditary motor and sensory neuropathies) or damage to the myelin sheath (e.g., Guillain-Barré syndrome) without a primary abnormality of the axon. It typically affects some Schwann cells while sparing others. The disintegrated myelin is engulfed initially by Schwann cells and then by macrophages. The denuded axon provides a stimulus for remyelination and the population of cells within the endoneurium has the capacity to replace the injured Schwann cells. These cells proliferate and encircle the axon, and in time remyelinate the denuded portion.

Axonal Degeneration. Axonal degeneration is caused by primary injury to a neuronal cell body or its axon. Damage to the axon may be due either to a focal event occurring at some point along the length of the nerve (e.g., trauma or ischemia) or to a more generalized abnormality affecting the neuronal cell body (neuropathy).

Damage to a peripheral nerve axon, whether by injury or neuropathy, results in degenerative changes, followed by breakdown of the myelin sheath and Schwann cells. In distal axonal degeneration, the proximal axon and neuronal cell body, which synthesizes the material required for nourishing and maintaining the axon, remain intact. In neuropathies and crushing injuries, in which the endoneurial tube remains intact, the outgrowing fiber grows down this tube to the structure that was originally innervated by the neuron (Fig. 36-7). However, it can take weeks or months for the regrowing fiber to reach its target organ and for communicative function to be reestablished. More time is required for the Schwann cells to form new myelin segments and for the axon to recover its original diameter and conduction velocity.

FIGURE 36-7. Sequential stages of efferent axon degeneration and regeneration within its endoneurial tube, after peripheral nerve crush injury. CNS, Central nervous system; PNS, Peripheral nervous system.
The successful regeneration of a nerve fiber in the PNS depends on many factors. If a nerve fiber is destroyed relatively close to the neuronal cell body, the chances are that the nerve cell will die; if it does, it will not be replaced. If a crushing type of injury has occurred, partial or often full recovery of function occurs. Cutting-type trauma to a nerve is an entirely different matter. Connective scar tissue forms rapidly at the wound site, and when it does, only the most rapidly regenerating axonal branches are able to get through to the intact distal endoneurial tubes. A number of scar-inhibiting agents have been used in an effort to reduce this hazard, but have met with only moderate success. In another attempt to improve nerve regeneration, various types of tubular implants have been used to fill longer gaps in the endoneurial tube.

Mononeuropathies

Mononeuropathies usually are caused by localized conditions such as trauma, compression, or infections that affect a single spinal nerve, plexus, or peripheral nerve trunk. Fractured bones may lacerate or compress nerves, excessively tight tourniquets may injure nerves directly or produce ischemic injury, and infections such as herpes zoster may affect a single segmental afferent nerve. Recovery of nerve function usually is complete after compression lesions and incomplete or faulty after nerve transection.

Carpal Tunnel Syndrome. Carpal tunnel syndrome is a relatively common entrapment mononeuropathy, caused by compression of the median nerve as it travels with the flexor tendons through a canal made by the carpal bones and transverse carpal ligament. It can be caused by a variety of conditions that produce a reduction in the capacity of the carpal tunnel (i.e., bony or ligamentous changes) or an increase in the volume of the tunnel contents (i.e., inflammation of the tendons, synovial swelling, or tumors). Carpal tunnel syndrome may be a feature of a number of systemic diseases, such as rheumatoid arthritis, hyperthyroidism, acromegaly, and diabetes mellitus. Most cases, however, are due to repetitive use of the wrist (i.e., flexion–extension movements and stress associated with pinching and gripping motions).

Carpal tunnel syndrome is characterized by pain, paresthesia (tingling), and numbness of the thumb and first, second, third, and half of the fourth digits of the hand; pain in the wrist and hand, which worsens at night; atrophy of the abductor pollicis muscle; and weakness in precision grip. All of these abnormalities may contribute to clumsiness of fine motor activity.

Diagnosis usually is based on sensory disturbances confined to median nerve distribution and a positive Tinel or Phalen sign. The Tinel sign is the development of a tingling sensation radiating into the palm of the hand that is elicited by light percussion over the median nerve at the wrist. The Phalen maneuver is performed by having the person hold the wrist in complete flexion for approximately a minute; if numbness and paresthesia along the median nerve are reproduced or exaggerated, the test result is considered to be positive. Electromyography and nerve conduction studies often are done to confirm the diagnosis and exclude other causes of the disorder.

Treatment includes a variety of options including nonsteroidal anti-inflammatory agents, injection of corticosteroids, immobilization of the wrist with splints, rehabilitation modalities (e.g., ultrasound, stretching, and strengthening exercises), and surgery. Measures to decrease the causative repetitive movements should be initiated. Splints may be confined to nighttime use. When splinting is ineffective, corticosteroids may be injected into the carpal tunnel to reduce inflammation and swelling. Surgical intervention consists of operative division of the volar carpal ligaments as a means of relieving pressure on the median nerve.

Polyneuropathies

Polyneuropathies involve demyelination or axonal degeneration of multiple peripheral nerves that leads to symmetric sensory, motor, or mixed sensorimotor deficits. Typically, the longest axons are involved first, with symptoms beginning in the distal part of the extremities. If the autonomic nervous system is involved, there may be postural hypotension, constipation, and impotence. Polyneuropathies can result from immune mechanisms (e.g., Guillain-Barré syndrome), toxic agents (e.g., arsenic polyneuropathy, lead polyneuropathy, alcoholic
polyneuropathy), and metabolic diseases (e.g., diabetes mellitus, uremia). Different causes tend to affect axons of different diameters and to affect sensory, motor, or autonomic neurons to different degrees.

**Guillain-Barré Syndrome.** Guillain-Barré syndrome is an acute life-threatening polyneuropathy. The syndrome defines a clinical entity that is characterized by rapidly progressive limb weakness and loss of tendon reflexes. It has been described as the most common cause of acute, flaccid paralysis in developed countries of the world, now that poliomyelitis has been eliminated. As a syndrome, there are several subtypes of the disorder, including pure motor axonal degeneration, axonal degeneration of both motor and sensory nerves, and a variant characterized by ophthalmoplegia (paralysis of eye muscles), ataxia (unsteady gait), and areflexia (lack of reflexes).

Guillain-Barré syndrome is thought to be an acute onset immune-mediated demyelinating neuropathy. Approximately two thirds of patients report having had an acute, influenza-like illness before the onset of symptoms. Controlled epidemiologic studies have linked it to infection with *Campylobacter jejuni*, cytomegalovirus, Epstein-Barr virus, and mycoplasma pneumoniae. A *C. jejuni* infection is often an antecedent to symptoms. In a few cases, the patient reports receiving a vaccination prior to onset of Guillain-Barré syndrome.

The disorder is characterized by progressive ascending muscle weakness of the limbs, producing a symmetric flaccid paralysis. Symptoms of paresthesia and numbness often accompany the loss of motor function. The rate of disease progression varies, and there may be disproportionate involvement of the upper or lower extremities. Paralysis may progress to involve the respiratory muscles. Autonomic nervous system involvement that causes postural hypotension, arrhythmias, facial flushing, abnormalities of sweating, and urinary retention is common. Pain is another common feature of Guillain-Barré syndrome. It is most common in the shoulder girdle, back, and posterior thighs and occurs with even the slightest of movements.

Guillain-Barré syndrome usually is a medical emergency. There may be a rapid development of respiratory failure and autonomic disturbances that threaten circulatory function. Treatment includes support of vital functions and prevention of complications such as skin breakdown and thrombophlebitis. Removing the circulating immune complexes via plasma exchange has been shown to decrease morbidity and shorten the course of the disease. Treatment is most effective if initiated early in the course of the disease. High-dose intravenous immunoglobulin therapy also has proved effective. Approximately 85% of persons with the disease achieve a full and spontaneous recovery within 6 to 12 months.

**Back Pain and Spinal Nerve Root Disorders**

The spinal cord and spinal nerve roots are located within the vertebral canal. The anterior portion of the spine consists of cylindrical vertebral bodies separated by intervertebral disks and held together by the anterior and posterior longitudinal ligaments. The posterior portion of the spine consists of the vertebral arches, each consisting of paired transverse processes, one posterior spinous process, and two superior articular facets. The functions of the posterior spine are to protect the spinal cord and nerves within the spinal canal and to stabilize the spine by providing sites for the attachment of muscles and ligaments.

Back pain is a common problem that affects an estimated two thirds of people at least once in their lifetime. It can result from a number of causes, including problems involving the vertebrae and intervertebral disks and facet joints or back muscles and ligaments, as well as disorders of the spinal nerve roots. Perhaps the most common causes are musculoskeletal injuries and age-related degenerative changes in the intervertebral disks and facet joints. Other causes include spinal nerve root compression due to intervertebral disk herniation and narrowing of the central canal due to spinal stenosis.

Pain-sensitive structures in the spine include the periosteum of the vertebrae, dura, facet joints, annulus fibrosus of the intervertebral disk, and posterior longitudinal ligament. Pain sensation is conveyed through afferent fibers in the spinal nerves. Local pain is caused by stretching of pain-sensitive structures that compress or irritate sensory nerve endings. Pain referred to the back may arise from abdominal or pelvic structures. Pain associated with muscle spasm is usually dull, and often accompanied by abnormal posture and stiff paraspinal muscles.

Nerve root injury (radiculopathy) is a common cause of neck, arm, low back, and leg pain. The pain is typically sharp and radiates to the arm or leg within the territory of the spinal root. Disorders affecting the upper lumbar segments tend to be referred to the lumbar area, groin, or anterior thigh; and those affecting the lower lumbar and upper sacral segments, to the buttocks and posterior thighs.

**Diagnosis and Treatment.** Although back problems are commonly attributed to a herniated disk, most acute back disorders are caused by less-serious problems. The diagnostic challenge is to identify those persons who require further evaluation for more serious problems such as malignancies, compression fractures, and vascular disorders. The diagnostic measures used in the evaluation of back pain include history and physical examination, including a thorough neurologic examination. Other diagnostic methods may include radiographs of the back and magnetic resonance imaging (MRI).

Treatment of back pain usually is conservative and consists of analgesic medications, muscle relaxants, and instruction in the correct mechanics for lifting and methods of protecting the back. Pain relief is usually provided using nonsteroidal anti-inflammatory drugs. Muscle relaxants may be used on a short-term basis. Bed rest, once the mainstay of conservative therapy, is now understood to be ineffective for acute back pain.
Conditioning exercises of the trunk muscles, particularly the back extensors, are often recommended.

**Intervertebral Disk Disorders.** The intervertebral disk is considered the most critical component of the load-bearing structures of the spinal column. It consists of a soft, gelatinous center called the *nucleus pulposus*, which is encircled by a strong ring of fibrocartilage called the *annulus fibrosus*. The structural components of the disk make it capable of absorbing shock and changing shape while allowing movement. With dysfunction, the nucleus pulposus can be squeezed out of place and herniate through the annulus fibrosus, a condition referred to as a **herniated or slipped disk** (see Fig. 36-9B).

The intervertebral disk can become dysfunctional because of trauma, the effects of aging, or degenerative disorders of the spine. Protrusion of the nucleus pulposus usually occurs posteriorly and toward the intervertebral foramen and its contained spinal nerve root, where the annulus fibrosus is relatively thin and poorly supported by either the posterior or anterior ligaments. Trauma results from activities such as lifting while in the flexed position, slipping, falling on the buttocks or back, or suppressing a sneeze. With aging, the gelatinous center of the disk dries out and loses much of its elasticity.

The level at which a herniated disk occurs is important (see Fig. 36-9C). The cervical and lumbar regions are the most flexible areas of the spine and are most often involved in disk herniations. Usually, herniation occurs at the lower levels of the lumbar spine, where the mass being supported and the bending of the vertebral column are greatest. When the injury occurs in the lumbar area, only the nerve fibers of the cauda equina are involved. Because these elongated dorsal and ventral roots contain endoneurial tubes of connective tissue, regeneration of the nerve fibers is likely. However, months may be required for full recovery to occur because of the distance to the innervated muscle or skin of the lower limbs.

The signs and symptoms of a herniated disk are localized to the area of the body innervated by the spinal nerve roots and include both motor and sensory manifestations (Fig. 36-10). Pain is the first and most common symptom of a herniated disk. The nerve roots of L4, L5, S1, S2, and S3 give rise to a syndrome of back pain, sometimes referred to as *sciatica*, which spreads down the back of the leg and over the sole of the foot. The pain is usually intensified with coughing, sneezing, straining, stooping, standing, and the jarring motions that occur during walking or riding. Slight motor weakness may occur, although major weakness is rare.

![Diagram of intervertebral disk](image)
The most common sensory deficits from spinal nerve root compression are paresthesias and numbness, particularly of the leg and foot. Knee and ankle reflexes also may be diminished or absent.

A herniated disk must be differentiated from other causes of acute back pain. Diagnostic measures include history and physical examination. Neurologic assessment includes testing of muscle strength and reflexes. The straight-leg test is an important diagnostic maneuver. It is done with the person in the supine position and is performed by passively raising the person’s leg. The test can also be done by slowly extending the knee while the person sits on a table, with both hip and knee flexed at 90 degrees. The maneuver is designed to apply traction along the nerve root, which exacerbates pain if the nerve root is acutely inflamed. Normally, it is possible to raise the leg approximately 90 degrees without causing discomfort of the hamstring muscles. The test result is positive if pain is produced when the leg is raised to 60 degrees or less. Other diagnostic methods include radiographs of the back, MRI, computed tomography (CT), and CT myelography.

Treatment usually is similar to that for back pain. Surgical treatment may be indicated when there is documentation of herniation by an imaging procedure, consistent pain, or consistent neurologic deficit that failed to respond to conservative therapy.

**Back Pain Emergencies.** Although acute back pain is usually a non–life-threatening condition, in 5% to 10% of persons it is a manifestation of a more serious pathologic process. Vascular catastrophes (ruptured abdominal aortic aneurysms and dissecting aortic aneurysms), malignancy, spinal cord compression syndromes, and infectious processes may all present as acute back pain.

Clinical findings, commonly referred to as red flags, that indicate the possibility of more serious disease include gradual onset of pain; age younger than 20 years or older than 50 years; thoracic back pain; history of trauma, fever, chills, night sweats, immunosuppression, or malignancy; unintentional weight loss; recent procedure known to cause bacteremia; and history of intravenous drug use. The gradual onset of pain may be indicative of malignancy or infection. Back pain that begins before 20 years of age suggests congenital or developmental disorders, and new-onset pain in persons 50 years of age or older is more likely to be a manifestation of serious conditions such as an aortic aneurysm, malignancy, or compression fracture. Pain that is aggravated by lying down is a red flag for malignancy or infection, and pain that improves with sitting or slight flexion of the spine suggests the presence of spinal stenosis. Persons with symptoms of large or rapidly evolving neurologic deficits require urgent evaluation for possible cauda equina syndrome, epidural abscess, or central disk herniation. Signs and symptoms that suggest possible cauda equina syndrome are low back pain associated with bilateral leg weakness (from multiple lumbar nerve root compressions), saddle area numbness, bowel and bladder incontinence, or impotence (indicating multiple sacral nerve compressions). Reports of neurologic symptoms such as paresthesia, motor weakness, and gait abnormalities also require additional diagnostic tests to rule out spinal cord compression.

**SUMMARY CONCEPTS**

- **Muscular dystrophy** is a term used to describe a number of disorders, including Duchenne muscular dystrophy, that produce progressive deterioration of the skeletal muscles. Myasthenia gravis is a disorder of the neuromuscular junction resulting from a deficiency of functional acetylcholine receptors, which causes weakness of the skeletal muscles.
- **Peripheral nerve disorders**, which involve motor and sensory neurons outside the CNS, include the mononeuropathies, such as carpal tunnel syndrome, that involve a single peripheral nerve;
and the polyneuropathies, such as Guillain-Barré syndrome, which involve multiple peripheral nerves leading to symmetric sensory, motor, or mixed sensorimotor deficits.

- Back pain and pain related to spinal nerve root irritation can be caused by a number of disorders including muscle and ligament strains, age-related degenerative spine disorders, disk herniation, and narrowing of the central vertebral canal due to spinal stenosis.

### Disorders of the Cerebellum and Basal Ganglia

Aside from the areas in the cerebral cortex that stimulate muscle contraction, two other brain structures, the cerebellum and basal ganglia, are also essential for normal motor function. Neither one can control muscle function by itself. Instead, they always function in association with other components of motor control.

### Disorders of the Cerebellum

The cerebellum has sometimes been referred to as the silent area of the brain because electrical stimulation does not produce any conscious sensation and rarely causes any motor movements. However, removal or damage to the cerebellum causes movements to become highly abnormal. The cerebellum is especially vital during rapid muscular activities such as running, typing, and even talking. Loss of cerebellar function can result in total incoordination of these functions even though paralysis does not occur.

The functions of the cerebellum are integrated into many connected afferent and efferent pathways throughout the brain. An extensive and important afferent pathway is the corticopontocerebellar pathway, which originates in the cerebral motor and premotor cortices as well as the somatosensory cortex. Other important afferent pathways link the cerebellum to input from the basal ganglia, muscle and joint information from the stretch receptors, visual input from the eyes, and balance and equilibrium sensation from the vestibular system in the inner ear. There are three general efferent pathways leading out of the cerebellum: (1) the vestibulocerebellar pathway that functions in close association with the brain stem vestibular nuclei to maintain equilibrium and posture; (2) the spinocerebellar pathway that provides the circuitry for coordinating the movements of distal portions of the limbs, especially the hands and fingers; and (3) the cerebrocerebellar pathway that transmits output information in an upward direction to the cerebral cortex, functioning in a feedback manner with the motor and somatosensory systems to coordinate sequential body and limb movements.

The signs of cerebellar dysfunction include cerebellar ataxia and tremor. They result from defects in the smooth, continuously correcting functions of the cerebellum, and occur on the side of the cerebellar damage. Disorders of cerebellar function are typically caused by a congenital defect, cerebrovascular event, or growing tumor.

Cerebellar gait ataxia is characterized by wide-based staggering, lurching, and uncontrolled gait. Visual monitoring of movement cannot compensate for cerebellar defects, and these abnormalities occur whether the eyes are open or closed. Because ethanol specifically affects cerebellar function, persons who are inebriated often walk with a staggering and unsteady gait. Rapid alternating movements such as supination–pronation—supination of the hands are jerky and performed slowly. Reaching to touch a target breaks down into small sequential components, each going too far, followed by overcorrection. The finger moves jerkily toward the target, misses, corrects in the other direction, and misses again, until the target is finally reached. This is called over- and underreaching or dysmetria.

Cerebellar tremor is a rhythmic back-and-forth movement of a finger or toe that worsens as the target is approached. The tremor results from the inability of the damaged cerebellar system to maintain ongoing fixation of a body part and to make smooth, continuous corrections in the trajectory of the movement; overcorrection occurs, first in one direction and then the other. Often, the tremor of an arm or leg can be detected during the beginning of an intended movement. The common term for cerebellar tremor is intention tremor. Cerebellar function, as it relates to tremor, can be assessed by asking a person to touch one heel to the opposite knee, to gently move the toes along the back of the opposite shin, or to touch the nose with a finger.

The ability to fix the eyes on a target also can be affected. Constant conjugate readjustment of eye position, called nystagmus, results and makes reading extremely difficult, especially when the eyes are deviated toward the side of cerebellar damage. Cerebellar function also can affect the motor skills of chewing, swallowing, and speech. Normal speech requires smooth control of respiratory muscles and highly coordinated control of the laryngeal, lip, and tongue muscles. Cerebellar dysarthria is characterized by slow, slurred speech of continuously varying loudness. Rehabilitative efforts directed by speech therapists include learning to slow the rate of speech and to compensate as much as possible through the use of less-affected muscles.

### Disorders of The Basal Ganglia

The basal ganglia are a group of deep, interrelated subcortical nuclei that play an essential role in control of movement. They function in the organization of inherited and highly learned and rather automatic movement programs, especially those affecting the trunk and...
proximal limbs. The basal ganglia are thought to be particularly important in starting, stopping, and monitoring movements executed by the cortex, especially those that are relatively slow and sustained, or stereotyped. They also help to regulate the intensity of these movements, and they act to inhibit antagonistic or unnecessary movements. The function of the basal ganglia is not limited to motor functions; they also are involved in cognitive and perceptual functions.

**Functional Properties of the Basal Ganglia**

The structural components of the basal ganglia include the caudate nucleus, putamen, and globus pallidus. They are located lateral and caudal to the thalamus, occupying a large portion of the interior of both cerebral hemispheres. The caudate and putamen are collectively referred to as the striatum, and the putamen and globus pallidus form a wedge-shaped region called the lentiform nucleus. Two other structures, the substantia nigra of the midbrain and the subthalamic nucleus of the diencephalon, are considered part of the basal ganglia (Fig. 36-11). The dorsal part of the substantia nigra contains cells that synthesize dopamine and are rich in a black pigment called melanin. The high concentration of melanin gives the structure a black color, hence the name substantia nigra. The axons of the substantia nigra form the nigrostriatal pathway, which supplies dopamine to the striatum. The subthalamic nucleus lies just below the thalamus and above the anterior portion of the substantia nigra. The glutaminergic cells of this nucleus are the only excitatory projections to the basal ganglia.

The basal ganglia have input structures that receive afferent information from the cerebral cortex and thalamus, internal circuits that connect the various structures of the basal ganglia, and output structures that deliver information to other brain centers. The neostriatum represents the major input structure for the basal ganglia. Virtually all areas of the cortex and afferents from the thalamus project to the neostriatum. The output areas of the basal ganglia, including the lateral globus pallidus, have both ascending and descending components. The major ascending output is transmitted to thalamic nuclei, which process all incoming information that is transmitted to the cerebral cortex. Descending output is directed to the midbrain, brain stem, and spinal cord.

The output functions of the basal ganglia are mainly inhibitory. Looping circuits from specific cortical areas pass through the basal ganglia to modulate the excitability of specific thalamic nuclei and control the cortical activity involved in highly learned, automatic, and stereotyped motor functions. The most is known about the inhibitory basal ganglia loop that is involved in modulating cortical motor control. This loop regulates the release of stereotyped movement patterns that add efficiency and gracefulness to cortically controlled movements. These movements include inherited patterns that add precision, efficiency, and balance to motion, such as the swinging of the arms during walking and running and the highly learned automatic postural and follow-through movements of throwing a ball or swinging a bat.

The basal ganglia also have a cognitive function in that they monitor sensory information coming into the brain and apply it to information stored in memory as a means of planning and sequencing motor movements. The cognitive control of motor activities determines, subconsciously and within seconds, which patterns of movement will be needed to achieve a goal. The caudate nucleus, which receives large amounts of input from the association areas of the brain, plays a major role in the cognitive control of motor activity.

**Basal Ganglia–Associated Movement Disorders**

Disorders of the basal ganglia comprise a complex group of motor disturbances characterized by tremor and other involuntary movements, changes in posture and muscle tone, and poverty and slowness of movement. They include tremors and tics, hypokinetic disorders, and hyperkinetic disorders (Table 36-1). Unlike disorders of the motor cortex and corticospinal (pyramidal) tract, lesions of the basal ganglia disrupt movement but do not cause paralysis. The various types of involuntary movements often occur in combination and appear to have a common underlying cause. Recent studies indicate that hypokinetic and hyperkinetic disorders can be explained as specific disturbances in the indirect and direct pathways that link the basal ganglia with the thalamocortical motor circuit. Accordingly, overactivity of the indirect pathway relative to the direct pathway would result in hypokinetic disorders such as Parkinson disease, and underactivity of the indirect pathway would result in hyperkinetic disorders such as chorea and ballismus.
## Characteristics of Basal Ganglia–Associated Movement Disorders

<table>
<thead>
<tr>
<th>Movement Disorder</th>
<th>Characteristics</th>

### Parkinson Disease

Parkinson disease is a progressive degenerative disorder of basal ganglia function that results in variable combinations of tremor, rigidity, and bradykinesia. Parkinson disease is the second most common neurodegenerative disease after Alzheimer disease. It usually begins after 50 years of age, with the prevalence increasing to 4% to 5% in those older than 85 years of age.

The clinical syndrome arising from the degenerative changes in basal ganglia function often is referred to as parkinsonism. Parkinson disease, the most common form of parkinsonism, is named after James Parkinson, a British physician who first described the disease in a paper he published in 1817 on the “shaking palsy.” In Parkinson disease, also known as idiopathic parkinsonism, dopamine depletion results from degeneration of the dopamine nigrostriatal system. Parkinsonism can also develop as a postencephalitic syndrome, as a side effect of therapy with antipsychotic drugs that block dopamine receptors, as a toxic reaction to a chemical agent, or as an outcome of severe carbon monoxide poisoning. Drug-induced parkinsonism can follow the administration of antipsychotic drugs in high doses (e.g., phenothiazines, butyrophenones). These drugs block dopamine receptors and dopamine output by the cells of the substantia nigra. Symptoms of parkinsonism also may accompany conditions such as cerebral vascular disease, brain tumors, repeated head trauma, or degenerative neurologic diseases that structurally damage the nigrostriatal pathway.

The primary brain abnormality found in persons with Parkinson disease is degeneration of the nigrostriatal pathway, with subsequent reduction in striatal concentrations of dopamine. Other brain areas are affected to a lesser extent. Although the cause of Parkinson disease is still unknown, it is widely believed that most cases are caused by an interaction of environmental and genetic factors. Over the past several decades, several pathologic processes (e.g., oxidative stress, apoptosis, and mitochondrial disorders) that might lead to degeneration have been identified.

There is increasing evidence that the development of Parkinson disease may be related to oxidative metabolites and the inability of neurons to render these products harmless. Of interest in terms of research was the development of Parkinson disease in several persons who had attempted to make a narcotic drug and instead synthesized a compound called MPTP (1-methyl-phenyl-2,3,6-tetrahydropyridine). This compound selectively destroys the dopaminergic neurons of the substantia nigra. This incident prompted investigations into the role of toxins that are produced by the body as a part of metabolic processes and those that enter the body from outside sources in the pathogenesis of Parkinson disease. One theory is that the auto-oxidation of catecholamines, such as dopamine, may injure neurons in the substantia nigra. MPTP is an inhibitor of the mitochondrial electron transport system that functions in the inactivation of these metabolites, suggesting that it may produce Parkinson disease in a manner similar to that of the naturally occurring disease.

The recent discovery of inherited forms of Parkinson disease suggests that genetic factors may also play a role in the pathogenesis of early-onset Parkinson disease. The first genetic mutation associated with...
Parkinson disease was found in the gene encoding α-synuclein, a member of a small family of proteins that are expressed preferentially in the substantia nigra.\textsuperscript{37,38} Although mutations in this gene cause a very rare, autosomal dominant form of the disease, the mutation has received considerable attention because α-synuclein is one of the major components of the Lewy bodies that are found in the brain tissue of persons with Parkinson disease. Mutations in a second gene that encodes the protein parkin are associated with an autosomal recessive, early-onset form of Parkinson disease.\textsuperscript{37} Numerous other genetic loci have been linked to Parkinson disease, but the genes remain to be mapped. Thus, the genetics of Parkinson disease are beginning to provide molecular clues that help explain the etiology, just as epidemiologic studies have delineated an array of environmental modulators of susceptibility, which can now be explored in the context of gene expression.\textsuperscript{39}

**Clinical Manifestations.** The cardinal manifestations of Parkinson disease are tremor, rigidity, and bradykinesia or slowness of movement (Fig. 36-12).\textsuperscript{33,34,40} Tremor is the most visible manifestation of the disorder. The tremor affects the distal segments of the limbs, mainly the hands and feet; head, neck, face, lips, and tongue; or jaw. It is characterized by rhythmic, alternating flexion and contraction movements (four to six beats per minute) that resemble the motion of rolling a pill between the thumb and forefinger. The tremor usually is unilateral, occurs when the limb is supported and at rest, and disappears with movement and sleep. The tremor eventually progresses to involve both sides of the body. R stiffness is defined as resistance to movement of both flexors and extensors throughout the full range of motion. It is most evident during passive joint movement and involves jerky, cogwheel-type or ratchetlike movements that require considerable energy to perform. Flexion contractions may develop as a result of the rigidity. As with tremor, rigidity usually begins unilaterally but progresses to involve both sides of the body.

Bradykinesia is characterized by slowness in initiating and performing movements and difficulty with sudden, unexpected stopping of voluntary movements. Unconscious associative movements occur in a series of disconnected steps rather than in a smooth, coordinated manner. This is the most disabling of the symptoms of Parkinson disease. Persons with the disease have difficulty initiating walking and difficulty turning. While walking, they may freeze in place and feel as if their feet are glued to the floor, especially when moving through a doorway or preparing to turn. When they walk, they lean forward to maintain their center of gravity; take small, shuffling steps without swinging their arms; and have difficulty changing their stride.

Manifestations of advanced-stage parkinsonism include falls, fluctuations in motor function, neuropsychiatric disorders, and sleep disorders. Loss of postural reflexes predisposes to falling, often backward. Emotional and voluntary facial movements become limited and slow as the disease progresses, and facial expression becomes stiff and masklike. There is loss of the blinking reflex and a failure to express emotion. The tongue, palate, and throat muscles become rigid; the person may drool because of difficulty in moving the saliva to the back of the mouth and swallowing it. Speech becomes slow and monotonous, without modulation, and poorly articulated.

Because the basal ganglia also influence the autonomic nervous system, persons with Parkinson disease often have excessive and uncontrolled sweating, sebaceous gland secretion, and salivation. Autonomic symptoms, such as lacrimation, dysphagia, orthostatic hypotension, thermal regulation, constipation, impotence, and urinary incontinence, may be present, especially late in the disease.

Cognitive dysfunction may also be an important feature associated with Parkinson disease. It occurs in approximately 20% to 30% of persons with the disease and develops late in the course of the disease.\textsuperscript{40} Deficits in executive functioning may be among the earliest signs of cognitive decline, as evidenced by difficulty in planning, starting, and carrying out tasks. Dementia, when it does occur, is usually a late manifestation of the disease, and the rate of decline is slow compared with Alzheimer disease.
Treatment. The approach to treatment of Parkinson disease must be highly individualized. It includes nonpharmacologic, pharmacologic, and, when indicated, surgical methods. Nonpharmacologic interventions offer group support, education, daily exercise, and adequate nutrition. Botulinum toxin injections may be used in the treatment of dystonias such as eyelid spasm and limb dystonias that frequently are associated with Parkinson disease. Persons with parkinsonism other than idiopathic Parkinson disease usually do not respond significantly to medications developed for Parkinson disease.

Pharmacologic treatment usually is determined by the severity of symptoms. Antiparkinson drugs act by increasing the functional ability of the underactive dopaminergic system, or by reducing the excessive influence of excitatory cholinergic neurons. Drugs that improve the function of the dopaminergic system include those that increase dopamine levels (levodopa), stimulate dopamine receptors (dopamine receptor agonists), or retard the breakdown of dopamine (monoamine oxidase-B inhibitors).

Levodopa, a dopamine agonist, is administered with carbidopa, which inhibits its peripheral metabolism, allowing therapeutic concentrations of the drug to enter the brain without disabling adverse effects. A later lism, allowing therapeutic concentrations of the drug to with carbidopa, which inhibits its peripheral metabo-
dase-B inhibitors).

the function of the dopaminergic system include those
that increase dopamine levels (levodopa), stimulate
dopamine receptors (dopamine receptor agonists), or
retard the breakdown of dopamine (monoamine ox-
dase-B inhibitors).

Levodopa, a dopamine agonist, is administered
with carbidopa, which inhibits its peripheral metabo-
allowing therapeutic concentrations of the drug to
enter the brain without disabling adverse effects. A later
adverse effect of levodopa treatment is the so-called
on–off phenomenon, in which frequent, abrupt, and
unpredictable fluctuations in motor performance occur
during the day. These fluctuations include “on” peri-
ods without dyskinesia, “on” periods with dyskinesia,
and periods of bradykinesia (the “off” response). Some
fluctuations reflect the timing of drug administration,
in which case the “on” response coincides with peak drug
levels and the “off” response with low drug levels.

Dopamine agonists such as pramipexole (Minaprex)
and ropinirole (Requip) directly stimulate dopamine
receptors. Rotigotine is a dopamine agonist that is sup-
plied in a transdermal system. The dopamine agonists
can be used as initial or adjunctive therapy in Parkinson
disease and can be given in combination with carbidopa/
levodopa. Rotigotine is only approved by the U.S. Food
and Drug Administration (FDA) for initial treatment of
Parkinson disease.

Amantidine, an antiviral agent, was found by chance
to have antiparkinson properties. It is thought to aug-
ment release of dopamine from the remaining intact
dopaminergic terminals in the nigrostriatal pathway of
persons with Parkinson disease. It is used to treat per-
sons with mild symptoms but no disability.

Several medications are used for adjuvant therapy
as the initial therapy becomes less effective in control-
ing motor complications. As the therapy less effec-
tively controls the symptoms, there is less “on time”
(when the symptoms are controlled) and more “off
time”. Apomorphine is a dopamine agonist that can be
given intravenously. It is often used as a rescue medica-
tion in patients experiencing sudden “off” periods or
delayed “on” periods. Monamine oxidase-B inhibitors,
such as selegiline and rasagiline, hinder the metabolic
breakdown of dopamine. Selegiline and rasagiline may
be used as adjunctive treatment to reduce mild on–off
fluctuations in the responsiveness of persons who are
receiving levodopa.

Because dopamine transmission is disrupted in
Parkinson disease, there is a preponderance of chol-
nergic activity. Anticholinergic drugs (e.g., trihexyph-
hdry, benztropine) are thought to restore a “balance”
between reduced dopamine and uninhibited cholinergic
neurons in the striatum. They are more useful in allevi-
ating tremor and rigidity than bradykinesia. The anticho-
ilnergic drugs lessen the tremors and rigidity and afford
some improvement of function. However, their potency
seems to decrease over time, and increasing the dosage
merely increases side effects such as blurred vision, dry
mouth, bowel and bladder problems, cognitive dysfunc-
tion, and hallucinations.

Deep brain stimulation, which involves the surgical
implantation of electrodes into the subthalamic nuclei
or the pars interna of the globus pallidus, is an option
for many persons who develop symptoms despite opti-
mal medical therapy. The electrodes are connected to a surgically implanted impulse generator that delivers
electrical simulation to block the abnormal nerve activ-
ity that causes tremor and abnormal motor activity in
Parkinson disease. The system allows the stimulation to
be programmed to control the individual person’s symp-
toms, and the stimulation parameters can be changed
over time as the disease progresses. Deep brain stimu-
lization is used for persons with Parkinson disease who
respond to levodopa but experience side effects associ-
ated with it (e.g., motor fluctuation or dyskinesia). It
is not a cure but serves to increase the duration of the
“on” periods, allows for a reduction in medication dos-
ages (in subthalamic nuclei stimulation), and improves
function. Of note, other movement disorders can be
treated by placing electrodes in different target sites
(e.g., thalamus for tremor and globus pallidus internus
for dystonia).

SUMMARY CONCEPTS

- Both uncoordinated and abnormal muscle
  movements can result from disorders of the
cerebellum and basal ganglia.

- The functions of the cerebellum, which
  are especially vital during rapid muscular
  movements, use afferent input from various
  sources, including stretch receptors,
  proprioceptors, tactile receptors in the skin,
  visual input, and the vestibular system. Signs
  of cerebellar disorders include dystaxia, ataxia,
tremor, and dysarthria.

- The basal ganglia organize basic movement
  patterns into more complex patterns and release
  them when commanded by the motor cortex,
  contributing gracefulness to cortically initiated

(continued)
Upper Motor Neuron Disorders

Upper motor neuron disorders involve neurons that are fully contained within the CNS. They include the motor neurons arising in the motor areas of the cortex and their fibers as they project through the brain and descend in the spinal cord. Disorders that affect UMN include multiple sclerosis and spinal cord injury. Stroke, which is a common cause of UMN damage, is discussed in Chapter 37. Amyotrophic lateral sclerosis is a mixed UMN and LMN disorder.

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS), also known as Lou Gehrig disease after the famous New York Yankees baseball player, is a devastating neurologic disorder that selectively affects motor function. Amyotrophic lateral sclerosis has an annual incidence of about 2 cases per 100,000 population. It is primarily a disorder of middle to late adulthood, with men being affected more frequently than women. The disease typically follows a progressive course, with a mean survival period of 2 to 5 years from the onset of symptoms.

Amyotrophic lateral sclerosis is characterized by the loss of anterior LMNs in the spinal cord and motor nuclei of the brain stem and UMN that originate in the motor cortex and descend via the pyramidal tract to synapse with the LMNs. The death of LMNs leads to denervation, with subsequent muscle fiber atrophy and shinkage of skeletal muscles. It is this fiber atrophy, called amyotrophy, that appears in the name of the disease. The loss of nerve fibers in lateral columns of the white matter of the spinal cord, along with fibrillary gliosis, imparts a firmness or sclerosis to this CNS tissue; the term lateral sclerosis designates these changes. A remarkable feature of the disease is that the entire sensory system, the regulatory mechanisms of control and coordination of movement, and the intellect remain intact. The neurons for ocular motility and the parasym pathetic neurons in the sacral spinal cord are also spared.

The pathogenesis of ALS is largely unknown, despite the identification of a number of genetic associations. Approximately 5% to 10% of cases are familial ALS, mostly with autosomal dominant inheritance. The rest are believed to be sporadic, with no family history of the disease. The gene for a subset of familial ALS has been mapped to the superoxide dismutase 1 (SOD1) gene on chromosome 21. SOD1 is a critical enzyme involved in protecting neurons from oxidative damage. Other suggested mechanisms of nerve injury are alterations in transport of molecules necessary for maintenance of the axon, neurofilament abnormalities, and glutamate-mediated excitotoxicity (see Chapter 37).

Manifestations of amyotrophic lateral sclerosis include those of both UMN and LMN dysfunction. Muscle cramps involving the distal legs often are an early symptom. The most common clinical presentation is slowly progressive weakness and atrophy in distal muscles of one upper extremity. This is followed by regional spread of muscle weakness, reflecting involvement of neighboring areas of the spinal cord. Eventually, UMN and LMNs involving multiple limbs and the head are affected. In the more advanced stages, muscles of the palate, pharynx, tongue, neck, and shoulders become involved, causing impairment of chewing, swallowing (dysphagia), and speech. Dysphagia with recurrent aspiration and weakness of the respiratory muscles produces the most significant acute complications of the disease. Death usually results from involvement of cranial nerves and respiratory musculature.

There are no specific tests for ALS. Diagnosis is based on a careful medical history, detailed physical and neurological examination, and electrophysiologic studies. Currently, there is no cure for ALS. The treatment of persons with ALS, which requires management of medical problems, severe disability, and psychosocial problems, is best provided by a multidisciplinary team. Measures to assist persons with the disorder manage their symptoms (e.g., weakness and muscle spasms, dysphagia, communication difficulty, excessive salivation, and emotional lability), nutritional status, and respiratory muscle weakness increase survival time. An antiglutamate drug, riluzole, is the only drug approved for the treatment of ALS. The drug is designed to decrease glutamate accumulation and slow the progression of the disease.

Multiple Sclerosis

Multiple sclerosis (MS) is an autoimmune demyelinating disorder characterized by inflammation and selective destruction of CNS myelin. It affects approximately 350,000 persons in the United States and more than 1 million worldwide. The age of onset is typically between 18 and 45 years. Women are affected twice as frequently as men.

As with other autoimmune disorders, the pathogenesis appears to involve both genetic and environmental influences. The risk for developing MS is 15-fold higher when the disease is present in a first-degree relative, and is even greater in monozygotic twins. People with the human leukocyte antigen (HLA)-DR2 haplotype (see...
Chapter 15) are particularly susceptible. Alternatively, certain environmental factors such as residence in a northern latitude, particularly before age 15, may trigger disease in genetically susceptible persons. Recently, low vitamin D levels have been linked to MS. Because the penetrance of ultraviolet (UV) light declines rapidly with increased distance from the equator, it has been suggested that the quantities of UV light required for production of vitamin D may be insufficient, especially in winter.\textsuperscript{46}

Pathophysiology

The pathophysiology of MS involves the demyelination of nerve fibers in the white matter of the brain, spinal cord, and optic nerve.\textsuperscript{37,46-49} In the CNS, myelin is formed by the oligodendrocytes, chiefly those lying among the nerve fibers in the white matter. The properties of the myelin sheath—high electrical resistance and low capacitance—permit it to function as an electrical insulator. Demyelinated nerve fibers display a variety of conduction abnormalities, ranging from decreased conduction velocity to conduction blocks.

The lesions of MS consist of hard, sharp-edged, demyelinated or sclerotic patches that are macroscopically visible throughout the white matter of the CNS (Fig. 36-13). These lesions, which represent the end result of acute myelin breakdown, are called plaques. The lesions have a predilection for the optic nerves, periventricular white matter, brain stem, cerebellum, and spinal cord white matter. Although the sequence of myelin breakdown is not well understood, it is known that the lesions contain small amounts of myelin basic proteins and increased amounts of proteolytic enzymes, macrophages, lymphocytes, and plasma cells. Acute, subacute, and chronic lesions often are seen at multiple sites throughout the CNS.

Clinical Manifestations

The interruption of neural conduction in the demyelinated nerves in MS is manifested by a variety of symptoms, depending on the location and extent of the lesion.\textsuperscript{46,47,51}

Areas commonly affected are the optic nerve (visual field), corticobulbar tracts (speech and swallowing), cortospinal tracts (muscle strength), cerebellar tracts (gait and coordination), spino cerebellar tracts (balance), medial longitudinal fasciculus (conjugate gaze function of the extraocular eye muscles), and posterior cell columns of the spinal cord (position and vibratory sensation). Typically, an otherwise healthy person presents with an acute or subacute episode of paresthesias, optic neuritis (i.e., visual clouding or loss of vision in part of the visual field with pain on movement of the globe), diplopia, or specific types of gaze paralysis.

Paresthesias are evidenced as numbness, tingling, burning sensations, or pressure on the face or involved extremities, with symptoms ranging from annoying to severe. The Lhermitte sign is an electric shock–like tingling down the back and onto the legs that is produced by flexion of the neck. Pain from spasticity also may be a factor that can be alleviated by appropriate stretching exercises. Other common symptoms are abnormal gait, bladder and sexual dysfunction, vertigo, nystagmus, fatigue, and speech disturbance. These symptoms usually last for several days to weeks, and then completely or partially resolve. After a period of normal or relatively normal function, new symptoms appear. Psychological manifestations, such as mood swings, may represent an emotional reaction to the nature of the disease or, more likely, involvement of the white matter of the cerebral cortex. Depression, euphoria, inattentiveness, apathy, forgetfulness, and loss of memory may occur.

Fatigue is one of the most common problems for persons with MS. Fatigue often is described as a generalized low-energy feeling not related to depression and different from weakness. Fatigue has a harmful impact on activities of daily living and sustained physical activity. Interventions such as spacing activities and setting priorities often are helpful.

The course of the disease may fall into one of four categories: relapsing-remitting, secondary progressive, primary progressive, or progressive relapsing.\textsuperscript{46} The relapsing-remitting form of the disease is characterized by episodes of acute worsening with recovery and a stable course between relapses. Secondary progressive disease involves a gradual neurologic deterioration with or without superimposed acute relapses in a person.

Magnetic resonance imaging (MRI), which has had a major impact on the diagnosis and subsequent follow-up of MS, has shown that the lesions of MS may occur in two stages: a first stage that involves the sequential development of small inflammatory lesions, and a second stage during which the lesions extend and consolidate and when demyelination and gliosis (plaque formation) occur. It is not known whether the inflammatory process, present during the first stage, is directed against myelin or against the oligodendrocytes that produce myelin.
with previous relapsing-remitting disease. Primary progressive disease is characterized by nearly continuous neurologic deterioration from onset of symptoms. The progressive relapsing category of disease involves gradual neurologic deterioration from the onset of symptoms but with subsequent superimposed relapses.

**Diagnosis and Treatment**

The diagnosis of MS is based on evidence of CNS lesions that are disseminated in time and space (i.e., occur in different parts of the CNS at least 3 months apart), with no explanation for the disease process.\(^46,47,51\) MRI, which is a sensitive diagnostic tool that is an adjunct to clinical diagnosis, can detect lesions even when CT scans appear normal. A computer-assisted method of MRI can measure lesion size. Many new areas of myelin abnormality are asymptomatic. Serial MRI studies can be done to detect asymptomatic lesions, monitor the progress of existing lesions, and evaluate the effectiveness of treatment. Although MRI can be used to provide evidence of disseminated lesions in persons with the disease, normal findings do not exclude the diagnosis. Electrophysiologic evaluations (e.g., evoked potential studies) and CT scans may assist in the identification and documentation of lesions.

Most treatment measures for MS are directed at modifying the course and managing the primary symptoms of the disease.\(^46,47\) The variability in symptoms, unpredictable course, and lack of specific diagnostic methods has made the evaluation and treatment of MS difficult. Persons who are minimally affected by the disorder require no specific treatment. The person should be encouraged to maintain as healthy a lifestyle as possible, including good nutrition and adequate rest and relaxation. Physical therapy may help maintain muscle tone. Every effort should be made to avoid excessive fatigue, physical deterioration, emotional stress, viral infections, and extremes of environmental temperature, which may precipitate an exacerbation of the disease.

The pharmacologic agents used in the treatment of MS fall into three categories: those used to (1) treat acute attacks or initial demyelinating episodes, (2) modify the course of the disease, and (3) treat symptoms of the disorder.\(^46\) Corticosteroids are the mainstay of treatment for acute attacks of MS. These agents are thought to reduce the inflammation, improve nerve conduction, and exert important immunologic effects. Long-term administration does not, however, appear to alter the course of the disease and can have harmful side effects. Adrenocorticotrophic hormone (ACTH) also may be used in the treatment of MS. Plasmapheresis has also proved beneficial in some cases.\(^46\)

Disease-modifying agents include interferon-β and glatiramer acetate.\(^46,47,51\) These agents have shown some benefit in reducing exacerbations in persons with relapsing-remitting MS. Interferon-β is a cytokine that acts as an immune enhancer. Two forms have been approved by the FDA for treatment of MS—interferon-β1a and interferon-β1b. Both are administered by injection, and both are usually well tolerated. Glatiramer acetate is a synthetic polypeptide that simulates parts of the myelin basic protein. Although the exact mechanism of action is unknown, the drug appears to block myelin-damaging T cells by acting as a myelin decoy. The drug is given daily by subcutaneous injection. Mitoxantrone, an anticancer drug, is recommended for persons with worsening forms of the disease. Because it is an anticancer drug, it is recommended that it only be administered by experienced health care professionals. Other promising therapies that focus on immune-mediated disease mechanisms are in development.

Among the medications used to manage the chronic problems associated with MS are dantrolene, baclofen, or diazepam for spasticity; cholinergic drugs for bladder problems; and antidepressant drugs for depression.

**Vertebral and Spinal Cord Injury**

Spinal cord injury (SCI) represents damage to the neural elements of the spinal cord. Spinal cord injury is primarily a disorder of young people, with nearly half of all injuries occurring in the 16- to 30-year-old age group.\(^51\) The most common cause of SCI is motor vehicle accidents, followed by falls, violence (primarily gunshot wounds), and recreational sporting activities.\(^53\) Life expectancy for persons with SCI continues to increase, but is somewhat below life expectancy for people without SCI.

Most SCIs involve damage to the vertebral column or supporting ligaments as well as the spinal cord. Because of extensive tract systems that connect sensory afferent neurons and LMNs with higher brain centers, SCIs commonly involve both sensory and motor function. Although the discussion in this section of the chapter focuses on traumatic SCI, much of the content is applicable to SCI caused by other disorders, such as congenital deformities (e.g., spina bifida), tumors, ischemia and infarction, and bone disease with pathologic fractures of the vertebrae.

**Injury to the Vertebral Column**

Injuries to the vertebral column include fractures, dislocations, and subluxations. A fracture can occur at any part of the bony vertebrae, causing fragmentation of the bone. It most often involves the pedicle, lamina, or processes (e.g., facets, see Fig. 36-9). Dislocation or subluxation (partial dislocation) injury causes the vertebral bodies to become displaced, with one overriding another and preventing correct alignment of the vertebral column. Damage to the ligaments or bony vertebrae may make the spine unstable. In an unstable spine, further unguarded movement of the spinal column can impinge on the spinal canal, causing compression or overstretching of neural tissue.

Most injuries result from some combination of compressive force or bending movements.\(^19\) Flexion injuries occur when forward bending of the spinal column exceeds the limits of normal movement. Typical flexion injuries result, for example, when the head is struck from behind, as in a fall with the back of the head as the point of impact. Extension injuries occur with excessive
forced bending (i.e., hyperextension) of the spine backward. A typical extension injury involves a fall in which the chin or face is the point of impact, causing hyperextension of the neck. Injuries of flexion and extension occur more commonly in the cervical spine (C4 to C6) than in any other area. Limitations imposed by the ribs, spinous processes, and joint capsules in the thoracic and lumbar spine make this area less flexible and less susceptible to flexion and extension injuries than the cervical spine.

A compression injury, causing the vertebral bones to shatter, squash, or even burst, occurs when there is spinal loading from a high-velocity blow to the top of the head or when landing forcefully on the feet or buttocks\(^{18}\) (Fig. 36-14A). This typically occurs at the cervical level (e.g., diving injuries) or in the thoracolumbar area (e.g., falling from a distance and landing on the buttocks). Compression injuries may occur when the vertebrae are weakened by conditions such as osteoporosis and cancer with bone metastasis. Axial rotation injuries can produce highly unstable injuries. Maximal axial rotation occurs in the cervical region, especially between C1 and C2, and at the lumbosacral joint\(^{18}\) (see Fig. 36-14B). Coupling of vertebral motions is common in injury when two or more individual motions occur (e.g., lateral bending and axial rotation).

**Acute Spinal Cord Injury**

Spinal cord injury involves damage to the neural elements of the spinal cord. The damage may result from direct trauma to the cord from penetrating wounds or indirect injury resulting from vertebral fractures, fracture-dislocations, or subluxations of the spine. The spinal cord may be contused, not only at the site of injury but also above and below the trauma site.\(^{18}\) Traumatic injury may be complicated by the loss of blood flow to the cord, with resulting infarction.

Sudden, complete transection of the spinal cord results in complete loss of motor, sensory, reflex, and autonomic function below the level of injury. The immediate response to SCI is often referred to as spinal shock. It is characterized by flaccid paralysis with loss of tendon reflexes below the level of injury, absence of somatic and visceral sensations below the level of injury, and loss of bowel and bladder function. Loss of systemic sympathetic vasomotor tone may result in vasodilation, increased venous capacity, and hypotension. These manifestations occur regardless of whether the level of the lesion eventually will produce spastic (UMN) or flaccid (LMN) paralysis. The basic mechanisms accounting for transient spinal shock are unknown. Spinal shock may last for hours, days, or weeks. Usually, if reflex function returns by the time the person reaches the acute care setting, the neuromuscular changes are reversible. This type of reversible spinal shock may occur in football injuries, in which jarring of the spinal cord produces a concussionlike syndrome with loss of movement and reflexes, followed by full recovery within days. In persons in whom the loss of reflexes persists, hypotension and bradycardia may become a critical but manageable problem. In general, the higher the level of injury, the greater is the effect.

**Pathophysiology.** The pathophysiology of acute SCI can be divided into two types: primary and secondary.\(^{18,54,55}\) The primary neurologic injury occurs at the time of injury and is irreversible. It is characterized by small hemorrhages in the gray matter of the cord, followed by edematous changes in the white matter that lead to necrosis of neural tissue. This type of injury results from the forces of compression, stretch, and

---

**FIGURE 36-14.** (A) Compression vertebral fracture secondary to axial loading as occurs when a person falls from a height and lands on the buttocks. (B) Rotational injury, in which there is concurrent fracture and tearing of the posterior ligamentous complex, is caused by extreme lateral flexion or twisting of the head or neck. (Modified from Hickey JV. The Clinical Practice of Neurological and Neurosurgical Nursing. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003:411–412.)
shear associated with fracture or compression of the spinal vertebrae, dislocation of vertebrae (e.g., flexion, extension, subluxation) or contusions due to jarring of the cord in the spinal canal. Penetrating injuries produce lacerations and direct trauma to the cord and may occur with or without spinal column damage. Lacerations occur when there is cutting or tearing of the spinal cord, which injures nerve tissue and causes bleeding and edema.

Secondary injuries follow the primary injury and promote the spread of injury. Although there is considerable debate about the pathogenesis of secondary injuries, the tissue destruction that occurs ends in progressive neurologic damage. After SCI, several pathologic mechanisms come into play, including vascular damage, neuronal injury that leads to loss of reflexes below the level of injury, and release of vasoactive agents and cellular enzymes. Vascular lesions (i.e., vessel trauma and hemorrhage) can lead to ischemia, increased vascular permeability, and edema. Blood flow to the spinal cord may be further compromised by spinal shock that results from a loss of vasomotor tone and neural reflexes below the level of injury. The release of vasoactive substances (i.e., norepinephrine, serotonin, dopamine, and histamine) from the wound tissue causes vasospasm and impedes blood flow in the microcirculation, producing further necrosis of blood vessels and neurons. The release of proteolytic and lipo- lytic enzymes from injured cells causes delayed swelling, demyelination, and necrosis in the neural tissue in the spinal cord.

Management. The goal of management of acute SCI is to reduce the neurologic deficit and prevent any additional loss of neurologic function. The specific steps in resuscitation and initial evaluation can be carried out at the trauma site or in the emergency department, depending on the urgency of the situation. Most traumatic injuries to the spinal column render it unstable, mandating immobilization measures such as collars and backboards and limiting the movement of persons at risk for or with known SCI. Every person with multiple trauma or head injury, including victims of traffic and sporting accidents, should be suspected of having sustained an acute SCI.

The goal of early surgical intervention for an unstable spine is to provide internal skeletal stabilization so that early mobilization and rehabilitation can occur. One of the more important aspects of early SCI care is the prevention and treatment of spinal or systemic shock and the hypoxia associated with compromised respiration. Correcting hypotension or hypoxia is essential to maintaining circulation to the injured cord.

The recognition that much of the posttraumatic degeneration of the spinal cord following injury is caused by secondary injuries has led to the search for neuroprotective strategies that would prevent or minimize these processes. Randomized controlled trials in the 1990s reported beneficial effects from a high-dose regimen of the glucocorticoid methylprednisolone administered soon after spinal cord injury. In recent years, the use of high-dose methylprednisolone has become controversial, largely based on the risk of serious adverse effects (e.g., gastric bleeding, wound infection, venous thrombosis, and steroid myopathy) versus what is perceived to be a modest neurologic benefit. Other neuroprotective agents, including monosialoganglioside sodium (GM-1 ganglioside), naloxone, and tirilazad, have been tested in multicenter clinical trials, but primary end points have not been achieved.

Riluzole, a sodium-channel blocker, approved for treatment of ALS, has also shown some promise in preventing secondary injury by blocking sodium channels. Recent investigations are exploring the effects of early cooling strategies (i.e., mild and moderate hypothermia) on recovery outcomes in persons with spinal cord injury.

Types and Classification of Spinal Cord Injury

Alterations in body function that result from SCI depend on the level of injury and the amount of cord involvement. Tetraplegia, sometimes referred to as quadriplegia, is the impairment or loss of motor or sensory function (or both) after damage to neural structures in the cervical segments of the spinal cord. Paraplegia refers to impairment or loss of motor or sensory function (or both) from damage of neural elements in the spinal canal in the thoracic, lumbar, or sacral segments of the spinal cord. With paraplegia, arm functioning is spared, but depending on the level of injury, functioning of the trunk, legs, and pelvic organs may be impaired. Paraplegia includes conus medullaris and cauda equina injuries (discussed later).

Further definitions of SCI describe the extent of neurologic damage as complete or incomplete. Complete cord injuries can result from severance of the cord, disruption of nerve fibers although they remain intact, or interruption of blood supply to that segment, resulting in complete destruction of neural tissue and UMN or LMN paralysis. With complete injuries, no motor or sensory function is preserved in sacral segments S4 to S6. Incomplete SCI implies there is some residual motor or sensory function below the level of injury.

The prognosis for return of function is better in an incomplete injury because of preservation of axonal function. Incomplete injuries may manifest in a variety of patterns, but can be organized into certain patterns or “syndromes” that occur more frequently and reflect the predominant area of the cord that is involved. Types of incomplete lesions include the central cord syndrome, anterior cord syndrome, Brown-Séquard syndrome, and conus medullaris syndrome.

Central Cord Syndrome. A condition called central cord syndrome occurs when injury is predominantly in the central gray or white matter of the cord (Fig. 36-15). Because the corticospinal tract fibers are organized with those controlling the arms located more centrally and those controlling the legs located more laterally, some external axonal transmission may

**Anterior Cord Syndrome.** Anterior cord syndrome usually is caused by damage from infarction of the anterior spinal artery, resulting in damage to the anterior two thirds of the cord. The deficits include loss of motor function provided by the corticospinal tracts and loss of pain and temperature sensations from damage to the lateral spinothalamic tracts. The posterior third of the cord is relatively unaffected, preserving the dorsal column axons that convey position, vibration, and touch sensations.

**Brown-Séquard Syndrome.** A condition called Brown-Séquard syndrome results from damage to a hemisection of the anterior and posterior cord. The effect is a loss of voluntary motor function from the
corticospinal tract, proprioception loss from the ipsilateral side of the body, and contralateral loss of pain and temperature sensations from the lateral spinothalamic tracts for all levels below the lesion.

**Conus Medullaris Syndrome.** The conus medullaris syndrome involves damage to the conus medullaris or the sacral cord (i.e., conus) and lumbar nerve roots in the neural canal. Functional deficits resulting from this type of injury usually result in flaccid bowel and bladder and altered sexual function. Sacral segments occasionally show preserved reflexes if only the conus is affected. Motor function in the legs and feet may be impaired without significant sensory impairment. Damage to the lumbosacral nerve roots in the spinal canal usually results in LMN and sensory neuron damage known as cauda equina syndrome. Functional deficits present as various patterns of asymmetric flaccid paralysis, sensory impairment, and pain.

**Disruption of Somatosensory and Skeletal Muscle Function**

Functional abilities after SCI are subject to various degrees of somatosensory and skeletal muscle function loss and altered reflex activity based on the level of cord injury and extent of cord damage (Table 36-2).

**Motor and Somatosensory Function.** Skeletal muscle function in cervical injuries ranges from complete dependence to independence with or without assistive devices in activities of mobility and self-care. The functional levels of cervical injury are related to C5, C6, C7, or C8 innervation. At the C5 level, deltoid and biceps function is spared, allowing full head, neck, and diaphragm control with good shoulder strength and full elbow flexion. At the C6 level, wrist dorsiflexion by the wrist extensors is functional, allowing tenodesis, which is the natural bending inward and flexion of the fingers when the wrist is extended and bent backward. Tenodesis is a key movement because it can be used to pick up objects when finger movement is absent. A functional C7 injury allows full elbow flexion and extension, wrist plantar flexion, and some finger control. At the C8 level, finger flexion is added.

Thoracic cord injuries (T1 to T12) allow full upper extremity control with limited to full control of intercostal and trunk muscles and balance. Injury at the T1 level allows full fine motor control of the fingers. Because of the lack of specific functional indicators at the thoracic levels, the level of injury usually is determined by sensory level testing.

Functional capacity in the L1 through L5 nerve innervations allows hip flexion, hip abduction (L1 to L3), movement of the knees (L2 to L5), and ankle dorsiflexion (L4 to L5). Sacral (S1 to S5) innervation allows for full leg, foot, and ankle control and innervation of perineal musculature for bowel, bladder, and sexual function.

**Reflex Activity.** Spinal cord reflexes are fully integrated in the spinal cord and can function independent of input from higher centers. Altered spinal reflex activity after SCI is essentially determined by the level of injury and whether UMNs or LMNs are affected. With UMN injuries at T12 and above, the cord reflexes remain...
intact, whereas communication pathways with higher centers have been interrupted. This results in spasticity of involved skeletal muscle groups and smooth and skeletal muscles that control bowel, bladder, and sexual function. In LMN injuries at T12 or below, the reflex circuitry itself has been damaged at the level of the spinal cord or spinal nerve, resulting in a decrease or absence of reflex function. The LMN injuries cause flaccid paralysis of involved skeletal muscle groups and the smooth and skeletal muscles that control bowel, bladder, and sexual function. However, injuries near the T12 level may result in mixed UMN and LMN deficits (e.g., spastic paralysis of the bowel and bladder with flaccid muscle tone).

After the period of spinal shock in a UMN injury, isolated spinal reflex activity and muscle tone that are not under the control of higher centers return. This may result in hypertonia and spasticity of skeletal muscles below the level of injury. These spastic movements are involuntary instead of voluntary, a distinction that needs to be explained to persons with SCI and their families. The antigravity muscles, the flexors of the arms and extensors of the legs, are predominantly affected. Spastic movements are usually heightened initially after injury, reaching a peak and then becoming stable in approximately 1.5 to 2 years.

The stimuli for reflex muscle spasm arise from somatic and visceral afferent pathways that enter the cord below the level of injury. The most common of these stimuli are muscle stretching, bladder infections or stones, fistulas, bowel distention or impaction, pressure areas or irritation of the skin, and infections. Because the stimuli that precipitate spasms vary from person to person, careful assessment is necessary to identify the factors that precipitate spasm in each person. Passive range-of-motion exercises to stretch the spastic muscles help to prevent spasm induced by muscle stretching, such as occurs with a change in body position.

Spasticity in itself is not detrimental and may even facilitate maintenance of muscle tone to prevent muscle wasting, improve venous return, and aid in mobility.

</table>

*Assistance refers to adaptive equipment, setup, or physical assistance.
Spasms become detrimental when they impair safety; they also reduce the ability to make functional gains in mobility and activities of daily living. Spasms also may cause trauma to bones and tissues, leading to joint contractures and skin breakdown.

**Respiratory Muscle Function.** Ventilation requires movement of the expiratory and inspiratory muscles, all of which receive innervation from the spinal cord. The main muscle of ventilation, the diaphragm, is innervated by segments C3 to C5 through the phrenic nerves. The intercostal muscles, which function in elevating the rib cage and are needed for coughing and deep breathing, are innervated by spinal segments T1 through T7. The major muscles of expiration are the abdominal muscles, which receive their innervation from levels T6 to T12.

Although the ability to inhale and exhale may be preserved at various levels of SCI, functional deficits in ventilation are most apparent in the quality of the breathing cycle and the ability to oxygenate tissues, eliminate carbon dioxide, and mobilize secretions. Cord injuries involving C1 to C3 result in a lack of respiratory effort, and affected patients require assisted ventilation. Although a C3 to C5 injury allows partial or full diaphragmatic function, ventilation is diminished because of the loss of intercostal muscle function, resulting in shallow breaths and a weak cough. Below the C5 level, as less intercostal and abdominal musculature is affected, the ability to take a deep breath and cough is less impaired. Maintenance therapy consists of muscle training to strengthen existing muscles for endurance and mobilization of secretions. The ability to speak is compromised with assisted ventilation, whether continuous or intermittent. Thus, ensuring adequate communication of needs is essential.

**Disruption of Autonomic Nervous System Function**

In addition to its effects on skeletal muscle function, SCI interrupts autonomic nervous system function below the site of injury. This includes sympathetic outflow from the thoracic and upper lumbar cord and parasympathetic outflow from the sacral cord. Because of their sites of exit from the CNS, the cranial nerves, such as the vagus, are unaffected. Depending on the level of injury, the spinal reflexes that control autonomic nervous system function are largely isolated from the rest of the CNS. The regulation and integration of reflex function by centers in the brain and brain stem are lacking. This results in a situation in which the autonomic reflexes below the level of injury are uncontrolled, whereas those above the level of injury function in a relatively controlled manner.

Sympathetic nervous system regulation of circulatory function and body temperature (i.e., thermoregulation) presents some of the most severe problems in SCI. The higher the level of injury and the greater the surface area affected, the more profound are the effects on circulation and thermoregulation. Persons with injury at the T6 level or above experience problems in regulating vasomotor tone, whereas those with injuries below the T6 level usually have sufficient sympathetic function to maintain adequate vasomotor function. The level of injury and its corresponding problems may vary among persons, and some dysfunctional effects may be seen at levels below T6. With lower lumbar and sacral injuries, sympathetic function remains essentially unaltered.

**Vasovagal Response.** The vagus nerve (cranial nerve X), which is unaffected in SCI, normally exerts a continuous inhibitory effect on heart rate. Vagal stimulation that causes a marked bradycardia is called the vasovagal response. Visceral afferent input to the vagal centers in the brain stem of persons with tetraplegia or high-level paraplegia can produce marked bradycardia when unchecked by a dysfunctional sympathetic nervous system. Severe bradycardia and even asystole can result when the vasovagal response is elicited by deep endotracheal suctioning or rapid position change. Preventive measures, such as hyperoxygenation before, during, and after tracheal suctioning, are advised. Rapid position changes should also be avoided or anticipated, and anticholinergic drugs should be immediately available to counteract severe episodes of bradycardia.

**Autonomic Dysreflexia.** Autonomic dysreflexia represents an acute episode of exaggerated sympathetic reflex responses that occur in persons with injuries at T6 and above, in which CNS control of spinal reflexes is lost (Fig. 36-18). It does not occur until spinal shock has resolved and autonomic reflexes return, most often within the first 6 months after injury. It is most unpredictable during the first year after injury, but can occur throughout the person’s lifetime.

Autonomic dysreflexia is characterized by vasospasm, hypertension ranging from mild (20 mm Hg above baseline) to severe (as high as 240/120 mm Hg, or higher), skin pallor, and gooseflesh associated with the piloerector response. Because baroreceptor function and parasympathetic control of heart rate travel by way of the cranial nerves, these responses remain intact. Continued hypertension produces a baroreflex-mediated vagal slowing of the heart rate to bradycardic levels. There is an accompanying baroreflex-mediated vasodilation, with flushed skin and profuse sweating above the level of injury, headache ranging from dull to severe and pounding, nasal stuffiness, and feelings of anxiety. A person may experience one, several, or all of the symptoms with each episode.

The stimuli initiating the dysreflexic response include visceral distention, such as a full bladder or rectum; stimulation of pain receptors, as occurs with pressure ulcers, dressing changes, and diagnostic or operative procedures; and visceral contractions, such as ejaculation, bladder spasms, or uterine contractions. In many cases, the dysreflexic response results from a full bladder.

Autonomic dysreflexia is a clinical emergency, and without prompt and adequate treatment, convulsions, loss of consciousness, and even death can occur. The major components of treatment include monitoring blood pressure while removing or correcting the initiating...
cause or stimulus. The person should be placed in an upright position, and all support hose or binders should be removed to promote venous pooling of blood and reduce venous return, thereby decreasing blood pressure. If the stimuli have been removed or the stimuli cannot be identified and the upright position is established but the blood pressure remains elevated, drugs that block autonomic function are administered. Prevention of the type of stimuli that trigger the dysreflexic event is advocated.

**Postural Hypotension.** Postural, or orthostatic, hypotension usually occurs in persons with injuries at T4 to T6 and above and is related to the interruption of descending control of sympathetic outflow to blood vessels in the extremities and abdomen. Pooling of blood, along with gravitational forces, impairs the return of venous blood to the heart, causing a decrease in cardiac output along with a drop in arterial blood pressure when the person is placed in an upright position. The disorder is characterized by dizziness, pallor, excessive sweating above the level of the lesion, complaints of blurred vision, and possible fainting. Postural hypotension usually is prevented by slow changes in position and measures to promote venous return.

**Disruption of Bladder, Bowel, and Sexual Function**

Among the most devastating consequences of SCI are the loss of bladder, bowel, and sexual function. Loss of bladder function results from disruption of neural pathways between the bladder and the reflex voiding center at the S2 to S4 level (i.e., a LMN lesion) or between the reflex voiding center and higher brain centers.
centers that coordinate sphincter control (i.e., a UMN lesion). Persons with UMN lesions or spastic bladders lack awareness of bladder filling (i.e., storage) and voluntary control of urination. In LMN lesions or flaccid bladder dysfunction, lack of awareness of bladder filling and lack of bladder tone render the person unable to urinate voluntarily or involuntarily (see Chapter 27).

Bowel elimination is a coordinated function involving the enteric nervous system, the autonomic nervous system, and the CNS. Persons with SCI above S2 to S4 develop spastic functioning of the defecation reflex and loss of voluntary control of the external anal sphincter. Damage to the cord at the S2 to S4 level causes flaccid functioning of the defecation reflex and loss of anal sphincter tone. Even though the enteric nervous system innervation of the bowel remains intact, without the defecation reflex, peristaltic movements are ineffective in evacuating stool.

In men, the lack of erectile ability or inability to experience penile sensations or orgasm is not a reliable indicator of fertility, which should be evaluated by an expert. In women, fertility is normally reestablished with the return of menses, which usually occurs at about 3 to 5 months after injury. There are hazards to pregnancy, labor, and use of birth control devices relative to SCI that require the services of knowledgeable health care providers.

### Disruption of Other Functions

#### Temperature Regulation

The central mechanisms for thermoregulation are located in the hypothalamus. In response to cold, the hypothalamus stimulates vasoconstrictor responses in peripheral blood vessels, particularly those of the skin. This results in decreased loss of body heat. Heat production results from increased metabolism, voluntary activity, or shivering. To reduce heat, hypothalamus-stimulated mechanisms produce vasodilation of skin blood vessels to dissipate heat, and sweating to increase evaporative heat losses.

After SCI, the communication between the thermoregulatory centers in the hypothalamus and the sympathetic effector responses below the level of injury is disrupted; the ability to control blood vessel responses that conserve or dissipate heat is lost, as are the abilities to sweat and shiver. Higher levels of injury tend to produce greater disturbances in thermoregulation. In tetraplegia and high paraplegia, there are few defenses against changes in the environmental temperature, and body temperature tends to assume the temperature of the external environment, a condition known as poikilothermy. Persons with lower-level injuries have various degrees of thermoregulation. Disturbances in thermoregulation are chronic and may cause continual loss of body heat. Treatment consists of education in the adjustment of clothing and awareness of how environmental temperatures affect the person’s ability to accommodate to these changes.

#### Deep Vein Thrombosis and Edema

Persons with SCI are at high risk for development of deep vein thrombosis (DVT) and pulmonary embolism, particularly during the first 2 to 3 weeks after injury. The high risk for DVT in patients with acute SCI is due to immobility, decreased vasomotor tone below the level of injury, and hypercoagulability and stasis of blood flow. Current preventative interventions include mechanical and pharmacological methods.

Mechanical methods of prevention include intermittent pneumatic compression, thigh-high graduated elastic compression stockings, and neuromuscular electrical stimulation. Pharmacologic methods include oral anticoagulants and low–molecular-weight heparin. Local pain, a common symptom of DVT, is often absent because of sensory deficits. Thus, a regular schedule of visual inspection for local signs of DVT (e.g., swelling) is important. Testing of persons at high risk for DVT includes plethysmography and duplex ultrasonography.

Edema is also a common problem in persons with SCI. The development of edema is related to decreased peripheral vascular resistance, decreased muscle tone in the paralyzed limbs, and immobility that causes increased venous pressure and abnormal pooling of blood in the abdomen, lower limbs, and upper extremities. Edema in the dependent body parts usually is relieved by positioning to minimize gravitational forces or by using compression devices (e.g., support stockings, binders) that encourage venous return.

#### Skin Integrity

The entire surface of the skin is innervated by cranial or spinal nerves organized into dermatomes that show cutaneous distribution. The CNS and autonomic nervous system also play a vital role in skin function. The sympathetic nervous system, through control of vasomotor and sweat gland activity, influences the health of the skin by providing adequate circulation, excretion of body fluids, and temperature regulation. The lack of sensory warning mechanisms and voluntary motor ability below the level of injury, coupled with circulatory changes, place the spinal cord–injured person at major risk for disruption of skin integrity (see Chapter 46). Significant factors associated with disruption of
skin integrity are pressure, shearing forces, and localized trauma and irritation. Relieving pressure, allowing adequate circulation to the skin, and skin inspection are primary ways of maintaining skin integrity. Of all the complications after SCI, skin breakdown is the most preventable.

**Future Directions in Repair of the Injured Spinal Cord**

There is a continued effort to determine new and innovative strategies for repairing the injured spinal cord. At present, these strategies focus on promoting the regrowth of interrupted nerve fibers, using nerve growth–stimulating factors or molecules that suppress inhibitors of neuronal extension; bridging spinal cord lesions with scaffolds that are impregnated with nerve growth factors, which promote axon growth and reduce the barriers caused by scar tissue; repairing damaged myelin and restoring nerve fiber conductivity in the lesion area; and enhancing CNS plasticity by promoting compensatory growth of spared, intact nerve fibers above and below the level of injury. Stem cell transplantation offers a promising therapeutic strategy for spinal cord injury repair.

Although these strategies may not allow for complete repair of the spinal cord or to recreate what was present before the injury, even small successes may be useful for someone with SCI.

**SUMMARY CONCEPTS**

- **Upper motor neuron (UMN) lesions** are those involving neurons completely contained in the central nervous system (CNS).
- **Amyotrophic lateral sclerosis** is a progressive and devastating neurologic disorder that selectively affects motor function. It affects lower motor neurons (LMNs) in the spinal cord as well as UMs in the brain stem and cerebral cortex.
- **Multiple sclerosis** is a slowly progressive demyelinating disease of the CNS that is characterized by exacerbations and remissions of paresthesias, optic neuritis, and motor weakness.
- **Spinal cord injury (SCI)** is a disabling neurologic condition of UMs in the spinal cord that produces various degrees of sensorimotor loss and altered reflex activity based on the level of injury and extent of cord damage. Depending on the level of injury, SCI is associated with ventilation and communication problems; autonomic nervous system dysfunction that predisposes to the vasovagal response, autonomic hyperreflexia, impaired body temperature regulation, and postural hypotension; impaired muscle pump and venous innervation leading to edema of dependent areas of the body and risk for deep vein thrombosis; altered sensorimotor integrity that contributes to uncontrolled muscle spasms, altered pain responses, and threats to skin integrity; alterations in bowel and bladder elimination; and impaired sexual function.

**REVIEW EXERCISES**

1. A 32-year-old woman presents with complaints of “drooping eyelids,” difficulty chewing and swallowing, and weakness of her arms and legs that is less severe in the morning but becomes worse as the day progresses. She complains that climbing stairs and lifting objects are becoming increasingly difficult. Clinical examination confirms weakness of the eyelid and jaw muscles. She is told that she may have myasthenia gravis and is scheduled for testing using the short-acting acetylcholinesterase inhibitor edrophonium (Tensilon).

   A. Explain the pathogenesis of this woman’s symptoms as it relates to myasthenia gravis.
   B. Explain how information from the administration of the acetylcholinesterase inhibitor edrophonium can be used to assist in the diagnosis of the disorder.

2. A 20-year-old man suffered spinal cord injury at the C2 to C3 level as the result of a motorcycle accident.

   A. Explain the effects of this man’s injury on ventilation and communication; sensorimotor function; autonomic nervous system function; bowel, bladder, and sexual function; and temperature regulation.
   B. Autonomic dysreflexia, which is a threat to persons with spinal cord injuries at T6 or above, is manifested by hypertension, often to extreme levels, and bradycardia; constriction of skin vessels below the level of injury; and severe headache and nasal stuffiness. Explain the origin of the elevated blood pressure and bradycardia. The condition does not occur until spinal shock has resolved, and usually occurs only in persons with injuries at T6 and above. Explain.

Anatomically and functionally, the brain is the most complex structure in the body. It controls our ability to think, our awareness of things around us, and our interactions with the outside world. Signals to and from various parts of the body are controlled by very specific areas in the brain. Therefore, the brain is much more vulnerable to lesions that in other organs might produce no significant effects. For example, an isolated renal infarct would not be expected to have a significant effect on kidney function, whereas an infarct of comparable size in a specific area of the brain could produce complete paralysis on one side of the body. Alterations in brain function can result from injury, cerebrovascular disease, infection, tumors, disruptions in electrical activity (seizures), or impairment of memory (impaired cognition or dementia).

**Brain Injury**

The brain is protected from external forces by the rigid confines of the skull and the cushioning afforded by the cerebrospinal fluid (CSF). The metabolic stability required by its electrically active cells is maintained by a number of regulatory mechanisms, including the blood–brain barrier and autoregulatory mechanisms that ensure adequate blood supply.

**Mechanisms of Brain Injury**

Injury to brain tissue can result from a number of conditions, including trauma, infections, tumors, and degenerative processes. Brain damage resulting from these disorders involves several common pathways, including hypoxia and ischemia, the effects of excitatory amino acid injury, and cerebral edema. In many cases the mechanisms are interrelated.

**Hypoxic and Ischemic Injury**

The brain relies on the ability of the cerebral circulation to deliver sufficient oxygen for its energy needs. Although the brain makes up only 2% of the body
weight, it receives one sixth of the resting cardiac output and accounts for 20% of the body's oxygen consumption.² By definition, hypoxia denotes a deprivation of oxygen with maintained blood flow, whereas ischemia represents a situation of greatly reduced or interrupted blood flow. The cellular effects of hypoxia and ischemia are quite different, and the brain tends to have different sensitivities to the two conditions. Hypoxia interferes with the delivery of oxygen, whereas ischemia interferes with the delivery of oxygen and glucose as well as the removal of metabolic wastes.

Hypoxia usually is seen in conditions such as exposure to reduced atmospheric pressure, carbon monoxide poisoning, severe anemia, and failure of the lungs to oxygenate the blood. Contrary to popular belief, hypoxia is fairly well tolerated, particularly in situations of chronic hypoxia. Neurons are capable of substantial anaerobic metabolism and are fairly tolerant of pure hypoxia, in which case it produces listlessness, drowsiness, and impaired problem solving. Unconsciousness and convulsions may occur when hypoxia is sudden and severe. However, the effects of severe hypoxia on brain function seldom are seen because the condition rapidly leads to cardiac arrest and ischemia.

Ischemia is seen in conditions of low blood flow. Cerebral ischemia can be focal, as in a stroke due to cerebral artery occlusion, or global, as in cardiac arrest.³ Cerebral artery occlusion leads to focal ischemia, and if sustained, to infarction (death) of brain tissue in the distribution of the affected vessel. The location of the infarct and extent of tissue damage that results is determined by modifying variables, of which collateral blood flow is the most important. The collateral circulation may even provide sufficient blood flow to the borders of the focal ischemic region to maintain a low level of metabolic activity, thereby preserving tissue integrity.

Within the brain, certain regions and cell populations are more susceptible than others to ischemic injury⁴ (Fig. 37-1). Areas of the brain located at the border zones between the overlapping territories supplied by the major cerebral arteries, sometimes called the watershed areas, are extremely vulnerable to ischemia. During events such as severe hypotension, these distal territories undergo a profound lowering of blood flow, predisposing to ischemia and infarction of brain tissues. As a consequence, areas of the cortex that are supplied by the major cerebral arteries usually regain function on recovery of adequate blood flow, whereas infarctions may occur in the watershed strips, resulting in focal neurologic deficits. Laminar necrosis refers to short, creeping segments of necrosis that occur within and parallel to the cerebral cortex, in areas supplied by the penetrating arteries

(see Fig. 37-1). The gray matter of the cerebral cortex receives its major blood supply through short penetrating arteries that emerge at right angles from larger vessels and then form a cascade as they repeatedly branch, forming a rich capillary network. An abrupt loss of arterial blood pressure markedly diminishes flow through these capillary channels.

Global ischemia occurs when blood flow is inadequate to meet the metabolic needs of the entire brain. The result is a spectrum of neurologic disorders reflecting diffuse brain dysfunction. Unconsciousness occurs within seconds of severe global ischemia, such as that resulting from cardiac arrest. If the cerebral circulation is restored immediately, consciousness is regained quickly. The unique vulnerability of the brain is attributed to its limited tolerance of ischemia and its response to reperfusion. The metabolic depletion of energy associated with ischemia can result in an inappropriate release of excitatory amino acid neurotransmitters, disrupted calcium homeostasis, free radical formation, mitochondrial injury, and activation of cell-death pathways. Although the threshold for ischemic neuronal injury is unknown, there is a period during which neurons can survive if blood flow is reestablished. Unfortunately, brain injury may be irreversible if the duration of ischemia is such that the threshold of injury has been reached.

**Excitatory Amino Acid Injury**

In many neurologic disorders, injury to neurons may be caused by inappropriate release of excitatory amino acid neurotransmitters such as glutamate. The neurologic conditions involved in excitotoxic injury range from acute events such as stroke, hypoglycemic injury, and trauma to chronic degenerative disorders such as Huntington disease and possibly Alzheimer dementia.

During prolonged ischemia, metabolic depletion of adenosine triphosphate (ATP) results in the inappropriate release of glutamate. This initiates cell damage by allowing excessive influx of calcium ions (Ca$^{2+}$) through glutamate–N-methyl-D-aspartate (NMDA) glutamate channels. Excess intracellular Ca$^{2+}$ leads to a series of calcium-mediated processes called the *calcium cascade* (Fig. 37-2), which results in the release of intracellular enzymes that cause protein breakdown, free radical formation, lipid peroxidation, deoxyribonucleic acid (DNA) fragmentation, mitochondrial injury, nuclear breakdown, and eventually cell death.

The effects of acute glutamate toxicity may be reversible if the excess glutamate can be removed or if its effects can be blocked before the full cascade progresses. Various strategies that would protect viable brain cells from irreversible damage in the setting of excitotoxicity are currently under investigation. Pharmacologic strategies being explored include those that inhibit the synthesis or release of excitatory neurotransmitters; block the NMDA receptors; prevent initiation of the calcium cascade; or block release of intracellular enzymes.

**Cerebral Edema**

Cerebral edema, or brain swelling, is an increase in tissue volume secondary to abnormal fluid accumulation. There are two types of brain edema: vasogenic and cytotoxic.

*Vasogenic edema* occurs with conditions that impair the function of the blood–brain barrier and allow transfer of water and proteins from the vascular into the interstitial space. It occurs in conditions such as hemorrhage, brain injury, and infectious processes (e.g., meningitis). Vasogenic edema occurs primarily in the white matter of the brain, possibly because the white matter is more compliant than the gray matter. Vasogenic edema can result in displacement of a cerebral hemisphere and various types of brain herniation. The functional manifestations of vasogenic edema include focal neurologic deficits, disturbances in consciousness, and severe intracranial hypertension.

*Cytotoxic edema* involves an increase in intracellular fluid. It can result from hypoxic states such as water intoxication or severe ischemia that impair the function of the sodium–potassium membrane pump. Ischemia also results in the inadequate removal of anaerobic metabolic end products such as lactic acid, producing extra-cellular acidosis. If blood flow is reduced to low levels for extended periods or to extremely low levels for a few minutes, cellular edema can cause the cell membrane to

**FIGURE 37-2.** The role of the glutamate–N-methyl-D-aspartate (NMDA) receptor in brain cell injury. DNA, deoxyribonucleic acid.
rupture, allowing the escape of intracellular contents into the surrounding extracellular fluid. This leads to damage of neighboring cells. Major changes in cerebral function, such as stupor and coma, occur with cytotoxic edema. The edema associated with ischemia may be severe enough to produce cerebral infarction with necrosis of brain tissue.

**Increased Intracranial Pressure, Herniation, and Hydrocephalus**

Intracranial pressure is, literally, the pressure inside the cranium. Its increase can cause herniations or hydrocephalus. Neurons can be injured when excessive pressure is exerted upon brain tissue, whether that pressure builds up gradually, such as from increasing CSF levels, or occurs suddenly, as from trauma.

The cranial cavity contains blood (approximately 10%), brain tissue (approximately 80%), and CSF (approximately 10%) in the rigid confines of a nonexpandable skull. Each of these three intracranial volumes contributes to the intracranial pressure, which normally is maintained within a range of 0 to 15 mm Hg when measured in the lateral ventricles. Increased intracranial pressure (ICP) is a common pathway for brain injury from different types of insults and agents.

The volumes of each of three intracranial components can vary slightly without causing marked changes in ICP. This is because small increases in the volume of one component can be compensated for by a decrease in the volume of one or both of the other two components. This association is called the Monro-Kellie hypothesis. Reciprocal compensation occurs among the three intracranial compartments. Of the three intracranial compartments, the CSF and blood volume are best able to compensate for changes in ICP, with the tissue volume being relatively restricted in its ability to change.

Initial increases in ICP are buffered by a translocation of CSF to the spinal subarachnoid space and increased reabsorption of CSF. The compensatory ability of the blood compartment is limited by the small amount of blood that is in the cerebral circulation, most of which is contained in the low-pressure venous system. As the volume-buffering capacity of this compartment becomes exhausted, venous pressure increases, and cerebral blood volume and ICP rise. Also, cerebral blood flow is highly controlled by autoregulatory mechanisms, which affect its compensatory capacity. For example, conditions such as ischemia and an elevated partial pressure of carbon dioxide (PCO$_2$) in the blood produce a compensatory vasodilation of the cerebral blood vessels. A decrease in PCO$_2$ has the opposite effect. For this reason, hyperventilation, which results in a decrease in PCO$_2$ levels, is sometimes used in the treatment of ICP.

The impact of increases in blood, brain tissue, or CSF volumes on ICP varies among individuals and depends on the amount of increase, effectiveness of compensatory mechanisms, and compliance or “distensibility” of brain tissue. An increase in intracranial volume will have little or no effect on ICP as long as the compliance is high. Factors that influence compliance include the amount of volume increase, the time frame for accommodation, and the size of the intracranial compartments. For example, small volume increments over long periods of time can be better accommodated than a comparable increase introduced over a short period of time.

The cerebral perfusion pressure (CPP), which represents the difference between the mean arterial blood pressure (MABP) and the ICP (CPP = MABP − ICP), is the pressure perfusing the brain. CPP (normally 70 to 100 mm Hg) is determined by the pressure gradient between the internal carotid artery and the subarachnoid veins. The MABP and ICP are monitored frequently in persons with brain conditions that increase ICP and impair brain perfusion. When the pressure in the cranial cavity approaches or exceeds the MABP, tissue perfusion becomes inadequate, cellular hypoxia results, and neuronal death may occur. The highly specialized cortical neurons are the most sensitive to oxygen deficit; a decrease in the level of consciousness is one of the earliest and most reliable signs of increased ICP. Continued cellular hypoxia leads to general neurologic deterioration, with the level of consciousness deteriorating from alertness to confusion, lethargy, obtundation, stupor, and coma.

**Brain Herniation**

The brain is protected by the nonexpandable skull and two supporting septa, the falx cerebri and the tentorium cerebelli, which divide the intracranial cavity into compartments that normally protect against excessive movement (Fig. 37-3A). The falx cerebri is a sickle-shaped septum that divides the supratentorial space into right and left hemispheres. The tentorium cerebelli (so named because it is shaped like a tent) is a double fold of dura mater that forms a sloping partition between the cerebrum and cerebellum. In the center of the tentorium is a large semicircular opening called the incisura or tentorial notch (Fig. 37-3B). The brain stem, blood vessels (anterior cerebral, internal carotid, posterior communicating, and posterior and superior cerebellar arteries), and oculomotor nerve (cranial nerve [CN] III) pass through the incisura.

Brain herniation represents a displacement of brain tissue under the falx cerebi or through the tentorial notch of the tentorium cerebelli. It occurs when an elevated ICP in one brain compartment causes displacement of the cerebral tissue toward an area of lower pressure. The different types of herniation syndromes are based on the area of the brain that has herniated and the structure under which it has been pushed. They commonly are divided into two broad categories, supratentorial and infratentorial, based on whether they are located above or below the tentorium.

**Supratentorial Herniation.** Progressive supratentorial lesions develop sequential signs and symptoms of oculomotor, motor, and respiratory function. This pattern follows the predictable continuum of rostral-to-caudal (head to tail) failure that proceeds from the diencephalon to the midbrain (ocular), followed by pons (motor),
The intracranial pressure (ICP) is the pressure within the intracranial cavity. It is determined by (1) the pressure-volume relationships among the brain tissue, cerebrospinal fluid (CSF), and blood in the intracranial cavity; (2) the Monro-Kellie hypothesis, which relates to reciprocal changes among the intracranial volumes; and (3) the compliance of the brain and its ability to buffer changes in intracranial volume.

1. **Intracranial Volumes and Pressure.** The ICP represents the pressure exerted by the essentially incompressible tissue and fluid volumes of the three compartments contained within the rigid confines of the skull—the brain tissue and interstitial fluid (80%), the blood (10%), and the CSF (10%).

2. **Monro-Kellie Hypothesis.** Normally, a reciprocal relationship exists among the three intracranial volumes such that the ICP is maintained within normal limits. Because these volumes are practically incompressible, a change in one component must be balanced by an almost equal and opposite effect in one or both of the remaining components. This is known as the Monro-Kellie hypothesis. Of the three intracranial volumes, the fluid in the CSF compartment is the most easily displaced. The CSF (A) can be displaced from the ventricles and cerebral subarachnoid space to the spinal subarachnoid space, and it can also undergo increased absorption or decreased production. Because most of the blood in the cranial cavity is contained in the low-pressure venous system, venous compression (B) serves as a means of displacing blood volume.
Compliance and the Volume-Pressure Curve. Compliance, which refers to the ease with which a substance can be compressed or deformed, is a measure of the brain’s ability to maintain its ICP during changes in intracranial volume. Compliance (C) represents the ratio of change (Δ) in volume (V) to change in pressure (P): \( C = \frac{\Delta V}{\Delta P} \).

The dynamic effects of changes in intracranial volume and compliance on ICP can be illustrated on a graph with the volume represented on the horizontal axis and ICP on the vertical axis. The shape of the curve demonstrates the effect on ICP of adding volume to the intracranial cavity.

From points A to B, the compensatory mechanisms are adequate, compliance is high, and the ICP remains relatively constant as volume is added to the intracranial cavity. At point B, the ICP is relatively normal, but the compensatory mechanisms have reached their limits; compliance is decreased, and ICP begins to rise with each change in volume. From points C to D, the compensatory mechanisms have been exceeded and ICP rises significantly with each increase in volume as compliance is lost.

(From Hickey JV. Neurological and Neurosurgical Nursing. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003:286.)

and eventually medullary (respiratory) function. The pattern of deterioration is fairly predictable unless vascular or obstructive complications occur and exaggerate the condition. Pupillary reactions to light is upper brain stem function (oculomotor nerve [CNIII]) and are especially useful when assessing the unconscious patient.

There are two major types of supratentorial herniation: cingulate and transtentorial.\(^1\^4\^7\) A cingulate herniation (see Fig. 37-3C [1]), which poses the less serious threat in terms of clinical outcomes, involves displacement of the cingulate gyrus and hemisphere beneath the sharp edges of the falx cerebri to the opposite side of the brain.\(^7\) This displacement can compress local blood supply and cerebral tissue, causing edema and ischemia, which further increase the degree of ICP elevation. There may also be compression of branches of the anterior cerebral artery with unilateral or bilateral leg weakness.

Transtentorial herniations result in two distinct syndromes: a central syndrome and an uncal syndrome, which is the most common herniation syndrome.\(^7\) Clinically, they display distinct patterns early in their course, but both merge in a similar pattern once they begin to involve structures at the level of the midbrain and below. Central transtentorial herniations (see Fig. 37-3C [2]) involve the downward displacement of the cerebral hemispheres, basal ganglia, diencephalon, and midbrain through the tentorial incisura. Bilateral small, reactive pupils and drowsiness are heralding signs. The uncal herniation syndrome occurs when an expanding lesion pushes the medial aspect of the temporal lobe, which contains the uncus and hippocampal gyrus, through the incisura of the tentorium (see Fig 37-3C [3]). As a result, the diencephalon and midbrain are compressed and displaced laterally to the opposite side of the tentorium. The oculomotor nerve (CN III) and the posterior cerebral artery are frequently compressed. The oculomotor nerve controls pupillary constriction; entrapment of this nerve results in ipsilateral pupillary dilation,
which usually is an early sign of uncal herniation. Consciousness may be unimpaired because the reticular activating system, which is responsible for wakefulness, has not yet been affected. As uncal herniations progress, there are changes in motor strength and coordination of voluntary movements because of compression of the descending motor pathways. It is not unusual for initial changes in motor function to occur ipsilateral to the side of the brain damage because of compression of the contralateral cerebral peduncles. Changes in consciousness and coma may follow due to compression of the midbrain against the opposite tentorial edge. Decerebrate posturing (Fig. 37-4B) may develop, followed by dilated, fixed pupils; flaccidity; and respiratory arrest.

Infratentorial Herniation. Infratentorial compartment lesions contributing to herniation are much less frequent than those of the supratentorial region. The infratentorial compartment contains both the brain stem and cerebellum. Herniation may occur superiorly (upward) through the tentorial incisura or inferiorly (downward) through the foramen magnum. Upward displacement of the brain stem and cerebellum through the tentorium results maximum pressure on the midbrain. The most prominent signs of upward herniation include: immediate onset of deep coma; small equal, fixed pupils; and abnormal respirations (slow rate with intermittent sighs or ataxia) and other vital signs. Downward herniation involves displacement of the midbrain through the tentorial notch or the cerebellar tonsils through the foramen magnum (Fig. 37-3C [4]). It often progresses rapidly and can cause death because it is likely to involve the lower brain stem centers that control vital cardiopulmonary functions.

Hydrocephalus

Hydrocephalus represents a progressive enlargement of the ventricular system due to an abnormal increase in CSF volume (see Chapter 34, Fig. 34-21). It can result because of overproduction of CSF, impaired
reabsorption of CSF, or obstruction of CSF flow in the ventricular system.

**Pathophysiology.** There are two types of hydrocephalus: communicating and noncommunicating. *Communicating hydrocephalus* is caused by impaired reabsorption of CSF from the arachnoid villi into the venous system. Decreased absorption can result from a block in the CSF pathway to the arachnoid villi or a failure of the villi to transfer the CSF to the venous system. It can occur if too few villi are formed, if postinfective (meningitis) scarring occludes them, or if the villi become obstructed with fragments of blood or infectious debris. Adenomas of the choroid plexus can cause an overproduction of CSF. This form of hydrocephalus is much less common than that resulting from decreased absorption of CSF.

*Noncommunicating* or obstructive hydrocephalus occurs when obstruction in the ventricular system prevents the CSF from reaching the arachnoid villi. Cerebrospinal fluid flow can be obstructed due to congenital malformations, tumors encroaching on the ventricular system, or inflammation or hemorrhage. Similar pathologic patterns occur with noncommunicating and communicating types of hydrocephalus. The cerebral hemispheres become enlarged, and the ventricular system beyond the point of obstruction becomes dilated (Fig. 37-5). The sulci on the surface of the brain become effaced and shallow, and the white matter reduced in volume.

**Clinical Manifestations.** In adults and children in whom the cranial sutures have fused, head enlargement does not occur. Acute-onset hydrocephalus usually is marked by symptoms of increased ICP, including headache, vomiting, and papilledema or deviation in eye movements due to pressure on the cranial nerves. If the obstruction is not relieved, progression to herniation ensues.

Signs and symptoms of hydrocephalus vary greatly, depending on age and rapidity of onset. When hydrocephalus develops in utero or before the cranial sutures of the skull have fused in infancy, the ventricles expand beyond the point of obstruction. The cranial sutures separate, the head expands, and there is bulging of the fontanelles. Because the skull is able to expand, signs of increased ICP may be absent, and intelligence spared. However, seizures are not uncommon, and in severe cases, optic nerve atrophy leads to blindness. Weakness and uncoordinated movement are common. Surgical placement of a shunt allows for diversion of excess CSF fluid, preventing extreme enlargement of the head and neurologic deficits.

**Diagnosis and Treatment.** The most common diagnostic studies are computed tomographic (CT) and magnetic resonance imaging (MRI). The usual treatment is a ventricular shunting procedure, which provides an alternative route for return of CSF to the circulation.

*Normal Pressure Hydrocephalus.* An important type of communicating hydrocephalus that is seen in older adults is called *normal-pressure hydrocephalus.* In normal-pressure hydrocephalus, there is ventricular enlargement with compression of cerebral tissue, but a normal CSF pressure. The signs and symptoms of normal-pressure hydrocephalus, which include memory changes, disturbances in gait, and urinary incontinence, usually have an insidious onset. The changes occur so slowly that they can be easily overlooked by the patient or his or her family or they may be attributed to the aging process. The accepted treatment for normal-pressure hydrocephalus is a ventricular shunt.

**Traumatic Brain Injury**

The term “head injury” is used to describe all structural damage to the head, including injury to the skull, brain, or both. The leading causes of head injury are motor vehicle accidents, bicycle crashes, battlefield trauma, sports injuries, falls, and assaults. Head injury with concussion is becoming increasingly recognized as a significant medical problem with significant morbidity and sometimes devastating complications. High-profile cases involving athletes and large numbers of returning armed services personnel with battlefield injuries have brought concussions to the forefront of concern for school athletic personnel and health care professionals.

The physical forces associated with head injury may result in skull fractures, brain injury, and vascular damage, all three of which can coexist. Skull fractures are frequently accompanied by intracranial lesions, and the presence of skull fracture greatly increases the risk of an underlying subdural and/or epidural hemorrhage.
Because the brain floats freely in the CSF within the rigid confines of the skull, blunt force to the head causes the brain to accelerate within the skull, and then decelerate abruptly upon hitting the inner skull surfaces. As the brain strikes the rough surface of the cranial vault, brain tissue, blood vessels, nerve tracts, and other structures are bruised and torn, resulting in contusions and hematomas (Fig. 37-6). A special type of acceleration-deceleration motion is angular rotation. It involves the rotational motion of the cerebral hemispheres in the anterior-posterior plane around the fixed-in-place brain stem, causing disruption of electrical and subcellular activities of neurons in the reticular activating system (RAS), which extends through the central core of the brain stem (Fig. 37-6).

There are two main stages in the development of brain damage after brain injury: primary and secondary. Primary injuries, which represent the immediate response to the initial injury, include focal lesions (contusions and hemorrhage) and diffuse injuries (concussion and diffuse axonal injuries). Secondary injuries involve complicating processes resulting from the initial injury, including brain swelling, and infection. Ischemia is considered the most common cause of secondary brain injury. It can result from the hypoxia and hypotension that occur during the resuscitation process or from the impairment of regulatory mechanisms that control cerebrovascular responses that maintain blood flow and oxygen supply.

Contusions

Contusions represent a bruising on the brain surface or a lacerations or tearing of brain tissue. Contusions can result from direct force, a depressed skull fracture, or a closed acceleration-deceleration injury. Closed injury contusions are often distributed along the rough, irregular inner surface of the brain and are more likely to occur in the frontal or temporal lobes, resulting in cognitive and motor deficits. The clinical effects of a contusion depend on its size and related cerebral edema. Small, unilateral, frontal lesions may be asymptomatic; whereas larger lesions may result in neurological defects. They can cause secondary mass effects from edema resulting in an increased ICF, and possible herniation syndromes. Persons suffering from cerebral contusions are usually managed medically with emphasis toward prevention of secondary injuries.

Hematomas

Hematomas result from vascular injury and bleeding. Depending on the anatomic position of the ruptured vessel, bleeding can occur in any of several compartments, including the epidural, subdural, and subarachnoid spaces, or into the brain itself (intracerebral hematoma).

Epidural Hematoma. An epidural hematoma is one that develops between the inner side of the skull and the dura (Fig. 37-7). It usually results from a tear in an artery, most often the middle meningeal, usually in association with a head injury in which the skull is fractured. Because bleeding is arterial in origin, rapid expansion of the hematoma compresses the brain. Epidural hematoma is more common in a young person because the dura is less firmly attached to the skull surface than in an older person; as a consequence, the dura can be easily separated from the inner surface of the skull, allowing the hematoma to grow.

Typically, a person with an epidural hematoma presents with a history of head injury and a brief period of unconsciousness followed by a lucid period in which consciousness is regained. There is then a rapid progression to unconsciousness. The lucid interval does not always occur, but when it does, it is of great diagnostic value. With rapidly developing unconsciousness,
there are focal symptoms related to the area of the brain involved. These symptoms can include ipsilateral pupil dilation and contralateral (opposite side) hemiparesis from uncal herniation. If the hematoma is not removed, the condition progresses, with increased ICP, tentorial herniation, and death. The prognosis is excellent, however, if the hematoma is removed before loss of consciousness occurs.

**Subdural Hematoma.** A subdural hematoma develops in the area between the dura and the arachnoid (subdural space) and usually is the result of a tear in the small bridging veins that connect veins on the surface of the cortex to dural sinuses. The bridging veins pass from the pial vessels through the CSF-filled subarachnoid space, penetrate the arachnoid and the dura, and empty into the intradural sinuses. These veins are readily snapped in head injury when the brain moves suddenly in relation to the cranium (Fig. 37-8). Bleeding can occur between the dura and arachnoid (i.e., subdural hematoma) or into the CSF-filled subarachnoid space (i.e., subarachnoid hematoma).

The venous source of bleeding in a subdural hematoma develops more slowly than the arterial bleeding in an epidural hematoma. Subdural hematomas are classified as acute, subacute, or chronic. This classification system is based on the approximate time before the appearance of symptoms. Symptoms of acute hematoma are seen within 24 hours of the injury, whereas subacute hematoma does not produce symptoms until 2 to 10 days after injury. Symptoms of chronic subdural hematoma may not arise until several weeks after the injury.

Acute subdural hematomas progress rapidly and have a high mortality rate because of the severe secondary injuries related to edema and increased ICP. The high mortality rate has been associated with uncontrolled ICP increase, loss of consciousness, decerebrate posturing (see Fig. 37-4B), and delay in surgical removal of the hematoma. The clinical picture is similar to that of epidural hematoma, except that there usually is no lucid interval. By contrast, in subacute subdural hematoma, there may be a period of improvement in the level of consciousness and neurologic symptoms, only to be followed by deterioration if the hematoma is not removed.

Symptoms of chronic subdural hematoma develop weeks after a head injury, so much later that the person may not remember having had a head injury. Chronic subdural hematoma is more common in older persons because brain atrophy causes the brain to shrink away from the dura and stretch fragile bridging veins. When these veins rupture, there is slow seepage of blood into the subdural space. Fibroblastic activity causes the hematoma to become encapsulated. The sanguinous (blood fluid) in this encapsulated mass, with its high concentration of osmotically-active particles, draws fluid from the surrounding subarachnoid space, causing the hematoma to expand and exert pressure on the surrounding brain tissue. In some instances, the clinical picture is less defined, with the most prominent symptom being a decreasing level of consciousness, as manifested by drowsiness, confusion, headache, and apathy.

**Traumatic Intracerebral Hematomas.** Traumatic intracerebral hematomas may be single or multiple. They can occur in any lobe of the brain but are most common in the frontal or temporal lobes, related to the bony prominences on the inner skull surface (Fig. 37-9). They may occur in association with the severe motion that the brain undergoes during head injury, or a contusion can coalesce into a hematoma. Intracerebral hematomas occur more frequently in older persons and alcoholics, whose cerebral vessels are more friable.
**Brain Concussion**

A cerebral concussion can be defined as a transient neurogenic dysfunction caused by mechanical force to the brain. It is characterized by distinct and microscopic findings, including axonal swelling, that are widely distributed in the cerebral hemispheric white matter, corpus callosum, and upper brain stem.

**Concussions**

A cerebral concussion can be defined as a transient neurogenic dysfunction caused by mechanical force to the brain. Acceleration–deceleration is the mechanism of injury, usually due to a nonpenetrating force such as a sudden blow to the head. There may be a momentary loss of consciousness without demonstrable symptoms, except for residual amnesia. Microscopic changes can often be detected in neurons and neuroglia within hours of injury, but brain imaging is usually negative. Although recovery usually takes place within 24 hours, mild symptoms, such as headache, irritability, insomnia, and poor concentration and memory, may persist for months. This is known as the postconcussion syndrome. The amnesia or memory loss usually includes an interval of time preceding the injury (retrograde amnesia) and following the injury (anterograde amnesia). The duration of retrograde amnesia correlates with the severity of the brain injury.

Traditionally, the diagnosis and management of concussion has relied heavily on the person’s self-reporting of symptoms. Because symptom resolution often precedes cognitive recovery and because many persons don’t report symptoms in an effort to return to their normal activities, additional neurophysiologic testing and monitoring can be useful. Neurophysiologic tests commonly evaluate decision-making ability, reaction time, attention, memory, and cognitive processing speed in an objective fashion. CT or MRI imaging is usually reserved for cases in which intracranial bleeding is suspected. Treatment, which is largely supportive, includes both physical and mental rest. Once symptoms have resolved, the person may begin shortened work days with decreased work demands. Students may benefit from short periods of reading and studying with frequent breaks. Athletes are advised to follow a slow stepwise return to play.

The complications of concussion, although rare, are potentially serious. Currently, the clinical and neuropathic consequences of repeated mild head injury are known as chronic traumatic encephalopathy. The disorders often manifest years or decades after the inciting head injuries with effects on behavior, cognition, and movement. Cognitive changes may occur early in the disease course and include loss of executive function and poor memory. A widely feared complication of concussion is the second-impact syndrome. It is thought to occur when someone who is still recovering from a recent concussion suffers a second head trauma. Significant morbidity and even death can result from edema caused by cerebral congestion that occurs.

**Diffuse Axonal Injury**

Diffuse axonal injury is caused by shearing of fragile axons by acceleration-deceleration forces at the time of trauma. The difference in acceleration–deceleration gradient on certain areas of the brain, permits generation of rotational forces that cause axonal shearing injury. It is characterized by distinct and microscopic findings, including axonal swelling, that are widely distributed in the cerebral hemispheric white matter, corpus callosum, and upper brain stem.

Diffuse axonal injury is characterized clinically by functional cerebral impairment, which may range from confusion to coma and death. The clinical diagnosis of diffuse axonal injury is based on immediate onset of unconsciousness in a person with significant cerebral trauma and no intracranial lesion noted on CT scan. Current treatment modalities focus on supportive care, especially for the unconscious person. Studies indicate that axonal injury evolves over a period of hours or days, suggesting that there may be an opportunity to arrest its progression and preserve axonal integrity.

**Manifestations of Diffuse Brain Injury**

Diffuse (global) brain injury, whether due to head trauma or other pathologic processes, is manifested by alterations in sensory, motor, and cognitive function and by changes in the level of consciousness. In contrast to a localized injury, which causes focal neurologic deficits without altered consciousness, global injury nearly always results in altered levels of consciousness, ranging from inattention to stupor or coma. Severe injury that seriously compromises brain function may result in brain death.
The cerebral hemispheres are the most susceptible to damage, and the most frequent sign of brain dysfunction is an altered level of consciousness and change in behavior. As the brain structures in the diencephalon, midbrain, pons, and medulla are sequentially affected, additional signs related to pupillary and eye movement reflexes, motor function, and respiration become evident (Table 37-1). Hemodynamic and respiratory instability are the last signs to occur because their regulatory centers are located low in the medulla.

In progressive brain deterioration, the person's neurologic capabilities appear to deteriorate in stepwise fashion. Similarly, as neurologic function returns, there usually is a stepwise progression to higher levels of consciousness. Deterioration of brain function from supratentorial lesions tends to follow a stepwise rostral-to-caudal progression, which is observed as the brain initially compensates for injury and subsequently decompensates with loss of autoregulation and cerebral perfusion. Infratentorial (brain stem) lesions may lead to an early, sometimes abrupt disturbance in consciousness without any orderly rostral to caudal progression of neurologic signs.

**Consciousness**

Consciousness is the state of awareness of self and the environment and of being able to become oriented to new stimuli. Its two major components are content and arousal. Content represents the sum of all the functions of the cerebral cortex, including both cognition and affective responses. Arousal and wakefulness require the concurrent functioning of both cerebral hemispheres and an intact RAS in the brain stem.

The RAS is a diffuse, primitive system of interlacing nerve cells and fibers in the brain stem that receives input from multiple sensory pathways (Fig. 37-10). Anatomically, the RAS constitutes the central core of the brain stem, extending from the medulla through the pons to the midbrain, which is continuous caudally with the spinal cord and rostrally with the subthalamus, hypothalamus, and thalamus. Fibers from the reticular formation also project to the autonomic nervous system and motor systems. The hypothalamus plays a predominant role in maintaining homeostasis through integration of somatic, visceral, and endocrine functions. Inputs from the reticular formation, vestibulospinal projections, and other motor systems are integrated to provide a continuously adapting background of muscle tone and posture to facilitate voluntary motor actions. Reticular formation neurons that function in regulation of cardiovascular, respiratory, and other visceral functions are intermingled with those that maintain other reticular formation functions.

The pathways for the ascending RAS travel from the medulla through the midbrain, such that lesions of the brain stem can interrupt RAS activity, leading to altered levels of consciousness and coma. Any deficit in level of consciousness, from mild confusion to stupor or coma, indicates injury to either the RAS or to both cerebral hemispheres concurrently. For example, consciousness may decline owing to severe systemic metabolic derangements that affect both hemispheres, or from head trauma causing shear injuries to white matter of both the RAS and the cerebral hemispheres. Brain injuries that affect a

These give rise to fibers synapsing in the nonspecific nuclei of the thalamus. From there, the nonspecific thalamic projections influence widespread areas of the cerebral cortex and limbic system.
hemisphere unilaterally and also spare the RAS, such as cerebral infarction, usually do not impair consciousness.

Levels of Consciousness. Levels of consciousness reflect awareness and response to the environment. A fully conscious person is totally aware of his or her surroundings and able to react to stimuli in the environment. Levels of consciousness exist on a continuum that includes consciousness, confusion, delirium, obtundation, stupor, and coma (Table 37-2).

The earliest signs of diminution in level of consciousness are inattention, mild confusion, disorientation, and blunted responsiveness. With further deterioration, the delirious person becomes markedly inattentive and variably lethargic or agitated. The person may progress to become obtunded and may respond only to vigorous or noxious stimuli.

Because of its simplicity of application, the Glasgow Coma Scale has gained almost universal acceptance as a method for assessing the level of consciousness in persons with brain injury (Table 37-3). Numbered scores are given to responses of eye opening, verbal utterances, and motor responses. The total score is the sum of the best response in each category.

Other Manifestations of Deteriorating Brain Function

Additional elements in the initial neurologic evaluation of a person with brain injury include checking for abnormalities in the size of the pupils and their reaction to light, evidence of decorticate or decerebrate posturing, and altered patterns of respiration.

Pupillary Reflexes and Eye Movements. Although the pupils may initially respond briskly to light, they become unreactive and dilated as brain function deteriorates. A bilateral loss of the pupillary light response is indicative of lesions of the brain stem. A unilateral loss of the pupillary light response may be due to a lesion of the optic or oculomotor pathways. The oculocephalic reflex (doll’s-head eye movement) can be used to determine whether the brain stem centers for eye movement are intact (Fig. 37-11). If the oculocephalic reflex is inconclusive, and if there are no contraindications, the oculovestibular test (i.e., cold caloric test, in which cold water is instilled into the ear canal) may be used to elicit nystagmus (see Chapter 38).

Decorticate and Decerebrate Posturing. With the early onset of unconsciousness, there is some combative and purposeful movement in response to pain. As coma progresses, noxious stimuli can initiate rigidity and abnormal postures if the motor tracts are interrupted at specific levels. These abnormal postures are classified as decorticate and decerebrate. Both are poor prognostic signs.

*GCS Score = E + M + V. Best possible score = 15; worst possible score = 3.
Decorticate (flexion) posturing is characterized by the arms being held tightly to the sides, with flexion of the arms, wrists, and fingers; and extension and internal rotation of the legs with plantar flexion of the feet (see Fig. 37-4A). Decorticate posturing results from lesions of the cerebral hemisphere or internal capsule.

Decerebrate (extensor) posturing results from increased muscle excitability (see Fig. 37-4B). It is characterized by rigidity of the arms with the wrists and fingers flexed and turned away from the body and with stiffly extended legs and plantar flexion of the feet. This response occurs with rostral-to-caudal deterioration, when lesions of the diencephalon extend to involve the midbrain and upper brain stem.

**Respiratory Responses.** Early respiratory changes include yawning and sighing, with progression to Cheyne-Stokes breathing, in which there is waxing and waning of respirations with variable periods of apnea. When the progression of injury continues to the midbrain, respirations change to neurogenic hyperventilation, in which the frequency of respirations may exceed 40 breaths per minute because of uninhibited stimulation of inspiratory and expiratory centers. With medullary involvement, respirations become ataxic (i.e., totally uncoordinated and irregular). Apnea may occur because of a lack of responsiveness to carbon dioxide stimulation. Complete ventilatory assistance is often required at this point.

**SUMMARY CONCEPTS**

- Many of the agents that cause brain damage do so through common and often interrelated pathways, including hypoxia or ischemia, accumulation of excitatory amino-acid neurotransmitters, and cerebral edema.
- Deprivation of oxygen (i.e., hypoxia) or blood flow (i.e., ischemia) can have deleterious effects on the brain structures. Ischemia can be focal, as in stroke, or global as occurs during cardiac arrest when blood flow is inadequate to meet the metabolic needs of the entire brain.
- Excitotoxicity is a final common pathway for neuronal cell injury and death. It is associated with excessive activity of excitatory amino-acid neurotransmitters, particularly glutamate.
- Cerebral edema represents an increase in brain volume secondary to abnormal fluid accumulation. Vasogenic edema occurs when integrity of the blood–brain is disrupted allowing intravascular fluid to move into the extracellular fluid surround brain cells; whereas, cytotoxic edema involves swelling of brain cells due to the movement of the extracellular fluid into the brain cells.
- The intracranial pressure (ICP) is the pressure exerted by the essentially incompressible tissue and fluid volumes of the three compartments contained within the rigid confines of the skull—brain tissue, blood, and cerebral spinal fluid (CSF). Excessive ICP can obstruct cerebral blood flow, destroy brain cells, displace brain tissue as in herniation, and otherwise damage delicate brain structures.
- Hydrocephalus represents enlargement of the CSF compartment owing to an abnormal CSF volume. It can result from impaired reabsorption from the arachnoid villi into the venous system (communicating hydrocephalus) or from obstruction of the ventricular system (noncommunicating hydrocephalus), which prevents the CSF from reaching the arachnoid villi.
- The term traumatic brain injury refers to injuries to the skull, brain, or both. The brain injuries can be primary, because of direct impact, or secondary, resulting from complicating processes that were initiated at the time of injury. They can be focal, as occurs with contusions and hematoma formation; or diffuse, as in concussion or diffuse axonal injury.
Cerebrovascular Disease

Cerebrovascular disease encompasses a number of disorders involving vessels in the cerebral circulation. As elsewhere in the circulation, cerebrovascular disorders can involve vessel occlusion or rupture that leads to either focal or localized brain damage or to global hypoxia-ischemia that causes widespread brain injury.

The Cerebral Circulation

The blood flow to the brain is supplied by the two internal carotid arteries anteriorly and the vertebral arteries posteriorly (Fig. 37-12A). The internal carotid artery, a terminal branch of the common carotid artery, branches into several arteries—the ophthalmic, posterior communicating, anterior choroidal, anterior cerebral, and middle cerebral arteries. Most of the arterial blood in the internal carotid arteries is distributed through the anterior and middle cerebral arteries (see Fig. 37-12B). The anterior cerebral arteries supply the medial surface of the frontal and parietal lobes and the anterior half of the thalamus, the corpus striatum, part of the corpus callosum, and the anterior limb of the internal capsule. The genu and posterior limb of the internal capsule and medial globus pallidus are fed by the anterior choroidal branch of the internal carotid artery.

The middle cerebral artery passes laterally, supplying the lateral basal ganglia and the insula, and then emerges on the lateral cortical surface, supplying the inferior frontal gyrus, the motor and premotor frontal cortex concerned with delicate face and hand control (Fig. 37-13). It is the major vascular source for the language cortices, the primary and association auditory cortices, and the primary and association somatosensory cortices for the face and hand. Because the middle cerebral artery is a continuation of the internal carotid, emboli arising in the internal carotid most frequently become lodged in branches of the middle cerebral artery. The consequences of ischemia of these areas may be the most devastating, resulting in damage to the fine manipulative skills of the face and upper limbs and to receptive and expressive communication functions (e.g., aphasia).

The two vertebral arteries arise from the subclavian artery and enter the foramina (opening) in the transverse spinal processes at the level of the sixth cervical vertebra and continue upward through the foramina of the upper six vertebrae. They wind behind the atlas and enter the skull through the foramen magnum and unite to form the basilar artery, which then diverges to terminate in the posterior cerebral arteries. Branches of the basilar and vertebral arteries supply the medulla, pons, cerebellum, midbrain, and caudal part of the diencephalon. The posterior cerebral arteries supply the remaining occipital and inferior regions of the temporal lobes and the thalamus.

The distal branches of the internal carotid and vertebral arteries communicate at the base of the brain through the circle of Willis; this anastomosis of arteries can provide continued circulation if blood flow through one of the main vessels is disrupted (see Fig. 37-12B). For instance, occlusion of one middle cerebral artery may have limited consequences if the anterior and posterior communicating arteries are patent, allowing collateral flow from the ipsilateral posterior cerebral and opposite carotid arteries. There are many normal variants across individuals in the completeness of the circle of Willis, such that collateral supply may be limited. Without collateral input, disruption of blood flow in a cerebral artery results in ischemic neural damage as metabolic needs of electrically active cells exceed nutrient supply.

The cerebral circulation is drained by two sets of veins that empty into the dural venous sinuses: the deep (great) cerebral venous system and the superficial venous system. In contrast to the superficial cerebral veins that travel through the pia mater on the surface of the cerebral cortex, the deep venous system is well protected. These vessels are directly connected to the sagittal sinuses in the falk cerebri by bridging veins. They travel through the CSF-filled subarachnoid space and penetrate the arachnoid and then the dura to reach the dural venous sinuses. This system of sinuses returns blood to the heart primarily through the internal jugular veins. The intracranial veins do not have valves. The direction of flow depends on gravity and pressures in the venous sinuses as compared with those of the extracranial veins. Increases in intrathoracic pressure, as can occur with coughing or performance of the Valsalva maneuver (i.e., exhaling against a closed glottis), produce a rise in

SUMMARY CONCEPTS (continued)

- Consciousness is a state of awareness of self and environment. It exists on a continuum from normal wakefulness and sleep to the pathologic continuum of stupor and coma. Any deficit in level of consciousness, from mild confusion to stupor or coma, indicates injury to either the ascending reticular activating (RAS) system or to both cerebral hemispheres concurrently. Consciousness may decline due to severe systemic metabolic derangements that affect both hemispheres, or from head trauma causing shear injuries to white matter of both the RAS and the cerebral hemispheres.

- Deterioration of brain function is manifested by alterations in sensory and motor function and changes in the level of consciousness. In progressive brain injury, coma usually follows a rostral-to-caudal progression with characteristic changes in levels of consciousness, the pupillary light response and eye movements, posturing, and respiratory responses.

central venous pressure that is reflected back into the internal jugular veins and then to the dural sinuses. This briefly raises the ICP.

**Regulation of Cerebral Blood Flow**

The blood flow to the brain is maintained at approximately 750 to 900 mL/minute or 15% of the resting cardiac output. The regulation of blood flow to the brain is controlled largely by autoregulatory or local mechanisms that respond to the metabolic needs of the brain. Cerebral autoregulation has been classically defined as the ability of the brain to maintain constant cerebral blood flow despite changes in systemic arterial pressure. This allows the cerebral cortex to adjust cerebral blood flow locally to satisfy its metabolic needs. The autoregulation of cerebral blood flow is efficient within a MAP range of approximately 60 to 140 mm Hg. Although total cerebral blood flow remains relatively stable throughout marked changes in cardiac output and arterial blood pressure, regional blood flow may vary markedly in response to local changes in metabolism. If blood pressure falls below 60 mm Hg, cerebral blood flow becomes severely compromised, and if it rises above the upper limit of autoregulation, blood flow increases rapidly and overstretches the cerebral vessels. In persons with hypertension, this autoregulatory range shifts to higher MAP levels.

Metabolic factors affecting cerebral blood flow include an increase in carbon dioxide and hydrogen ion concentrations. Increased carbon dioxide provides a potent stimulus for vasodilation—a doubling of the PCO₂ in the blood results in a doubling of cerebral blood flow. Carbon dioxide is thought to increase cerebral blood flow by first combining with water to form carbonic acid, with subsequent dissociation into hydrogen ions, which then causes vasodilation of the cerebral vessels. Other substances, such as lactic acid and pyruvic acid, which increase the acidity of brain tissues, will produce a similar increase in cerebral blood flow. Oxygen deficiency also influences cerebral blood flow.

Except during periods of intense brain activity, the rate of oxygen utilization by the brain remains within a narrow range. If blood flow to the brain becomes insufficient to supply this needed amount of oxygen, the oxygen deficiency causes the cerebral vessels to dilate, returning cerebral blood flow to near normal.

The sympathetic nervous system also contributes to the control of blood flow in the large cerebral arteries and the arteries that penetrate into the brain substance. Under normal physiologic conditions, local regulatory and autoregulatory mechanisms override the effects of sympathetic stimulation. However, when local mechanisms fail, sympathetic control of cerebral blood pressure becomes important. For example, when the arterial pressure rises to very high levels during strenuous exercise or in other conditions, the sympathetic nervous system constricts the large and intermediate-sized superficial blood vessels as a means of protecting the smaller, more easily damaged vessels. Sympathetic reflexes are also thought to cause vasospasm in the intermediate and large arteries in some types of brain damage, such as that caused by rupture of a cerebral aneurysm.

**Stroke (Brain Attack)**

Stroke is the syndrome of acute focal neurologic deficit resulting from a vascular induced disorder that injures brain tissue. Stroke remains one of the leading causes of morbidity and mortality in the United States. The term brain attack has been promoted to raise awareness that time-dependent tissue damage occurs and that rapid emergency treatment is necessary, similar to that with heart attack.

There are two main types of strokes: ischemic and hemorrhagic. Ischemic strokes reflect infarctions caused by an interruption of blood flow in a cerebral vessel and are the most common type of stroke, accounting for about 87% of all strokes. The less common hemorrhagic strokes, which have a much higher fatality rate than ischemic strokes, are caused by spontaneous bleeding into brain tissue. Intracerebral hemorrhage can also result from ruptured cerebral aneurysms and bleeding from arteriovenous malformations. Additionally, the latest classifications define silent CNS infarction as ischemic lesions found incidentally on imaging, and transient ischemic attack (TIA) reflecting transient symptoms without infarction on imaging.

**Ischemic Stroke**

Ischemic strokes result from a diverse set of cerebrovascular obstruction by thrombosis or emboli (Fig. 37-14). Among the major risk factors for ischemic
Classification. Various methods have been used to classify ischemic cerebrovascular disease. A common classification system identifies the five main mechanisms of stroke as stroke subtypes and their frequency: 20% large artery atherosclerotic disease (both thrombosis and arterial emboli); 25% small vessel or penetrating artery disease (so-called lacunar stroke); 20% cardioembolic embolism; 30% cryptogenic stroke (undetermined cause); and 5% other causes (i.e., migraine, vessel dissection, coagulopathy).7

Ischemic Penumbra in Evolving Stroke. During the evolution of a stroke, there usually is a central core of dead or dying cells, surrounded by an ischemic band or area of minimally perfused cells called the penumbra (“halo”). Brain cells of the penumbra receive marginal blood flow, and their metabolic activities are impaired. Although the area undergoes an “electrical failure,” the structural integrity of the brain cells is maintained.4,23 Reversal of the penumbra injury depends on the successful and timely return of adequate circulation, the volume of toxic products released by the neighboring dying cells, the degree of cerebral edema, and alterations in local blood flow. If the toxic products result in additional death of cells in the penumbra, the core of dead or dying tissue enlarges, and the volume of surrounding ischemic tissue increases.

Transient Ischemic Attacks. Transient ischemic attacks (TIAs) are brief episodes of neurologic dysfunction resulting from focal cerebral ischemia not associated with infarction.18,24–26 A TIA or “ministroke” is equivalent to “brain angina” and reflects a temporary disturbance in cerebral blood flow, which reverses before infarction occurs, analogous to angina in relation to heart attack. The traditional definition of TIAs as a neurologic deficit resolving within 24 hours was developed before the mechanisms of ischemic cell damage and the penumbra were known and before the newer, more advanced methods of neuroimaging became available. A more accurate definition now is a transient deficit without time limits, best described as a zone of penumbra without central infarction.20 The causes of TIAs are the same as those of ischemic stroke and include atherosclerotic disease of cerebral vessels and emboli. Transient ischemic attacks are important because they may provide warning of impending stroke. In fact, the risk for stroke is 15% in the 3 months following a TIA.20 Diagnosis of TIA before a stroke may permit surgical or medical intervention that prevents an eventual stroke and associated neurologic deficits.

Large Vessel (Thrombotic) Stroke. Thrombi are the most common cause of ischemic strokes, usually occurring in atherosclerotic blood vessels.1,4 In the cerebral circulation, atherosclerotic plaques are most commonly found at arterial bifurcations of large arteries. Common sites of plaque formation include the origins of the internal carotid and vertebral arteries, and junctions of the basilar and vertebral arteries. Cerebral infarction can result from an acute local thrombosis and occlusion at the site of chronic atherosclerosis, with or without embolization of the plaque material distally, or from critical perfusion failure distal to a stenosis (watershed). These infarcts often affect the cortex, causing aphasia or hemineglect, visual field defects, or transient

monocular blindness (amaurosis fugax). In most cases of stroke, a single cerebral artery and its territories are affected. Usually, thrombotic strokes are seen in older persons and frequently are accompanied by evidence of atherosclerotic heart or peripheral arterial disease. The thrombotic stroke is not associated with activity and may occur in a person at rest.

**Small Vessel Stroke (Lacunar Infarct).** Lacunar infarcts are small (<15 mm wide) infarcts located in the deep, noncortical parts of the brain or in the brain stem. They are found in the territory of single, deep, penetrating arteries supplying the internal capsule, basal ganglia, or brain stem. They result from occlusion of the smaller penetrating branches of large cerebral arteries, commonly the middle cerebral and posterior cerebral arteries. The infarcted tissue eventually scars to leave small, rounded cavities, or lacunae ("lakes"). They are thought to result from arteriosclerosis, commonly in the settings of chronic hypertension or diabetes. Because of their size and location, lacunar infarcts usually do not cause cortical deficits such as aphasia or apraxia. Instead, they produce classic recognizable "lacunar syndromes" such as pure motor hemiplegia, pure sensory hemiplegia, and dysarthria with clumsy hand syndrome. Because CT scans are not sensitive enough to detect these tiny infarcts, diagnosis used to depend on clinical features alone. The use of MRI has allowed frequent visualization of small vessel infarcts and is obligatory to confirm such a lesion.

**Embolic Stroke.** An embolic stroke is caused by a moving blood clot that travels from its origin to the brain. It usually affects the larger proximal cerebral vessels, with emboli often lodging at bifurcations. The most frequent site of embolic strokes is the middle cerebral artery, reflecting the large territory of this vessel and its position at the terminus of the carotid artery. Although most cerebral emboli originate from a thrombus in the left heart, they also may originate in an atherosclerotic plaque in the carotid arteries. The embolus travels quickly to the brain and becomes lodged in a smaller artery through which it cannot pass. Embolic stroke usually has a sudden onset with immediate maximum deficit.

Various cardiac conditions predispose to formation of emboli that produce embolic stroke, including rheumatic heart disease, atrial fibrillation, recent myocardial infarction, ventricular aneurysm, and bacterial endocarditis. More recently, the use of transesophageal echocardiography, which better images the interatrial septum, has implicated a patent foramen ovale as a source for paradoxical venous embolus to the arterial system. Advances in the diagnosis and treatment of heart disease can be expected to favorably alter the incidence of embolic stroke.

**Hemorrhagic Stroke**

The most frequently fatal stroke is caused by the spontaneous rupture of an intracerebral vessel. With rupture of a blood vessel, hemorrhage into the brain tissue occurs, resulting in a focal hematoma and sometimes intraventricular hemorrhage, edema, compression of the brain contents, or spasm of the adjacent blood vessels. The most common predisposing factors are advancing age and hypertension. Other causes of hemorrhage are aneurysm, trauma, erosion of the vessels by tumors, arteriovenous malformations, blood coagulation disorders, vasculitis, and drugs. A cerebral hemorrhage occurs suddenly, usually when the person is active. Vomiting commonly occurs at the onset, and headache is common. Focal symptoms depend on which vessel is involved. In the most common situation, hemorrhage into the basal ganglia results in contralateral hemiplegia, with initial flaccidity progressing to spasticity. The hemorrhage and resultant edema exert great pressure on the brain substance, and the clinical course progresses rapidly to coma and frequently to death.

Treatment of hemorrhagic stroke focuses on intensive management of the increased arterial and intracranial pressures, and prevention of hematoma expansion. Initial promising results with use of recombinant factor VII to limit hematoma expansion were deflated by the occurrence of thromboembolic complications. In patients with anticoagulant-associated hemorrhages, use of prothrombin complex concentrate has been more successful than vitamin K administration.

**Acute Stroke Management**

The specific manifestations of stroke or TIA are determined by the cerebral artery that is affected, by the area of brain tissue that is supplied by that vessel, and by the adequacy of the collateral circulation. Symptoms of stroke/TIA always are sudden in onset and focal, and usually are one-sided. The most common symptom is weakness of the face and arm, and sometimes also of the leg. Other frequent stroke symptoms are unilateral numbness, vision loss in one eye (amaurosis fugax) or to one side (hemianopia), language disturbance (aphasia), slurred speech (dysarthria), and sudden, unexplained imbalance or ataxia. In the event of TIA, symptoms rapidly resolve spontaneously, usually within minutes, although the underlying mechanisms are the same as for stroke.

Stroke signs depend on the specific vascular territory compromised (Table 37-5). As a generalization, carotid ischemia causes monocular visual loss or aphasia (dominant hemisphere) or hemineglect (nondominant hemisphere), contralateral sensory or motor loss, or other discrete cortical signs such as apraxia and agnosia. Vertebrobasilar ischemia induces ataxia, diplopia, hemianopia, vertigo, cranial nerve deficits, contralateral hemiplegia, sensory deficits (either contralateral or crossed, i.e., contralateral body and ipsilateral face), and arousal defects. Discrete subsets of these vascular syndromes usually occur, depending on which branches of the involved artery are blocked.

**Diagnosis.** Accurate diagnosis of acute stroke, based on a complete history and thorough physical and neurologic examination, is designed to determine the presence of
hemorrhage or ischemia, identify the stroke or TIA mechanism (i.e., large-vessel or small-vessel, atherothrombotic, cardioembolic, hemorrhagic, cryptogenic, or other), characterize the severity of clinical deficits, and unmask the presence of risk factors. A careful history, including documentation of previous TIAs, the time of onset and pattern and rapidity of system progression, the specific focal symptoms (to determine the likely vascular territory), and any coexisting diseases, can help to determine the type of stroke that is involved.

Computed tomographic scans and magnetic resonance imaging have become essential brain imaging tools in diagnosing stroke, differentiating cerebral hemorrhage from ischemia, and excluding intracranial lesions that mimic stroke clinically. CT scans are a necessary screening tool in the acute setting for rapid identification of hemorrhage, but are insensitive to ischemia within 24 hours and to any brain stem or small infarcts. MRI is superior for imaging ischemic lesions in all territories and differentiating other nonstroke pathologic processes (e.g., tumors, contusion, infection). Newer MRI techniques such as perfusion- and diffusion-weighted imaging (DWI) can reveal cerebral ischemia immediately after onset and identify areas of potentially reversible damage (i.e., penumbra).

Vascular imaging is accomplished with CT angiography (CTA), magnetic resonance angiography (MRA), catheter-based “conventional” arteriography, and ultrasonography. All except ultrasonography can demonstrate the site of vascular abnormality (intracranial and extracranial) and afford visualization of most intracranial vascular areas. MRA is noninvasive and most widely available, but less sensitive and specific than CTA or catheter angiography. CT angiography is exquisitely detailed for a noninvasive technique, but is limited in availability and requires iodinated contrast, which is nephrotoxic. Catheter angiography remains the gold standard in sensitivity and allows visualization of dynamic patterns of collateral flow, but is invasive and requires significant contrast doses. CT angiography and magnetic resonance angiography have largely replaced angiography as a screening tool for vascular lesions. Ultrasonographic techniques allow quick bedside assessment of the carotid bifurcation (duplex ultrasonography) or of flow velocities in the cerebral circulation (transcranial Doppler).

**Treatment.** Treatment of acute ischemic stroke has changed markedly since the early 1990s, with an emphasis on salvaging brain tissue, preventing secondary stroke, and minimizing long-term disability. The care of patients with stroke has shifted away from the “nearest hospital” to stroke centers that have been certified by some external agency, most commonly the state or Joint Commission. Certification establishes that a hospital can manage stroke patients with appropriate care throughout the continuum—from emergency treatments, through the inpatient stay, and into the rehabilitation phase. With this advancement, the medical and lay communities acknowledge that care of the patient with stroke requires specialized personnel and resources to minimize stroke’s devastating effects, as stroke is the leading cause of adult disability in the United States.

Stoke care begins with emergency treatments aimed at reversing the evolving ischemic brain injury. The realization that there is a window of opportunity during

*Depend on hemisphere involved and adequacy of collaterals.
which ischemic but viable brain tissue can be salvaged has led to the use of reperfusion techniques and neuroprotective strategies in the early treatment of ischemic stroke. Although the results of emergent treatment of hemorrhagic stroke have been less dramatic, continued efforts to reduce disability have been promising.

Reperfusion techniques include thrombolytic therapy (administered either intravenously or intra-arterially), catheter-directed mechanical clot disruption, and augmentation of cerebral perfusion pressure during acute stroke. The first and only agent approved by the U.S. Food and Drug Administration (FDA) for treatment of acute ischemic stroke is tissue plasminogen activator (tPA). A subcommittee of the Stroke Council of the American Heart Association has developed guidelines for the use of tPA for acute stroke. These guidelines recommend that in persons with suspected stroke, the diagnosis of hemorrhagic stroke be excluded through the use of CT scanning before administration of I.V. thrombolytic therapy, which must be administered within 3 hours of onset of symptoms, or 4.5 hours in some cases. The major risk of treatment with thrombolytic agents is intracranial hemorrhage of the infarcted brain. A number of conditions, including therapeutic levels of oral anticoagulant medications, a history of gastrointestinal or urinary tract bleeding in the previous 21 days, prior stroke or head injury within 3 months, major surgery within the past 14 days, and a blood pressure greater than 185/110 mm Hg, are considered contraindications to intravenous thrombolytic therapy.

Emerging experimental treatments for ischemic stroke are being increasingly used as alternative methods of reperfusion beyond intravenous thrombolysis. New catheter-based methods allow recanalization of a directly visualized cerebral clot with intra-arterial techniques, often beyond the 4.5-hour window. Patient candidates for invasive reperfusion strategies are generally identified using newer perfusion imaging techniques such as CT or MR perfusion in order to detect a region of reversible injury (ischemic penumbra) and to exclude completed infarcts. Once a penumbra is found, the interventional specialist might mechanically disrupt the clot, extract the clot (thrombectomy), or deliver the thrombolytic drug intra-arterially at the clot surface, or urgently stent intracranial vessels to restore flow and rescue the penumbra. Additional methods (drugs, ultrasound, hypothermia) aimed at either extending that therapeutic window until revascularization occurs or improving recanalization rates are under active investigation. These methods require an experienced interventional angiography team, neurocritical care services, and extensive institutional infrastructure, and thus remain limited to tertiary care centers.

**Poststroke Management and Deficits**

Poststroke treatment is aimed at preventing recurrent stroke and medical complications while promoting the fullest possible recovery of function. The risk of stroke recurrence is highest in the first week after a stroke or TIA, so the early implementation of antiplatelet agents in most cases, or warfarin (an anticoagulant) in cardioembolic stroke, is imperative. Long-term stroke recurrence is most effectively prevented with aggressive reduction of risk factors, primarily hypertension, diabetes, smoking, and hyperlipidemia. In cases of carotid territory stroke with carotid stenosis, revascularization with surgery or stenting should be considered. Early hospital care also requires careful prevention of aspiration, deep vein thrombosis, and falls. Recovery is maximized with early and aggressive rehabilitation efforts that include all members of the rehabilitation team—physician, nurse, speech therapist, physical therapist, and occupational therapist—and the family.

**Poststroke Motor Deficits**. Poststroke motor deficits are most common, followed by deficits of language, sensation, and cognition. After a stroke affecting the corticospinal tracts such as the motor cortex, posterior limb of the internal capsule, basis pontis, or medullary pyramids, there is profound weakness on the contralateral side (hemiparesis; see Chapter 36, Fig. 36-4). Involvement at the level of the motor cortex is most often in the territory of the middle cerebral artery, usually with a sparing of the leg, which is supplied by the anterior cerebral artery. Subcortical lesions of the corticospinal tracts cause equal weakness of the face, arm, and leg. Within 6 to 8 weeks, the initial weakness and flaccidity are replaced by hyperreflexia and spasticity. Spasticity involves an increase in the tone of affected muscles and usually an element of weakness. The flexor muscles usually are more strongly affected in the upper extremities and the extensor muscles more strongly affected in the lower extremities. There is a tendency toward foot drop; outward rotation and circumduction of the leg with gait; flexion at the wrist, elbow, and fingers; lower facial paresis; slurred speech; an upgoing toe to plantar stimulation (Babinski sign); and dependent edema in the affected extremities. A slight corticospinal lesion may be indicated only by clumsiness in carrying out fine coordinated movements rather than obvious weakness. Passive range-of-motion exercises help to maintain joint function and to prevent edema, shoulder subluxation (i.e., incomplete dislocation), and muscle atrophy, and may help to reestablish motor patterns. If no voluntary movement or movement on command appears within a few months, significant function usually will not return to that extremity.

**Poststroke Dysarthria and Aphasia**. Two key aspects of verbal communication are speech and language. Speech involves the mechanical act of articulating verbal sounds, the “motor act” of verbal expression, whereas language involves the written or spoken use of symbolic formulations, such as words or numbers. Dysarthria is a disorder of speech, which manifests as the imperfect articulation of speech sounds or changes in voice pitch or quality. It results from a stroke affecting the muscles of the pharynx, palate, tongue, lips, or mouth and does not relate to the content of speech. A person with dysarthria may demonstrate slurred speech while still retaining language ability, or may have a concurrent
language problem as well. Aphasia is a general term that encompasses varying degrees of inability to comprehend, integrate, and express language. Aphasia may be localized to the dominant cerebral cortex or thalamus—on the left side in 95% of people who are right handed and 70% of people who are left handed. In children, language dominance can readily shift to the unaffected hemisphere, resulting in more transient language deficits after stroke. A stroke in the territory of the middle cerebral artery is the most common aphasia-producing stroke.

Aphasia can be categorized as receptive or expressive, or as fluent or nonfluent. Receptive or fluent speech requires little or no effort, is intelligible, and is of increased quantity. The term fluent refers only to the ease and rate of verbal output, and does not relate to the content of speech or the ability of the person to comprehend what is being said. Verbal utterances are often paraphasic, meaning that letters, syllables, or whole words are substituted for the target words. There are three categories of fluent aphasia: Wernicke, anomic, and conduction aphasia. Wernicke aphasia is characterized by an inability to comprehend the speech of others or to comprehend written material. Lesions of the posterior superior temporal or lower parietal lobe (areas 22 and 39) are associated with receptive or fluent aphasia. Anomic aphasia is speech that is nearly normal except for difficulty in finding singular words. Conduction aphasia is manifest as impaired repetition and speech riddled with letter substitutions, despite good comprehension and fluency. Conduction aphasia (i.e., disconnection syndrome) results from destruction of the fiber system under the insula that connects the Wernicke and Broca areas.

Expressive or nonfluent aphasia is characterized by an inability to easily communicate spontaneously or translate thoughts or ideas into meaningful speech or writing. Speech production is limited, effortful, and halting and often may be poorly articulated because of a concurrent dysarthria. The person may be able, with difficulty, to utter or write two or three words, especially those with an emotional overlay. Comprehension is normal, and the person seems to be fully aware of his or her deficits but is unable to correct them. This often leads to frustration, anger, and depression. Expressive, nonfluent aphasia is associated with lesions of the Broca area at the dominant inferior frontal lobe cortex (areas 44 and 45).

Poststroke Cognitive and Other Deficits. Stroke can also cause cognitive, sensory, visual, and behavioral deficits. One distinct cognitive syndrome is that of hemineglect or hemi-inattention. Usually caused by strokes affecting the nondominant (right) hemisphere, hemineglect is the inability to attend to and react to stimuli coming from the contralateral (left) side of space. Affected persons may not visually track, orient, or reach to the neglected side. They may neglect to use the limbs on that side, despite normal motor function, and may not shave, wash, or comb that side. Such persons are unaware of this deficit, which is another form of their neglect (anosognosia). Other cognitive deficits include impaired ability to carry out previously learned motor activities despite normal sensory and motor function (apraxia), impaired recognition with normal sensory function (agnosia), memory loss, behavioral syndromes, and depression. Sensory deficits affect the body contralateral to the lesion and can manifest as numbness, tingling paresthesias, or distorted sensations such as dysesthesia and neuropathic pain. Visual disturbances from stroke are diverse, but most common are hemianopia from a lesion of the optic radiations between the lateral geniculate body and the temporal or occipital lobes, and monocular blindness from occlusion of the ipsilateral central retinal artery, a branch of the internal carotid artery.

Intracranial Hemorrhage

Intracranial hemorrhages can occur at any site within the brain. They usually result from rupture of small atherosclerotic vessels, as in hemorrhagic stroke; rupture of an aneurysm; or arteriovenous malformations.

Aneurysmal Subarachnoid Hemorrhage

An aneurysm is a bulge at the site of a localized weakness in the muscular wall of an arterial vessel. Most cerebral aneurysms are small saccular aneurysms called berry aneurysms. They usually occur in the anterior circulation and are found at bifurcations and other junctions of vessels such as those in the circle of Willis (Fig. 37-15). They are thought to arise from a congenital defect in the media of the involved vessels. Their incidence is higher in persons with certain disorders, including polycystic kidney disease, fibromuscular dysplasia, coarctation of the aorta, and arteriovenous malformations of the brain.1,4 Other causes of cerebral aneurysms are atherosclerosis, hypertension, and bacterial infections.

![Common sites of berry aneurysms.](Image)
Aneurysmal subarachnoid hemorrhage represents bleeding into the subarachnoid space caused by a ruptured cerebral aneurysm. Bleeding into the subarachnoid space can extend well beyond the site of origin, flooding the basal cistern, ventricles, and spinal subarachnoid space. The incidence of rupture increases with age, occurring most commonly between 40 and 60 years of age. The probability of rupture increases with the size of the aneurysm; aneurysms larger than 10 mm in diameter have a 50% chance of bleeding at some point during the course of a year. Of the various factors that may predispose to aneurysmal subarachnoid hemorrhage, cigarette smoking, hypertension, and excessive alcohol intake appear to constitute the greatest threat. Rupture may occur at any time, but often occurs with acute increases in ICP, such as with straining at stool. The mortality rate for subarachnoid hemorrhage is high (33% to 50%), with the majority of deaths occurring within the first few days of hemorrhage.

The signs and symptoms of cerebral aneurysms can be divided into two phases: those presenting before rupture and those presenting after rupture. Most small aneurysms are asymptomatic; intact aneurysms frequently are found at autopsy as an incidental finding. Large aneurysms may cause chronic headache, neurologic deficits, or both. Persons with subarachnoid hemorrhage often have a history of atypical headaches occurring days to weeks before the onset of hemorrhage, suggesting the presence of a small leak. These headaches are characterized by sudden onset and often are accompanied by nausea, vomiting, and dizziness. Persons with these symptoms may be mistakenly diagnosed as having tension or migraine headaches.

The onset of subarachnoid aneurysmal rupture often is heralded by a sudden and severe headache, described as “the worst headache of my life.” If the bleeding is severe, the headache may be accompanied by collapse and loss of consciousness. Vomiting may accompany the presenting symptoms. Other manifestations include signs of meningeal irritation such as nuchal rigidity (neck stiffness) and photophobia (light intolerance); cranial nerve deficits, especially CN II, and sometimes CN III and CN IV (diplopia and blurred vision); stroke syndromes (focal motor and sensory deficits); cerebral edema and increased ICP; and pituitary dysfunction (diabetes insipidus and hyponatremia). Hypertension, a frequent finding, and cardiac arrhythmias result from massive release of catecholamines triggered by the subarachnoid hemorrhage.

The course of treatment after aneurysm rupture depends on the extent of neurologic deficit. The best outcomes are achieved when the aneurysm can be secured early and prevention of complications initiated. Persons with mild to no neurologic deficits may undergo cerebral arteriography and early aneurysm obliteration with surgery or endovascular coiling, usually within 24 to 72 hours. Surgery involves craniotomy and inserting a specially designed silver clip that is tightened around the neck of the aneurysm. This procedure offers protection from rebleeding and may permit removal of the hematoma. The use of endovascular techniques such as balloon embolization and platinum coil electrothrombosis is an alternative to surgery, particularly in posterior circulation aneurysms or poor surgical candidates. Early outcomes and fewer complications are better with coiling, while long-term rebleeding rates are reduced with surgery. Some persons with subarachnoid hemorrhage are managed medically for 10 days or more in an attempt to improve their clinical status before surgery or coiling.

The complications of aneurysmal rupture include rebleeding, vasospasm with cerebral ischemia, hydrocephalus, hypothalamic dysfunction, and seizure activity. Rebleeding and vasospasm are the most serious and most difficult to treat. Rebleeding, which usually occurs on the first day after the initial rupture, results in further and usually catastrophic neurologic deficits.

Cerebral vasospasm is a dreaded complication of aneurysmal rupture. The condition is difficult to treat and is associated with a high incidence of morbidity and mortality. Usually, the condition develops within 3 to 10 days (peak, 7 days) after aneurysm rupture and involves a focal narrowing of the cerebral artery or arteries that can be visualized on arteriography or by transcranial Doppler. The neurologic status gradually deteriorates as blood supply to the brain in the region of the spasm is decreased; this usually can be differentiated from the rapid deterioration seen in rebleeding. Vasospasm is treated by attempting to maintain adequate cerebral perfusion pressure through the use of vasoactive drugs or administration of large amounts of intravenous fluids to increase intravascular volume and produce hemodilution. There is risk for rebleeding from this therapy. Early surgery may provide some protection from vasospasm. Endovascular techniques, including balloon dilation, have been developed to treat spasmodic arterial segments mechanically. Nimodipine, a drug that blocks calcium channels and selectively acts on cerebral blood vessels, may be used to prevent or treat vasospasm.

Another complication of aneurysm rupture is the development of hydrocephalus. It is caused by plugging of the arachnoid villi with products from lysis of blood in the subarachnoid space. Hydrocephalus is diagnosed by serial CT scans showing increasing size of the ventricles and by the clinical signs of increased ICP. Hydrocephalus may respond to osmotic diuretics, but if neurologic deterioration is significant, surgical placement of a shunt is indicated.
Arteriovenous Malformations

Arteriovenous malformations are a complex tangle of abnormal arteries and veins linked by one or more s-40,41 tunnels (Fig. 37-16). These vascular networks lack a capillary bed, and the small arteries have a deficient muscularis layer. Arteriovenous malformations are thought to arise from failure in development of the capillary network in the embryonic brain. As the child’s brain grows, the malformation acquires additional arterial contributions that enlarge to form a tangled collection of thin-walled vessels that shunt blood directly from the arterial to the venous circulation. Arteriovenous malformations typically present before 40 years of age and affect men and women equally. Rupture of vessels in the malformation causing hemorrhagic stroke accounts for approximately 2% of all strokes.

The hemodynamic effects of arteriovenous malformations are twofold. First, blood is shunted from the high-pressure arterial system to the low-pressure venous system without the buffering advantage of the capillary network. The draining venous channels are exposed to high levels of pressure, predisposing them to rupture and hemorrhage. Second, the elevated arterial and venous pressures divert blood away from the surrounding tissue, impairing tissue perfusion. Clinically, this is evidenced by slowly progressive neurologic deficits. The major clinical manifestations of arteriovenous malformations are intracerebral and subarachnoid hemorrhage, seizures, headache, and progressive neurologic deficits. Headaches often are severe, and persons with the disorder may describe them as throbbing and synchronous with their heartbeat. Other, focal symptoms depend on the location of the lesion and include visual symptoms (i.e., diplopia and hemianopia), hemiparesis, mental deterioration, and speech deficits.

Definitive diagnosis often is obtained through cerebral angiography. Treatment methods include surgical excision, endovascular occlusion, and radiation therapy.40 Because of the nature of the malformation, each of these methods is accompanied by some risk for complications. If the arteriovenous malformation is accessible, surgical excision usually is the treatment of choice. Endovascular treatment involves the insertion of microcatheters into the cerebral circulation for delivery of embolic materials (e.g., microballoons, sclerosing agents, microcoils, or quick-drying glue) into the arteriovenous malformation vessels.41 Radiation therapy (also known as radiosurgery) may involve the use of a gamma knife, proton beam, or linear accelerator.
Infections of the brain may be classified according to the structure involved—meninges (meningitis) or parenchymal brain tissue (encephalitis). They also may be classified by the type of invading organism: bacterial, viral, or other. In general, pathogens enter the CNS from the bloodstream or by direct invasion through a skull fracture, or, rarely, by contamination during surgery or lumbar puncture. Local extension from an adjacent structure (e.g., infected sinus, tooth, middle ear) may also occur.

Meningitis

Meningitis is an inflammation of the pia mater, the arachnoid, and the CSF-filled subarachnoid space. Inflammation spreads rapidly because of CSF circulation around the brain and spinal cord. The inflammation usually is caused by an infection, but chemical meningitis can occur. There are two types of acute infectious meningitis: acute purulent meningitis (usually bacterial) and acute lymphocytic (usually viral) meningitis. Factors responsible for the severity of meningitis include virulence of the pathogen, host factors, brain edema, and the presence of permanent neurologic sequelae.

Acute Bacterial Meningitis

Acute bacterial meningitis, which has a high potential for morbidity and mortality, is an inflammatory process of the leptomeninges and CSF within the subarachnoid space. Most cases of bacterial meningitis are caused by Streptococcus pneumoniae (pneumococcus) or Neisseria meningitidis (meningococcus), except in neonates, who are more commonly infected by group B streptococci. The development of effective vaccines against Haemophilus influenzae and S. pneumoniae has resulted in a profound decline in bacterial meningitis among children in the United States. Among adults, however, the incidence of meningitis has not changed. Epidemics of meningococcal meningitis occur in settings such as colleges and the military, where young people reside in close contact with each other. Other pathogens in adults are gram-negative bacilli and Listeria monocytogenes. The very young and the very old are at highest risk for pneumococcal meningitis. Risk factors associated with contracting meningitis include head trauma with basilar skull fractures, otitis media, sinusitis or mastoiditis, neurosurgery, dermal sinus tracts, systemic sepsis, or immunocompromise.

In the pathophysiologic process of bacterial meningitis, the microorganisms replicate and undergo lysis in the CSF, releasing endotoxins and cell wall fragments that cause inflammation, characterized by a cloudy, purulent exudate (Fig. 37-17). Thrombophlebitis of the bridging veins and dural sinuses or obliteration of arterioles by inflammation may develop, causing vascular congestion and infarction in the surrounding tissues. Ultimately, the meninges thicken and adhesions form. These adhesions may impinge on the cranial nerves, giving rise to cranial nerve palsies, or may impair the outflow of CSF, causing hydrocephalus.

The most common symptoms of acute bacterial meningitis are sudden onset of headache, fever, and stiffness of the neck (nuchal rigidity), sometimes accompanied by other symptoms such as vomiting, photophobia, and confusion. The diagnosis of meningitis is often made by obtaining a cerebrospinal fluid (CSF) sample and identifying the causative organism through a Gram stain or other diagnostic tests. Early treatment with antibiotics is essential to prevent complications such as brain abscesses, hearing loss, and neurological sequelae.
by nausea, vomiting, photophobia, and altered mental status. Other signs include seizures, cranial nerve palsies, and focal cerebral signs. Meningococcal meningitis is characterized by a petechial (petite hemorrhagic spots) rash with palpable purpura (bleeding into the skin) in most people. These petechiae vary in size from pinhead to large ecchymoses or even areas of skin gangrene, often associated with rapid onset of hypotension, acute adrenal hemorrhage (Waterhouse-Friderichsen syndrome), and multiple organ failure. Persons infected with *H. influenzae* or *S. pneumoniae* may present with difficulty in arousal and seizures, whereas those with *N. meningitidis* infection may present with delirium or coma. Cranial nerve damage (especially CN VIII, with resulting deafness) and hydrocephalus may occur as complications of pyogenic meningitis.

Diagnosis of bacterial meningitis is based on the history and physical examination, along with laboratory data. A stiff neck is an early sign of meningeal irritation. Moving the neck forward, either actively or passively, is difficult. Two assessment techniques can help determine whether meningeal irritation is present. The **Kernig sign** is resistance to extension of the knee while the person is lying with the hip flexed at a right angle. The **Brudzinski sign** is elicited when flexion of the neck induces flexion of the hip and knee. These postures reflect resistance to the painful stretching of the inflamed meninges from the lumbar level to the head. Lumbar puncture findings, which are necessary for accurate diagnosis, include a cloudy and purulent CSF under increased pressure. Bacteria can be seen on smears and can easily be cultured with appropriate media. Occasionally, previous antibiotic use limits culture sensitivities, in which case latex agglutination or polymerase chain reaction (PCR) testing for *N. meningitidis, H. influenzae,* and *Listeria* species can be used. Because complications associated with lumbar puncture include life-threatening cerebral herniation, at-risk patients (i.e., those who are immunocompromised, had a seizure within a week, have papilledema, or have specific neurologic abnormalities) should have a CT scan before undergoing the procedure.

Treatment includes urgent administration of antimicrobial therapy while diagnostic testing ensues. Delay in initiation of antimicrobial therapy, most frequently because of performance of medical imaging before performance of lumbar puncture or transfer to another medical facility, can result in poor outcomes. Because of the emergence of penicillin- and cephalosporin-resistant strains of *S. pneumoniae*, a combination of antimicrobial agents is usually used. Effective antimicrobial treatment produces rapid lysis of the pathogen, which produces inflammatory mediators that have the potential for exacerbating the abnormalities of the blood–brain barrier. To suppress this pathologic inflammation, adjunctive corticosteroid therapy is increasingly administered with or just before the first dose of antibiotics in patients of all ages.

Persons who have been exposed to someone with meningococcal meningitis should be treated prophylactically with antibiotics. A quadrivalent polysaccharide–protein conjugate vaccine is now available to protect against meningococcal meningitis. The vaccine is recommended for adolescents aged 11 to 18 years, first-year college students living in dormitories, military recruits, and microbiologists with occupational exposure. The vaccine is also recommended for persons aged ≥ 9 months who travel to or reside in regions in which meningococcal disease is endemic and for all persons aged ≥ 2 months with conditions such as complement component deficiencies or anatomic or functional asplenia. The vaccine dosing schedule varies by age at time of previous vaccination.

### Viral Meningitis

Viral meningitis can be caused by many different viruses, most often enteroviruses, including coxsackievirus, poliovirus, and echovirus. Others include Epstein-Barr virus, mumps virus, herpes simplex virus (HSV), and West Nile virus. Often the virus cannot be identified.

Viral meningitis manifests in much the same way as bacterial meningitis, but the course is less severe and the CSF findings are markedly different. There are lymphocytes in the CSF rather than polymorphonuclear cells, the protein content is only moderately elevated, and the sugar content usually is normal. The acute viral meningitides are self-limited and usually require only symptomatic treatment, except for herpes simplex virus (HSV) type 2, which responds to intravenous acyclovir.

### Encephalitis

Encephalitis represents a generalized infection of the parenchyma of the brain or spinal cord. It usually is caused by a virus, but it also may be caused by bacteria, fungi, and other organisms. The nervous system is subject to invasion by many viruses, such as arbovirus, poliovirus, and rabies virus. The mode of transmission may be the bite of a mosquito (arbovirus), a rabid animal (rabies virus), or ingestion (poliovirus). Common causes of encephalitis in the United States are herpes simplex virus (HSV) and West Nile virus. Less-frequent causes of encephalitis are toxic substances such as ingested lead and vaccines for measles and mumps. Encephalitis caused by human immunodeficiency virus (HIV) infection is discussed in Chapter 16.

The pathologic picture of encephalitis includes local necrotizing hemorrhage, which ultimately becomes generalized, with prominent edema. There is progressive degeneration of nerve cell bodies. The histologic picture, although rather general, may demonstrate some specific characteristics. For example, the poliovirus selectively destroys the cells of the anterior horn of the spinal cord.

Like meningitis, encephalitis is characterized by fever, headache, and nuchal rigidity, but more often patients also experience neurologic disturbances, such as lethargy, disorientation, seizures, focal paralysis, delirium, and coma. Diagnosis of encephalitis is made by clinical history and presenting symptoms, in addition to traditional CSF studies.
Types of Tumors

The term brain tumor refers to a collection of intracranial neoplasms, each with its own histology, site of origin, treatment, and prognosis. For most neoplasms, the term malignant is used to describe the tumor’s lack of cell differentiation, its invasive nature, and its ability to metastasize. However, the terms benign and malignant do not apply to brain tumors in the same sense as they do to tumors in other parts of the body. In the brain, even a well-differentiated and histologically benign tumor may grow and cause death because of its location. Also, tumors in the brain are rarely benign because surgery rarely cures. Most histologically benign tumors infiltrate the normal brain tissue, preventing total resection and allowing for tumor recurrence. Furthermore, brain tumors seldom metastasize, except within the CNS itself.

Brain tumors can be divided into three basic types: primary intracranial tumors of neuroepithelial tissue (e.g., neuroglia, neurons), primary intracranial tumors that originate in the cranial cavity but are not derived from the brain tissue itself (e.g., meninges, primary CNS lymphoma, pituitary gland tumors [discussed in Chapter 32]), and metastatic tumors. Collectively, neuroepithelial tumors are the most common type of primary brain tumor in adults, and medulloblastomas the most common type in children. Whatever the type, brain tumors commonly present with symptoms related to a disruption in neuronal activity (seizures), signs of increased ICP (progressive headache, nausea and vomiting, drowsiness, visual abnormalities), focal motor or sensory deficits, and cognitive dysfunction.

Neuroepithelial Tumors

Neuroepithelial tumors, which are the most common form of primary brain tumors, derive from astrocytes, oligodendrocytes, and ependymal cells. Gliomas are divided into four grades: grades I and II are low-grade tumors, whereas grade III and IV are high-grade tumors.

Astrocytomas. There are two types of astrocyte tumors: infiltrating and noninfiltrating astrocytomas. Infiltrating astrocytomas account for 80% of adult primary brain tumors. They occur most commonly in the fourth through the sixth decade. Although they usually are found in the cerebral hemispheres, they also can occur in the cerebellum, brain stem, or spinal cord. The most common presenting signs and symptoms are seizures, headaches, and focal neurologic deficits related to the location of the tumor. Infiltrating astrocytomas are characterized by a spectrum of histologic differentiation that includes diffuse astrocytomas (grade II); anaplastic astrocytomas (grade III); and the least differentiated and most aggressive, glioblastomas (grade IV).

The grade I designation is reserved for the noninfiltrating pilocytic astrocytomas, which are distinguished from other astrocytomas by their cellular appearance and their benign behavior. Typically, they occur in children and young adults and usually are located in the cerebellum, but they also can be found in the floor and walls of the third ventricle, in the optic chiasm and nerves, and occasionally in the cerebral hemispheres. These tumors grow slowly and, in the cerebellum particularly, may be treated by resection.

Oligodendrogliomas. Oligodendrogliomas are tumors of the oligodendrocytes or their precursors. They represent approximately 5% to 15% of neogiolial tumors and are most common in the fourth and fifth decades of life. The tumors are found mostly in the cerebral hemispheres, with a predilection for white matter. The prognosis of persons with oligodendrogliomas is less predictable than for persons with infiltrating astrocytomas.
It depends on the histologic grade of the tumor, its location, and, more recently, recognition of molecular features that can be linked to chemosensitivity.50 Due to their delicate vasculature, the oligodendroglial tumors are prone to spontaneous hemorrhage.

Ependymomas. Ependymomas are derived from the single layer of epithelium that lines the ventricles and spinal canal. Although they can occur at any age, they are most likely to occur in the first two decades of life and most frequently affect the fourth ventricle; they constitute 5% to 10% of brain tumors in this age group.1 In adults, the spinal cord is the most common location. The clinical features depend on the location of the neoplasm. Intracranial tumors are often associated with hydrocephalus and evidence of increased ICP.

Medulloblastomas
Tumors of neuronal origin (e.g., medulloblastomas) usually occur during infancy and childhood.48 This is in accord with the principle that a cell must be capable of replication to undergo neoplastic transformation. Medulloblastoma is thought to originate from a primitive cell type in the cerebellum arising from one of the two cerebellar germinal zones: the ventricular zone that forms the outermost boundary, or the external germinal layer that lines the outside of the cerebellum.

Medulloblastomas have a bimodal distribution, peaking at 3 or 4 years of age and then again at 8 or 9 years of age.48 Children usually present with signs and symptoms of increased ICP (i.e., headache, nausea, vomiting, mental status changes, hypertension) and cerebellar dysfunction (i.e., ataxia, balance problems, movement disorders). The tumor is highly malignant, and the prognosis for untreated children is dismal. However, the tumor is highly radiosensitive; with total excision and irradiation, the 5-year survival rate is as high as 75%.

Meningiomas
Meningiomas develop from the meningotheelial cells of the arachnoid and are outside the brain. They usually have their onset in the middle or later years of life and constitute approximately 20% of primary brain tumors in this age group.1 Meningiomas are slow-growing, well-circumscribed, and often highly vascular tumors. They usually are benign, and complete removal is possible if the tumor does not involve vital structures.

Primary Central Nervous System Lymphomas
Primary CNS lymphomas have increased in incidence by a factor of 10 in the past several decades.14 These deep, periventricular, and diffuse tumors are especially common in immunocompromised persons, including those with acquired immunodeficiency syndrome (AIDS) and immunosuppression after transplantation.

Most primary brain lymphomas are of B-cell origin. Primary lymphomas of the CNS are highly aggressive, and recurrence is common despite treatment. Behavioral and cognitive changes, which are the most common presenting symptoms, occur in about 65% of patients; hemiparesis, aphasia, and visual field deficits in about 50%; and seizures in 15% to 20%.

Metastatic Tumors
Metastatic tumors, mostly carcinomas, affect approximately 20% to 40% of persons with cancer.50 The five most common sites for metastasis are the lung, breast, skin (melanoma), kidney, and gastrointestinal tract.1,52,53 Within the brain there is regional selectivity for growth metastasis from the different primary types of cancer: melanoma is more typically found in the frontal and temporal lobes, breast cancer in the cerebellum and basal ganglia, and non–small cell lung cancer in the occipital lobe. Thus, it appears that tumor-specific interactions with brain tissue mediate the establishment and proliferation of brain metastasis. Recent investigations have begun to elucidate the mechanisms of such molecular mechanisms. For women with breast cancer, hormone receptor and human epidermal growth factor receptor-2 status is predictive of brain metastasis risk.50

Clinically evident brain metastases present with signs of increased ICP, mental status changes, seizures, and focal neurologic deficits. Management of persons with CNS metastasis consists of symptomatic and definitive therapies. The mainstays of symptomatic control are corticosteroids for tumor-related edema, anti-epileptic drugs for seizure control, and multidisciplinary interventions aimed at minimizing neurologic disability.50-52

Manifestations
The clinical manifestations of brain tumors depend on the size and location of the tumor. General signs and symptoms include headache, nausea, vomiting, mental changes, papilledema, visual disturbances (e.g., diplopia), alterations in sensory and motor function, and seizures.7,47 Because the volume of the intracranial cavity is fixed, brain tumors cause a generalized increase in ICP when they reach sufficient size or produce edema. Cerebral edema usually is of the vasogenic type, which develops around the tumors and is characterized by an increased extracellular fluid volume. The edema is thought to result from increased permeability of tumor capillary endothelial cells. Tumors can also obstruct the flow of CSF in the ventricular cavities and produce hydrocephalic dilation of the proximal ventricles and atrophy of the cerebral hemispheres. With very slow-growing tumors, complete compensation of ventricular volumes can occur, but with rapidly growing tumors, increased ICP is an early sign.

The brain itself is insensitive to pain. The headache that accompanies brain tumors results from compression or distortion of pain-sensitive dural or vascular structures. It may be felt on the same side of the head as the tumor, but more commonly is diffuse. In the early stages, the headache is mild and occurs in the morning on awakening and improves with head elevation. The headache becomes more constant as the tumor enlarges.
and often is worsened by coughing, bending, or sudden movements of the head. Vomiting occurs with or without nausea, may be projectile, and is a common symptom of increased ICP and brain stem compression. Direct stimulation of the vomiting center, which is located in the medulla, may contribute to the vomiting that occurs with brain tumors. The vomiting is often associated with headache. Papilledema (edema of the optic disk) results from increased ICP and obstruction of the CSF pathways. It is associated with decreased visual acuity, diplopia, and deficits in the visual fields. Visual defects associated with papilledema often are the reason that persons with a brain tumor seek medical care.

Personality and mental changes such as depression are common with brain tumors. Persons with brain tumors often are irritable initially and later become quiet and apathetic. They may become forgetful, seem preoccupied, and appear to be psychologically depressed. Because of the mental changes, a psychiatric consultation may be sought before a diagnosis of brain tumor is made.

Focal signs and symptoms are determined by the location of the tumor. Tumors arising in the frontal lobe may grow to a large size, increase the ICP, and cause signs of generalized brain dysfunction before focal signs are recognized. Tumors that impinge on the visual system cause visual loss or visual field defects long before generalized signs develop. Certain areas of the brain have a relatively low threshold for seizure activity. Temporal lobe tumors often produce seizures as their first symptom. Hallucinations of smell or hearing and déjà vu phenomena are common focal manifestations of temporal lobe tumors. Brain stem tumors commonly produce upper and lower motor neuron signs, such as weakness of facial muscles and ocular palsies that occur with or without involvement of sensory or long motor tracts. Cerebellar tumors often cause ataxia of gait.

**Diagnosis and Treatment**

The diagnosis of brain tumors relies mainly on MRI. Gadolinium-enhanced MRI is the test of choice for identifying and localizing the presence and extent of tumor involvement. Computed tomographic scans may fail to reveal certain mass lesions such as low-grade tumors or posterior fossa masses. Diagnostic maneuvers that suggest a possible tumor and indicate the need for MRI include physical and neurologic examinations, visual field and funduscopic examination, and sometimes electroencephalography (EEG). Approximately 75% of persons with a brain tumor have an abnormal EEG, which can indicate an underlying structural lesion warranting MRI. Cerebral angiography can be used to visualize the tumor’s vascular supply, information that is important when planning surgery. MRI may be supplemented with positron emission tomography to better characterize the metabolic properties of the tumor, which is useful in planning treatment. Magnetic resonance angiography and CT angiography can be used to distinguish vascular masses from tumors.

The three general methods for treatment of brain tumors are surgery, irradiation, and chemotherapy. Surgery is part of the initial management of virtually all brain tumors; it establishes the diagnosis and achieves tumor removal in many cases. However, the degree of removal may be limited by the location of the tumor and its invasiveness. Stereotactic surgery uses three-dimensional coordinates and CT and MRI to precisely localize a brain lesion. Ultrasonographic technology has been used for localizing and removing tumors. The ultrasonic aspirator, which combines a vibrating head with suction, permits atraumatic removal of tumors from cranial nerves and important cortical areas. An important adjunct to some types of surgery is intraoperative monitoring of evoked potentials. For example, evoked potentials can be used to monitor auditory, visual, speech, or motor responses during surgery done under local anesthesia.

Most malignant brain tumors respond to external irradiation. Irradiation can increase longevity and sometimes can allay symptoms when tumors recur. The treatment dose depends on the tumor’s histologic type, radioresponsiveness, and anatomic site and on the level of tolerance of the surrounding tissue. A newer technique called *gamma knife* combines stereotactic localization of the tumor with radiosurgery, allowing delivery of high-dose radiation to deep tumors while sparing the surrounding brain tissue. Radiation therapy is avoided in children younger than 2 years of age because of the long-term effects, which include developmental delay, panhypopituitarism, and secondary tumors.

The use of chemotherapy for brain tumors is somewhat limited by the blood–brain barrier. Chemotherapeutic agents can be administered intravenously, intra-arterially, intrathecally (i.e., into the spinal canal), as wafers impregnated with a drug and implanted into the tumor at the time of surgery.

Seizure Disorders

A seizure represents an abrupt and transient occurrence of signs and/or symptoms resulting from an abnormal, excessive discharge from an aggregate of neurons in the brain. Manifestations of a seizure, which vary according to site of discharge, can include sensory, motor, autonomic, or psychic phenomena. A convolution refers specifically to a motor seizure involving the entire body. Seizure activity is the most common disorder encountered in pediatric neurology, and among adults its incidence is exceeded only by cerebrovascular disorders. In most persons, the first seizure episode occurs before 20 years of age. After 20 years of age, a seizure is caused most often by a structural change, trauma, tumor, or stroke.

Clinically, seizures may be categorized as provoked (secondary or acute symptomatic) or unprovoked (primary or idiopathic). Provoked seizures may occur during almost all serious illnesses or injuries affecting the brain, including metabolic derangements, infections, tumors, drug abuse, vascular lesions, and brain injury. Unprovoked seizures are those for which no identifiable cause can be determined, and are thought to be genetic. Most unprovoked seizures occur in the setting of an epileptic syndrome. Persons with this type of seizure usually require chronic administration of antiepileptic medications to limit seizure recurrences. Epilepsy is characterized by recurrent seizures that are not provoked by other illnesses or circumstances.

Many theories have been proposed to explain the cause of the abnormal brain electrical activity that occurs with seizures. Seizures may be caused by alterations in permeability or distribution of ions across neuronal cell membranes. Another cause may be decreased inhibition of excitability of neurons. Neurotransmitter imbalances such as an acetylcholine excess or excitability of neurons. Neurotransmitter imbalances such as an acetylcholine excess or $\gamma$-aminobutyric acid (GABA, an inhibitory neurotransmitter) deficiency have also been proposed as causes. Certain epilepsy syndromes have been linked to specific genetic mutations in ion channels.

Provoked Seizures

Provoked seizures include febrile seizures, seizures precipitated by systemic metabolic conditions, and those that follow a primary insult to the CNS. Transient systemic metabolic disturbances may precipitate seizures. Examples include electrolyte imbalances, hypoglycemia, hypoxia, hypocalcemia, uremia, alkalosis, and rapid withdrawal of sedative drugs. Specific CNS injuries such as toxemia of pregnancy, water intoxication, meningitis, trauma, cerebral hemorrhage and stroke, and brain tumors may precipitate a seizure. In most cases of provoked seizures, treatment of the immediate underlying cause often results in their resolution.

Febrile Seizures

One form of provoked seizures is febrile seizures that occur in children, between the ages of 6 and 60 months, with a temperature of 100.4°F (38°C) or higher that is not the result of a CNS infection or metabolic disorder. The fact that febrile seizures occur in this age group suggest that factors related to specific stages of brain development contribute to their occurrence. A simple febrile seizure is a primary generalized seizure associated with fever that lasts for a maximum of 15 minutes and does not recur within a 24-hour period. Between 2% and 5% of neurologically healthy infants experience one simple seizure without any long-term ill effects.

Complex febrile seizures are more prolonged (>15 minutes), are focal, and/or recur within 24 hours. Febrile status epilepticus is a febrile seizure lasting longer than 30 minutes. Whether prolonged febrile seizures lead to epilepsy is still uncertain.

Unprovoked (Epileptic) Seizures

The International League Against Epilepsy (ILAE) Commission on Classification and Terminology determines seizure type by clinical symptoms and EEG activity. It divides epileptic seizures into two broad categories: focal and generalized. Focal seizures are those in which the seizure begins in a specific or focal area of one cerebral hemisphere. Generalized seizures are those which begin simultaneously in both hemispheres. The system also has a category of unknown origin, such as epileptic spasms (Chart 37-1).

Focal Seizures

Focal seizures, which are the most common type of seizures among newly diagnosed cases of epilepsy, can be viewed as those with neural networks limited to one
into six broad categories: tonic–clonic, absence seizures, psychomotor seizures, myoclonic seizures, clonic seizures, and atonic seizures. These seizures are divided according to their manifestations; that is, they may occur without or with impairment of consciousness or awareness.

**Focal Seizures Without Impairment of Consciousness or Awareness.** This type of seizure usually involves one hemisphere and is not accompanied by loss of consciousness or awareness. The observed clinical signs and symptoms depend on the area of the brain where the abnormal electrical activity is taking place. There may be involuntary motor movements; somatosensory disturbances, such as tingling and crawling sensations; or special sensory disturbances, such as visual, auditory, gustatory, or olfactory phenomena. When abnormal cortical discharge stimulates the autonomic nervous system, flushing, tachycardia, diaphoresis, hypotension or hypertension, or pupillary changes may be evident. This type of focal seizure may be preceded by an aura, a term that has traditionally been used to describe the stereotyped warning sign of an impending seizure activity described by the affected person. The aura actually represents a simple partial seizure, affecting only a small area of the brain. A history of an aura is clinically useful to identify the seizure as focal and not generalized in onset. However, absence of an aura does not reliably exclude a focal onset because many focal seizures generalize too rapidly to generate an aura.

**Focal Seizures with Impairment of Consciousness.** These types of seizures, which arise from the temporal lobe, involve impairment of consciousness. The seizure begins in a localized area of the brain but may progress rapidly to involve both hemispheres. These seizures, sometimes referred to as psychomotor seizures, are often accompanied by automatisms or repetitive non-purposeful activities such as lip smacking, grimacing, patting, or rubbing clothing. Confusion during the postictal period (after a seizure) is common. Hallucinations and illusional experiences such as déjà vu (a sense of unfamiliarity with a known environment) have been reported. There may be overwhelming fear, uncontrolled forced thinking or a flood of ideas, and a feeling of detachment and depersonalization. A person with this type of seizure disorder may be misdiagnosed as having a psychiatric disorder.

**Generalized Seizures**

Generalized-onset seizures are the most common type in young children. The seizures are classified as primary or generalized when clinical signs, symptoms, and supporting EEG changes indicate involvement of both hemispheres at onset. The clinical symptoms include unconsciousness and involve varying bilateral degrees of symmetric motor responses without evidence of localization to one hemisphere. These seizures are divided into six broad categories: tonic–clonic, absence seizures (typical, atypical, myoclonic absence, absence of eyelid myoclonia), myoclonic seizures (myoclonic, myoclonic atonic, myotonic clonic), clonic seizures, tonic seizures, and atonic seizures (Chart 37-1).

**Tonic-Clonic Seizures.** Tonic-clonic seizures, formerly called grand mal seizures, are the most common major motor seizures. Frequently, a person has a vague warning (probably a simple focal seizure) and experiences a sharp tonic contraction of the muscles with extension of the extremities and immediate loss of consciousness. Incontinence of bladder and bowel is common. Cyanosis may occur from contraction of airway and respiratory muscles. The tonic phase is followed by the clonic phase, which involves rhythmic bilateral contraction and relaxation of the extremities. At the end of the clonic phase, the person remains unconscious until the RAS begins to function again. This is called the postictal phase. The tonic-clonic phases last approximately 60 to 90 seconds.

**Absence Seizures.** Absence seizures are generalized, nonconvulsive epileptic events and are expressed mainly as disturbances in consciousness. Formerly referred to as petit mal seizures, absence seizures typically occur only in children and cease in adulthood or evolve to generalized motor seizures. Children may present with a history of school failure that predate the first evidence of seizure episodes. Although typical absence seizures have been characterized by a blank stare, motionlessness, and unresponsiveness, motion occurs in many cases of absence seizures. This motion takes the form of automatisms such as lip smacking, mild clonic motion (usually in the eyelids), increased or decreased postural tone, and autonomic phenomena. There often is a brief loss of contact with the environment. The seizure usually lasts only a few seconds, and then the child is immediately able to resume normal activity. The manifestations often are so subtle that they may pass unnoticed.

Atypical absence seizures are similar to typical absence seizures except for greater alterations in muscle tone and less-abrupt onset and cessation. In practice, it is difficult to distinguish typical from atypical absence seizures without the benefit of supporting EEG findings. However, it is important to distinguish between complex focal and absence seizures because the drugs of choice for treatment are different. Medications that are effective for focal seizures may increase the frequency of absence seizures.

**Myoclonic Seizures.** Myoclonic seizures involve brief involuntary muscle contractions induced by stimuli of cerebral origin. A myoclonic seizure involves bilateral jerking of muscles, generalized or confined to the face, trunk, or one or more extremities. Tonic seizures are characterized by a rigid, violent contraction of the muscles, fixing the limbs in a strained position. Clonic seizures consist of repeated contractions and relaxations of the major muscle groups.

**Tonic Seizures.** Similar to the tonic phase of tonic–clonic seizures, tonic seizures are characterized by contraction of the voluntary muscles so that the body stiffens with
legs and arms extended. If the person is standing, they may fall to the ground.

**Clonic Seizures.** Clonic seizures, which are similar to those seen during the clonic phase of a tonic-clonic seizure, are characterized by repetitive rhythmic muscular contractions that are bilateral and symmetric, and are accompanied by hyperventilation.

**Atonic Seizures.** In atonic seizures, there is a sudden, split-second loss of muscle tone leading to slackening of the jaw, drooping of the limbs, and falling to the ground. These seizures also are known as “drop attacks.”

**Diagnosis and Treatment**

The diagnosis of seizure disorders is based on a thorough history and neurologic examination, including a full description of the seizure. The physical examination and laboratory studies help exclude any metabolic disorder (e.g., hyponatremia) that could precipitate seizures. Magnetic resonance imaging scans are used to identify structural defects such as temporal lobe sclerosis or underlying congenital malformations causing the seizure. One of the most useful diagnostic tests is the EEG, which is used to record changes in the brain’s electrical activity. It is used to support the clinical diagnosis of epilepsy, to provide a guide for prognosis, and to assist in classifying the seizure disorder.

The first rules of treatment are to protect the person from injury during a seizure, preserve brain function by aborting or preventing seizure activity, and treat any underlying disease. People with epilepsy should be advised to avoid situations that could be dangerous or life-threatening if seizures occur. The management of seizure disorders focuses on treatment of the underlying conditions that cause or contribute to the seizures, avoidance of precipitating factors, suppression of recurrent seizures by prophylactic therapy with antiepileptic medications, surgery or neurostimulation, and addressing psychological and social issues.

**Antiepileptic Drug Therapy**

Antiepileptic drug therapy is the mainstay of treatment for most persons with epilepsy. It is individualized for each patient based on the different types and causes of seizures as well as medication efficacy and side effects.

Antiepileptic drugs act mainly by suppressing repetitive firing of isolated neurons that act as epileptogenic foci for seizure activity or by inhibiting the transmission of electrical impulses involved in seizure activity. Because of their selective mechanisms of action, different drugs are used to treat the different types of seizures. For example, ethosuximide, which suppresses the brain wave activity associated with lapses of consciousness, is used in the treatment of absence seizures, but is not effective for tonic-clonic seizures that progress from focal seizures.

More than 20 drugs are available for the treatment of epilepsy. This group includes 12 new antiepileptic drugs that have been approved for use in the United States in the past several decades. The goal of pharmacologic treatment is to bring the seizures under control with the least possible disruption in lifestyle and minimum of side effects from the medication. Whenever possible, a single drug should be used. Monotherapy eliminates drug interactions and additive side effects. Determining the proper dose of the anticonvulsant drug is often a long and tedious process, which can be very frustrating for the person with epilepsy. Blood tests are often used to determine that the blood concentration is within the therapeutic range. Consistency in taking the medication is essential. Antiepileptic drug use never should be discontinued abruptly. Special consideration is needed when a person taking an antiepileptic medication becomes ill and must take additional medications. Some drugs act synergistically, and others interfere with the actions of other medications. This situation needs to be carefully monitored to avoid overmedication or interference with successful seizure control.

Women of child-bearing age require special consideration concerning fertility, contraception, and pregnancy. Many of the drugs interact with oral contraceptives; some affect hormone function or decrease fertility. All such women should be advised to take folic acid supplementation. For women with epilepsy who become pregnant, antiseizure drugs increase the risk for congenital abnormalities and other perinatal complications. Carbamazepine, phenytoin, phenobarbital, primidone, and valproic acid can interfere with vitamin D metabolism and predispose to osteoporosis.

**Surgical and Neurostimulation Therapy**

Surgical treatment may be an option for persons with epilepsy who are refractory to drug treatment. With the use of modern neuroimaging and surgical techniques, a single epileptogenic lesion can often be identified and removed without leaving a neurologic deficit. The most common surgery consists of removal of the amygdala and an anterior part of the hippocampus and entorhinal cortex, as well as a small part of the temporal pole, leaving the lateral temporal neocortex intact. Another surgical procedure involves partial removal of the corpus callosum to prevent spread of a unilateral seizure to a generalized seizure.

Neurostimulation, with the development of a variety of different devices and targets of stimulation, is a rapidly evolving field in the treatment of epilepsy. Methods of external (noninvasive) trigeminal stimulation have been developed and are currently being evaluated. These methods seem promising not only as therapy, but also as a useful predictor of success with other forms of stimulation therapy. A subcutaneous implantable device is also being evaluated.

**Generalized Convulsive Status Epilepticus**

Seizures that do not stop spontaneously or occur in succession without recovery are called *status epilepticus.*
Neurocognitive Disorders

Neurocognitive disorders involve changes in spectrum of memory and cognitive functions. Memory is the process by which information is encoded, stored, and later retrieved, while cognition is the process by which information is reduced, elaborated, transformed, and used.

Cognition involves the perception of sensory input and the ability to learn and manipulate new information, recognize familiar objects and recall past experiences, solve problems, think abstractly, and make judgments. Dementia or nonnormative cognitive decline can be caused by any disorder that permanently damages large association areas of the cerebral hemispheres or subcortical areas subserving memory and cognition. It is a common and disabling disorder in the elderly and, because of the rapidly increasing elderly population, is a growing public health problem. The disorder is characterized by impairment of short- and long-term memory, deficits in abstract thinking, impaired judgment and other higher cortical functions, abnormalities of speech, and personality changes. These changes eventually become severe enough that they interfere with day-to-day functioning. Common causes of dementia are Alzheimer disease, vascular dementia, frontotemporal dementia, Wernicke-Korsakoff syndrome, and Huntington chorea.

The diagnosis of dementia is based on assessment of the presenting problem; history about the person that is provided by an informant (someone who has known the person, usually a family member); complete physical and neurologic examination; evaluation of cognitive, behavioral, and functional status; and laboratory and imaging studies. Depression is the most common treatable illness that may masquerade as dementia, and it must be excluded when a diagnosis of dementia is considered. This is important because cognitive functioning usually returns to baseline levels after depression is treated. Screening evaluations for subdural hematoma, cerebral infarcts, cerebral tumors, and normal-pressure hydrocephalus are also recommended. These and other reversible forms of dementia that should be ruled out can be remembered by the mnemonic DEMENTIA: Drugs (drugs with anticholinergic activity), Emotional (depression), Metabolic (hypothyroidism), Eyes and ears (declining vision and hearing), Normal-pressure hydrocephalus, Tumor or other space-occupying lesions, Infection (human immunodeficiency virus infection or syphilis), Anemia (vitamin B12 or folate deficiency).

Alzheimer Disease

Dementia of the Alzheimer type is the most common type of dementia. The disorder affects more than 5.2 million Americans, and is the sixth leading cause of death. The risk for development of Alzheimer disease (AD) increases with age, starting at a level of 4% of persons under age 65 years, 13% of persons 65 to 74 years, 44% of persons 75 to 84 years, and 38% of persons age 85 years or older.69
Pathology

Alzheimer disease most often presents with a subtle onset of memory loss followed by slowly progressive dementia that has a course of several years. Evidence from familial forms of AD indicates that the accumulation of a peptide (amyloid beta or Aβ) in the brain initiates a chain of events that result in the morphologic changes of AD and dementia. This peptide is derived from a larger membrane-spanning protein known as amyloid precursor protein (APP), which can be processed in either of two ways. It can be cleaved by the enzymes, α-secretase and γ-secretase, in a proteolytic pathway that prevents the formation of Aβ, or it can be cleaved by β-secretase and γ-secretase in a pathway that generates Aβ.

Diagnostic imaging of the brain reveals diffuse atrophy of the cerebral cortex with enlargement of the ventricles (Fig. 37-18). The major microscopic features of Alzheimer disease include neuritic (senile) plaques, patches or flat areas composed of clusters of degenerating nerve terminals arranged around a central amyloid core. In the cytoplasm of abnormal neurons are neurofibrillary tangles, which consist of fibrous proteins that are wound around each other in a helical fashion. These tangles are resistant to chemical or enzymatic breakdown, and they persist in brain tissue long after the neuron in which they arose has died and disappeared. Smaller cerebral vessels also exhibit amyloid angiopathy, in which there is deposition of Aβ in vessel walls.

Some plaques and tangles can be found in the brains of older persons who do not show cognitive impairment. The number and distribution of the plaques and tangles appear to contribute to the intellectual deterioration that occurs with Alzheimer disease. In persons with the disease, the plaques and tangles are found throughout the neocortex and in the hippocampus and amygdala, with relative sparing of the primary sensory cortex. Hippocampal function in particular may be compromised by the pathologic changes. The hippocampus is crucial to information processing, acquisition of new memories, and retrieval of old memories.

Neurochemically, AD has been associated with a decrease in the level of choline acetyltransferase activity in the cortex and hippocampus. This enzyme is required for the synthesis of acetylcholine, a neurotransmitter that is associated with memory. The reduction in choline acetyltransferase is quantitatively related to the numbers of neuritic plaques and severity of dementia.

It is likely that AD is caused by several factors that interact differently in different persons. Progress in the genetics of inherited early-onset AD shows that mutations in at least three genes—the APP gene on chromosome 21; presenilin-1 (PS1), a gene on chromosome 14; and presenilin-2 (PS2), a gene on chromosome 1—can cause AD in certain families. The APP gene is associated with an autosomal dominant form of early-onset AD and can be tested clinically. Virtually all persons with Down syndrome (trisomy 21) exhibit the pathologic features of AD as they age. Presenilin-1 and presenilin-2, both intracellular proteins, are components of γ-secretase and possibly part of a multiprotein complex containing the proteolytic site for breakdown of Aβ.

A fourth gene, the apolipoprotein E (ApoE) gene, has been found to increase the risk of AD and lowers the age of onset of the disease. The gene, which is found on chromosome 19, has three common alleles—E2, E3, or E4. Each person inherits one copy of the gene from each parent. An increased risk of late-onset and sporadic AD is associated with inheritance of the E4 gene, particularly if it is inherited from both parents. Conversely, the E2 gene may confer some protection. The age of onset in late-onset AD also correlates with the gene, with E4/E4

![FIGURE 37-18. Functional imaging of the brain with positron emission tomography (PET). Perfusion and metabolism in a normal brain (A) and hypoperfusion and hypometabolism due to brain atrophy in a brain with Alzheimer disease (B) (From Alzheimer’s Disease: Unraveling the Mystery Images. National Institutes of Health, National Institute of Aging.)](image-url)
inherited exhibiting the earliest age (younger than 70 years). The APOE genotype is not, however, an absolute determinant of who will develop AD. Just how these different APOE alleles influence the risk of AD continues to remain poorly understood.

**Manifestations**

Alzheimer-type dementia follows an insidious and progressive course. The hallmark symptoms are loss of short-term memory and denial of such memory loss, with eventual disorientation, impaired abstract thinking, apraxias, and changes in personality and affect. Various stages of the disease have been recognized; all are characterized by progressive degenerative changes. The initial changes are often subtle, characterized by a short-term memory loss that often is difficult to differentiate from the normal memory loss that often occurs in the elderly, and usually is reported by caregivers and denied by the person. Although most elderly persons have trouble retrieving from memory incidental information and proper names, persons with AD randomly forget important and unimportant details. They forget where things are placed, get lost easily, and have trouble remembering appointments and performing novel tasks. Mild changes in personality, such as lack of spontaneity, social withdrawal, and loss of a previous sense of humor, occur during this stage.

As the disease progresses, the person with AD enters the moderate stage. This stage may last several years and is marked by a more global impairment of cognitive functioning. During this stage, there are changes in higher cortical functioning needed for language, spatial relationships, and problem solving. Depression may occur in persons who are aware of their deficits. There is extreme confusion, disorientation, lack of insight, and inability to carry out the activities of daily living. Personal hygiene is neglected, and language becomes impaired because of difficulty in remembering and retrieving words. Behavioral changes can include agitation, sleep problems, restlessness and wandering, aggression, and suspiciousness. Some persons may become hostile and abusive toward family members. Persons who enter this stage become unable to live alone and should be assisted in making decisions about supervised placement with family members or friends or in a community-based facility.

Severe AD is the last stage of the disease. It is characterized by a loss of ability to respond to the environment. Individuals in this stage require total care and spend most of their time bedridden. Death can occur as a result of complications related to chronic debilitation.

**Diagnosis and Treatment**

Alzheimer disease is essentially a diagnosis of exclusion. There are no peripheral biochemical markers or tests for the disease. The diagnosis can be confirmed only by microscopic examination of tissue obtained from a cerebral biopsy or at autopsy. The diagnosis is based on clinical findings.

A diagnosis of Alzheimer disease requires the presence of dementia established by clinical examination and documented by results of a Mini-Mental State Examination, Blessed Dementia Test, or similar mental status test; no disturbance in consciousness; onset between 40 and 90 years of age, most often after 65 years of age; and absence of systemic or brain disorders that could account for the memory or cognitive deficits. Brain imaging, CT scan, or MRI is done to exclude other brain disease. Metabolic screening should be done for known reversible causes of dementia such as vitamin B12 deficiency, thyroid dysfunction, and electrolyte imbalance.

There is no curative treatment for Alzheimer disease. Drugs are used primarily to slow the progression and to control depression, agitation, or sleep disorders. Two major goals of care are maintaining the person’s socialization and providing support for the family. Self-help groups that provide support for family and friends have become available, with support from the AD and Related Disorders Association. Day care and respite centers are available in many areas to provide relief for caregivers and appropriate stimulation for the patient.

Although there is no current drug therapy that is curative for Alzheimer disease, cholinesterase inhibitors have been shown to be effective in slowing the progression of the disease by potentiating the action of available acetylcholine. These drugs (e.g., donepezil, rivastigmine, galantamine) inhibit acetylcholinesterase, preventing the metabolism of endogenous acetylcholine, and are used in the early stages of the disease for mild cognitive impairment. Again, such therapy does not halt the disease but can slow its progression. Memantine, an N-methyl-D-aspartate antagonist, has been approved by the FDA for treatment of moderate to severe AD. This medication may act by interfering with the glutamatergic excitotoxicity caused by the ischemia (discussed under mechanisms of brain injury) and amyloid deposits associated with the disease, or it may provide symptomatic improvement through effects on the function of hippocampal neurons. This medication, like the cholinesterase inhibitors, modestly delays functional loss.

Other treatments for Alzheimer disease include agents that are thought to have a neuroprotective effect. Aβ seems to exert its neurotoxic effects through a variety of secondary mechanisms, including oxidative injury and lipid peroxidation of cell membranes, and inflammation. Several strategies have involved the use of anti-inflammatory agents and antioxidants (vitamins E and C). Several, but not all, epidemiologic studies provide evidence supporting the concept that vitamin E and vitamin C have a role in delaying the onset of AD. In some, but not all, trials, *G. biloba* had small but statistically significant effects compared with placebo in persons with Alzheimer disease.

Psychotropic medications, such as antipsychotics and mood stabilizers, may be used to assist in the behavioral management of the disease. Interventions also include environmental adjustments, behavioral intervention, and education and support for caregivers.
Other Types of Dementia

Cerebrovascular injury, brain tissue atrophy, alcoholism, and genetic disorders can also result in dementia.

Vascular Dementia

Vascular dementia is caused by brain injury resulting from ischemic or hemorrhagic damage. Vascular dementia is the second most common cause of cognitive impairment in the elderly. The incidence is closely associated with hypertension, but also with arrhythmias, stroke, peripheral vascular disease, lipid abnormalities, and diabetes mellitus. The usual onset is between the ages of 55 and 70 years, and more men are affected than women. The vessel disorders associated with vascular dementia include atherosclerosis, small vessel disease, cerebral amyloid angiopathy, brain infarcts, and cerebral hemorrhage. In addition to the impact of cerebral vascular lesions on dementia, the association between Alzheimer disease and vascular dementia points to a possible pathogenic link between AD and blood vessel causes of dementia.

Slowness in psychomotor functioning is a main clinical feature of this dementia, and symptoms of depression are present in up to 60% of patients with this disease. The onset may be gradual or abrupt, the course usually is a stepwise progression, and there are focal neurologic symptoms related to local areas of infarction.

Frontotemporal Dementia

Frontotemporal dementia (FTD) refers to a group of disorders associated with atrophy of the frontal and anterior temporal lobes of the brain. Originally known as Pick disease, FTD now refers to a syndrome that includes primary progressive aphasia, corticobasal degeneration, progressive supranuclear palsy, and semantic dementias. The disease often begins between 45 and 64 years of age, and is one of the most common forms of dementia in persons younger than 65 years.

The pathophysiology of FTD is not well understood. The disease is characterized by extensive atrophy of the frontotemporal regions, with the involved cortex being severely depleted of neurons. Most recently, mutations of the progranulin gene on chromosome 17 have been associated with intranuclear inclusions found in the brain tissue of persons with the disorder. Progranulin is a growth factor with multiple functions, including neuronal survival. Other than mutations linked to chromosome 17, several other chromosomes have been implicated in FTD, including mutations in chromosomes 3 and 9.

There are two distinct clinical presentations of FTD: behavior and language. The former is more common, with behavioral presentations of disinhibited and impulsive actions or apathy, with inappropriate social behavior. Unlike Alzheimer disease, which usually begins with memory difficulties, FTD begins with very disruptive behaviors that can be quite extreme, and can be misdiagnosed as schizophrenia or psychotic depression. The second type of FTD behavior involves disturbances in understanding or expressing language.

Diagnosis of FTD is based on evidence of cognitive impairment and exclusion of other illnesses that cause cognitive and behavioral deficits. Neuroimaging can be helpful in distinguishing FTD from other types of cognitive disorders. Typically, structural imaging shows anterior temporal and frontal lobe atrophy.

There is no specific cure for FTD. Treatment is focused on symptom management and support for patients, families, and caregivers. Current research focuses on molecular biology to better understand the underlying disease and the potential for identification of novel treatments, particularly disease-modifying treatments.

Wernicke-Korsakoff Syndrome

Wernicke-Korsakoff syndrome most commonly results from chronic alcoholism. Wernicke disease is characterized by acute weakness and paralysis of the extraocular muscles, nystagmus, ataxia, and confusion. The affected person also may have signs of peripheral neuropathy. The person has an unsteady gait and complains of diplopia. There may be signs attributable to alcohol withdrawal such as delirium, confusion, and hallucinations. This disorder is caused by a deficiency of thiamine (vitamin $B_6$), which directly interferes with production of glucose, the brain’s main nutrient. Many of the symptoms are reversed when nutrition is improved with supplemental thiamine.

The Korsakoff component of the syndrome involves the chronic phase with severe impairment of recent memory. There often is difficulty in dealing with abstractions, and the person’s capacity to learn is defective. Confabulation (i.e., recitation of imaginary experiences to fill in gaps in memory) probably is the most distinctive feature of the disease. Polyneuritis also is common. Unlike Wernicke disease, Korsakoff psychosis does not improve significantly with treatment.

Huntington Disease

Huntington disease (HD) is a hereditary disorder characterized by chronic progressive chorea, psychological changes, and dementia. Although the disease is inherited as an autosomal dominant disorder, the age of onset most commonly is in the fourth and fifth decades. By the time the disease has been diagnosed, the person often has passed the gene on to his or her children. Approximately 10% of HD cases are juvenile onset. Children with the disease rarely live to adulthood.

Huntington disease is caused by a polyglutamine trinucleotide repeat expansion in the HD gene. The HD gene, located on chromosome 4, encodes a protein known as huntingtin. Normal HD genes contain 6 to 35 copies of the trinucleotide repeat; an expansion of repeats beyond this level is associated with disease. There is an inverse relationship between repeat number and age of onset, such that longer repeats are associated with earlier onset. Repeat expansions occur during spermatogenesis, so that paternal transmission is associated with early onset in the next generation. Although the biologic function of normal huntingtin remains unknown, there is little evidence to suggest...
that the disease is caused by an insufficiency related to the mutated gene. Rather, the expansion of the polyglutamine region of the HD gene seems to bestow a toxic gain of function on the protein.1

Huntington disease produces localized death of brain cells. The first and most severely affected neurons are those of the basal ganglia that modulate motor output. These neurons normally function to dampen motor activity; thus, their degeneration in HD results in increased motor output, often manifested as choreiform movements. Although chorea is the prototypical movement disorder, the full spectrum of motor impairment in HD includes eye movement disorders, myoclonus, ataxia, dysarthria and dysphagia, and spasticity. Depression and personality changes are the most common early psychological manifestations; memory loss often is accompanied by impulsive behavior, moodiness, antisocial behavior, and a tendency toward emotional outbursts. Persons with HD universally go through cognitive decline, mental slowing, and impaired problem-solving abilities, and eventually become demented. Cognitive decline also heralds the juvenile onset of HD.

There is no cure for Huntington disease. The treatment is largely symptomatic. Drugs may be used to treat the dyskinesias and behavioral disturbances. Genetic testing can predict whether a person will develop the disease.

SUMMARY CONCEPTS

- Cognition refers to all the processes by which sensory input is transformed, reduced, elaborated, stored, recovered, and used.

- Dementia represents a syndrome of deterioration in cognitive function severe enough to interfere with occupational or social performance. The most common cause of dementia is Alzheimer disease, an insidious and progressive disorder that begins with memory impairment and terminates in an inability to recognize family or friends and the loss of control over bodily functions.

- Other forms of dementia include vascular dementia due brain injury resulting from ischemic or hemorrhagic damage; frontotemporal dementia with atrophy of the frontal and temporal lobes; Wernicke-Korsakoff syndrome most often resulting from chronic alcoholism; and Huntington disease, a hereditary disorder characterized by chronic and progressive chorea, psychological changes, and dementia.

1. A 20-year-old man who was an unbelted driver involved in a motor vehicle accident presents in coma.
   A. What are the clinical signs of coma?
   B. What areas of the brain are involved in coma?
   C. Which complications of traumatic head injury might lead to coma?
   D. What are the key treatment options to manage elevated intracranial pressure?

2. A 65-year-old woman presents with a 1-hour history of right-sided weakness and aphasia. An immediate CT scan of the brain is negative.
   A. Where is the brain pathology?
   B. What are the indications to administer intravenous tissue plasminogen activator?
   C. What are the possible causes of stroke, and what diagnostic tests would reveal the cause?

3. A child is taken to the emergency department with lethargy, fever, and a stiff neck on examination.
   A. What findings on initial lumbar puncture indicate bacterial versus viral meningitis?
   B. In the case of bacterial meningitis, what are the most likely organisms, and which antibiotics should be started?

4. A 60-year-old man develops involuntary shaking of his right arm that spreads to the face, after which he collapses with whole-body shaking and loss of consciousness. After 1 minute, the shaking stops and he is confused and disoriented.
   A. What type of seizure is suggested by the clinical manifestations?
   B. Assuming this is his first seizure, what diagnostic tests should be performed to identify a cause for the seizure?
   C. If he has a long history of similar recurrent seizures, what treatments should be instituted? What treatments should be considered if he has failed multiple adequate trials of anticonvulsant medications?

The special senses allow us to view and hear what is going on around us, to maintain our balance, and to communicate effectively with others. This chapter focuses on the eye and disorders of vision; the ear and disorders of hearing; and the vestibular system and disorders of equilibrium and balance.

The Eye and Disorders of Vision

There are 286 million people worldwide who are visually impaired—38 million are blind and 248 million have partial vision loss that cannot be corrected. Disorders of vision can result from a number of conditions including those that affect the lens (cataract), retina (retinopathy and macular degeneration), and intraocular pressure (glaucoma) (Fig. 38-1).

General Structure of the Eye

The optic globe, commonly called the eyeball, is a remarkably mobile, nearly spherical structure contained in a pyramid-shaped cavity of the skull called the orbit. The eyeball is composed of three layers: an outer layer, which includes the white, opaque sclera and the transparent cornea; a middle vascular layer called the uvea, which includes the choroid, ciliary body, and iris; and an inner neural layer, which includes an outer pigment epithelium and an inner neural retina (Fig. 38-2). Exposed surfaces of the eyes are protected by the eyelids, which are mucous membrane–lined skin flaps that provide a means for shutting out most light. Tears bathe the anterior surface of the eye, keeping the conjunctiva and corneal epithelium moist and washing away foreign material.
Disorders of the Conjunctiva and Cornea

The conjunctiva is a thin layer of mucous membrane that lines the anterior surface of both eyelids as the palpebral conjunctiva and folds back over the anterior surface of the optic globe as the ocular or bulbar conjunctiva (see Fig. 38-2). The bulbar conjunctiva covers the sclera or white portion of the eyeball, but not the cornea. The conjunctiva provides a barrier against foreign objects and produces lubricating mucus that bathes the eye and keeps it moist.

The cornea functions as a protective membrane and transparent window through which light passes as it...
moves toward the retina (Fig. 38-3A). The cornea also contributes to the refraction (i.e., bending) of light rays and focusing of vision.

Although transparent, the cornea consists of three cellular layers: an extremely thin outer epithelial layer, which is continuous with the bulbar conjunctiva; a middle layer called the substantia propria; and an inner endothelial layer, which lies next to the aqueous humor of the anterior chamber. The substantia propria is composed of regularly arranged collagen bundles embedded in a mucopolysaccharide matrix. This organization of the collagen fibers, which makes the substantia propria transparent, is necessary for light transmission. Hydration within a limited range is necessary to maintain the spacing of the collagen fibers and transparency. The three layers of the cornea are separated by two important basement membranes; Bowman and Descemet membranes (Fig. 38-3B). Bowman membrane, which lies between the corneal epithelium and the underlying corneal stroma, acts as a barrier to infection. It does not regenerate; if damaged, an opaque scar forms that can impair vision. Descemet membrane, which lies between the corneal endothelium and stroma, has a feltlike appearance and consists of interwoven fibers and pores. Unlike Bowman membrane, it regenerates readily after injury.

The cornea is avascular and obtains its nutrient and oxygen supply by diffusion from the blood vessels of the adjacent sclera, the aqueous humor at its deep surface, and tears that bathe its surface. The corneal epithelium is heavily innervated by sensory neurons. Epithelial damage causes discomfort that ranges from a foreign body sensation and burning of the eyes to severe, incapacitating pain. Reflex lacrimation is also common.

**Conjunctivitis**

 Conjunctivitis, or inflammation of the conjunctiva (i.e., red eye), is one of the most common eye disorders. Most cases are due to viral or bacterial infections. Other causes include allergens, chemical agents, and physical irritants. The mode of transmission of infectious conjunctivitis is usually direct contact by way of the fingers,
towels, etc., to the opposite eye or other persons. It may also be through contaminated eye drops.

Depending on the cause, conjunctivitis can vary in severity from a mild hyperemia (redness) with tearing to severe conjunctivitis with purulent drainage. The conjunctiva is extremely sensitive to irritation and inflammation. Symptoms of conjunctivitis include foreign body sensation, a scratching or burning sensation, itching, and photophobia or light sensitivity. Severe pain suggests corneal rather than conjunctival disease. A discharge, or exudate, may be present. It is usually watery when the conjunctivitis is caused by allergy, a foreign body, or viral infection, and mucopurulent (mucus mixed with pus) in the presence of bacterial or fungal infection. Infectious forms of conjunctivitis are usually bilateral, whereas unilateral disease suggests sources of irritation such as foreign bodies.

The diagnosis of conjunctivitis is based on history, physical examination, and microscopic and culture studies to identify the cause. Because a red eye may be the sign of several eye conditions, it is important to differentiate between redness caused by conjunctivitis, which affects peripheral conjunctival blood vessels (Fig. 38-4), and that caused by more serious eye disorders, such as corneal lesions and acute glaucoma, which affects blood vessels radiating around the edge of the cornea. Conjunctivitis also produces only mild discomfort compared with the moderate to severe discomfort associated with corneal lesions or the severe and deep pain associated with acute glaucoma.

**Viral Conjunctivitis.** Adenoviruses are the most common causes of viral conjunctivitis. The infection, which is highly contagious, causes generalized conjunctival hyperemia, copious tearing, and minimal exudate, and is often accompanied by pharyngitis, fever, and malaise. Viral conjunctivitis usually spreads through direct contact with contaminated fingers, swimming pool water, or personal items. Children are affected more often than adults. The disease usually lasts for at least 2 weeks and may be complicated by visual symptoms due to epithelial and subepithelial corneal involvement. There is no specific treatment for this type of viral conjunctivitis. Preventive measures include hygienic measures and avoiding shared use of eyedroppers, eye makeup, goggles, and towels. Persons who use contact lenses should wear them until the infection clears.

**Bacterial Conjunctivitis.** Common agents of bacterial conjunctivitis are staphylococci, streptococci (particularly *S. pneumoniae*), *Haemophilus* species, *Pseudomonas*, and *Moraxella*. The infection usually is characterized by large amounts of yellow-green drainage. The eyelids are sticky, and there may be excoriation of the lid margins. Treatment measures include local application of antimicrobial agents. The disorder usually is self-limited, lasting approximately 10 to 14 days if untreated and 1 to 3 days if properly treated.

Gonorrheal conjunctivitis, usually acquired through contact with genital secretions, is a severe, sight-threatening ocular infection. The symptoms, include conjunctival redness and edema; lid swelling and tenderness; and swollen preauricular lymph nodes. Treatment includes systemic antimicrobial drugs supplemented with ocular antimicrobials. Because of the increasing prevalence of penicillin-resistant *N. gonorrhoeae*, the choice of an antimicrobial agent should be determined by current information regarding antimicrobial sensitivity.

**Chlamydial, or inclusion, conjunctivitis,** is usually a benign, suppurrative conjunctivitis transmitted by the types of *Chlamydia trachomatis* (serotypes D through K) that causes venereal infections (see Chapter 41). It is commonly spread by contact with genital secretions and occurs in newborns of mothers with *C. trachomatis* infections of the birth canal. It is usually treated with appropriate oral antimicrobial agents.

Trachoma, a more serious form of infection, is caused by a different strain of *C. trachomatis* (serotypes A, B, and C). This form of chlamydial infection affects the conjunctiva and causes ulceration and scarring of the cornea. It is the leading cause of preventable blindness in the world, and is seen mostly in developing countries. It is transmitted by direct human contact, contaminated objects (fomites), and flies.

**Allergic Conjunctivitis.** Allergic conjunctivitis encompasses a spectrum of conjunctival conditions usually characterized by itching. The most common of these is seasonal allergic rhinoconjunctivitis, or hay fever. Seasonal allergic conjunctivitis is an immunoglobulin E (IgE)-mediated hypersensitivity reaction precipitated by small air-borne allergens such as pollens. It typically causes bilateral tearing, itching, and redness of the eyes.

The treatment of seasonal allergic rhinoconjunctivitis includes allergen avoidance and the use of cold compresses and eye washes with tear substitute. Allergic conjunctivitis also has been successfully treated with topical mast cell stabilizers, histamine type 1 (H1) receptor antagonists, and topical nonsteroidal anti-inflammatory drugs. Systemic antihistamines may be useful in prolonged allergic conjunctivitis. In severe cases, a short course of topical corticosteroids may be required to afford symptomatic relief.

![FIGURE 38-4. Gonococcal conjunctivitis of right eye. Note injection (redness) of the peripheral conjunctival blood vessels. (From the Centers for Disease Control and Prevention Public Health Image Library. No. 6784.)](image)
**Corneal Trauma**

The integrity of the epithelium and endothelium is necessary to maintain hydration of the cornea within a limited range. The integrity of the endothelium is more important than the epithelium, and damage to the endothelial cells is far more serious, causing edema of the cornea and loss of transparency. With corneal edema, the cornea appears dull, uneven, and hazy; visual acuity decreases; and iridescent vision (i.e., rainbows around lights) occurs.

Trauma that causes abrasions of the cornea can be extremely painful, but if minor, the abrasions usually heal in a few days. The epithelial layer can regenerate, and small defects heal without scarring. If the stroma is damaged, healing occurs more slowly, and the danger of infection is increased. Injuries to the Bowman membrane and the stromal layer heal with scar formation that impairs the transmission of light.

**Keratitis**

*Keratitis*, or inflammation of the cornea, can be caused by infections, misuse of contact lenses, hypersensitivity reactions, ischemia, trauma, defects in tearing, and interruption in sensory innervation, as occurs with local anesthesia. Scar tissue formation due to keratitis is the limitation in sensory innervation, as occurs with local anesthesia. Keratitis can be infectious or noninfectious and non-ulcerative or ulcerative. In non-ulcerative keratitis, all the layers of the epithelium may be affected, but the epithelium remains intact. There are a number of causes of epithelial keratitis, including epidemic keratoconjunctivitis caused by adenoviruses 8 and 19 and ultraviolet (UV) light exposure. Most cases of UV keratitis occur in welders with inadequate eye protection, but may also occur with tanning booth and other UV lamp exposure, and from sun reflecting off snow.

*Ulcerative keratitis* is an inflammatory process in which parts of the corneal epithelium, stroma, or both are destroyed. Causes of ulcerative keratitis include infectious agents (e.g., *S. aureus*, *S. pneumoniae*, *C. trachomatis*), exposure trauma, and use of extended-wear contact lenses (i.e., *Pseudomonas* and *Acanthamoeba* keratitis). Bacterial keratitis is aggressive and demands immediate care. *Moorens ulcer* is a chronic, indolent, but painful ulcerative keratitis that occurs in the absence of infection. It is usually seen in older persons and may affect both eyes. Although the cause is unknown, an autoimmune origin is suspected.

*Herpes Simplex Keratitis*. Herpes simplex virus (HSV) keratitis, which usually is unilateral, is an important cause of ocular morbidity. With the exception of neonatal infections, which are usually due to HSV type 2 (genital herpes) acquired during the birth process, most cases of herpes keratitis are caused by HSV type 1 (labial [lip] herpes). The disease can occur as either a primary or recurrent infection. Primary epithelial infections are the optical counterpart of labial herpes with similar immunologic and pathologic features as well as a similar time course (see Chapter 46).

The first manifestations of recurrent herpes keratitis are irritation, photophobia, and tearing. Some reduction in vision may occur when the lesion affects the central part of the cornea. Because corneal anesthesia occurs early in the disease, the symptoms may be minimal. A history of fever blisters or other herpetic infection is often noted, but corneal lesions may be the only sign of recurrent herpes infection. Typically, the corneal lesions involve the epithelium and heal without scarring. Lesions that involve the stromal layer of the cornea produce increasingly severe corneal opacities.

Any person with herpes simplex keratitis and an acute red eye should be referred urgently to an ophthalmologist. The treatment of HSV keratitis includes the use of topical antiviral agents to promote healing. Oral antiviral agents (e.g., acyclovir) may be helpful for treatment of severe keratitis and as prophylaxis against recurrence, particularly in persons with compromised immune function. Although corticosteroids may control the damaging inflammatory responses, they do so at the expense of facilitating viral replication. With a few exceptions, their use is contraindicated.

*Varicella Zoster Ophthalmicus*. Herpes zoster or *shingles* is a relatively common infection due to the herpesvirus that causes varicella (chickenpox). Herpes ophthalmicus, which represents 10% to 25% of all cases of herpes zoster, occurs when reactivation of the latent virus occurs in the ganglia of the ophthalmic division of the trigeminal nerve. Immunocompromised persons, particularly those with human immunodeficiency virus (HIV) infection, are at higher risk for developing herpes zoster ophthalmicus than those with a normally functioning immune system.

Herpes zoster ophthalmicus usually presents with malaise, fever, headache, and burning and itching of the periorbital area. These symptoms commonly precede the ocular eruption by a day or two. The rash, which is initially vesicular, becomes pustular and then crusting (see Chapter 46). Involvement of the tip of the nose and lid margins indicates a high likelihood of ocular involvement. Ocular signs include conjunctivitis, keratitis, and anterior uveitis, often with elevated intraocular pressure. Persons with corneal disease present with varying degrees of decreased vision, pain, and sensitivity to light.

Treatment includes the use of oral and intravenous antiviral drugs. Initiation of treatment within the first 72 hours after the appearance of the rash reduces the incidence of ocular complications but not the postherpetic neuralgia (see Chapter 35). Many cases of herpes zoster and herpes zoster ophthalmicus can now be prevented with the herpes zoster vaccine.

*Acanthamoeba Keratitis*. *Acanthamoeba* is a free-living cyst-forming protozoan that thrives in polluted water containing bacteria and organic material. *Acanthamoeba* keratitis is a rare but sight-threatening complication that typically occurs in people who wear...
soft contact lens, particularly overnight or without proper disinfection. It also may occur in non–contact lens wearers after exposure to contaminated water or soil.

Acanthamoeba keratitis is characterized by severe pain, redness of the eye, and photophobia. Diagnosis is confirmed by scrapings and culture with specially prepared medium. In the early stages of infection, epithelial debridement may be beneficial. Treatment includes intensive use of topical antimicrobials. However, the organism may encyst within the corneal stroma, making treatment more difficult. Keratoplasty may be necessary in advanced disease to arrest the progression of the infection.

Disorders of the Lens

The lens is a remarkable structure, which like that in a camera, functions to bring images into focus on the retina. The lens is an avascular, transparent, biconvex structure, the posterior side of which is more convex than the anterior side. It is positioned just posterior to the iris and is held in place by suspensory ligaments known as the zonules, which are composed of numerous fibrils that arise from the ciliary body (see Fig. 38-3B). The pull of the zonular fibers and lens capsule is normally under tension, causing the lens to have a flattened shape for distant vision. Relaxation of the fibers allows the lens to assume a more spherical shape for near vision. There are no pain fibers, blood vessels, or nerves in the lens.

The lens has three principal components: the lens capsule, a subcapsular epithelium, and lens fibers. The lens capsule is a transparent elastic structure that envelopes the entire lens. The subcapsular epithelium is a cuboidal layer of cells that is present on the anterior surface of the lens. The lens fibers, which constitute the bulk of the lens, continue to produce new fibers throughout life, with the older fibers being compressed into the central nucleus of the lens. This causes the lens to gradually become larger and less elastic with age.

Refraction refers to deflection or bending of light as it passes from one transparent medium to another of different density. When parallel light rays pass through the center of a lens, their direction is not changed; however, the divergent rays passing peripherally through a lens are bent (Fig. 38-5A). The refractive power of a lens is usually described as the distance (in meters) from its surface to the point at which the rays come into focus on the retina (i.e., focal length). Usually, this is reported as the reciprocal of this distance (i.e., diopters). For example, a lens that brings an object into focus at 0.5 m has a refractive power of 2 diopters (1.0/0.5 = 2.0). The closer the object, the more divergent the peripheral rays, and the stronger and more precise the focusing system must be.

In the eye, the major refraction of light begins at the convex corneal surface. Further refraction occurs as light moves from the posterior corneal surface to the aqueous humor, from the aqueous humor to the anterior lens surface, from the anterior lens surface to the posterior lens surface, and from the posterior lens surface to the vitreous humor.

Disorders of Refraction

A perfectly shaped eyeball and cornea result in optimal visual acuity, producing a sharp image in focus at all points on the surface of the retina. Unfortunately, individual differences in eyeball length result in inappropriate focal image formation. If the anterior-posterior dimension of the eyeball is too short, the point of focus will fall behind the retina. This is called hyperopia, or farsightedness (see Fig. 38-5B). In such cases, the accommodative changes of the lens (to be discussed) can bring distant images into focus, but near images become blurred. If the anterior-posterior dimension of the eyeball is too long, the focus point falls in front of the retina. This condition is called myopia, or nearsightedness (see Fig. 38-5C). Persons with myopia can see close objects without a problem because accommodative changes in their lens bring near objects into focus, but distant objects are blurred. A refractive defect of the corneal surface, or astigmatism, is usually the result.
of an asymmetric bowing of the cornea, but it also can result from defects in the cornea, lens, or retina.

Both hyperopia and myopia, as well as astigmatism, can be corrected with the appropriate lens. Refractive corneal surgeries such as laser in situ keratomileusis (LASIK), photorefractive keratotomy, and radial keratotomy can be performed to correct the corneal curvature in persons with myopia.\(^{17}\)

**Disorders of Accommodation**

The ability of the eye to adjust its focus from far to near objects by changing the shape of its lens is called accommodation. Accommodation is associated with convergence of the eyes (focusing the vision on a near point), pupillary constriction, and thickening of the lens through contraction of the ciliary muscle of the eye.\(^{16}\) Contraction of muscle fibers in the ciliary body is controlled mainly by parasympathetic stimulation of the oculomotor nerve (CN III). Paralysis of the ciliary muscle resulting in pupillary dilation, with loss of accommodation, is called cycloplegia. Pharmacologic cycloplegia through the use of a topical anticholinergic agent is sometimes used to aid in refractive examination of the eye, particularly in small children.

The term presbyopia refers to a decrease in accommodation that occurs because of aging.\(^{16}\) The normal proliferative process in the lens nucleus that occurs throughout life causes the lens to thicken and its capsule to become less elastic, so that the range of focus or accommodation is diminished. As a result, the person begins to notice the inability to read small print or discriminate close objects. This is usually worse in dim light, on arising in the morning, or when the person is fatigued.

**Cataracts**

A cataract is a lens opacity that interferes with the transmission of light to the retina. Aging is the most common cause of cataracts, and most people over age 60 have some degree of lens opacity. Although aging is the most important cause of cataracts, other factors such as heredity, environmental influences, systemic diseases (e.g., diabetes mellitus), drugs, and trauma may be involved.\(^{15,18}\)

Long-term exposure to sunlight (ultraviolet radiation) has been associated with increased risk of cataract formation. Corticosteroids have been implicated as causative agents in cataract formation. Both systemic and inhaled corticosteroids have been cited as risk factors.\(^{19}\)

**Clinical Manifestations.** The manifestations of cataracts depend on the extent of opacity and whether the defect is bilateral or unilateral. Cataracts are usually bilateral (with the exception of traumatic or congenital cataracts). Age-related cataracts, which are typically the result of opacification of the lens nucleus (nuclear sclerosis), are characterized by increasingly blurred vision and visual distortion.\(^{15,20}\) Dilation of the pupil in dim light improves vision. In addition to decreased visual acuity, cataracts tend to cause light entering the eye to be scattered, thereby producing glare or the abnormal presence of light in the visual field (see Fig. 38-1C).

**Diagnosis and Treatment.** Diagnosis of cataracts is based on ophthalmoscopic examination and the degree of visual impairment on the Snellen vision test. On ophthalmoscopic examination, a cataract may appear as a gross opacity filling the pupillary aperture, or as an opacity silhouetted against the red background of the fundus. Other tests that determine the potential ability to see well after surgery, such as electrophysiologic testing in which the response to visual stimuli is measured electronically, may be done.

There is no effective medical treatment for cataract. Although strong bifocal lenses, magnification, appropriate lighting, and visual aids may help, surgery is the only treatment for cataract.\(^{15,20}\) It is commonly performed on an outpatient basis with the use of local anesthesia. The cataract lens is typically fragmented into fine pieces, which then are aspirated from the eye, and an intraocular lens implanted. Monofocal intraocular lenses that correct for distance vision are available. Although eyeglasses may still be needed for near vision, the recent introduction of multifocal intraocular lenses has reduced the need for both distance and near vision corrective eyeglasses.

**Childhood Cataract.** Childhood cataracts can be divided into two groups: congenital (infantile) cataracts, which are present at birth or appear shortly thereafter, and acquired cataracts, which occur later and are usually related to a specific cause.\(^{15,21}\) About one third of childhood cataracts are hereditary; another third are secondary to metabolic or infectious processes or associated with a variety of syndromes; and the final third results from undetermined causes. The development of congenital or infantile cataracts depend on the total dose of the agent and the stage of development at the time of exposure. It is during the last trimester of fetal life, genetically or environmentally influenced malformation of the superficial lens fibers can occur. Congenital lens opacities may occur in children of diabetic mothers. The presence of bilateral cataracts is often inherited and associated with other disease conditions, so genetic testing is required.

Most congenital cataracts are not progressive and are not dense enough to cause significant visual impairment.\(^{15}\) However, cataracts that are dense, central, and larger than 2 mm in diameter require surgical management on an urgent basis. If not treated within the first 2 months of life, visual deprivation produces irreversible loss of vision\(^{15,21}\) (i.e., amblyopia, to be discussed).

**Disorders of The Retina**

The retina is the most complex structure of the eye. It receives visual images produced by the optical system of the eye and converts the light energy into an electric signal that is transmitted by way of the optic nerve to the visual cortex, where the image is perceived.\(^{16,22,23}\) Disorders of the retina and its function include disorders of the retinal vessels such as retinopathies that cause
hemorrhage and the development of opacities; separation of the pigment and sensory layers of the retina (i.e., retinal detachment); and macular degeneration. Because the retina has no pain fibers, most diseases of the retina do not cause pain, nor do they produce redness of the eye.

The retina is composed of two layers: an outer pigment (melanin-containing) epithelium and an inner neural layer\(^{16,22}\) (Fig. 38-6A). The outer surface of the pigmented layer, a single-cell-thick lining, abuts the choroid and extends anteriorly to cover the ciliary body and the posterior side of the iris. Its pigmented epithelial cells, like those of the choroid, absorb light and prevent it from scattering. The pigment layer also stores large quantities of vitamin A, which is an important precursor of the photosensitive visual pigments.

The inner light-sensitive neural retina covers the inner aspect of the eyeball.\(^{16,22}\) The neural retina is composed of three layers of neurons: a posterior layer of photoreceptors (rods and cones), a middle layer of bipolar cells, and an inner layer of ganglion cells that communicate with the photoreceptors (see Fig. 38-6B). Light must pass through the transparent inner layers of the sensory retina before it reaches the photoreceptors. Impulses produced in response to light spread from the photoreceptors to the bipolar neurons and other interneurons and then to the ganglionic cells, where action potentials are generated. The interneurons, which have cell bodies in the bipolar layer, play an important role in modulating retinal function. The optic disk, where the optic nerve exits the eye, is the weak part of the eye because it is not reinforced by the sclera. It also forms the blind spot because it is not backed by photoreceptors, and light focused on it cannot be seen. People do not notice the blind spot because of a sophisticated visual function called “filling in,” which the brain uses to deal with missing visual input.

Two types of photoreceptors are present in the retina: rods capable of black–white discrimination and cones capable of color discrimination.\(^{16,22,24}\) Rod-based vision is particularly sensitive to detecting light, especially moving light stimuli, at the expense of clear pattern discrimination. Rod vision is particularly adapted for night and low-level illumination. Cone receptors, which are selectively sensitive to different wavelengths of light, provide the basis for color vision. Three types of cones, or cone-color systems, respond to the blue, green, and red portions of the visible electromagnetic spectrum. Cones do not have the dark adaptation capability of rods. Consequently, the dark-adapted eye is a rod receptor eye with only black–gray–white experience (scotopic or night vision). The light-adapted eye (photopic vision) adds the capacity for color discrimination.

Both rods and cones contain chemicals that change configuration on exposure to light and, in the process, generate electric signals that lead to the action potentials generated by the ganglionic cells. The light-sensitive chemical in rods is called rhodopsin, and the light-sensitive chemicals in cones are called cone or color pigments. Both types of photoreceptors are thin, elongated, mitochondria-filled cells with a single, highly modified cilium (Fig. 38-6C). The cilium has a short base, or inner
segment, and a highly modified outer segment. The cell membrane of the outer segment is tightly folded to form membranous disks (rods) or conical shapes (cones) containing visual pigment. These disks are continuously synthesized at the base of the outer segment and shed at the distal end. Discarded membranes are phagocytized by the retinal pigment cells. If this phagocytosis is disrupted, as in a condition called retinitis pigmentosa, the sensory retina degenerates.

An area near the center of the retina, called the macula lutea (i.e., “yellow spot”), is especially adapted for acute and detailed vision.16 This area is composed entirely of cones. In the central portion of the macula, the fovea centralis (foveola), the blood vessels and innermost layers are displaced to one side instead of resting on top of the cones. This allows light to pass unimpeded to the cones without passing through several layers of the retina. Many of these cones are connected one to one with ganglionic cells, an arrangement that favors high acuity.

**Retinal Blood Supply**

The blood supply for the retina is derived from two sources: the choriocapillaris (i.e., the capillary layer of the choroid) and branches of the central retinal artery (Fig. 38-7A). Oxygen and other nutrients are supplied by diffusion from blood vessels in the choroid. Because the choriocapillaris provides the only blood supply for the fovea centralis, detachment of this part of the sensory retina from the pigment epithelium causes irreparable loss of vision. The central artery, which is a branch of the ophthalmic artery, supplies the rest of the retina. Retinal veins follow a distribution parallel to the arterial branches and carry venous blood to the central vein of the retina, which exits the back of the eye through the optic disk.

Funduscopic examination of the eye with an ophthalmoscope provides the means for examining the retinal blood vessels and other aspects of the retina (Fig. 38-7B). Because the retina is an embryonic outgrowth of the brain and the blood vessels are to a considerable extent representative of brain blood vessels, the ophthalmoscopic examination of the fundus of the eye permits the study and diagnosis of metabolic and vascular diseases of the brain as well as pathologic processes that are specific to the retina.

**Retinopathies**

Retinopathies, which involve the small blood vessels of the retina, are characterized by changes in vessel structure and the development of microaneurysms, neovascularization, hemorrhage, and retinal opacities.24,25 Microaneurysms are outpouchings of the retinal vasculature. On ophthalmoscopic examination, they appear as minute, unchanging red dots associated with blood vessels. Microaneurysms tend to leak plasma, resulting in localized edema that gives the retina a hazy appearance. They may also bleed, but areas of hemorrhage and edema tend to clear spontaneously. However, they reduce visual acuity if they encroach on the macula and cause degeneration before they are absorbed. Neovascularization involves the formation of new blood vessels. They can develop from the choriocapillaris, extending between the pigment and the sensory layers of the retina; or from the retinal veins, extending between the sensory retina and the vitreous cavity and sometimes into the vitreous. These new blood vessels are fragile, leak protein, and are likely to bleed. Although

---

![Diagram of retinal blood supply and funduscopic image.](image-url)
the cause of neovascularization is uncertain, research links the process with a vascular endothelial growth factor (VEGF) produced by the lining of blood vessels. Hypoxia is a key regulator of VEGF-induced retinal neovascularization. It is likely that other growth factors and signaling systems are also involved.

**Opacities** represent a loss of retinal transparency due to hemorrhages, exudates, cotton-wool spots, edema, and tissue proliferation. The development of exudates often results in the destruction of the underlying retinal pigment and choroid layer. **Cotton-wool patches** are retinal opacities with hazy, irregular outlines. They occur in the nerve fiber layer of the retina and are associated with retinal trauma, severe anemia, papilledema, and diabetic retinopathy.

**Diabetic Retinopathy.** Diabetic retinopathy is one of the leading causes of blindness in the Western world, particularly among individuals of working age. Chronic hyperglycemia, hypertension, hypercholesteremia, and smoking are all risk factors for the development and progression of the disorder. People with type 1 (insulin-dependent) diabetes do not usually develop the disorder until at least 3 to 5 years after the onset of the disease, whereas those with type 2 diabetes may have retinopathy as a presenting symptom at the time of diagnosis.

Diabetic retinopathy can be divided into two types: nonproliferative (or background) and proliferative. **Nonproliferative** retinopathy is confined to the retina. It involves engorgement of the retinal veins, thickening of the capillary endothelial basement membrane, and development of capillary microaneurysms (Fig. 38-8A,B). Small intraretinal hemorrhages may develop and microinfarcts may cause cotton-wool spots and leakage of exudates. The most common cause of decreased vision in persons with background retinopathy is macular edema. The edema is caused primarily by the breakdown of the blood-retina barrier at the level of the capillary endothelium, allowing leakage of fluid and plasma constituents into the surrounding retina.

**Proliferative** diabetic retinopathy represents a more severe retinal change than background retinopathy (Fig. 38-8C,D). It is characterized by formation of new fragile blood vessels (i.e., neovascularization) at the optic disk and elsewhere in the retina, which is often the

---

**FIGURE 38-8.** (A) Nonproliferative (background) retinopathy showing microaneurysms. (B) Ocular fundus of a patient with background diabetic retinopathy. Several yellowish “hard” exudates (which are rich in lipids) and several relatively small retinal hemorrhages are present. (C) Proliferative retinopathy. (D) Ocular fundus in a patient with proliferative retinopathy. A vascular frond (branching pattern of preretinal neovascularization) has extended anterior to the retina. (B and D from Klintworth GK. The eye. In: Rubin R, Strayer DS, eds. Rubin’s Pathology: Clinicopathologic Foundations of Medicine. 6th ed. Philadelphia, PA: Wolters Kluwer Health | Lippincott Williams & Wilkins; 2012:1403.)
first detectable sign of diabetic retinopathy. These vessels grow in front of the retina along the posterior surface of the vitreous or into the vitreous. They threaten vision in two ways. First, they often leak blood into the vitreous cavity and decrease visual acuity. Second, they attach firmly to the retinal surface and the posterior surface of the vitreous chamber, such that normal movement of the vitreous humor may exert a pull on the retina, causing retinal detachment and progressive blindness.

Current guidelines recommend that persons with diabetes have yearly eye examinations. Persons with any level of macular edema, severe nonproliferative diabetic retinopathy, or any proliferative retinopathy require the prompt care of an ophthalmologist experienced in the management and treatment of diabetic retinopathy. Women with preexisting diabetes who plan to become pregnant or are pregnant should have a comprehensive eye examination and be counseled about the risk for initiation or progression of diabetic retinopathy.

Preventing diabetic retinopathy from developing or progressing is considered the best approach to preserving vision. Growing evidence suggests that careful control of blood glucose levels in persons with diabetes mellitus may retard the onset and progression of retinopathy. There also is a need for intensive management of hypertension and hyperlipidemia, both of which have been shown to increase the risk of diabetic retinopathy in persons with diabetes.

Treatment strategies for diabetic retinopathy include laser photocoagulation applied directly to leaking microaneurysms and grid photocoagulation with a checkerboard pattern of laser burns applied to diffuse areas of leakage and thickening. Because laser photocoagulation destroys the proliferating vessels and the ischemic retina, it reduces the stimulus for further neovascularization. Intravitreal injections of anti-VEGF agents are also being used to reduce active neovascularization and vitreous hemorrhage. Vitrectomy may be used for removing vitreous hemorrhage and severing vitreoretinal membranes that develop.

**Hypertensive Retinopathy.** As with other blood vessels in the body, the retinal vessels undergo changes in response to chronically elevated blood pressure. In the initial, vasoconstrictor stage, there is vasoconstriction and an increase in retinal arterial tone because of local autoregulatory mechanisms. On ophthalmoscopy, this stage is represented by a general narrowing of the retinal arterioles. Persistently elevated blood pressure results in the compensatory thickening of arteriolar walls, which effectively reduces capillary perfusion pressure. With severe uncontrolled hypertension, there is disruption of the blood-retina barrier, necrosis of smooth muscle and endothelial cells, exudation of blood and lipids, and retinal ischemia. These changes are manifested in the retina by microaneurysms, intraretinal hemorrhages, hard exudates, and cotton-wool patches. Swelling of the optic disk may occur at this stage and usually indicates severely elevated blood pressure (malignant hypertension). Elderly persons often have more rigid vessels that are unable to respond to the same degree as those in younger individuals.

**Retinal Detachment.** Retinal detachment involves the separation of the neurosensory retina from the pigment epithelium. The disorder, which is one of most time-critical events seen in an emergency department, occurs when traction on the inner sensory layer or a tear in this layer allows fluid, usually vitreous, to accumulate between the two layers of the retina. There are three types of retinal detachments: exudative, traction, and rhegmatogenous.

**Exudative Detachment.** Exudative (or serous) retinal detachment results from the accumulation of serous or hemorrhagic fluid in the subretinal space due to severe hypertension, inflammation, or neoplastic effusions. It usually resolves with successful treatment of the underlying disease and without visual impairment.

**Traction Retinal Detachment.** Traction retinal detachment occurs with mechanical forces on the retina, usually mediated by fibrotic tissue, resulting from previous hemorrhage (e.g., from diabetic retinopathy), injury, infection, or inflammation. Intraocular surgery such as vitrectomy may produce traction on the peripheral retina that causes eventual detachment months or even years after surgery. Correction of traction retinal detachment requires disengaging scar tissue from the retinal surface, and vision outcomes are often poor.

**Rhegmatogenous Detachment.** Rhegmatogenous detachment, the most common type of retinal detachment, is a full thickness break (“rhegma”) in the sensory retina, with the passage of liquefied vitreous through the break into the subretinal space. Although typically an acute event, detachment is a consequence of lifelong liquefaction of the vitreous humor, and is highly age-dependent with 27% of patients in their seventies and 63% in their eighties. As the collagenous and mucopolysaccharide matrix of the vitreous humor begins to liquefy and shrink, it pulls away from the retinal surface. Rhegmatogenous detachment occurs when the liquid vitreous enters the subretinal space through a retinal tear (Fig. 38–9). Detachment of the neural retina from the retinal pigment layer separates the visual receptors from their major blood supply, the choroid. If retinal detachment continues for some time, permanent destruction and blindness of that part of the retina occur. Persons with high grades of myopia or nearsightedness may have abnormalities in the peripheral retina that predispose to sudden detachment. In moderate to severe myopia, the anteroposterior length of the eye is increased, and the retina tends to be thinner and more prone to formation of a hole or tear. As a result, there is greater vitreoretinal traction, and posterior vitreous detachment may occur at a younger age than in persons without myopia.

**Clinical Manifestations.** The primary symptom of retinal detachment is painless changes in vision. Commonly, flashing lights or sparks, followed by small floaters or spots in the field of vision, are early symptoms. As detachment progresses, the person...
perceives a shadow or dark curtain progressing across the visual field. Large peripheral detachments may occur without involvement of the macula, so that visual acuity remains unaffected.

**Diagnosis and Treatment.** Diagnosis of retinal detachment is based on a history of visual disturbances (e.g., presence of floaters, luminous rays, or light flashes) and the ophthalmoscopic appearance of the retina. The direct (handheld) ophthalmoscope is useful in detecting an altered red reflex sometimes associated with retinal detachment. However, because the view is narrow, a negative examination with direct ophthalmoscopy cannot exclude the diagnosis of retinal detachment. Ophthalmologists and optometrists use indirect examination techniques that greatly enhance visualization of the peripheral retina.

Because there is a variable interval between a retinal break and retinal detachment, treatment methods focus on early detection and prevention of further vitreous detachment and retinal tear formation. Symptomatic retinal breaks are usually treated with laser or cryotherapy to seal the retinal tears so that the vitreous humor can no longer leak into the subretinal space. The primary treatment of traction retinal detachment is vitreoretinal surgery.

**Macular Degeneration**

Macular degeneration is characterized by degenerative changes in the central portion of the retina (the macula) that result primarily in loss of central vision (see Figure 38-1B). Age-related macular degeneration (AMD) is the most common cause of reduced vision in the elderly. The causes are poorly understood. In addition to older age, identifiable risk factors include cigarette smoking, obesity, and low dietary intake of lutein, omega 3 fatty acids, zinc, and vitamins A, C, and E. Increasing evidence suggests that genetic factors may also play a role.

Age-related macular degeneration is commonly classified simply as “early” or “late.” Late AMD is further subdivided into geographic atrophy (“dry”) and neovascular (“wet”). Although both late forms are progressive and usually bilateral, they differ in manifestations, prognosis, and management.

**Geographic Atrophic Degeneration.** Geographic atrophic degeneration is characterized by gradually progressive visual loss of moderate severity due to atrophy and degeneration of the outer retina and retinal pigment epithelium. Because it does not involve leakage of blood or serum, it is commonly referred to as dry macular degeneration. The level of associated visual impairment is variable and may be minimal, and the atrophic changes may stabilize or progress slowly (Fig. 38-10A). However, people with this form of AMD need to be followed closely because the neovascular form may
develop suddenly at any time. Careful monitoring for metamorphopsia, or distorted vision of straight lines, can aid in the early detection of retinal damage.

**Neovascular Degeneration.** The neovascular form of AMD is characterized by the formation of a choroidal neovascular membrane. These new blood vessels have weaker walls than normal and are prone to leakage; thus, this form is commonly referred to as “wet.” The leakage of serous or hemorrhagic fluid into the subretinal space causes separation of the pigmented epithelium from the neurosensory retina. Over time, the subretinal hemorrhages organize to form scar tissue, causing death of the underlying retinal tissue and loss of all visual function in the corresponding macular area (see Fig. 38-10B). Although some subretinal neovascular membranes may regress spontaneously, the natural course is toward irreversible loss of central vision.

**Diagnosis and Treatment.** The early stages of subretinal neovascularization may be difficult to detect with an ophthalmoscope. Therefore, there is a need to be alert for recent or sudden changes in central vision, blurred vision, or scotomata (visual field areas in which vision is depressed or absent). Persons with late-stage disease often find it difficult to see at long distances (e.g., in driving), do close work (e.g., reading), see faces clearly, or distinguish colors. However, they may not be severely incapacitated because the peripheral retinal function usually remains intact.

Effective therapies for neovascular macular degeneration include thermal laser photocoagulation, photodynamic therapy, and intravitreal injections of VEGF inhibitors. Conventional retinal laser photocoagulation can achieve direct destruction of a choroidal neovascular membrane. Photodynamic laser therapy involves the intravenous injection of a dye that is subsequently activated by retinal laser irradiation to produce selective vascular damage. Recognition of the key role that VEGF plays in choroidal neovascularization pathogenesis led to development of VEGF inhibitors, a class of drugs that has now become the preferred treatment for neovascular macular degeneration. These drugs are given by intravitreal injection.

In addition to currently used and forthcoming treatments, there is interest in the so-called preventative category of treatments. Tobacco smoking is consistently identified as a preventable age-related macular degeneration risk; thus, its elimination should be one of the first therapeutic recommendations. Preventative recommendations also include dietary supplementation containing high-dose antioxidants and minerals (vitamins E and C, zinc, and β-carotene) for persons at risk for developing macular degeneration and for slowing the progression of age-related macular degeneration in persons with the disease. However, more experimental data and randomized clinical trials are needed to support their therapeutic value, the most effective composition in terms of single- or multiple-supplement combinations, and dosing of the particular supplements.

**Disorders of Intraocular Pressure**

The intraocular pressure reflects that of the aqueous humor that fills the anterior and posterior chambers of the eye. The aqueous humor is produced by the ciliary body and passes from the posterior chamber through the pupil into the anterior chamber (see Fig. 38-11A). Aqueous humor leaves through the trabecular meshwork at the iridocorneal angle between the anterior iris and the cornea. It then drains into the canal of Schlemm, a thin-walled vein that extends circumferentially around the iris, for return to the venous circulation. Intraocular pressure results from a balance of several factors, including the rate of aqueous humor production by the ciliary body, the resistance to flow between the iris and ciliary body, and its rate of removal by the drainage system (trabecular meshwork and canal of Schlemm). Normally, the rate of aqueous humor secretion is equal to the rate of outflow, and the intraocular pressure is maintained within a normal range of 10 to 21 mm Hg.

Glaucoma is a chronic, pressure-induced degenerative neuropathy that produces changes in the optic nerve and visual field loss (see Fig. 38-1D). Glaucoma is commonly classified as open-angle or angle-closure glaucoma depending on the appearance of the iridocorneal angle, and according to whether it is a primary or secondary disorder.

**Open-Angle Glaucoma**

Open-angle glaucoma, which is the most common form of glaucoma, results from an abnormality of the trabecular meshwork that controls the flow of aqueous humor into the canal of Schlemm without obstruction at the iridocorneal angle (see Fig. 38-11B). Open-angle glaucoma is usually asymptomatic and chronic, causing progressive damage to the optic nerve and vision loss unless it is appropriately treated. Elevated intraocular pressure is a primary factor; however, some eyes tolerate elevated intraocular pressure without developing disk or visual field changes, whereas others develop glaucomatous changes with consistently normal intraocular pressures (normal-tension glaucoma).

**Clinical Manifestations.** Because open-angle glaucoma is usually asymptomatic, it is often suspected when abnormal intraocular pressure measurements or optic disk abnormalities are found during a routine eye examination. The normal optic disk has a central depression called the optic nerve cup (Fig. 38-12). In glaucoma, the neuroretinal rim of the optic nerve becomes progressively thinner, thereby enlarging the optic nerve cup, a phenomenon referred to as optic nerve cupping. Its cause is loss of retinal ganglion cell axons, along with supporting glia and vasculature. Because changes in the optic cup precede visual field loss, regular ophthalmoscopic examinations are important to detect damage to retinal ganglion axons before visual field loss occurs.

**Diagnosis and Treatment.** Diagnostic methods include applanation tonometry (measurement of intraocular
The elevation in intraocular pressure in persons with open-angle glaucoma is usually treated pharmacologically or, in cases where pharmacologic treatment fails, by increasing aqueous outflow through a surgically created pathway. Drugs used in the long-term management of glaucoma fall into five classes: \( \beta \)-adrenergic antagonists, prostaglandin analogs, \( \alpha \)-adrenergic agonists, carbonic anhydrase inhibitors, and cholinergic agonists. Most glaucoma drugs are applied topically as eye drops. 

Topical \( \beta \)-adrenergic antagonists, which are thought to lower intraocular pressure by decreasing aqueous humor production, are usually the drugs of first choice. Prostaglandin analogs, which increase the outflow of aqueous humor through the iris root and ciliary body, are highly effective first-line or adjuvant agents. The \( \alpha \)-adrenergic agonists cause an early decrease in production of aqueous humor by constricting the vessels supplying the ciliary body. Carbonic anhydrase inhibitors reduce the secretion of aqueous humor. Cholinergic drugs, which exert their effects by increasing the effects of acetylcholine (a postganglionic neurotransmitter for the parasympathetic nervous system), increase aqueous outflow through contraction of the ciliary muscle and pupillary constriction.

When a reduction in intraocular pressure cannot be maintained through pharmacologic methods, laser or surgical trabeculoplasty may become necessary. With laser trabeculoplasty, the microburns created by the laser treatment scar rather than penetrate the trabecular meshwork, a process thought to enlarge the outflow channels by increasing the tension exerted on the trabecular meshwork. Cryotherapy, diathermy, and

**FIGURE 38-11.** (A) Normally, aqueous humor, which is secreted in the posterior chamber, gains access to the anterior chamber by flowing through the pupil. In the angle of the anterior chamber, it passes through the canal of Schlemm into the venous system. (B) In open-angle glaucoma, the outflow of aqueous humor is obstructed at the trabecular meshwork. (C) In angle-closure glaucoma, the aqueous humor encounters resistance to flow through the pupil. Increased pressure in the posterior chamber produces a forward bowing of the peripheral iris, so that the iris blocks the trabecular meshwork.

**FIGURE 38-12.** Optic nerve head in glaucoma. The anterior part of the optic nerve is decompressed (“optic cupping” arrows), and the blood vessels crossing the margin of the optic nerve head are displaced to the nasal side. The fundus appears dark because the eye of an African-American patient contains numerous pigmented melanocytes in the choroid. (From Klintworth GK. The eye. In: Rubin R, Strayer DS, eds. Pathology; Clinicopathologic Foundations of Medicine. 6th ed. Philadelphia, PA: Wolters Kluwer Health | Lippincott Williams & Wilkins; 2012:1410).
high-frequency ultrasound may be used in some cases to destroy the ciliary epithelium and reduce aqueous humor production.

**Angle-Closure Glaucoma**

Angle-closure glaucoma results from occlusion of the iridocorneal angle itself, impairing access to the drainage aqueous humor (see Fig. 38-11C). An acute attack is often precipitated by pupillary dilation, which causes the iris to thicken, thus blocking the circulation between the posterior and anterior chambers. Angle-closure glaucoma usually occurs as the result of an inherited anatomic defect that causes a shallow anterior chamber. It is more commonly seen in people of Asian or Inuit (Eskimo) descent and in people with hyperopia. This defect becomes exaggerated in older adults as the peripheral iris is anteriorly displaced by the increase in lens thickness that occurs with aging.

**Clinical Manifestations.** Manifestations of acute angle-closure glaucoma are related to sudden, intermittent increases in intraocular pressure. These occur after prolonged periods in the dark, emotional upset, and other conditions that cause extensive and prolonged dilation of the pupil. Administration of pharmacologic agents, such as atropine, that cause pupillary dilation (mydriasis) also can precipitate an acute episode. Attacks of increased intraocular pressure are manifested by ocular pain and blurred or iridescent vision caused by corneal edema. The pupil may be enlarged and fixed. Symptoms are often spontaneously relieved by sleep and conditions that promote pupillary constriction. With repeated or prolonged attacks, the eye becomes reddened, and edema of the cornea may develop, giving the cornea a hazy appearance. A unilateral, often excruciating, headache is common. Nausea and vomiting may occur, causing the headache to be confused with migraine.

Subacute angle-closure glaucoma is characterized by short episodes of elevated intraocular pressure that subside spontaneously. There are recurrent short episodes of unilateral pain, conjunctival redness, and blurring of vision associated with halos around lights. Attacks often occur in the evenings and resolve overnight. Examination between attacks may show only a narrow anterior chamber angle. Although the episodes resolve spontaneously, there is accumulated damage to the anterior chamber angle. Subacute angle closure may also progress to acute angle closure.

**Diagnosis and Treatment.** Acute angle-closure glaucoma is an ophthalmic emergency that must be differentiated from conjunctivitis, uveitis, or corneal disorders. Treatment is initially directed at reducing the intraocular pressure, usually with pharmacologic agents. Once the intraocular pressure is under control, a laser peripheral iridotomy may be performed to create a permanent opening between the anterior and posterior chambers, allowing the aqueous humor to bypass the pupillary block. The anatomic abnormalities responsible for angle-closure glaucoma are usually bilateral, and prophylactic surgery is often performed on the other eye.

**Disorders of Neural Pathways and Cortical Centers**

Full visual function requires the normally developed brain-related functions of photoreception and the pupillary reflex. These functions depend on the integrity of all visual pathways, including retinal circuitry and the pathway from the optic nerve to the visual cortex and other visual regions of the brain and brain stem.

Visual information is carried to the brain by axons of the retinal ganglion cells, which form the optic nerve. The two optic nerves meet and fuse in the optic chiasm, beyond which they are continued as the optic tracts (Fig. 38-13). In the optic chiasm, axons from the nasal retina of each eye cross to the opposite side and join with the axons of the temporal retina of the contralateral eye to form the optic tracts.

Fibers of the optic tracts synapse in the lateral geniculate nucleus (LGN) of the thalamus. Axons from neurons in the LGN form the optic radiations that travel to the primary visual cortex in the occipital lobe. The pattern of information transmission established in the optic tract is retained in the optic radiations. For example, the axons from the right visual field, represented by the nasal retina of the right eye and the temporal retina of the left eye, are united at the chiasm. They continue through the left optic tract and left optic radiation to the left visual cortex (area 17), which is located in the occipital lobe of the brain (Fig. 38-14). Immediately surrounding the visual cortex are the visual association cortices (areas 18 and 19), which function in adding meaningfulness to the visual experience.
The visual field refers to the area that is visible during fixation of vision in one direction (see Fig. 38-13). As with a camera, the simple lens system of the eye inverts the image of the external world on each retina. In addition, the right and left sides of the visual field also are reversed. Most of the visual field is binocular, with both eyes focusing on one object and then fusing two images into one. The right binocular visual field (the nasal half of the right eye and the temporal half of the left eye) is seen by the left retinal halves of each eye. Likewise, the left binocular field is seen by the right retinal halves of each eye. This binocular field is subdivided into central and peripheral portions. Central portions of the retina provide high visual acuity and correspond to the field focused on the central fovea. The peripheral and surrounding portion provides the capacity to detect objects, particularly moving objects. Beyond the visual field shared by both eyes, the left lateral periphery of the visual field is seen exclusively by the left nasal retina, and the right peripheral field by the right nasal retina.

**Disorders of the Optic Pathways**

Among the disorders that can interrupt the visual pathway are trauma, tumors, and vascular lesions. Trauma and tumors can produce direct injury or impinge on the optic pathways. Vascular insufficiency in any one of the arterial systems of the retina or visual pathways can seriously affect vision. For example, normal visual function depends on the adequacy of blood flow in the ophthalmic artery and its branches—the central retinal artery; the anterior and middle cerebral arteries, which supply the intracranial optic nerve, chiasm, and optic tracts; and the posterior cerebral artery, which supplies the LGN, optic radiation, and visual cortex. The adequacy of posterior cerebral artery function depends on that of the vertebral and basilar arteries that supply the brain stem.

**Visual Field Defects**

Visual field defects result from damage to the visual pathways or the visual cortex (see Fig. 38-13). The testing of the visual fields of each eye and of the two eyes together is useful in localizing lesions affecting the system. Perimetry or visual field testing, in which the visual field of each eye is measured and plotted in an arc, is used to identify defects and determine the location of lesions.

Blindness in one eye is called anopia. If half of the visual field for one eye is lost, the defect is called hemianopia; if a quarter of the field is lost, it is called quadrantanopia. Loss of the temporal or peripheral visual fields on both sides results in a narrow binocular field, commonly called tunnel vision. The loss of different
half-fields in the two eyes is called a heteronymous loss, and the abnormality is called heteronymous hemianopia. Destruction of one or both lateral halves of the chiasm is common with multiple aneurysms of the circle of Willis (see Chapter 37). In this condition, the function of one or both temporal retinas is lost, and the nasal fields of one or both eyes are lost. The loss of the temporal fields (nasal retina) of both eyes is called bitemporal heteronymous anopia. With both eyes open, the person with bilateral defects still has the full binocular visual field.

Loss of the optic tract, LGN, full optic radiation, or complete visual cortex on one side results in loss of the corresponding visual half-fields in each eye. Homonymous means “the same” for both eyes. In left-side lesions, the right visual field is lost for each eye and is called complete right homonymous hemianopia. Partial injury to the left optic tract, LGN, or optic radiation can result in the loss of a quarter of the visual field in both eyes. This is called homonymous quadrantanopia, and depending on the lesion it can involve the upper (superior) or lower (inferior) fields. The LGN, optic radiation, and visual cortex all receive their major blood supply from the posterior cerebral artery; unilateral occlusion of this artery results in complete loss of the opposite field (i.e., homonymous hemianopia). Bilateral occlusion of these arteries results in total cortical blindness.

The Extraocular Eye Muscles and Disorders of Eye Movement

For complete function of the eyes, it is necessary that the two eyes point toward the same fixation point and that the retinal and central nervous system (CNS) visual acuity mechanisms are functional. Despite slight variations in the view of the external world for each eye, it is important that these two images become fused, which is a forebrain function. Binocular fusion is controlled by ocular reflex mechanisms that adjust the orientation of each eye to produce a single image. If these reflexes fail, diplopia or double vision occurs.

Binocular vision depends on three pairs of extraocular muscles—the medial and lateral recti, the superior and inferior recti, and the superior and inferior obliques (Fig. 38-15). Each of the three sets of muscles in each eye is reciprocally innervated so that one muscle relaxes when the other contracts. Reciprocal contraction of the medial and lateral recti moves the eye from side to side (adduction and abduction); the superior and inferior recti move the eye up and down (elevation and depression). The oblique muscles rotate (intorsion and extorsion) the eye around its optic axis. A seventh muscle, the levator palpebrae superioris, elevates the upper eyelid.

The extraocular muscles are innervated by three cranial nerves. The trochlear nerve (CN IV) innervates the superior oblique, the abducens nerve (CN VI) innervates the lateral rectus, and the oculomotor nerve (CN III) innervates the remaining four muscles. Table 38-1 describes the function and innervation of the extraocular muscles.

Normal vision depends on the coordinated action of the entire visual system and a number of central control systems. It is through these mechanisms that an object is simultaneously imaged on the fovea of both eyes and perceived as a single image. Strabismus and amblyopia are two disorders that affect this highly integrated system.

Strabismus

Strabismus, or squint, refers to any abnormality of eye coordination or alignment that results in loss of binocular vision. Strabismus affects approximately 4% of children younger than 6 years of age.39-41 Because 30% to 50% of these children sustain permanent secondary loss of vision, or amblyopia (to be discussed), early diagnosis and treatment are essential.

Strabismus may be divided into two forms: paralytic, in which there is weakness or paralysis of one or more of the extraocular muscles; and nonparalytic, in which there is no primary muscle impairment. In terms of
standard terminology, the disorders of eye movement are described according to the direction of movement. **Esotropia** refers to medial deviation, **exotropia** to lateral deviation, **hypertropia** to upward deviation, **hypotropia** to downward deviation, and **cyclotropia** to torsional deviation (Fig. 38-16).

**Nonparalytic Strabismus.** Nonparalytic esotropia is the most common type of strabismus. The individual ocular muscles have no obvious defect and the amount of deviation is constant or relatively constant in the various directions of gaze. With persistent deviation, secondary abnormalities may develop because of

overactivity or underactivity of the extraocular muscles in some fields of gaze.

The disorder may be nonaccommodative, accommodative, or a combination of the two. Infantile esotropia is the most common cause of nonaccommodative strabismus. It occurs in the first 6 months of life, with large-angle deviations, in otherwise developmentally and neurologically normal infants. Eye movements are full, and the child often uses each eye independently to alter fixation (cross-fixation). The cause of the disorder is unclear. Research suggests that idiopathic strabismus may have a genetic basis, since siblings often present with similar disorders. Accommodative strabismus is caused by disorders such as uncorrected hyperopia of a significant degree, in which the esotropia occurs with accommodation that is undertaken to focus clearly. Onset of this type of esotropia characteristically occurs between 18 months and 4 years of age because accommodation is not well developed until that time. The disorder most often is monocular but may be alternating.

Paralytic Strabismus. Paralytic strabismus results from paresis (i.e., weakness) or plegia (i.e., paralysis) of one or more of the extraocular muscles. When the normal eye fixates, the affected eye is in the position of primary deviation. In the case of esotropia, there is weakness of one of the lateral rectus muscles. When the affected eye fixates, the unaffected eye is in a position of secondary deviation.

Paralytic strabismus is uncommon in children but accounts for nearly all cases of adult strabismus; it can be caused by infiltrative processes (e.g., Graves disease; see Chapter 32), myasthenia gravis, stroke, and direct optical trauma. In infants, paralytic strabismus can be caused by birth injuries affecting the extraocular muscles or the cranial nerves supplying these muscles. In general, binocular vision can be maintained when paralytic strabismus is corrected.

Treatment. Treatment of strabismus is directed toward the development of normal visual acuity, correction of the deviation, and superimposition of the retinal images to provide binocular vision. Early and adequate treatment is crucial because a delay in or lack of treatment can lead to amblyopia and permanent loss of vision.

Treatment includes both surgical and nonsurgical methods. Infantile esotropia is usually treated surgically by weakening the medial rectus muscle on each eye while the infant is under general anesthesia. Recurrences are common with infantile esotropia, and multiple surgeries are often required.

Nonsurgical treatment includes glasses, occlusive patching, and eye exercises (i.e., pleoptics). Glasses are often used in the treatment of accommodative esotropia that occurs with hypermetropia. Because accommodation is linked with convergence, focusing drives the eyes inward, producing esotropia. In infants and toddlers, intermittent exotropia is commonly treated with patching for 1 to 2 hours daily for several months. The use of over-minus glasses stimulates accommodative convergences, which contracts the exotropic drift. Vision therapy involves exercises to stimulate convergence and techniques to train the visual system to recognize the suppressed images. Surgical treatment of intermittent exotropia is indicated when conservative methods fail to correct the deviation. Early treatment of children with intermittent exotropia is not as crucial as it is for those with constant deviations because stereopsis can still develop.

A relatively new form of treatment involves the injection of botulinum toxin type A (Botox) into the extraocular muscle to produce paralysis of that extraocular muscle. Paralysis of the muscle shifts the eye into the field of action of the antagonist muscle. During the time the eye is deviated, the paralyzed muscle is stretched, whereas the antagonistic muscle is contracted. Usually two or more injections of the drug are necessary to obtain a lasting effect.

Amblyopia

Amblyopia, sometimes called lazy eye, describes a decrease in visual acuity resulting from abnormal visual development in infancy or early childhood. It is the most common cause of monocular visual impairment, affecting 1% to 4% of the population. With early detection and treatment, most cases of amblyopia are reversible and the most severe forms of the condition can be prevented.

Normal development of the thalamic and cortical circuitry necessary for binocular visual perception requires simultaneous binocular use of each fovea during a critical period early in life (0 to 5 years). Amblyopia can result from visual deprivation (e.g., cataracts, ptosis) or abnormal binocular interactions (e.g., strabismus, anisometropia) during visual immaturity. In infants with unilateral cataracts that are dense, central, and larger than 2 mm in diameter, this period is before 2 months of age. In conditions causing abnormal binocular interactions, one image is suppressed to provide clearer vision. In esotropia, vision of the deviated eye is suppressed to prevent diplopia. A similar situation exists in anisometropia, in which the refractive indexes of the two eyes are different. Although the eyes are correctly aligned, they are unable to focus together, and the image of one eye is suppressed.

The reversibility of amblyopia depends on the maturity of the visual system at the time of onset and the duration of the abnormal experience. Occasionally in strabismus, some persons alternate eye fixation and do not experience significant amblyopia or diplopia. With late adolescent or adult onset, this habit pattern must be unlearned after correction. Amblyopia is remarkably responsive to treatment if the treatment is initiated early in life; thus, all infants and young children should be evaluated for visual conditions that could lead to amblyopia.

The American Academy of Pediatrics in association with the American Association of Certified Orthoptists, American Association of Pediatric Ophthalmology and Strabismus, and American Academy of Ophthalmology recommends that all newborn infants be examined in the nursery for structural abnormalities and have a red
reflex test performed to check for abnormalities in the back of the eye (posterior segment) and opacities in the visual axis, such as cataracts or corneal opacity. Visual examinations should then be performed during all well-child visits. These should include age-appropriate evaluation of visual acuity, ocular alignment, and ocular media clarity (cataracts, tumors).

The treatment of children at risk for development of amblyopia must be instituted well before the age of 6 years to avoid the suppression phenomenon. Surgery for congenital cataracts and ptosis should be done early. Severe refractive errors should be corrected. In children with strabismus, the alternate blocking of the vision in one eye and then the other with a patch forces the child to use both eyes for form discrimination. The duration of occlusion of vision in the good eye must be short (2 to 4 hours per day) and closely monitored, or deprivation amblyopia can develop in the good eye as well.

SUMMARY CONCEPTS

- The eyeball, or optic globe, which is a complex sensory organ that provides the sense of vision, is protected posteriorly by the bony structures of the orbital cavity and anteriorly by the eyelids. The eyeball is composed of three layers: an outer layer, which includes the white, opaque sclera and the transparent cornea; a middle vascular layer called the uvea, which includes the choroid, ciliary body, and iris; and an inner neural layer, which includes an outer pigment epithelium and the inner, light-sensitive retina, which is connected to the optic nerve.

- A conjunctiva lines the inner surface of the eyelids and covers the eyeball to the junction of the cornea and sclera. Conjunctivitis, also called red eye or pink eye, may result from bacterial or viral infection, allergic reactions, or the injurious effects of chemical agents, physical agents, or radiant energy.

- Keratitis, or inflammation of the cornea, can be caused by infections, hypersensitivity reactions, ischemia, defects in tearing, or trauma. Trauma or disease that involves the stromal layer of the cornea heals with scar formation and permanent opacification. These opacities interfere with the transmission of light and may impair vision.

- The lens is a biconvex, transparent, flexible structure that can change shape to allow precise focusing of light on the retina. Refraction refers to the ability of the lens to bend light rays in order to focus an object on the retina. In hyperopia, or farsightedness, the image falls behind the retina, and in myopia, or nearsightedness, it falls in front of the retina. Accommodation is the process by which a clear image is maintained as the gaze is shifted from a far object to a near object. Presbyopia is a change in the lens that occurs because of aging such that the lens becomes thicker and less able to change shape and accommodate for near vision. A cataract is characterized by increased lens opacity.

- The retina covers the inner aspect of the posterior two thirds of the eyeball and is continuous with the optic nerve. It contains the photoreceptors for vision: the rods, for black and white discrimination, and the cones, for color vision. The retinopathies are visual disorders involving the small blood vessels of the retina, which can result from a number of local and systemic disorders, including diabetes mellitus and hypertension. Retinal detachment involves separation of the sensory receptors from their blood supply; it causes blindness unless reattachment is accomplished promptly. Macular degeneration, which is a leading cause of blindness in the elderly, is characterized by loss of central vision resulting from destructive changes in the central fovea.

- Glaucoma is a chronic, degenerative visual field loss usually associated with an increase in intraocular pressure due to impaired outflow of aqueous humor from the anterior chamber of the eye. Glaucoma is commonly classified as open-angle glaucoma, in which impaired outflow of aqueous humor is due to dysfunction of the drainage system, and angle-closure glaucoma, in which occlusion of the anterior chamber angle impairs access to the drainage system.

- Eye movement, which is controlled by the extraocular muscles, provides for alignment of the eyes and binocular vision. Strabismus, which involves abnormalities in coordination of eye movements, can be caused by weakness or paralysis of the extraocular muscles (paralytic strabismus), inappropriate length or insertion of the extraocular muscles (nonparalytic strabismus), or accommodation disorders. The neural pathways for vision develop during infancy. Amblyopia is a condition of diminished vision that results from inadequately developed CNS circuitry due to visual deprivation or abnormal binocular interactions during the period of visual immaturity.
The Ear and Disorders of Auditory Function

The ears are paired organs consisting of an external and middle ear, which function in capturing, transmitting, and amplifying sound; and an inner ear, which contains the receptive organs that are stimulated by sound waves (i.e., hearing) or head position and movement (i.e., balance).

Disorders of the External Ear

The external ear is a funnel-shaped structure that conducts sound waves to the tympanic membrane. It consists of the auricle, the external acoustic meatus (ear canal), and the lateral surface of the tympanic membrane.2,16 (Fig. 38-17). Modified sebaceous glands in the auditory canal secrete a waxlike substance called cerumen or earwax that has certain antimicrobial properties and is thought to serve a protective function.

The tympanic membrane or eardrum is a thin, transparent membrane, approximately 1 cm in diameter, which separates the external ear from the middle ear. It is covered with thin skin externally and the mucous membrane of the middle ear internally. The tympanic membrane is attached in a manner that allows it to vibrate freely when audible sound waves enter the external auditory canal. Movements of the membrane are transmitted through the middle ear to the inner ear.

Impacted Cerumen

Although the ear normally is self-cleaning, the cerumen can accumulate in the narrow ear canal, causing reversible hearing loss.47 Impacted cerumen usually produces no symptoms unless it hardens and touches the tympanic membrane, or the canal becomes irritated by a buildup of hardened cerumen, causing pain, itching, and a sensation of fullness. As the canal becomes completely occluded, there may be a feeling of fullness, a conductive hearing loss, and tinnitus (i.e., ringing in the ears). In most cases, cerumen can be removed by gentle irrigation using a bulb syringe and warm tap water. Alternatively, health care professionals may remove cerumen using an otoscope for guidance along with a wire loop or plastic cerumen curette. A ceruminolytic agent is usually reserved for impacted or hardened cerumen that occurs without ear discharge, pain, rash, or irritation.

Otitis Externa

Otitis externa is an inflammation of the external ear that can vary in severity from mild dermatitis to severe cellulitis.46,48 It can be caused by infectious agents, irritation (e.g., wearing hearing aids or earphones), or allergic reactions. Predisposing factors include frequent exposure to moisture in the ear canal (i.e., swimmer’s ear), trauma to the canal caused by cleaning or scratching, and allergies or skin conditions such as psoriasis. It commonly occurs in the summer and is manifested by itching, redness, tenderness, and narrowing of the ear canal because of swelling. Inflammation of the auricle or ear canal makes movement of the ear painful. There may be watery or purulent drainage and intermittent hearing loss.

Treatment usually includes the use of ear drops containing an appropriate antimicrobial or antifungal agent in combination with a corticosteroid to reduce inflammation.48 Persons with acute otitis externa (AOE) should preferably abstain from water sports, protect the

Disorders of the Middle Ear and Eustachian Tube

The middle ear, or tympanic cavity, is a small, air-filled,
mucosa-lined cavity in the petrous portion of the temporal
bone (see Fig. 38-17). It is bounded anteriorly by the
tympanic membrane, and spanned by three tiny bones,
the auditory ossicles, which are connected by two synovial
joints and are covered with the epithelial lining of the
cavity. There are two openings in the medial wall of the
middle ear—the oval (vestibular) window and the round
(cochlear) window—that communicate with the inner ear.

The three auditory ossicles (the malleus, the incus, and
the stapes) connect the tympanic membrane with the oval
window. The malleus (“hammer”) has its handle firmly
fixed to the upper portion of the tympanic membrane. The
head of the malleus articulates with the incus (“anvil”),
which links the malleus to the stapes (“stirrup”), whose
footplate fits into the oval window. Arrangement of the
ear ossicles is such that their lever movements transmit
vibrations from the tympanic membrane to the oval
window and from there to the fluid in the inner ear.

The middle ear is connected to the nasopharynx
by the eustachian or auditory tube, which is located
in a gap in the bone between the anterior and medial
walls of the middle ear (see Fig. 38-17). The eustachian
tube serves three basic functions: (1) ventilation of
the middle ear, along with equalization of middle ear
and ambient pressures; (2) protection of the middle
ear from unwanted nasopharyngeal sound waves and
secretions; and (3) drainage of middle ear secretions
into the nasopharynx. The nasopharyngeal entrance to
the eustachian tube, which usually is closed, is opened
by the action of the tensor veli palatini muscle, which
is innervated by the trigeminal cranial nerve (CN V).
Opening of the eustachian tube, which normally occurs
with swallowing and yawning reflexes, provides the
mechanism for equalizing the pressure of the middle
ear with that of the atmosphere. This equalization
ensures that the pressures on both sides of the tympanic
membrane are the same, so that sound transmission is
not reduced and rupture of the tympanic membrane
does not result from sudden changes in atmospheric
pressure, as occurs during airplane travel. The
eustachian tube is lined with a mucous membrane that
is continuous posteriorly with the tympanic cavity and
anteriorly with that of the nasopharynx. Infections
from the nasopharynx can travel from the nasopharynx
along the mucous membrane of the eustachian tube
to the middle ear, causing acute otitis media. Toward
the nasopharynx, the eustachian tube becomes lined
by columnar epithelium with mucus-secreting cells.
Hypertrophy of these mucus-secreting cells is thought
to contribute to the mucoid secretions that develop during
certain types of otitis media.

Eustachian Tube Disorders

Abnormalities in eustachian tube function are important
factors in the pathogenesis of middle ear infections. There
are two important types of eustachian tube dysfunction:
abnormal patency and obstruction (Fig. 38-18). The
abnormally patent tube either does not close or does
not close completely. In infants and children with an
abnormally patent tube, air and secretions often are
pumped into the eustachian tube during crying and nose
blowing.

Obstruction can be functional or mechanical. Functional
obstruction results from the persistent
collapse of the eustachian tube due to a lack of tubal
stiffness or poor function of the tensor veli palatini
muscle that controls the opening of the eustachian
tube (see Fig. 38-18B). It is common in infants and
young children because the amount and stiffness of the
cartilage supporting the eustachian tube are less than
in older children and adults. Changes in the structure

FIGURE 38-18. Disorders of the eustachian tube.TVP, tensor
veli palatini: (A) normal patency, (B) functional obstruction,
(C) mechanical obstruction. (Developed from Bluestone CD.
Recent advances in the pathogenesis, diagnosis, and
of the craniofacial base also render the tensor muscle less efficient for opening the eustachian tube in this age group. In addition, craniofacial disorders, such as a cleft palate, alter the attachment of the tensor muscle, producing functional obstruction of the eustachian tube.

**Mechanical obstruction** results from internal obstruction or external compression of the eustachian tube (see Fig. 38-18C). Ethnic differences in the structure of the palate may increase the likelihood of obstruction. The most common internal obstruction is caused by swelling and secretions resulting from allergy and viral respiratory infections. With obstruction, air in the middle ear is absorbed, causing a negative pressure and the transudation of serous capillary fluid into the middle ear.

**Otitis Media**

*Otitis media* (OM) refers to inflammation of the middle ear without reference to etiology or pathogenesis (Fig. 38-19A). Inflammation of the middle ear may present as acute otitis media or otitis media with effusion. Acute otitis media (AOM) refers to the rapid onset of signs and symptoms of a middle ear infection. Otitis media with effusion (OME) refers to inflammation of the middle ear with the presence of fluid in the middle ear without signs and symptoms of an acute ear infection. It is important to differentiate OME from AOM to avoid unnecessary use of antimicrobial agents.

**Risk Factors.** Otitis media may occur in any age group, but is seen most frequently in infants and young children between the ages of 3 months and 3 years, with the peak incidence between 6 and 11 months. There is a second peak incidence at about 5 years of age that is believed to be associated with entrance into school. Risk factors include premature birth, male gender, ethnicity (Native American, Inuit), family history of recurrent OM, presence of siblings in the household, genetic syndromes, and low socioeconomic status. It is more frequent in children with orofacial abnormalities such as cleft lip and palate.

The most important factor that contributes to OM is believed to be a dysfunction of the eustachian tube that allows reflux of fluid and bacteria into the middle ear from the nasopharynx. There are two reasons for the increased risk of OM in infants and young children: the eustachian tube is shorter, more horizontal, and wider in this age group than in older children and adults; and infection can spread more easily through the eustachian canal of infants who spend most of their day in the supine position. Bottle-fed infants have a higher incidence of OM than breast-fed infants, probably because they are held in a more horizontal position during feeding, and swallowing while in the horizontal position facilitates the reflux of milk into the middle ear. Breast-feeding also provides for the transfer of protective maternal antibodies to the infant.

Measures to reduce the risk for development of OM during the first 6 months of life include breast-feeding, avoidance or elimination of bottle propping, and reduction or elimination of pacifier use. Other ways

![FIGURE 38-19. Disorders of the middle ear. (A) Otitis media. Otitis involves inflammation of the tympanic cavity. Infection often enters through the eustachian tube. (B) Cholesteatoma, a cystlike mass of the middle ear that often extends to involve the temporal bone. (C) Otosclerosis involving formation of new, spongy bone around the stapes and oval window.](image-url)
to reduce the risk of developing OM include minimal exposure to group settings and avoidance of exposure to passive tobacco smoke.\textsuperscript{51} Prevention of OM during the respiratory illness season has been demonstrated by immunoprophylaxis with influenza vaccines. Immunization with pneumococcal vaccine has also been reported to reduce the incidence of OM, but the reported overall effect has been small.\textsuperscript{51,52}

**Etiology.** Most cases of AOM follow an uncomplicated upper respiratory tract infection that has been present for several days. The most common bacteria in AOM are \textit{S. pneumoniae}, nontypeable \textit{H. influenzae}, and \textit{Moraxella catarrhalis}.\textsuperscript{51} The overall incidence of these pathogens has changed with widespread use of the conjugate pneumococcal vaccine, with nontypeable \textit{H. influenzae} replacing \textit{S. pneumoniae} as the most common pathogen.\textsuperscript{51} Evidence of respiratory viruses is also found in the middle ear exudates in children with AOM, either alone or, more commonly, in association with pathogenic bacteria. Of these viruses, rhinovirus and respiratory syncytial virus (RSV) are found most often.\textsuperscript{54} It remains unclear whether viruses alone can cause AOM or whether their role is limited to setting the stage for bacterial invasion and, perhaps, amplifying the inflammatory response.

The etiologies of AOM and OME are interrelated. Acute infection is usually followed by residual inflammation and effusion that, in turn, predisposes to recurrent infection. Middle ear effusion, which is a component of both AOM and OME, is an expression of underlying mucosal inflammation.

**Clinical Manifestations.** Acute otitis media is characterized by an acute onset of otalgia (ear pain), fever, and hearing loss. Children older than 3 years of age may have rhinorrhea or a runny nose, vomiting, and diarrhea. In contrast, younger children often have nonspecific signs and symptoms that manifest as ear tugging, irritability, nighttime awakening, and poor feeding. Key diagnostic criteria include ear pain that interferes with activity or sleep, tympanic membrane erythema (redness), and middle ear effusion.\textsuperscript{50–52} Perforation of the tympanic membrane may occur acutely, allowing purulent material from the middle ear to drain into the external auditory canal. This may prevent spread of the infection into the temporal bone or intracranial cavity. Healing of the tympanic membrane usually follows resolution of the infection.

Otitis media with effusion is often an asymptomatic condition.\textsuperscript{51,53} There may be mild intermittent ear pain, complaints of ear fullness, and “popping.” Secondary manifestations in infants may include ear rubbing, excessive irritability, and sleep disturbances. Hearing loss, even when not suggested by the child, is evidenced by a seeming lack of attentiveness, behavioral changes, and failure to respond to conversation-level speech. There may be problems related to school performance, balance problems and unexplained clumsiness, or delayed speech and language development.\textsuperscript{52} The duration of the effusion may range from less than 3 weeks to more than 3 months. Many cases of OME resolve spontaneously, but 30\% to 40\% of children have recurrent OME, and 5\% to 10\% of episodes last 1 year or longer.\textsuperscript{52}

**Diagnosis.** The diagnosis of OM is based on recent and usually acute onset of symptoms, presence of middle ear effusion, and signs and symptoms of middle ear inflammation, including erythema or redness with mild bulging of the tympanic membrane and otalgia or ear pain. Younger, nonverbal children with OM may present with holding, tugging, or rubbing of the ear. Nonspecific symptoms may include excessive crying, fever, or changes in sleep or behavior patterns.\textsuperscript{54} Other evidence of infection includes mild bulging of the tympanic membrane, onset of ear pain of less than 48 hours, or intense redness of the tympanic membrane.

Both AOM without otorrhea (drainage from the ear) and OME are accompanied by otoscopic signs of middle ear effusion—namely, the presence of at least two of three tympanic membrane abnormalities: white, yellow, amber, or occasionally blue discoloration; opacification other than scarring; and decreased or absent motility. With OME the tympanic membrane is often cloudy with distinct impairment of mobility, and an air–fluid level or bubble may be visible in the middle ear. The overall importance of distinguishing normal ear status from AOM versus OME is avoidance of unnecessary use of antibiotics along with the potential of adverse effects and antimicrobial resistance.

The diagnosis of AOM can also be confirmed using tympanometry or acoustic reflectometry. A tympanogram is obtained by using a small probe that is placed snugly into the external ear canal. A sound stimulus generator then transmits acoustic energy into the canal, while a vacuum pump introduces positive and negative pressures into the ear canal. A microphone in the instrument detects returning sound energy. The tympanogram provides a determination of the degree of negative pressure present in the middle ear. It detects disease when present but is less reliable when disease is absent. Acoustic reflectometry detects reflected sound waves from the middle ear and provides information on whether an effusion is absent or present. Increased reflected sound correlates with an increased likelihood of effusion. This technique is most useful in children older than 3 months, and its success depends on user technique.

**Treatment.** The treatment of AOM focuses on symptom control and management of the underlying pathologic process. A number of options for pain management are available, including the local application of heat and use of analgesic drugs such as acetaminophen and ibuprofen.\textsuperscript{51} Myringotomy (incision in the tympanic membrane) can be used for relief of pressure in the child with severe pain, providing almost immediate relief.

The extensive use of antimicrobial agents contributes to the development of bacterial resistance. Observation without antimicrobial agents is an option in a child
with uncomplicated AOM. This approach involves joint decision making between the clinician and parents, a system for close follow-up, and beginning antibiotics if symptoms worsen or there is no improvement within 48 to 72 hours.52

Most cases of OME resolve spontaneously within a 3-week to 3-month period. The management options for this duration include observation only, antimicrobial therapy, or combination antimicrobial and corticosteroid therapy.52,54 A hearing evaluation is recommended when OME persists for 3 months or longer or at any time that language delay, learning problems, or a significant hearing loss is suspected. Children with recurrent OM should be evaluated to rule out any anatomic variations (e.g., enlarged adenoids), allergies, and immunologic abnormalities. Referral to an otolaryngologist is indicated if the effusion persists for 4 months or longer.

Surgical treatment (e.g., tympanostomy tubes, adenoidectomy) may be indicated for OME if the effusion has persisted for 4 months or longer and is accompanied by persistent hearing loss and other manifestations; if recurrent or persistent effusion occurs in children at risk regardless of hearing status; or if there is structural damage to the tympanic membrane or middle ear.54 Tympanostomy tube insertion is the preferred initial procedure and does not typically include the removal of adenoids unless the child has additional indications, such as postnasal obstruction from enlarged adenoids. Adenoidectomy plus myringotomy (without tube insertion) has been shown to have comparable efficacy in children 4 years of age or older but is more invasive, with additional surgical and anesthetic risks.54

Complications of Otitis Media. The complications of OM include hearing loss and extratemporal complications, including those affecting the middle ear, mastoid, adjacent structures of the temporal bone, and intracranial structures.

Hearing loss, which is a common complication of OM, usually is conductive and temporary based on the duration of the effusion. Hearing loss that is associated with fluid collection usually resolves when the effusion clears. Permanent hearing loss may occur as the result of damage to the tympanic membrane or other middle ear structures. Cases of sensorineural hearing loss are rare.

The mastoid antrum and air cells constitute a portion of the temporal bone and may become inflamed as an extension of acute or chronic OM.51 The disorder causes necrosis of the mastoid process and destruction of the bony intercellular matrix, which are visible by radiologic examination. Mastoid tenderness and drainage of exudate through a perforated tympanic membrane can occur. Chronic mastoiditis can develop as the result of chronic middle ear infection. The usefulness of antimicrobial agents for this condition is limited. Mastoid or middle ear surgery, along with other medical treatment, may be indicated.

Cholesteatomas are cystlike lesions of the middle ear, usually associated with chronic otitis media (see Fig. 38-19B). Measuring 1 to 4 cm in diameter, they are lined with keratinizing squamous epithelium or mucus-secreting epithelium and filled with amorphous debris (derived largely from desquamated epithelium).51 Although precise mechanisms involved in their development are unclear, it is proposed that chronic inflammation and perforation of the eardrum with ingrowth of squamous epithelium or metaplasia of the secretory epithelium of the middle ear are contributing factors. These lesions can erode the ossicles, the labyrinth, the adjacent mastoid bone, and the surrounding soft tissues. Although often thought of as a complication of otitis media, a cholesteatoma may also occur as a congenital condition. Symptoms commonly include painless drainage from the ear and hearing loss. Treatment involves microsurgical techniques to remove the cholesteatomatous material.

Intracranial complications are uncommon since the advent of antimicrobial therapy. Although rare, these complications can develop when the infection spreads through vascular channels, by direct extension, or through preformed pathways such as the round window.53 These complications are seen more often with chronic suppurative OM and mastoiditis. They include otogenic meningitis, brain abscess, lateral sinus thrombophlebitis or thrombosis, labyrinthitis, and facial nerve paralysis. Any child who develops persistent headache, tinnitus, stiff neck, or visual or other neurologic symptoms should be investigated for possible intracranial complications.

Otosclerosis

Otosclerosis refers to the formation of new spongy bone around the stapes and oval window, which results in progressive deafness55,56 (see Fig. 38-19C). In most cases, the condition is familial and follows an autosomal dominant pattern with variable penetrance. Otosclerosis may begin at any time in life but usually does not appear until after puberty, most frequently between the ages of 20 and 30 years. The disease process accelerates during pregnancy.

Otosclerosis begins with resorption of bone in one or more foci. During active bone resorption, the bone structure appears spongy and softer than normal (i.e., otospongiosis). The resorbed bone is replaced by an overgrowth of new, hard, sclerotic bone. The process is slowly progressive, involving more areas of the temporal bone, especially in front of and posterior to the stapes footplate. As it invades the footplate, the pathologic bone increasingly immobilizes the stapes, reducing the transmission of sound. Pressure of otosclerotic bone on middle ear structures or the vestibulocochlear nerve (CN VIII) may contribute to the development of sensorineural hearing loss, tinnitus, and vertigo (to be discussed).

The symptoms of otosclerosis involve an insidious conductive hearing loss. Initially, the affected person is unable to hear a whisper or someone speaking at a distance. In the earliest stages, the bone conduction by which the person’s own voice is heard remains relatively unaffected. At this point, the person’s own voice sounds unusually loud, and the sound of chewing becomes intensified. Because of bone conduction, most of these persons can hear fairly well on the telephone, which provides an amplified signal.
The treatment of otosclerosis can be medical or surgical. A carefully selected, well-fitting hearing aid may allow a person with conductive deafness to lead a normal life. Sodium fluoride has been used with some success in the medical treatment of otospongiosis. Because much of the conductive hearing loss associated with otosclerosis is caused by stapedial fixation, surgical treatment involves stapedectomy with stapedial reconstruction using the patient’s own stapes or a stapedial prosthesis.

Disorders of Inner Ear and Central Auditory Pathways

Located in the bony wall of the petrous part of the temporal bone, the inner ear contains a bony labyrinth (meaning 'maze'), or system of intercommunicating channels and the receptors for hearing and position sense. A thin-walled, membranous labyrinth floats inside the outer bony wall, or the bony labyrinth (see Fig. 38-17). Two separate fluids are found in the inner ear: the perilymph or periotic fluid, which separates the bony labyrinth from the membranous labyrinth, and the endolymph or otic fluid, which fills the membranous labyrinth. Localized dilatations of the labyrinth develop into three main sensory areas: the semicircular canals, the vestibule, and the cochlea (see Fig. 38-17). The receptors in the cochlea are sensitive to sound, and those in the semicircular canals and vestibule are sensitive to changes in head position and maintenance of balance.

The cochlea is a shell-shaped part of the bony labyrinth that consists of three parallel compartments: the scala media or middle compartment of the cochlear canal, the scala vestibuli, and the scala tympani (Fig. 38-20). The scala media is an endolymph-containing space that is continuous with the lumen of the saccule and contains the spiral organ of Corti, the receptor organs for hearing. The scala vestibuli and scala tympani are perilymph spaces that communicate with each other at the apex of the cochlea through a small channel called the helicotrema. The scala vestibuli begins at the oval window, and the scala tympani ends at the round window.

The organ of Corti is composed of supporting cells; a flexible, fibrous "floor" called the basilar membrane; and several long rows of cochlear hair cells. Sound waves, delivered to the oval window by the stapes footplate, are transmitted to the perilymph and vibrate the basilar membrane. Transduction of sound stimuli occurs when the cilia of the cochlear hair cells are bent by this sound-induced movement.

Afferent fibers from the organ of Corti have their cell bodies in the spiral ganglion of the cochlear nerve. Auditory information travels along the vestibulocochlear nerve (CN VIII) and then to the cochlear nuclei in the caudal pons and midbrain to the thalamus. On the way many secondary nerve fibers pass to the opposite side of the brain. From the thalamus, the auditory pathway passes to the primary auditory cortex (area 41) and the auditory association cortex (areas 42 and 22) where the meaningfulness of sound is perceived (see Fig. 38-14). Because some of the fibers from each ear cross, each auditory cortex receives impulses from both ears.

Tinnitus

Tinnitus is the perception of abnormal ear or head noises not produced by an external stimulus. Although it often is described as "ringing of the ears," it may also assume a hissing, roaring, buzzing, or humming sound. Tinnitus may be constant, intermittent, and unilateral or bilateral. The condition affects both sexes equally, most prevalent between 40 and 70 years of age, and occasionally affects children.

Although tinnitus is a subjective experience, for clinical purposes it is subdivided into objective and subjective tinnitus. Objective tinnitus refers to those rare cases in which the sound is detected or potentially detectable by another observer. Typical causes of objective tinnitus include vascular abnormalities or neuromuscular disorders. For example, in some vascular disorders, sounds generated by turbulent blood flow (e.g., arterial bruits or venous hums) are conducted to the auditory system. Vascular disorders typically produce a pulsatile form of tinnitus. Subjective tinnitus refers to noise perception when there is no sound stimulation of the cochlea. A number of causes and conditions have been associated with subjective tinnitus.

![FIGURE 38-20. Path taken by sound waves reaching the inner ear.](image-url)
tinnitus. Intermittent periods of mild, high-pitched tinnitus lasting for several minutes are common in normal-hearing persons. Impacted cerumen is a benign cause of tinnitus, which resolves after the earwax is removed. Medications such as aspirin and stimulants such as nicotine and caffeine can cause transient tinnitus. Conditions associated with more persistent tinnitus include noise-induced hearing loss, presbycusis (sensorineural hearing loss that occurs with age), hypertension, atherosclerosis, head injury, and cochlear or labyrinthine infection or inflammation. The physiologic mechanism underlying subjective tinnitus is largely unknown. It seems likely that there are several mechanisms, including abnormal firing of auditory receptors, dysfunction of cochlear neurotransmitter function or ionic balance, and alterations in central processing of the signal.

Treatment measures for tinnitus are designed to reduce the symptoms, rather than effect a cure. They include elimination of drugs or other substances, such as caffeine, some cheeses, red wine, and foods containing monosodium glutamate, that are suspected of causing tinnitus. Tinnitus retraining therapy, which includes directive counseling and extended use of low-noise generators to facilitate auditory adaptation to the tinnitus, has met with considerable success.

Central Auditory Pathway Disorders

The auditory pathways in the brain involve communication between the two sides of the brain at many levels. As a result, strokes, tumors, abscesses, and other focal abnormalities seldom produce more than a mild reduction in auditory acuity on the side opposite the lesion. For intelligibility of auditory language, lateral dominance becomes important. On the dominant side, usually the left side, the more medial and dorsal portion of the auditory association cortex is of crucial importance. This area is called the Wernicke area, and damage to it is associated with auditory receptive aphasia. Persons with damage to this area of the brain can speak intelligibly and read normally but are unable to understand the meaning of major aspects of audible speech.

Irritative foci that affect the auditory radiation or the primary auditory cortex can produce roaring or clicking sounds, which appear to come from the auditory environment of the opposite side (i.e., auditory hallucinations). Focal seizures that originate in or near the auditory cortex often are immediately preceded by the perception of ringing or other sounds preceded by a prodrome (i.e., aura). Damage to the auditory association cortex, especially if bilateral, results in deficiencies of sound recognition and memory. If the damage is in the dominant hemisphere, speech recognition can be affected (i.e., sensory or receptive aphasia).

Hearing Loss

Nearly 36 million Americans have some degree of hearing loss. It affects persons of all age groups. Two to 3 out of every 1000 children in the United States are born deaf or hard of hearing. Approximately 30% of adults between the ages of 65 and 74 years and approximately 47% of those age 75 and older have hearing loss.

The level of hearing is measured in decibels (dB), where 0 dB is the threshold for perception of sound at a given frequency in persons with normal hearing. A 10-fold increase in sound pressure level from 0 dB is measured as 20 dB. Hearing loss is classified as mild (26 to 40 dB), moderate (41 to 55 dB), severe (71 to 90 dB), or profound (91 dB or greater). “Hard of hearing” is defined as hearing loss between 20 and 25 dB in adults and greater than 15 dB in children. Profound deafness is defined as hearing loss greater than 90 dB in adults or 70 dB in children.

There are many causes of hearing loss or deafness. Most fit into the categories of conductive, sensorineural, or mixed deficiencies that involve a combination of conductive and sensorineural function deficiencies of the same ear. Chart 38-1 summarizes common causes of hearing loss. Hearing loss may be genetic or acquired, sudden or progressive, unilateral or bilateral, partial or complete, reversible or irreversible.

Conductive Hearing Loss

Conductive hearing loss occurs when auditory stimuli are not adequately transmitted through the auditory canal, tympanic membrane, middle ear, or ossicle chain to the inner ear. Temporary hearing loss can occur as the result of impacted cerumen in the outer ear or fluid in the middle ear. Foreign bodies, including pieces of cotton and insects, may impair hearing. More permanent causes of hearing loss are thickening or damage of the tympanic membrane or involvement of the bony structures (ossicles and oval window) of the middle ear caused by otosclerosis or Paget disease.

Sensorineural Hearing Loss

Sensorineural, or perceptive, hearing loss occurs with disorders that affect the inner ear, auditory nerve, or auditory pathways of the brain. With this type of deafness, sound waves are conducted to the inner ear, but abnormalities of the cochlear apparatus or auditory nerve decrease or distort the transfer of information to the brain. Abnormal function resulting from damage or malformation of the central auditory pathways and circuitry is included in this category.

Sensorineural hearing loss can vary with respect to onset and severity, and can affect one or both ears. It may have a genetic cause or result from an infection, other illness, trauma, or exposure to loud noise. Hearing loss that has its onset before speech-language acquisition is typically defined as prelingual, and that known to have developed after speech development as postlingual.

Genetic hearing loss may result from mutation in a single gene (monogenetic) or from a combination of mutations in different genes and environmental factors (multifactorial). Genetic forms of hearing loss also can be classified as being part of a syndrome in which other abnormalities are present, or as nonsyndromic, in which deafness is the only abnormality.

Environmentally induced deafness can occur through direct exposure to excessively intense sound, as in the workplace or at a concert. Sustained or repeated exposure to noise pollution at sound intensities greater than 100 to 120 dB can cause corresponding mechanical damage to the organ of Corti. Severe damage can result in permanent sensorineural deafness to the affected sound frequencies.

A number of infections can cause sensorineural hearing loss. Deafness or some degree of hearing impairment is the most common serious complication of bacterial meningitis in infants and children. The mechanism causing hearing impairment is thought to be a suppurrative labyrinthitis or neuritis resulting in the loss of hair cells and damage to the auditory nerve. Sudden sensorineural hearing loss represents an abrupt loss of hearing that occurs instantaneously or on awakening. It is most commonly caused by viral infections or circulatory disorders.

Among the neoplasms that impair hearing are acoustic neuromas. Acoustic neuromas are benign Schwann cell tumors affecting CN VIII. These tumors usually are unilateral and cause hearing loss by compressing the cochlear nerve or interfering with blood supply to the nerve and cochlea. Other neoplasms that can affect hearing include meningiomas and metastatic brain tumors. The temporal bone is a common site of metastases.

Drugs that damage inner ear structures are labeled ototoxic. Vestibular symptoms of ototoxicity include light-headedness, giddiness, and dizziness; if toxicity is severe, cochlear symptoms consisting of tinnitus or hearing loss occur. Hearing loss is sensorineural and may be bilateral or unilateral, or they may be transient, as often is the case with salicylate toxicity, or they may be permanent. Several classes of drugs have been identified as having ototoxic potential, including the aminoglycoside antimicrobials and some other basic antimicrobials, antimarial drugs, some chemotherapeutic drugs, loop diuretics, and salicylates (aspirin). The risk of ototoxicity depends on the total dose of the drug and its concentration in the bloodstream. It is increased in persons with impaired kidney functioning and in those previously or currently treated with another potentially ototoxic drug.

Diagnosis and Treatment of Hearing Loss

Diagnosis of hearing loss is aided by careful history of associated otologic factors such as otalgia, otorrhea, tinnitus, and self-described hearing difficulties; physical examination to detect the presence of conditions such as otorrhea, impacted cerumen, or injury to the tympanic membrane; and hearing tests. Testing for hearing loss involves a number of methods, including a person’s reported ability to hear an observer’s voice, use of a tuning fork to test air and bone conduction, audioscopes, and auditory brain stem evoked responses (ABRs).

Tuning forks are used to differentiate conductive and sensorineural hearing loss. Audioscopes can be used to assess a person’s ability to hear pure tones at 1000 to 2000 Hz (usual speech frequencies). The ABR uses electroencephalographic (EEG) electrodes and high-gain amplifiers to produce a record of brain wave activity elicited during repeated acoustic stimulations of either or both ears. It involves subjecting the ear to loud clicks and using a computer to analyze nerve impulses as they are processed in the midbrain. Imaging studies such as computed tomography (CT) scans and magnetic resonance imaging (MRI) can be done to determine the site of a lesion and the extent of damage.

Untreated hearing loss can have many consequences. Social isolation and depressive disorders are common in the hearing-impaired. Hearing-impaired people may avoid social situations where background noise makes conversation difficult to hear. Safety issues, both in and out of the home, may become significant. Treatment measures for hearing loss range from simple removal of impacted cerumen in the external auditory canal to surgical procedures, such as those used to reconstruct the tympanic membrane.

Hearing aids remain the mainstay of treatment for many persons with conductive and sensorineural hearing loss. With the advent of microcircuitry, hearing aids are now being designed with computer chips that allow multiple programs to be placed in a single hearing aid. The various programs allow the user to select a specific...
Hearing Loss in Infants and Children

Even mild or unilateral hearing loss can have a detrimental effect on the language development and hearing-associated learning of the young child. In the United States, the average incidence of hearing loss is 1.1 per 1000 infants. The cause of hearing impairment in children depends on whether the hearing loss is conductive or sensorineural. Most conductive hearing loss is caused by middle ear infections. Causes of sensorineural hearing impairment include genetic, infectious, traumatic, and ototoxic factors.

Genetic causes are probably responsible for as much as 50% of sensorineural hearing loss in children. The most common infectious cause of congenital sensorineural hearing loss is cytomegalovirus (CMV), which infects 1 out of every 100 newborns in the United States each year; of these, about 1200 to 2000 have sensorineural hearing loss. Of particular concern is the fact that congenital CMV infection can cause both symptomatic and asymptomatic hearing loss in the newborn. Some children with congenital CMV infection, who were asymptomatic as newborns, have suddenly lost residual hearing at 4 to 5 years of age. Postnatal causes of sensorineural hearing loss include β-hemolytic streptococcal sepsis in the newborn, and although less frequent with the routine administration of the conjugate pneumococcal vaccine, S. pneumoniae bacterial meningitis is the most frequent cause after the neonatal period. Other causes of sensorineural hearing loss are toxins and trauma.

Hearing impairment can have a major impact on the development of a child; therefore, early identification through screening programs is strongly advocated. The currently recommended screening techniques are either the transient evoked otoacoustic emissions (OAE) or the ABR. Both methodologies are noninvasive, relatively quick (<5 minutes), and easy to perform. The OAE measures sound waves generated in the inner ear (cochlea) in response to clicks or tone bursts emitted and recorded by a minute microphone placed in the external ear canals of the infant. The ABR uses three electrodes pasted to the infant’s scalp to measure the EEG waves generated by clicks. Because many children become hearing impaired after the neonatal period and are not identified by neonatal screening programs, it is recommended that all infants with risk factors for delayed onset of progressive hearing loss receive ongoing audioligic and medical monitoring for 3 years and at appropriate intervals thereafter.

Once hearing loss has been identified, a full developmental and speech and language evaluation is needed. Parental involvement and counseling are essential. Children with sensorineural hearing loss should be evaluated for possible hearing aid use by a pediatric audiologist. Hearing aids may be fitted for infants as young as 2 months of age. Infants and young children with profound congenital or prelingual deafness have benefited from multichannel cochlear implants. Because of the increased risk of pneumococcal meningitis, children who receive implants should receive age-appropriate immunization against pneumococcal disease.

Hearing Loss in the Elderly

The term presbycusis is used to describe degenerative hearing loss that occurs with advancing age. The degenerative changes that impair hearing may begin in the fifth decade of life and may not be clinically apparent until later. The hearing loss is typically gradual, bilateral, and characterized by high-frequency hearing loss. It is further characterized by reduced hearing sensitivity and speech understanding in noisy environments, slowed central processing of acoustic information, and impaired localization of sound sources. The disorder first reduces the ability to understand speech and, later, the ability to detect, identify, and localize sounds. The most common complaint of persons with presbycusis is that they cannot hear, but rather that they cannot understand what is being said. High-frequency warning sounds, such as beepers, turn signals, and escaping steam, are not heard and localized, with potentially dangerous results.

Given the high prevalence of hearing loss in people of retirement age and its adverse effects on well-being, screening for hearing loss should be performed at annual health care visits. Clinical measures for hearing loss such as whispered voice tests and finger friction tests are reportedly imprecise and are not reliable methods for screening. Screening audiometry administered by someone trained in its use is a practical and cost-effective method for detecting significant hearing loss.

The majority of hearing loss in the elderly is sensorineural. In mild to severe loss, the most effective treatment is hearing amplification with hearing aids, lip reading, and assistive listening devices (e.g., hearing aids with the telephone, captioning on televised programs, flashing alarms). Cochlear implants are indicated at any age for people with bilateral hearing losses not materially helped by hearing aids.
The outer ear collects sound vibrations and channels them to the tympanic membrane, which separates the outer ear from the middle ear. The middle ear is an air-filled cavity in the temporal bone that amplifies the sound waves and transmits them to the fluid-filled inner ear.

The middle ear is connected to the nasopharynx by the eustachian tube, which opens briefly during swallowing to allow for equalization of air pressures on either side of the tympanic membrane. The eustachian tube is lined with a mucous membrane that is continuous with the nasopharynx, allowing infections from the nasopharynx to travel along the eustachian tube to the middle ear.

Otitis media (OM) refers to inflammation of the middle ear. It can represent an acute otitis media (AOM) that has an abrupt onset and is usually related to bacterial infection, or otitis media with effusion (OME) that is associated with fluid in the middle ear without the manifestations of infection and which does not usually require treatment with antimicrobial agents.

The inner ear houses two separate sensory systems: the auditory and vestibular systems. The auditory system contains the cochlea whose receptors convert sound waves to nerve impulses that are transmitted via the cochlear nerve to the auditory cortex.

Hearing is a special sensory function that incorporates the sound-transmitting properties of the external ear canal, the eardrum that separates the external and middle ear, the bony ossicles of the middle ear, the sensory receptors of the cochlea in the inner ear, the neural pathways of the vestibulocochlear or auditory nerve, and the primary auditory and auditory association cortices.

Hearing loss or deafness can be caused by conductive disorders, in which auditory stimuli are not transmitted through the structures of the outer and middle ears to the sensory receptors in the inner ear; by sensorineural disorders that affect the inner ear, auditory nerve, or auditory pathways; or by a combination of conductive and sensorineural disorders.

The Vestibular System and Disorders of Equilibrium

The vestibular apparatus, which is part of the inner ear, serves to maintain a sense of equilibrium and orientation in space. The equilibrium sense, which is also dependent on vision and input from stretch receptors in muscles and tendons, serves to maintain and assist recovery of a stable body and head position through control of postural reflexes, and to maintain a stable visual field despite marked changes in head position.

The Vestibular System

The structures of vestibular system, collectively referred to as the vestibular apparatus, are located in the bony labyrinth of the inner ear next to and continuous with the cochlea of the auditory system. Like the cochlea, the vestibular apparatus consists of two fluid-filled compartments—an outer bony labyrinth that is filled with perilymph and an inner membranous labyrinth that is filled with endolymph.

The bony membranous labyrinth is divided into three semicircular ducts and two large chambers known as the utricle and saccule (Fig. 38-21A). The semicircular ducts sense angular and rotary movements of the head, and the utricle and saccule sense forward and backward movement of the head.

The three semicircular ducts (anterior, posterior, and lateral) are arranged at right angles to each other and represent all three planes of space. Each of these ducts has an enlarged swelling at one end called an ampulla. The ampulla of each of the semicircular ducts contains a ridge that is covered by a sensory epithelium with tufts of hair cells that are covered by a flexible gelatinous cap called the cupula (see Fig. 38-21B). The ampulla of the three semicircular ducts, the lateral, anterior, and posterior ducts, are oriented in one of three planes of space. The lateral (horizontal) ducts are in the same plane, whereas the anterior (superior) duct of one side is parallel with the posterior (inferior) duct on the other side, and the two function as a pair. Thus, regardless of which plane one moves in, there will be receptors to detect movement. Impulses from the semicircular ducts are particularly important in reflex movement of the eyes. During head rotation the eyes slowly drift in the opposite direction and then jump rapidly back toward the direction of rotation to establish a new fixation point.

Located on the inside surface of each utricle and saccule is a small sensory area about 2 mm in diameter called the macula that responds to our sense of static equilibrium (see Fig. 38-21C). Each macula is a flat epithelial patch containing supporting cells and sensory hair cells, which synapse with sensory endings of the vestibular nerve. These hair cells are embedded in a gelatinous mass, the otolithic membrane, which is studded with tiny stones (calcium carbonate crystals) called otothts. Although they are small, the density of the otoths increases the membrane’s weight and its resistance to change in
motion. When the head is tilted, the gelatinous mass shifts its position because of the pull of the gravitational field, bending the cilia of the macular hair cells (see Fig. 38-21D). In a condition called benign paroxysmal positional vertigo (sensation of whirling or spinning motion), the otoliths become dislodged from their gelatinous base, causing a vertigo that is precipitated by changes in the recumbent head position (to be discussed).

The response to body imbalance, such as stumbling, must be fast and reflexive. Hence, information from the vestibular system goes directly to vestibular nuclei in the brain stem or to the cerebellum. The vestibular nuclei, which form the main integrative center for balance, also receive input from visual and somatic receptors, particularly from stretch receptors in the neck muscles that report the angle or inclination of the head. The vestibular nuclei integrate this information and then send impulses to the brain stem centers that control the extraocular eye movements and reflex movements of the neck, limb, and trunk muscles. These reflex movements include the vestibulo-ocular reflexes that keep the eyes still as the head moves and the vestibulospinal reflexes that allow the body to maintain or regain balance. Neurons of the vestibular nuclei also project to the thalamus and cortex, providing the basis for the subjective experiences of position in space and of rotation. Moreover, connections with the chemoreceptor trigger zone of the brain stem stimulate the vomiting center, accounting for the nausea and vomiting that often are associated with motion sickness and vestibular disorders.

**Nystagmus**

The term nystagmus refers to the involuntary eye movements that preserve eye fixation on stable objects in the visual field during angular and rotational movements of the head.\(^\text{16}\) As the body rotates, the vestibulo-ocular reflexes cause a slow compensatory
drifting of eye movement in the opposite direction, thus stabilizing the binocular fixation point. This pattern of slow–fast–slow movements is nystagmus (Fig. 38-22). Clinically, the direction of nystagmus is named for the fast phase of nystagmus.

Spontaneous nystagmus that occurs without head movement or visual stimuli is always pathologic. It seems to appear more readily and more severely with fatigue and to some extent can be influenced by psychological factors. Nystagmus due to a CNS pathologic process, in contrast to vestibular end-organ or vestibulocochlear nerve sources, seldom is accompanied by vertigo. If present, the vertigo is mild. Nystagmus eye movements can be tested by caloric stimulation or rotation (to be discussed).

**Vertigo**

Disorders of vestibular function are characterized by a condition called vertigo, in which an illusion of motion occurs. With vertigo, the person may be stationary and the environment in motion (i.e., objective vertigo) or the person may be in motion and the environment stationary (i.e., subjective vertigo). Persons with vertigo frequently describe a sensation of spinning, “to-and-fro” motion, or falling.

Vertigo should be differentiated from light-headedness, faintness, or syncope. Presyncope, which is characterized by a feeling of light-headedness or “blacking out,” is commonly caused by postural hypotension (see Chapter 18) or a stenotic lesion in the cerebral circulation that limits blood flow. An inability to maintain normal gait may be described as dizziness despite the absence of objective vertigo. The unstable gait may be caused by disorders of sensory input (e.g., proprioception), peripheral neuropathy, or gait problems, and usually is corrected by touching a stationary object such as a wall or table.

Vertigo can result from central or peripheral vestibular disorders. Vertigo due to peripheral vestibular disorders tends to be severe in intensity and episodic or brief in duration. In contrast, vertigo due to central vestibular causes tends to be mild and constant and chronic in duration.

Motion sickness is a form of normal physiologic vertigo. It is caused by repeated rhythmic stimulation of the vestibular system, such as that encountered in car, air, or boat travel. Vertigo, malaise, nausea, and vomiting are the principal symptoms. Autonomic signs, including lowered blood pressure, tachycardia, and excessive sweating, may occur. Hyperventilation, which commonly accompanies motion sickness, produces changes in blood volume and pooling of blood in the lower extremities that lead to postural hypotension and sometimes to syncope. Some persons experience a variant of motion sickness, complaining of sensing the rocking motion of the boat after returning to ground. This usually resolves after the vestibular system becomes accustomed to the stationary influence of being back on land.

**Disorders of Peripheral Vestibular Function**

Disorders of peripheral vestibular function occur when signals from the vestibular apparatus are distorted, as in benign paroxysmal positional vertigo, or are unbalanced by unilateral involvement of one of the vestibular organs, as in Ménière disease. The inner ear is vulnerable to injury caused by fracture of the petrous portion of the temporal bones; by infection of nearby structures, including the middle ear and meninges; and by blood-borne toxins and infections. Damage to the vestibular system can occur as an adverse effect of certain drugs or from allergic reactions to foods. The aminoglycosides (e.g., streptomycin, gentamicin) have a specific toxic affinity for the vestibular portion of the inner ear. Alcohol can cause transient episodes of vertigo. The cause of peripheral vertigo remains unknown in approximately half of the cases.

Severe irritation or damage of the vestibular end-organs or nerves results in severe balance disorders reflected by instability of posture, ataxia, and falling.
accompanying vertigo. Adaptation usually occurs within a few days, after which the person is usually able to walk and even drive a car. Such a person relies heavily on visual and proprioceptive input from muscle and joint sensors, and has severe orientation difficulty in the dark, particularly when traversing uneven terrain.

Benign Paroxysmal Positional Vertigo

Benign paroxysmal positional vertigo (BPPV) is the most common cause of pathologic vertigo and usually develops after the fourth decade of life. It is characterized by brief periods of vertigo, usually lasting less than 1 minute, that are precipitated by a change in head position.77,78 The most prominent symptom of BPPV is vertigo that occurs in bed when the person rolls into a lateral position. It also commonly occurs when the person is getting in and out of bed, bending over and straightening up, or extending the head to look up.

Benign paroxysmal positional vertigo is thought to result from damage to the delicate sensory organs of the inner ear, the semicircular ducts, and otoliths (see Fig. 38-21). In persons with BPPV, the calcium carbonate particles (otoliths) from the utricle become dislodged and become free-floating debris within the endolymph of a semicircular duct, most commonly the posterior duct, which is the most dependent part of the inner ear. Movement of the free-floating debris causes this portion of the vestibular apparatus to become more sensitive, such that any movement of the head in the plane parallel to the posterior duct may cause vertigo and nystagmus. There usually is a several-second delay between head movement and onset of vertigo, representing the time it takes to generate the exaggerated endolymph activity. Symptoms usually subside with continued movement, probably because the movement causes the debris to be redistributed throughout the endolymph system and away from the posterior semicircular duct.

Diagnosis is based on tests that involve the use of a change in head position to elicit vertigo and nystagmus. BPPV often is successfully treated with drug therapy to control vertigo-induced nausea. Nondrug therapies using habituation exercises and otolith repositioning are successful in many people. Otolith repositioning involves a series of maneuvers in which the head is moved to different positions in an effort to reposition the free-floating debris in the endolymph of the semicircular ducts.

Acute Vestibular Neuritis

Acute vestibular neuritis represents an inflammation of the vestibular nerve and is characterized by an acute onset (usually hours) of vertigo, nausea, and vomiting lasting several days and not associated with auditory or other neurologic manifestations. Most persons experience gradual improvement over 1 to 2 weeks, but some develop recurrent episodes.79 A large percentage report an upper respiratory tract illness 1 to 2 weeks before onset of symptoms, suggesting a viral origin. The condition also can occur in persons with herpes zoster oticus. In some persons, attacks of acute vestibulopathy recur over months or years. There is no way to determine whether a person who experiences a first attack will have repeated attacks.

Ménière Disease

Ménière disease is a disorder of the inner ear due to distention of the endolymphatic compartment of the inner ear, causing a triad of hearing loss, vertigo, and tinnitus.80–82 A number of mechanisms have been postulated, including an increased production of endolymph, decreased production of perilymph accompanied by a compensatory increase in volume of the endolymphatic sac, and decreased absorption of endolymph caused by malfunction of the endolymphatic sac or blockage of endolymphatic pathways.

A number of conditions, such as trauma, infection (e.g., syphilis), and immunologic, endocrine (i.e., adrenal-pituitary insufficiency and hypothyroidism), and vascular disorders have been proposed as possible causes of Ménière disease. The most common form of the disease is an idiopathic form thought to be caused by a single viral injury to the fluid transport system of the inner ear. One area of investigation has been the relation between autoimmune disorders and Ménière disease.

Ménière disease is characterized by fluctuating episodes of tinnitus, feelings of ear fullness, and violent rotary vertigo that often renders the person unable to sit or walk. There is a need to lie quietly with the head fixed in a comfortable position, avoiding all head movements that aggravate the vertigo. Symptoms referable to the autonomic nervous system, including pallor, sweating, nausea, and vomiting, usually are present. The more severe the attack, the more prominent the autonomic manifestations. Fluctuating hearing loss occurs with a return to normal after the episode subsides. Initially the symptoms tend to be unilateral, resulting in rotary nystagmus caused by an imbalance in vestibular control of eye movements. Because initial involvement usually is unilateral and the sense of hearing is bilateral, many persons with the disorder are not aware of the full extent of their hearing loss. However, as the disease progresses, the hearing loss stops fluctuating and progressively worsens, with both ears tending to be affected so that the prime disability becomes one of deafness. The episodes of vertigo diminish and then disappear, although the person may be unsteady, especially in the dark.

Methods used in the diagnosis of Ménière disease include audiograms, vestibular testing by electronystagmography, and petrous pyramid radiographs. The administration of hyperosmolar substances, such as glycerin and urea, often produces acute temporary hearing improvement in persons with Ménière disease and sometimes is used as a diagnostic measure of endolymphatic hydrops. The diuretic furosemide also may be used for this purpose.

The management of Ménière disease focuses on attempts to reduce the distention of the endolymphatic space, and can be medical or surgical. Pharmacologic management consists of suppressant drugs (e.g., prochlorperazine, promethazine, diazepam), which act centrally to decrease the activity of the vestibular
Diuretics are used to reduce endolymph fluid volume. A low-sodium diet is recommended in addition to these medications. The steroid hormone prednisone may be used to maintain satisfactory hearing and resolve dizziness. Intratympanic gentamicin therapy has been used for ablation of the vestibular system. This treatment is mainly effective in controlling vertigo and does not alter the underlying pathologic process. Surgical methods include the creation of an endolymphatic shunt in which excess endolymph from the inner ear is diverted into the subarachnoid space or the mastoid (endolymphatic sac surgery), and vestibular nerve section. Advances in vestibular nerve section have facilitated the monitoring of CN VII and CN VIII potentials as a means of preventing hearing damage.

**Disorders of Central Vestibular Function**

Abnormal nystagmus and vertigo can occur as a result of CNS lesions involving the cerebellum and lower brain stem. Central causes of vertigo include brain stem ischemia, tumors, and the demyelinating effects of multiple sclerosis. When brain stem ischemia is the cause of vertigo, it usually is associated with other brain stem signs, such as diplopia, ataxia, dysarthria, or facial weakness. Compression of the vestibular nuclei by cerebellar tumors invading the fourth ventricle results in progressively severe signs and symptoms. In addition to abnormal nystagmus and vertigo, vomiting and a broad-based and dystaxic gait become progressively more evident.

In contrast to peripherally generated nystagmus, CNS-derived nystagmus is relatively constant rather than episodic; can occur in any direction rather than being primarily horizontal or rotatory; often changes direction through time; cannot be suppressed by visual fixation; and does result in rapid diminution or “fatigue,” as with peripheral abnormalities.

**Tests of Vestibular Function**

Diagnosis of vestibular disorders is based on a description of the symptoms, a history of trauma or exposure to agents that are destructive to vestibular structures, and physical examination. Tests of eye movements (i.e., nystagmus) and muscle control of balance and equilibrium often are used.

*Electronystagmography* (ENG) is a precise and objective diagnostic method of evaluating nystagmic eye movements. Electrodes are placed lateral to the outer canthus of each eye and above and below each eye, and a ground electrode is placed on the forehead. With ENG, the velocity, frequency, and amplitude of spontaneous or induced nystagmus and the changes in these measurements brought by a loss of fixation, with the eyes open or closed, can be quantified. *Caloric testing* involves elevating the head 30 degrees and irrigating each external auditory canal separately with 30 to 50 mL of ice water. The resulting changes in temperature, which are conducted through the petrous portion of the temporal bone, set up convection currents that mimic the effects of angular acceleration. In an unconscious person with a functional brain stem and intact vestibulo-ocular reflexes, the eyes exhibit a jerk nystagmus lasting 2 to 3 minutes, with the slow component toward the irrigated ear followed by rapid movement away from the ear. With impairment of brain stem function, the response becomes perverted and eventually disappears. An advantage of the caloric stimulation method is the ability to test the vestibular apparatus on one side at a time. The test is never done on a person who does not have an intact eardrum or those who have blood or fluid collected behind the eardrum.

*Rotational testing* involves the use of a motor-driven revolving chair or platform. Unlike caloric testing, rotational testing depends only on the inner ear and is unrelated to conditions of the external ear or temporal bone. Motor-driven chairs or platforms can be precisely controlled, and multiple graded stimuli can be delivered in a relatively short period. Testing usually is performed in the dark without visual influence and with selected light stimuli. Eye movements are usually monitored using ENG. A major disadvantage of the method is that both ears are tested simultaneously.

The *Romberg test* is used to demonstrate disorders of static vestibular function. It is done by having a person stand with his or her feet together and arms extended forward so that the degree of sway and arm stability can be observed. The person then is asked to close his or her eyes. Deficiency in vestibular static input is indicated by greatly increased sway and a tendency for the arms to drift toward the side of deficiency. If vestibular input is severely deficient, the subject falls toward the deficient side.

**Treatment of Vestibular Disorders**

Depending on the cause, vertigo may be treated pharmacologically. There are two types of drugs used in the treatment of vertigo. First are the drugs used to suppress the illusion of motion. These include drugs such as antihistamines (e.g., meclizine, cyclizine, dimenhydrinate, and promethazine) and anticholinergic drugs (e.g., scopolamine, atropine) that suppress the vestibular system. The second type includes drugs used to relieve the nausea and vomiting that commonly accompany the condition. Antidopaminergic drugs (e.g., phenothiazines) and benzodiazepines commonly are used for this purpose.

Vestibular rehabilitation, a relatively new treatment modality for peripheral vestibular disorders, has met with considerable success. It commonly is done by physical therapists and uses a home exercise program that incorporates habituation exercises, balance retraining exercises, and a general conditioning program. The habituation exercises take advantage of physiologic fatigue of the neurovegetative response to repetitive movement or positional stimulation and are done to decrease motion-provoked vertigo, light-headedness, and unsteadiness. The exercises are selected to provoke the vestibular symptoms. The person moves quickly into the position that causes symptoms, holds the position until the symptoms subside, relaxes, and then repeats the exercise for a prescribed number of times. The exercises usually are repeated twice daily.
The habituation effect is characterized by decreased sensitivity and duration of symptoms. It may occur as little as 2 weeks or take as long as 6 months. Balance retraining exercises consist of activities directed toward improving individual components of balance that may be abnormal. General conditioning exercises, a vital part of the rehabilitation process, are individualized to the person’s preferences and lifestyle.

### SUMMARY CONCEPTS

- Receptors for the vestibular system that respond to changes in rotational and linear acceleration of the head are located in the fluid-filled semicircular ducts of the inner ear.
- The vestibular system has extensive interconnections with neural pathways controlling vision, hearing, balance, and autonomic nervous system function. Signals from the vestibular system initiate head and eye movements to stabilize the visual field and make adjustments in the posture muscles that maintain balance.
- Disorders of vestibular function can result from repeated stimulation of the vestibular system such as during car, air, and boat travel (motion sickness); acute infection of the vestibular pathways (acute vestibular neuritis); dislodgement of otoliths that participate in the receptor function of the vestibular system (benign paroxysmal positional vertigo); or distention of the endolymphatic compartment of the inner ear (Ménière disease).

### REVIEW EXERCISES

1. The mother of a 3-year-old boy notices that his left eye is red and watery when she picks him up from day care. He keeps rubbing his eye as though it itches. The next morning, she notices that both eyes are red, swollen, and watering. Being concerned, she takes him to the pediatrician in the morning and is told that he has “conjunctivitis.” She is told that the infection should go away by itself.
   
   **A.** What part of the eye is involved?
   **B.** What type of conjunctivitis do you think this child has (bacterial, viral, or allergic)?
   **C.** Why didn’t the pediatrician order an antimicrobial drug?
   **D.** Is the condition contagious? What measures should she take to prevent its spread?

2. During a routine eye examination to get new glasses because she had been having difficulty with her distant vision, a 75-year-old woman is told that she is developing cataracts.
   
   **A.** What types of visual changes occur as the result of a cataract?
   **B.** What can the woman do to prevent the cataracts from getting worse?
   **C.** What treatment may she eventually need?

3. A 50-year-old woman is told by her eye doctor that her intraocular pressure is slightly elevated and that although there is no evidence of damage to her eyes at this time, she is at risk for developing glaucoma and should have regular eye examinations.
   
   **A.** Describe the physiologic mechanisms involved in the regulation of intraocular pressure.
   **B.** Differentiate between open-angle and angle-closure glaucoma in terms of their pathology, manifestations, and treatment.
   **C.** See Figure 38-12 to relate the “optic disk cupping” that occurs with glaucoma to the visual field loss that occurs with the disorder.

4. The parents of a newborn infant have been told that their son has congenital cataracts and will require cataract surgery to prevent losing his sight.
   
   **A.** Explain why the infant is at risk for losing his sight if the cataracts are not removed.
   **B.** When should this procedure be done to prevent loss of vision?

5. A mother notices that her 13-month-old child is fussy and tugging at his ear and refuses to eat his breakfast. When she takes his temperature, it is 100°F. Although the child attends day care, his mother has kept him home and made an appointment with the child’s pediatrician. In the physician’s office, his temperature is 100.2°F, he is somewhat irritable, and he has a clear nasal drainage. His left tympanic membrane shows normal landmarks and motility on pneumatic otoscopy. His right tympanic membrane shows erythematous and there is decreased motility on pneumatic otoscopy.
   
   **A.** What risk factors are present that predispose this child to the development of acute otitis media?
   **B.** Are his signs and symptoms typical of otitis media in a child of this age?
   **C.** What are the most likely pathogens? What treatment would be indicated?
   **D.** Later in the week, the mother notices that the child does not seem to hear as well as he did before developing the infection. Is this a common occurrence, and should the mother be concerned about transient hearing loss in a child of this age?
6. A granddaughter is worried that her grandfather is “losing his hearing.” Lately, he has been staying away from social gatherings that he always enjoyed, saying everybody mumbles. He is defiant in maintaining that there is nothing wrong with his hearing. However, he does complain that his ears have been ringing a lot lately.

- A. What are common manifestations of hearing loss in the elderly?
- B. What type of evaluation would be appropriate for determining if this man has a hearing loss, and the extent of his hearing loss?
- C. What are some things the granddaughter might do so that her grandfather could hear her better when she is talking to him?

7. A 70-year-old man complains that he gets this terrible feeling “like the room is moving around” and becomes nauseated when he rolls over in bed or bends over suddenly. It usually goes away once he has been up for a while. He has been told that his symptoms are consistent with benign paroxysmal positional vertigo.

- A. What is the pathophysiology associated with this man’s vertigo?
- B. Why do the symptoms subside once he has been up for a while?
- C. What methods are available for treatment of the disorder?

Chapter 39

Disorders of the Male Genitourinary System

The male genitourinary system is subject to a number of structural and functional disorders, all of which can affect urine elimination, sexual function, and fertility. This chapter is divided into three parts: (1) the physiologic basis of male reproductive function, including hormone production, spermatogenesis, and neural control of sexual function; (2) disorders of the male genitourinary structures, including the penis, scrotum and testes, and prostate gland; and (3) disorders of childhood and changes that occur as a result of the aging process.

Physiologic Basis of Male Reproductive Function

Testicular Function
- Hormone Production
- Spermatogenesis
- Semen Production
- Hypothalamic/Pituitary Control of Testicular Function

Sexual Function
- Neural Control of Male Sexual Function
- Erectile Dysfunction

Disorders of the Penis, the Scrotum and Testes, and the Prostate
- Disorders of the Penis
  - Inflammation and Infection
  - Peyronie Disease
  -Priapism
  - Neoplasms of the Penis
- Disorders of the Scrotum and Testes
  - Disorders of the Testicular Tunica
  - Testicular Torsion
  - Epididymitis
  - Orchitis
  - Neoplasms of the Scrotum and Testes
- Disorders of the Prostate
  - Prostatitis
  - Benign Prostatic Hyperplasia
  - Cancer of the Prostate

Disorders in Childhood and Aging
- Disorders of Childhood
  - Hypospadias and Epispadias
  - Phimosis and Paraphimosis
  - Cryptorchidism
- Changes Related to Aging

The male genitourinary system is composed of the paired gonads, or testes; genital ducts; accessory genital organs; and penis (Fig. 39-1). The testes function in the production of androgens or male sex hormones and spermatozoa; the ductile system aids in the storage and transport of spermatozoa; and the accessory genital organs produce the fluid constituents of semen. The penis functions in both urine elimination and sexual function.
Testicular Function

The two primary functions of the testes or male gonads are steroidogenesis, or synthesis of androgens or male sex hormones, and spermatogenesis, or sperm production. The testes are paired ovoid organs that lie within the scrotum, which hangs outside the abdominal cavity. The testes are surrounded by two tunics. The outer tunic is the two-layered tunica vaginalis derived from the peritoneum. The inner tunic is the tunica albuginea, the dense connective tissue capsule of the testes (Fig. 39-2).

Septal extensions of the tunica albuginea divide the testes into 200 to 300 wedge-shaped compartments or lobules. Each lobule contains one to four tightly coiled seminiferous tubules, in which sperm are produced, and a connective tissue stroma, in which the androgen-producing Leydig or interstitial cells are located.

Hormone Production

The testes produce several male sex hormones, including testosterone, dihydrotestosterone, and androstenedione. Testosterone, which is the most abundant of these hormones, is considered the main testicular hormone. The adrenal cortex also produces androgens, albeit in much smaller quantities (<5% of the total male androgens) than the testes. Larger amounts of testosterone are formed from dihydrotestosterone and androstenedione in other tissues of the body, especially the liver. In addition to testosterone, small amounts of estrogens are formed in the male. Some of this estrogen, thought to be formed from testosterone, plays an important role in spermatogenesis.

Testosterone is metabolized in the liver and excreted by the kidneys. In the bloodstream, testosterone exists in an unbound (free) or a bound form. The bound form is attached to plasma proteins, including albumin and the sex hormone–binding protein produced by the liver. Only approximately 3% of circulating testosterone is unbound and therefore able to enter the cell and exert its metabolic effects. Much of the testosterone that becomes fixed to the tissues is converted to dihydrotestosterone, especially in certain target tissues such as the prostate gland. Some of the actions of testosterone depend on this conversion, whereas others do not.
Testosterone exerts a number of biologic effects in the male (Chart 39-1). In the male embryo, it is essential for appropriate differentiation of the internal and external genitalia, and in the fetus it is necessary for descent of the testes. Testosterone is essential to the development of primary and secondary male sex characteristics during puberty and for the maintenance of these characteristics during adult life. It causes growth of pubic, chest, and facial hair; it produces changes in the larynx that result in the male bass voice; and it increases the thickness of the skin and the activity of the sebaceous glands, predisposing to acne.

Most of the actions of testosterone and other androgens result from increased protein synthesis in target tissues. Androgens function as anabolic agents in males and females to promote metabolism and musculoskeletal growth. They greatly affect the development of muscle mass during puberty, with boys averaging approximately 50% more of an increase in muscle mass than girls.1

**Spermatogenesis**

Spermatogenesis, which occurs in the seminiferous tubules of the testes, is the sequence of events that leads to the formation of male germ cells or spermatozoa. The process begins shortly before puberty and continues throughout a man’s life.

The seminiferous tubules are composed of two types of cells: Sertoli cells and spermatogenic cells1-3 (Fig. 39-3A). Sertoli cells are tall columnar cells with extensive cytoplasmic processes that surround the spermatogenic cells and form tight junctions with other Sertoli cells. Also known as supporting or sustentacular cells, Sertoli cells provide structural organization for the tubules; they supply both physical and nutritional support for the developing germ cells; and their tight junctions prevent the passage of proteins from the interstitial space into the lumen of the seminiferous tubules, thus forming a blood-testis barrier.2,3 In addition, these cells have been shown to be responsible for the movement of spermatozoa from the base of the tubule toward the lumen and for the release of mature sperm into the lumen. They also phagocytose damaged germ cells and residual bodies formed during the last stage of spermatogenesis. Finally, in response to follicle-stimulating hormone (FSH) or testosterone, the Sertoli cells secrete androgen-binding protein. This substance, which has a high affinity for androgens, provides high concentrations of testosterone to the developing germ cells during spermatogenesis.

Spermatogenic cells, the source of spermatozoa, are organized in poorly defined layers of progressive development between adjacent Sertoli cells. Both spermatogenesis and oogenesis, its counterpart in the female, involve a unique kind of nuclear division in which the chromosome number is reduced from 46 to 23 (see Chapter 5).
The process of spermatogenesis begins with the spermatogonial phase, during which the spermatogonia undergo mitotic division to form more spermatogonia as well as primary spermatocytes (Fig. 39-3B). During the next phase of spermatogenesis, the primary spermatocyte undergoes meiotic division during which its 46 chromosomes (23 pairs) are divided so that 23 chromosomes go to one secondary spermatocyte and the other 23 to another secondary spermatocyte. During the final stage of spermatogenesis, the secondary spermatocytes divide to form spermatids, which develop into mature spermatozoa or sperm cells.

After their development in the seminiferous tubules, the spermatozoa move into a highly convoluted network of ducts called the rete testis (see Fig. 39-2). The spermatozoa are then transported through the efferent ductules and into a single duct called the epididymis, which is the final site for sperm maturation. The epididymis also serves as a reservoir for sperm. Sperm can be stored in the epididymis for several months. If held longer they are eventually phagocytized by the epithelial cells of the epididymis. When the male is sexually stimulated and ejaculates, the smooth muscle in the wall of the epididymis contracts vigorously, moving sperm into the next segment of the ductal system, the ductus deferens, also called the vas deferens (Fig. 39-4). The ductus deferens ascends along the posterior border of the testes and then enters the abdomen in the spermatic cord, which serves as a conduit for all of the structures passing to and from the testes. After leaving the spermatic cord, the ductus deferens descends in the pelvis to the level of the bladder, where its distal end enlarges to form the ampulla. Surgical disconnection of the vas deferens in the scrotal area (i.e., vasectomy) serves as an effective method of male contraception. Because sperm are stored in the ampulla, men can remain fertile for 4 to 5 weeks after performance of a vasectomy.

**Semen Production**

The accessory genital glands include the paired seminal vesicles and bulbourethral glands and the single prostate gland (see Fig. 39-1). These glands secrete fluids that form the bulk of the ejaculatory fluid or semen.

The seminal vesicles, which lie on the posterior wall of the bladder, consist of highly tortuous tubes that secrete fluid for the semen. Each of the paired seminal vesicles is lined with secretory epithelium containing an abundance of fructose, prostaglandins, and several other proteins. The fructose secreted by the seminal vesicles provides the energy for sperm motility. The prostaglandins are thought to assist in fertilization by making the cervical mucus more receptive to sperm and by causing reverse peristaltic contractions in the uterus and fallopian tubes to move the sperm toward the ovaries. A short excretory duct from each seminal vesicle combines with the ampulla of the ductus deferens to form the ejaculatory duct, which enters the posterior part of the prostate and continues through until it ends in the prostatic portion of the urethra. Contraction of the smooth muscle coat of the seminal vesicles during ejaculation discharges their secretion into the ejaculatory ducts and helps to flush sperm out of the urethra.

The prostate, which is the largest of the accessory glands, is located in the pelvis, inferior to the bladder, where it surrounds the prostatic portion of the urethra. The prostate gland secretes a thin, milky, alkaline fluid containing citric acid, calcium, acid phosphate, a clotting enzyme, and a probrinolysin. During ejaculation, the capsule of the prostate contracts, and the added fluid increases the bulk of the semen. Both vaginal secretions and the fluid from the vas deferens are strongly acidic. Because sperm mobilization occurs at a pH of 6.0 to 6.5, the alkaline nature of the prostatic secretions is essential for successful fertilization of the ovum.
The bulbourethral glands are peanut-sized glands located on either side of the membranous urethra (see Fig. 39-1). A duct of each gland joins the initial portion of the penile urethra. The glands, which structurally resemble mucus-secreting glands, produce a clear mucus-like secretion. Sexual stimulation causes release of the secretion, which constitutes the major portion of the preseminal fluid and serves to lubricate the penile urethra.

**Hypothalamic/Pituitary Control of Testicular Function**

The hypothalamus and the anterior pituitary gland play an essential role in promoting spermatogenesis in the testes and maintaining the endocrine function of the testes by means of the gonadotropic hormones (i.e., anterior pituitary hormones that promote the function and growth of the testes in the male). The synthesis and release of the gonadotropic hormones from the pituitary gland are regulated by gonadotropin-releasing hormone (GnRH), which is synthesized by the hypothalamus and secreted into the hypothalamohypophysial portal circulation (Fig. 39-5).

Two gonadotropic hormones are secreted by the pituitary gland: FSH and luteinizing hormone (LH). In the male, LH also is called interstitial cell-stimulating hormone. The production of testosterone by the interstitial cells of Leydig is regulated by LH. Follicle-stimulating hormone binds selectively to Sertoli cells surrounding the seminiferous tubules, where it functions in the initiation of spermatogenesis. Under the influence of FSH, Sertoli cells produce androgen-binding protein, plasminogen activator, and inhibin. Androgen-binding protein binds testosterone and serves as a carrier and storage site for testosterone in Sertoli cells. Although FSH is necessary for the initiation of spermatogenesis, full maturation of the spermatozoa requires testosterone. Androgen-binding protein also serves as a carrier of testosterone from the testes to the epididymis. Plasminogen activator, which converts plasminogen to plasmin, functions in the final detachment of mature spermatozoa from Sertoli cells.

Circulating levels of the gonadotropic hormones are regulated in a negative feedback manner by testosterone. High levels of testosterone suppress LH secretion through a direct action on the pituitary and an inhibitory effect on the hypothalamus. Follicle-stimulating hormone is thought to be inhibited by a substance called inhibin, produced by Sertoli cells. Although two forms of inhibin have been identified, only inhibin B has been found in males. Inhibin suppresses FSH release from the pituitary gland without effecting LH release. The pituitary gonadotropic hormones and Sertoli cells in the testes form a classic negative feedback loop in which FSH stimulates inhibin secretion and increased inhibin levels suppress FSH release from the hypothalamus. Unlike the cyclic hormonal pattern in the woman, in the man, FSH, LH, and testosterone secretion and spermatogenesis occur at relatively unchanging rates during adulthood.

**Sexual Function**

The penis is the male external genital organ through which the urethra passes. It functions both as a sexual organ and as an organ of urine elimination. Anatomically, the external penis consists of a shaft that ends in a tip called the glans (see Fig. 39-1). The loose skin of the shaft folds to cover the glans, forming what is called the prepuce, or foreskin. It is the foreskin that is removed during circumcision. The glans of the penis contains many sensory nerves, making this the most sensitive portion of the penile shaft. The shaft of the penis is composed of three masses of erectile tissue held together by fibrous strands and covered with a thin layer of skin (Fig. 39-6B). The two dorsal masses of tissue are called the corpora cavernosa and the third ventral mass, in which the spongy part of the urethra is enclosed, is called the corpus spongiosum. The corpora cavernosa and corpus spongiosum are cavernous sinuses that normally are relatively empty but become engorged with blood during penile erection.

The physiology of the male sex act involves a complex interaction between autonomic nervous system-mediated spinal cord reflexes, higher neural centers, and the vascular system (Fig. 39-6A). It involves erection, emission, ejaculation, and detumescence. Erection involves increased flow of blood into the corpora cavernosa and penile rigidity, emission is the contraction of the vas deferens and ampulla with expulsion of sperm into the internal urethra, and ejaculation is the
expulsion of semen from the urethra. Detumescence, or penile relaxation, results from outflow of blood from the corpora cavernosa.

**Neural Control of Male Sexual Function**

The penis is innervated by both the autonomic and somatic nervous systems. In the pelvis, the sympathetic and parasympathetic components of the autonomic nervous system merge to form what are called the **cavernous nerves**. Erection is under the control of the parasympathetic nervous system, and ejaculation and detumescence are under the control of the sympathetic nervous system. Somatic innervation, which occurs through the pudendal nerve, is responsible for penile sensation and contraction and relaxation of the extracorporeal striated bulbocavernosus and ischiocavernosus muscles.

Erection is a neurovascular process involving the autonomic nervous system, neurotransmitters and endothelial relaxing factors, the vascular smooth muscle of the arteries and veins supplying the penile tissue, and the trabecular smooth muscle of the sinusoids of the corpora cavernosa. It involves increased flow of blood into the corpora cavernosa due to relaxation of the trabecular smooth muscle that surrounds the sinusoidal spaces and compression of the veins controlling outflow of blood from the venous plexus. Erection is mediated by parasympathetic impulses that pass from the sacral segments of the spinal cord through the pelvic nerves to the penis. Parasympathetic stimulation results in release of nitric oxide, a nonadrenergic–noncholinergic neurotransmitter, which causes relaxation of the trabecular smooth muscle of the corpora cavernosa. This relaxation permits the inflow of blood into the sinususes of the cavernosa at pressures approaching those of the arterial blood pressure. Because the erectile tissues of the cavernosa are surrounded by a nonelastic fibrous covering, high pressure in the sinusoids causes ballooning of the erectile tissue to such an extent that the penis becomes hard and elongated. At the same time, contraction of the somatic innervated ischiocavernous muscles forcefully compresses the blood-filled corpora cavernosa, producing a further increase in intercavernous pressures. During this phase of erection, inflow and outflow of blood cease.

Parasympathetic innervation must be intact and nitric oxide synthesis must be active for erection to occur. Nitric oxide activates guanyl cyclase, an enzyme that increases the concentration of cyclic guanosine monophosphate (cGMP), which in turn causes smooth muscle relaxation. Other smooth muscle relaxants (e.g., prostaglandin E{	extsubscript{2}} analogs and α-adrenergic antagonists), if present in high enough concentrations, can independently cause sufficient cavernosal relaxation to result in erection. Many of the drugs that have been developed to treat erectile dysfunction act at the levels of these mediators.

Detumescence or penile relaxation is largely a sympathetic nervous system response. It results from a cessation of neurotransmitter release, the breakdown of second messengers such as cGMP, or sympathetic discharge during ejaculation. Contraction of the trabecular smooth muscle opens the venous channels so that the trapped blood can be expelled and penile flaccidity can return.

**Erectile Dysfunction**

Erectile dysfunction (ED) is defined as the inability to achieve and maintain an erection sufficient to permit satisfactory sexual intercourse. It has been estimated that the disorder affects about 150 million men worldwide. Erectile dysfunction is commonly classified as psychogenic, organic, or mixed psychogenic and organic. Organic etiologies are the most common.

Psychogenic causes of ED include performance anxiety, a strained relationship with a sexual partner, depression, and overt psychotic disorders such as schizophrenia. Depression is a common cause of ED. Psychogenic factors can be further exacerbated by the side effects of many of the therapies used to treat these disorders, which can themselves cause ED.

Organic causes span a wide range of pathologic processes. They include neurogenic, hormonal, vascular, drug-induced, and penile-related etiologies. Neurogenic disorders such as Parkinson disease, stroke, and cerebrovascular trauma often contribute to ED by decreasing libido or preventing the initiation of erection. In spinal cord injury, the extent of neural impairment depends on the
level, location, and extent of the lesion. Somatosensory innervation of the genitalia is essential to the reflex mechanisms involved in erection; this becomes important with aging and conditions such as diabetes that impair peripheral nerve function. Extensive pelvis surgery, especially radical prostatectomy (even so-called “nerve-sparing” procedures), are common causes of erectile dysfunction (ED) due to both direct and indirect nerve damage.

Hormonal causes of ED include a decrease in androgen levels because of both primary and secondary hypogonadism. Androgen levels may be decreased because of aging (andropause). Hyperprolactinemia from any cause interferes with both reproduction and erectile function. This is because prolactin acts centrally to inhibit the release of the hypothalamic GnRH that controls the release of the pituitary gonadotrophic hormones, LH and FSH. Elevated prolactin levels may also interfere with normal functioning at the level of the gonad.

Common risk factors for generalized penile arterial insufficiency include hypertension, hyperlipidemia, cigarette smoking, diabetes mellitus, and pelvic irradiation. In hypertension, erectile function is impaired not so much by the increased blood pressure as by the associated stenotic arterial lesions. Focal stenosis of the common penile artery most often occurs in men who sustained blunt pelvic or perineal trauma (e.g., from bicycling accidents). Failure of the veins to close completely during an erection (veno-occlusive dysfunction) may occur in men with large venous channels that drain the corpora cavernosa. Other disorders that impair venous occlusion are degenerative changes involving the tunica albuginea, as in Peyronie disease.

Many drugs are reported to cause ED, including antidepressant, antipsychotic, and antiandrogen, and antihypertensive medications. Cigarette smoking can induce vasoconstriction and penile venous leakage because of its effects on cavernous smooth muscle and can double the risk of erectile dysfunction. Alcohol in small amounts may increase libido and improve erection; however, in large amounts it can cause central sedation, decreased libido, and transient ED.

Aging is known to increase the risk of ED. After 50 years of age, the overall prevalence of ED is reported to be greater than 50%. Many of the pathologic processes that contribute to ED are more common in older men, including diabetes, hyperlipidemia, vascular disease, and the long-term effects of cigarette smoking. Age-related declines in testosterone may also play a role (andropause). Psychosocial problems such as depression, esteem issues, partner relationships, history of substance abuse, and anxiety and fear of performance failure also may contribute to ED in older men.

A diagnosis of ED requires careful history (medical, sexual, and psychosocial), physical examination, and laboratory tests aimed at determining what other tests are needed to rule out organic causes of the disorder. Because many medications, including prescribed, over-the-counter, and illicit drugs, can cause ED, a careful drug history is indicated.

Erectile dysfunction is now recognized as a marker for cardiovascular disease, and is now considered a component of the metabolic syndrome (a collection of cardiovascular risk factors; see Chapter 33). The presence of ED can be an early warning sign of underlying vascular disease (coronary, cerebrovascular, and peripheral) which can be asymptomatic especially in patients with type 2 diabetes. It has been proposed that men with smaller penile arteries (diameter 1–2 mm) suffer obstruction from atherosclerotic plaque burden earlier than those with larger coronary (3–4 mm), carotid (5–7 mm), or iliofemoral (6–8 mm) arteries, hence ED may be symptomatic before a coronary event. In addition, the association between ED and the metabolic syndrome may be related to the underlying endothelial dysfunction seen in both conditions (see Chapter 18). Men with ED should be evaluated for coexisting vascular disease and cardiovascular risk factors should be modified or treated (e.g., smoking, diabetes, hypertension, and hyperlipidemia).

Treatment methods include psychosexual counseling, androgen replacement therapy (when androgen deficiency is confirmed), oral and intracavernous drug therapy, vacuum constriction devices, and surgical treatment (prosthetic and vascular surgery). Among the commonly prescribed drugs used for the treatment of ED are the selective inhibitors of phosphodiesterase type 5 (PDE-5), the enzyme that inactivates cGMP (sildenafil, vardenafil, and tadalafil). These drugs act by facilitating corporal smooth muscle relaxation in response to sexual stimulation. The concomitant use of PDE-5 inhibitors and nitrates (used, for example, in ischemic heart disease) is absolutely contraindicated because of the risk of profound hypotension. The PDE-5 inhibitors are taken orally. Alprostadil, a prostaglandin E1 analog, acts by producing relaxation of cavernous smooth muscle. It is either injected directly into the cavernosa (with diffusion into the opposite cavernosa) or placed in the urethra as a minisuppository. Phentolamine (a-adrenergic receptor antagonist) and papaverine (smooth muscle relaxant) are also administered by intracavernous injection.
Disorders of the Penis, the Scrotum and Testes, and the Prostate

The male genitourinary system is subject to structural defects, inflammation and infection, and neoplasms, all of which can affect urine elimination, sexual function, and fertility.

Disorders of the Penis

Disorders of the penis include congenital defects (discussed in the section on disorders of childhood), acute and chronic inflammatory conditions, Peyronie disease, priapism, and neoplasms.

Inflammation and Infection

The term balanitis refers to local inflammation of the glans penis and balanoposthitis to inflammation of the glans penis and overlying prepuce. The condition may result from trauma, irritation, or infection caused by a wide array of organisms. Among the most common infectious agents are Candida albicans, anaerobic bacteria, and pyogenic bacteria. A significant number of inflammatory conditions are caused by sexually transmitted infections (see Chapter 41). Balanitis due to C. albicans infection may be a presenting feature or result from poorly controlled diabetes mellitus.

Acute superficial balanoposthitis is characterized by erythema of the glans and prepuce. An exudate in the form of malodorous discharge may be present. It usually is encountered in males with phimosis (a tight foreskin) or a large, redundant prepuce that interferes with cleanliness and predisposes to bacterial growth in the accumulated secretions and smegma (i.e., debris from the desquamated epithelia). Extension of the erythema and edema may lead to extensive scarring and a condition called phimosis, in which the prepuce cannot be retracted easily over the glans prepuce. When the stenotic prepuce is forcibly retracted over the glans prepuce, the circulation can be compromised causing congestion, swelling, and pain, a condition known as paraphimosis.

Balanitis xerotica obliterans is a chronic, sclerosing, atrophic process of the glans penis that occurs in uncircumcised men. It is clinically and histologically similar to the lichen sclerosus that is seen in women (see Chapter 40). Typically, the lesions consist of grayish-white plaques on the surface of the glans penis and the prepuce. The foreskin is thickened and fibrous and is not retractable. Although balanitis xerotica obliterans was once considered a benign condition, it is now recognized as a precancerous state. Treatment measures include circumcision and topical or intralesional injections of corticosteroids.

Peyronie Disease

Peyronie disease involves a localized and progressive fibrosis of unknown origin that affects the tunica albuginea (i.e., the tough, fibrous sheath that surrounds the corpora cavernosa) of the penis. It is named after Francois de la Peyronie, who in 1743 described a patient who had “rosary beads of scar tissue to cause upward curvature of the penis during erection.” The disorder is characterized initially by an inflammatory process that results in dense fibrous plaque formation. The plaque usually is on the dorsal midline of the shaft, causing upward bowing of the shaft during erection (Fig. 39-7). Some men may develop scarring on both the dorsal and ventral aspects of the shaft, causing the penis to be straight but shortened or have a lateral bend. The fibrous tissue prevents lengthening of the involved area during erection, making intercourse difficult and painful. The disease usually occurs in middle-aged or elderly men.

The manifestations of Peyronie disease include painful erection, bent erection, and the presence of a hard mass at the site of fibrosis. Approximately two thirds of men complain of pain as a symptom. The pain is thought to be generated by inflammation of the adjacent fascial tissue and usually disappears as the inflammation resolves.
During the 1st year or so after formation of the plaque, while the scar tissue is undergoing the process of remodeling, penile distortion may increase, remain static, or resolve and disappear completely. In some cases, the scar tissue may progress to calcification and formation of bonelike tissue.

Diagnosis is based on history and physical examination. Ultrasonography may be used to diagnose the disorder. Although surgical intervention can be used to correct the disorder, it is often delayed because in many cases the disorder is self-limiting. Less invasive treatments include the administration of oral agents with antioxidant properties (e.g., vitamin E, colchicine); pentoxifylline, a drug that is thought to reduce blood viscosity, allowing it to flow more easily through partially obstructed areas; and intralesional treatments, including corticosteroids.

**Priapism**

Priapism is an involuntary, prolonged (>4 hours), abnormal and painful erection that continues beyond, or is unrelated to, sexual stimulation. Priapism is a true urologic emergency because the prolonged erection can result in ischemia and fibrosis of the erectile tissue with significant risk of subsequent impotence. Priapism can occur at any age, in the newborn as well as other age groups. Sickle cell disease or neoplasms are the most common cause in boys between 5 and 10 years of age.

Priapism is caused by impaired blood flow in the corpora cavernosa of the penis. Priapism is classified as primary (idiopathic) or secondary to a disease or drug effect. Secondary causes include hematologic conditions (e.g., leukemia, sickle cell disease, polycythemia), neurologic conditions (e.g., stroke, spinal cord injury), and renal failure. Between 6% and 42% of males with sickle cell disease are affected at some stage by priapism. The relative deoxygenation and stasis of cavernosal blood during erection is thought to increase sickling. Various medications, such as erectile dysfunction drugs, antihypertensive drugs, anticoagulant drugs, antidepressant agents, alcohol, and marijuana, can contribute to the development of priapism. Currently, intracavernous injection therapy for erectile dysfunction is one of the more common causes of priapism.

The diagnosis of priapism usually is based on clinical findings. Color Doppler studies of penile blood flow, penile ultrasonography, and computed tomography (CT) scans may be used to determine intrapelvic pathology. Initial treatment measures include analgesics, sedation, and hydration. Urinary retention may necessitate catheterization. Local measures include ice packs and cold saline enemas, aspiration and irrigation of the corpus cavernosum with plain or heparinized saline, or instillation of α-adrenergic drugs. If less aggressive treatment does not produce detumescence, a temporary surgical shunt may be established between the corpus cavernosum and the corpus spongiosum.

The prognosis for whether fibrosis or erectile failure will occur is determined by the severity and duration of blood stasis. Persistent stasis priapism is known to result in impaired erectile function and tissue fibrosis unless resolved within 24 to 48 hours of onset.

**Neoplasms of the Penis**

Although relatively rare (<1% of male genital tumors) in developed countries of the world, cancer of the penis may account for 10% to 20% of all genital malignancies in areas such as Africa and South America. When it is diagnosed early, penile cancer is highly curable. The greatest hindrance to early diagnosis is a delay in seeking medical attention.

The cause of penile cancer is unknown. Several risk factors have been proposed, including poor genital hygiene, human papillomavirus (HPV) infection, ultraviolet radiation exposure, increasing age, and immunodeficiency states. Circumcision confers protection, and hence cancer of the penis is extremely rare in men circumcised at birth. It is thought that circumcision is associated with better genital hygiene, which, in turn, reduces exposure to carcinogens that may accumulate in smegma and decreases the likelihood of potentially oncogenic strains of HPV. Ultraviolet radiation is thought to have a carcinogenic effect on the penis. Men who were treated for psoriasis with ultraviolet A radiation (i.e., PUVA) have had a reported increased incidence of genital squamous cell carcinomas. Because of this observation, it is suggested that men should shield their genital area when using tanning salons. Immunodeficiency states (e.g., acquired immunodeficiency syndrome [AIDS]) also may play a role in the pathogenesis of penile cancer. Dermatologic lesions with precancerous potential include balanitis xerotica obliterans (discussed under penile inflammatory conditions) and giant condylomata acuminata. Giant condylomata acuminata, or genital warts, are cauliflower-like...
lesions arising on the prepuce or glans as a result of HPV infection (see Chapter 41).

Most penile cancers are of squamous epithelial cell origin and include carcinoma in situ, which is restricted to the epithelium and does not infiltrate the underlying dermis, and invasive carcinomas.\(^{14-16}\) In situ carcinomas of the penis are include Bowen disease and erythroplasia of Queyrat.\(^{15}\) Bowen disease appears as a sharply demarcated, erythematous or grayish-white plaque on the shaft of the penis. Erythroplasia of Queyrat manifests as single or multiple shiny red, sometimes velvety plaques on the glans or foreskin. In approximately 10% of men, these lesions may transform into infiltrating squamous cell cancer.\(^{14,15}\)

Invasive squamous cell carcinoma of the penis usually begins as a small lump or ulcer on the glans or inner surface of the prepuce. The lesions are usually slow growing and have often been present for a year or more before being brought to medical attention. The lesions are usually nonpainful until they undergo secondary ulceration and infection.\(^{14-16,22}\) If phimosis is present, there may be painful swelling, purulent drainage, or difficulty urinating. Metastasis to the inguinal lymph node is characteristic of early-stage disease, but widespread dissemination is uncommon until the lesion is far advanced.

Diagnosis usually is based on physical examination and biopsy results. Computed tomography scans, penile ultrasonographic studies, and magnetic resonance imaging (MRI) may be used in the diagnostic workup. Treatment options vary according to stage, size, location, and invasiveness of the tumor. Carcinoma in situ may be treated conservatively with fluorouracil cream application or laser treatment.\(^{22}\) Conservative treatment requires frequent follow-up examinations. Surgery remains the mainstay of treatment for invasive carcinoma.

**Disorders of the Scrotum and Testes**

The testes, or male gonads, are two egg-shaped structures located outside the abdominal cavity in the scrotum. Embryologically, they develop in the abdominal cavity and then descend through the inguinal canal into a pouch of peritoneum (which becomes the tunica vaginalis) in the scrotum during the seventh to ninth months of fetal life.\(^{23}\) As they descend, the testes pull their arteries, veins, lymphatics, nerves, and conducting excretory ducts with them. These structures are encased by the cremaster muscle and layers of fascia that constitute the spermatic cord (Fig. 39-8A). The descent of the testes is thought to be mediated by testosterone, which is active during this stage of fetal development.

After descent of the testes, the inguinal canal closes almost completely. Failure of this canal to close predisposes to the development of an inguinal hernia later in life (Fig. 39-8B). An inguinal hernia or “rupture” is a protrusion of the parietal peritoneum and part of the intestine through an abnormal opening from the abdominal cavity. A loop of small bowel may become incarcerated in an inguinal hernia (strangulated hernia), in which case the lumen of the bowel may become obstructed and its vascular supply compromised.

The testes and epididymis are completely surrounded by the tunica vaginalis, a serous pouch derived from the peritoneum during fetal descent of the testes into the scrotum. The tunica vaginalis has an outer parietal layer and a deeper visceral layer that adheres to the dense fibrous covering of the testes, the tunica albuginea. The tunica albuginea protects the testes and gives them their ovoid shape. A space exists between these two layers that typically contains a few milliliters of clear fluid. The cremaster muscles, which are bands of skeletal muscle arising from the internal oblique muscles of the trunk, elevate the testes. The testes receive their arterial blood supply from the long testicular arteries, which branch from the aorta. The testicular veins, which drain the testes, arise from a venous network called the pampiniform plexus that surrounds the spermatic artery. The testes are innervated by fibers from both divisions of the autonomic nervous system. Associated sensory nerves

---

**FIGURE 39-8.** (A) Anterior view of the spermatic cord and inguinal canal and coverings of the spermatic cord and testes. (B) Indirect inguinal hernia. (Adapted from Moore KL, Agur AM. Essentials of Clinical Anatomy. 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2002:130, 138.)
transmit pain impulses, resulting in excruciating pain, especially when the testes are hit forcibly.

The scrotum, which houses the testes, is made up of a thin outer layer of darkly pigmented skin that is continuous with the outer skin of the groin. Under the outer skin lies the closely related dartos fascia, a fat-free fascial layer with smooth muscle fibers (i.e., dartos muscle) that is responsible for the wrinkled appearance of the scrotum. This layer contains a septum that separates the two testes. Because the dartos muscle attaches to the skin, its contraction causes the scrotum to wrinkle when cold, reducing the surface area of the scrotum and assisting the cremaster muscles in holding the testes closer to the body.

The location of the testes in the scrotum is important for sperm production, which is optimal at 2°C to 3°C below body temperature (35°C to 37.4°C). Two mechanisms maintain the temperature of the testes at a level consistent with sperm production. One is the pampiniform plexus of testicular veins that surround the testicular artery. This plexus absorbs heat from the arterial blood, cooling it as it enters the testes. The other is the dartos and cremaster muscles, which respond to decreases in testicular temperature by moving the testes closer to the body. Prolonged exposure to elevated temperatures, as a result of prolonged fever or the dysfunction of thermoregulatory mechanisms, can impair spermatogenesis. Some tight-fitting undergarments hold the testes against the body and are thought to contribute to a decrease in sperm counts and infertility by interfering with the thermoregulatory function of the scrotum.

**Disorders of the Testicular Tunica**

Disorders of the testicular tunica represent scrotal swelling or enlargement due to an accumulation of fluid (hydrocele), blood (hematocele), or sperm (spermatocele) between the layers of the tunica vaginalis, or to dilation of the testicular veins (varicocele) (Fig. 39-9).

**Hydrocele.** A hydrocele forms when excess fluid collects between the layers of the tunica vaginalis (Fig. 39-9B). It may be unilateral or bilateral and can develop as a primary congenital defect or as a secondary condition. Acute hydrocele may develop after local injury, epididymitis or orchitis, gonorrhea, lymph obstruction, or germ cell testicular tumor, or as a side effect of radiation therapy. Chronic hydrocele is more common. Fluid collects about the testis, and the mass grows gradually. Its cause is unknown, and it usually develops in men older than 40 years.

Most cases of hydrocele in male infants and children are caused by a patent processus vaginalis, which is continuous with the peritoneal cavity. There are reports that the mass increases in size during the day and decreases at night if the hydrocele communicates with the peritoneal cavity. In many cases hydrocele is associated with an indirect inguinal hernia.

Most hydroceles of infancy close spontaneously; therefore, they are not repaired before 1 year of age. If the hydrocele persists beyond 2 years of age, surgical treatment usually is indicated.

Hydroceles are palpated as cystic masses that may attain massive proportions. If there is enough fluid, the mass may be mistaken for a solid tumor. Transillumination of the scrotum (i.e., shining a light through the scrotum to visualize its internal structures) or ultrasonography can help to determine whether the mass is solid or cystic and whether the testicle is normal. A dense hydrocele that does not illuminate should be differentiated from a testicular tumor. If a hydrocele develops in a young man without apparent cause, careful evaluation is needed to exclude cancer or infection.

In an adult male, a hydrocele is a relatively benign condition. The condition often is asymptomatic, and no treatment is necessary. When symptoms do occur, the feeling may be that of heaviness in the scrotum or pain in the lower back. In cases of secondary hydrocele, the primary condition is treated. If the hydrocele is painful or cosmetically undesirable, surgical correction is indicated.

**Hematocele.** A hematocele is an accumulation of blood in the tunica vaginalis, which causes the scrotal skin to become dark red or purple. It may develop as a result of an abdominal surgical procedure, scrotal trauma, a bleeding disorder, or a testicular tumor.
Spermatocèle. A spermatocèle is a painless, sperm-containing cyst that forms at the end of the epididymis. It is located above and posterior to the testis, is attached to the epididymis, and is separate from the testes. Spermatocèles may be solitary or multiple and usually are less than 1 cm in diameter. They are freely movable and should transilluminate. Spermatocèles rarely cause problems, but a large one may become painful and require excision.

Varicocele. A varicocele is characterized by varicosities of the pampiniform plexus, a network of veins supplying the testes (Fig. 39-9C). The left side is more commonly affected because the left internal spermatic vein inserts into the left renal vein at a right angle, whereas the right spermatic vein has a more oblique insertion into the inferior vena cava. In the standing male, this particular anatomy may cause higher pressures to be transmitted to the left scrotal veins and result in retrograde reflux into veins of the pampiniform plexus. If the condition persists, there may be damage to the elastic fibers and hypertrophy of the vein walls, as occurs in formation of varicose veins in the leg. Sperm concentration and motility are decreased in men with varicoceles. Varicoceles rarely are found before puberty, and the incidence is highest in males between 15 and 35 years of age. Symptoms of varicocele include an abnormal feeling of heaviness in the left scrotum, although many are asymptomatic. Usually, a varicocele is readily diagnosed on physical examination with the man in the standing and recumbent positions. Typically, the varicocele disappears in the lying position because of venous decompression into the renal vein. Scrotal palpation of a varicocele has been compared to feeling a “bag of worms.” Additional diagnostic methods include ultrasonography, radioisotope scanning, and spermatic venography.

Treatment options for varicocele include surgical ligation or sclerosing with a percutaneous transvenous catheter under fluoroscopic guidance. It has been suggested that men with abnormalities in their semen and a varicocele show some degree of improvement in fertility after obliteration of the dilated veins. However, the effectiveness of varicocele treatment in men from subfertile couples is still debated, especially when other assisted reproductive techniques (e.g., intracytoplasmic sperm injection [ICSI]) may be effective with as few as 20 sperm. Aside from improving fertility, other reasons for surgery include the relief of the sensation of “heaviness” and cosmetic improvement.

Testicular Torsion

Testicular torsion is a twisting of the spermatic cord that suspends the testis and the spermatic vessels that supply the testis with blood above the tunica vaginalis. The torsion probably occurs during fetal or neonatal descent of the testes before the tunica adheres to the scrotal wall. When the torsion occurs in utero, the baby is born with a large firm, non-tender testis. Usually the ipsilateral testis is echymotic. In these cases the torsed testis is rarely viable because of the time that has elapsed. In other cases the initial examination is normal, and acute scrotal swelling is recognized subsequently. In these cases, the torsed testis may occasionally be saved. The use of surgical treatment (orchiopexy [in which the testes is attached to the scrotum] and orchiectomy [removal of the testis]) is controversial. There are multiple animal studies indicating that failure to remove the torsed testis may produce an autoimmune response that affects the normal testis.

Intravaginal torsion involves twisting of the spermatic cord within the tunica vaginalis. It is a true surgical emergency, and early recognition and treatment are necessary if the testicle is to be saved. Intravaginal testicular torsion can occur at any age, but is more common during adolescence. Torsion usually occurs in the absence of any precipitating event and is thought to be due to abnormal fixation of the testis within the tunica vaginalis, allowing the testis to twist, especially during periods of testicular growth such as puberty. The torsion obstructs venous drainage, with resultant edema and hemorrhage, and subsequent arterial obstruction. Males usually present in severe distress within hours of onset and often have nausea, vomiting, and tachycardia. The affected testis is large and tender, with pain radiating to the inguinal area.

Testicular torsion must be differentiated from epididymitis, orchitis, and trauma to the testis. On physical examination, the testicle often is high in the scrotum and in an abnormal orientation. These changes are caused by the twisting and shortening of the spermatic cord. The degree of scrotal swelling and redness depends on the duration of symptoms. The cremasteric reflex, normally elicited by stroking the medial aspect of the thigh and observing testicular retraction, frequently is absent.
Color Doppler ultrasonography is increasingly used in the evaluation of suspected testicular torsion. Treatment includes surgical detorsion and orchectomy. Orchectomy is carried out when the testis is deemed nonviable after surgical detorsion. Testicular salvage rates are directly related to the duration of torsion. Because the opposite testicle usually is affected by the same abnormal attachments, prophylactic fixation of that testis often is performed.

**Epididymitis**

Epididymitis is an inflammation of the epididymis, the elongated cordlike structure that is located along the posterior border of the testis and functions in the transport and storage of sperm⁹⁻¹⁰ (see Fig. 39-4). The cause of epididymitis varies with age. Most cases of epididymitis in men younger than 35 years are due to sexually transmitted infections such as *Chlamydia trachomatis* and *Neisseria gonorrhoeae*. In men older than 35, epididymitis is generally caused by infection with common urinary tract pathogens, such as *Escherichia coli* and *Pseudomonas*. In prepubertal children, the disorder usually is associated with congenital urinary tract abnormalities and infection with gram-negative rods.

Infections may reach the epididymis through the vas deferens, in which case the pressure associated with voiding or physical strain may force pathogen-containing urine from the urethra or prostate up the ejaculatory duct and through the vas deferens into the epididymis. Infections may also reach the epididymis through the lymphatics of the spermatic cord. Risk factors for epididymitis in all men include sexual activity, heavy physical exertion, and bicycle or motorcycle riding. Recent urinary tract surgery or instrumentation and anatomic abnormalities such as prostatic obstruction are risk factors in older men.

Epididymitis is characterized by unilateral pain and swelling, accompanied by erythema and edema of the overlying scrotal skin that develops over a period of 24 to 48 hours. Initially, the swelling and induration are limited to the epididymis. The distinction between the testis and epididymis becomes less evident as the inflammation progresses, and the testis and epididymis become one mass. There may be tenderness over the groin (spermatic cord) or in the lower abdomen. Symptoms of lower urinary tract infection, such as fever, frequency, urgency, and dysuria, may be present. Whether urethral discharge is present depends on the organism causing the infection; it usually accompanies gonorrheal infections, is common in chlamydial infections, and is less common in infections caused by gram-negative organisms.

Laboratory findings usually reveal an elevated white blood cell count. Urinalysis and urine culture are important in the diagnosis of epididymitis, with bacteriuria and pyuria suggestive of the disorder; however, the urinalysis may be normal. If the diagnosis remains uncertain, color Doppler ultrasonography may be useful, revealing increased blood flow to the affected testis.

Treatment of epididymitis includes bed rest, scrotal elevation and support, analgesics, nonsteroidal anti-inflammatory agents, and antibiotics. Bed rest with scrotal support improves lymphatic drainage.²⁹ The choice of antibiotics is determined by age, physical findings, urinalysis, Gram stain results, cultures, and sexual history. Sexual activity or physical strain may exacerbate the infection and worsen the symptoms, and should be avoided. If a sexually transmitted disease is suspected, it is important to ensure that the sexual partner receives treatment.

**Orchitis**

Orchitis is an infection of the testes. It can be precipitated by a primary infection in the genitourinary tract, or the infection can be spread to the testes through the epididymis, bloodstream, or lymphatics.²⁹ It can develop as a complication of a systemic infection, such as parotitis (i.e., mumps), scarlet fever, or pneumonia. Probably the best known of these complications is orchitis caused by the mumps virus.³¹

Mumps orchitis is now rarely seen in children younger than 10, but is the most common complication of mumps infection in the postpubertal male, occurring in approximately 20% to 30% of adolescent boys and young men with mumps. Although the incidence of mumps orchitis has dramatically declined since the introduction of childhood vaccination programs, a sharp increase in mumps and mumps orchitis has recently been reported in the United States² and the United Kingdom.³¹ It is also important to note that mumps remains epidemic in many countries throughout the world, and the mumps vaccine is only used in 57% of the World Health Organization member-countries.³¹

The onset of mumps orchitis is sudden; it usually occurs approximately 3 to 4 days after the onset of the parotitis and is characterized by fever, painful enlargement of the testes, and small hemorrhages into the tunica albuginea. Unlike epididymitis, the urinary symptoms are absent. The symptoms usually run their course in 7 to 10 days. The residual effects seen after the acute phase of the infection include hyalinization of the seminiferous tubules and atrophy of the testes (seen in half of affected men). Spermatogenesis is irreversibly impaired in approximately 30% of testes damaged by mumps orchitis. If both testes are involved (which occurs in 10% to 30% of cases), permanent sterility can result, but is rare.³¹ Androgenic hormone function is usually maintained in these cases.

**Neoplasms of the Scrotum and Testes**

Tumors can develop in the scrotum or the testes. Benign scrotal tumors are common and often do not require treatment. Carcinoma of the scrotum is rare and usually is associated with exposure to carcinogenic agents. Almost all solid tumors of the testes are malignant.

**Scrotal Cancer** Cancer of the scrotum was the first cancer directly linked to a specific occupation when, in the 1800s, it was associated with chimney sweeps.³³
Studies have linked this cancer to exposure to tar, soot, and oils. Most squamous cell cancers of the scrotum are linked to poor hygiene and chronic inflammation. Exposure to PUVA or HPV also has been associated with the disease. The mean age of presentation with the disease is 60 years, often preceded by 20 to 30 years of chronic irritation.

In the early stages, cancer of the scrotum may appear as a small tumor or wartlike growth that eventually ulcerates. The thin scrotal wall lacks the tissue reactivity needed to block the malignant process; more than one half of the cases seen involve metastasis to the lymph nodes. Because this tumor does not respond well to chemotherapy or irradiation, the treatment includes wide local excision of the tumor with inguinal and femoral node dissection. Prognosis correlates with lymph node involvement.

**Testicular Cancer.** Testicular cancer accounts for 1% to 2% of all neoplasms in men. Although relatively rare, it is the most common cause of cancer in 20- to 35-year-old males. In the past, testicular cancer was a leading cause of death among men entering their most productive years. Since the late 1970s, however, advances in therapy have transformed an almost invariably fatal disease into one that is highly curable.

Although the cause of testicular cancer is unknown, several predisposing influences may be important: cryptorchidism, genetic factors, and disorders of testicular development. The strongest association has been with cryptorchid or undescended testis. Family clustering of the disorder has been described, although a well-defined pattern of inheritance has not been established. Men with disorders of testicular development, including those with Klinefelter syndrome and testicular feminization, also have a higher risk.

The majority of testicular tumors are of germ cell origin. Germ cell tumors can be classified as seminomas and nonseminomas. Seminomas account for approximately 50% of germ cell tumors and are most frequent in the fourth decade of life. Seminomas tend to retain the phenotypic features of spermatogonia and are of the type of germ cell tumor most likely to produce a uniform population of cells. The nonseminoma tumors include embryonal carcinoma, teratoma, choriocarcinoma, and yolk cell carcinoma derivatives. They usually contain more than one cell type and are less differentiated than seminomas. Embryonal carcinomas are the least differentiated of the tumors, with the capacity to differentiate into other nonseminomatous cell types. They occur most commonly in the 20- to 30-year-old age group. Choriocarcinoma is a rare and highly malignant form of testicular cancer that is identical to tumors that arise in placental tissue. Yolk sac tumors mimic the embryonic yolk sac histologically. They are the most common type of testicular tumors in infants and children up to 3 years of age, and in this age group have a very good prognosis. Teratomas are composed of somatic cell types from two or more germine layers (ectoderm, mesoderm, or endoderm). They constitute less than 3% of germ cell tumors and can occur at any age from infancy to old age. They usually behave as benign tumors in children, but contain minute foci of cancer cells in adults.

Often the first sign of testicular cancer is a slight enlargement of the testicle that may be accompanied by some degree of discomfort. This may be an ache in the abdomen or groin or a sensation of dragging or heaviness in the scrotum. Frank pain may be experienced in the later stages, when the tumor is growing rapidly and hemorrhaging occurs. Testicular cancer can spread when the tumor may be barely palpable. Approximately 10% of men present with symptoms related to metastatic disease. Signs of metastatic spread include swelling of the lower extremities, back pain, neck mass, cough, hemoptysis, or dizziness. Gynecomastia (breast enlargement) may result from human chorionic gonadotropin (hCG)-producing tumors and occurs in about 5% of men with germ cell tumors. Although routine screening and monthly self-examination in young men has been recommended, studies have not shown that they improve outcomes. However, men with suggestive signs and symptoms should be carefully evaluated to avoid delayed diagnosis or misdiagnosis.

The diagnosis of testicular cancer requires a thorough urologic history and physical examination. A painless testicular mass may be cancer. Conditions that produce an intrascrotal mass similar to testicular cancer include epididymitis, orchitis, hydrocele, or hematoma. The examination for masses should include palpation of the testes and surrounding structures, transillumination of the scrotum, and abdominal palpation. Testicular ultrasonography can be used to differentiate testicular masses. CT scans and MRI are used in assessing metastatic spread.

Tumor markers that measure protein antigens produced by malignant cells may provide information about the existence of a tumor and the type of tumor present. Three tumor markers are of importance in the diagnosis and management of testicular cancer: \( \alpha \)-fetoprotein (AFP), \( \beta \)-hCG, and lactic acid dehydrogenase (LDH). \( \alpha \)-Fetoprotein is normally present in fetal serum in high levels, but should be present in only trace amounts beyond the age of 1 year. \( \beta \)-Human chorionic gonadotropin is a hormone produced by the placenta in pregnant women, and should not be present in significant levels in the normal male. Elevated serum LDH levels, a cellular enzyme found in muscle, liver, kidneys, and brain, has been shown to correlate with the mass of tumor cells. Lactic acid dehydrogenase is often elevated in widespread, metastatic testicular cancer.

The basic treatment of all testicular cancers includes orchiectomy, which is done at the time of diagnostic exploration. Depending on the histologic characteristics of the tumor and the clinical stage of disease, radiation or chemotherapy may be used after orchiectomy. Rigorous follow-up in all men with testicular cancer is necessary to detect recurrences, most of which occur within 2 years of the end of treatment. Testicular cancer is a disease in which even recurrence is highly treatable. With appropriate treatment, the prognosis for men with testicular cancer is excellent. Even patients with more advanced disease have excellent chances for long-term survival.
Disorders of the Prostate

The prostate gland is a walnut-sized fibromuscular and glandular organ that encircles the urethra just inferior to the bladder (see Fig. 39-1). The segment of urethra that travels through the prostate gland is called the prostatic urethra. The prostatic urethra is lined by a thin layer of smooth muscle that is continuous with the bladder wall. This smooth muscle represents the true involuntary sphincter of the male posterior urethra. Because the prostate surrounds the urethra, it can produce urinary obstruction when it becomes enlarged.

The prostate gland is made up of many secretory glands arranged in three concentric areas surrounding the prostatic urethra, into which they open. The component glands of the prostate include the (1) small mucosal glands associated with the urethral mucosa, (2) intermediate submucosal glands that lie peripheral to the mucosal glands, and (3) large main prostatic glands that are situated toward the outside of the gland.

Prostatitis

Prostatitis refers to a variety of inflammatory disorders of the prostate gland, some bacterial and some not. It may occur spontaneously, as a result of catheterization or instrumentation, or secondary to other diseases of the male genitourinary system. As an outcome of two consensus conferences, the National Institutes of Health has established a classification system with four categories of prostatitis syndromes: acute bacterial prostatitis, chronic bacterial prostatitis, chronic prostatitis/pelvic pain syndrome, and asymptomatic inflammatory prostatitis. Men with asymptomatic inflammatory prostatitis have no subjective symptoms and are detected incidentally on biopsy or examination of prostatic fluid.

Acute Bacterial Prostatitis. Acute bacterial prostatitis often is considered a subtype of urinary tract infection. The most likely etiology of acute bacterial prostatitis is an ascending urethral infection or reflux of infected urine into the prostatic ducts. E. coli, other gram-negative rods, and enterococci, organisms known to cause urethritis, are the most common infectious agents. Risk of infection is increased in persons with impaired host defenses (e.g., due to diabetes or human immunodeficiency [HIV] infection), recent catheterization or instrumentation of the urinary tract, or urethral strictures.

The manifestations of acute bacterial prostatitis include fever and chills, malaise, myalgia, arthralgia, frequent and urgent urination, dysuria, and urethral discharge. Dull, aching pain often is present in the perineum, rectum, or sacrococcygeal region. The urine may be cloudy and malodorous because of urinary tract infection. Rectal examination reveals a swollen, tender, warm prostate with scattered soft areas. Prostatic massage produces a thick discharge with white blood cells that grows large numbers of pathogens on culture.

Acute prostatitis usually responds to appropriate antimicrobial therapy chosen in accordance with the sensitivity of the causative agents in the urethral discharge. Depending on the urine culture results, antibiotic therapy usually is continued for at least 4 to 6 weeks. Because acute prostatitis often is associated with anatomic abnormalities, a thorough urologic examination usually is performed after treatment is completed.

A persistent fever indicates the need for further investigation for an additional site of infection or a prostatic abscess. Computed tomography scans and transrectal ultrasonography of the prostate are useful in the diagnosis of prostatic abscesses. Prostatic abscesses, which are relatively uncommon since the advent of effective antibiotic therapy, are found more commonly in men with diabetes mellitus.

Chronic Bacterial Prostatitis. In contrast to acute bacterial prostatitis, chronic bacterial prostatitis is a subtle disorder that is difficult to treat. Men with the disorder typically present with recurrent urinary tract infections with persistence of the same strain of pathogenic bacteria in the prostatic fluid and urine. Organisms responsible for chronic bacterial prostatitis usually are the gram-negative enterobacteria (E. coli, Proteus, or Klebsiella) or Pseudomonas.

The symptoms are variable and include frequent and urgent urination, dysuria, perineal discomfort, and low back pain. Occasionally, myalgia and arthralgia accompany the other symptoms. Secondary epididymitis sometimes is associated with the disorder. Most men are afebrile but have a history of recurrent or relapsing urinary tract infections. Others may be asymptomatic and the diagnosis made after investigation of bacteriuria.

The most accurate method of establishing a diagnosis is by urine cultures. Even after an accurate diagnosis has been established, treatment of chronic prostatitis often is difficult and frustrating. Long-term therapy with an appropriate oral antimicrobial agent is the mainstay of treatment. Selection of an appropriate agent is important since antimicrobial drugs penetrate poorly into the chronically inflamed prostate.

Chronic Prostatitis/Chronic Pelvic Pain Syndrome. Chronic prostatitis/pelvic pain syndrome is both the most common and least understood of the prostatitis syndromes. The category is divided into two types, inflammatory and noninflammatory, based on the presence of leukocytes in the prostatic fluid. The inflammatory type was previously referred to as nonbacterial prostatitis, and the noninflammatory type as prostatodynia.

A large group of men with prostatitis have pain along the penis, testicles, and scrotum; painful ejaculation; low back pain; rectal pain radiating to the inner thighs; urinary symptoms; decreased libido; and impotence, but they have no bacteria in the urinary system. Men with nonbacterial prostatitis often have inflammation of the prostate with an elevated leukocyte count and abnormal inflammatory cells in their prostatic secretions. The cause of the disorder is unknown, and efforts to prove the presence of unusual pathogens (e.g., mycoplasmas, Chlamydia, trichomonads, viruses) have been
largely unsuccessful. It also is thought that nonbacterial prostatitis may be an autoimmune disorder.

Men with noninflammatory prostatitis have symptoms resembling those of nonbacterial prostatitis but have negative urine culture results and no evidence of prostatic inflammation (i.e., normal leukocyte count). The cause of noninflammatory prostatitis is unknown, but because of the absence of inflammation, the search for the cause of symptoms has been directed toward extraprostatic sources. In some cases, there is an apparent functional obstruction of the bladder neck near the external urethral sphincter; during voiding, this results in higher-than-normal pressures in the prostatic urethra that cause intraprostatic urine reflux and chemical irritation of the prostate by urine. In other cases, there is an apparent myalgia (i.e., muscle pain) associated with prolonged tension of the pelvic floor muscles. Emotional stress also may play a role.

Treatment methods for chronic prostatitis/pelvic pain syndrome are highly variable and require further study. Antibiotic therapy is used when an occult infection is suspected. Treatment often is directed toward symptom control. In men with irritative urination symptoms, α-adrenergic blocking agents and/or 5α-reductase inhibitors (such as finasteride) may be beneficial. Noncentered treatment methods such as physical therapy, myofascial trigger point release therapy, and relaxation techniques may provide some symptom relief.45

Benign Prostatic Hyperplasia

Benign prostatic hyperplasia (BPH), also called nodular hyperplasia of the prostate, is a common age-related, nonmalignant enlargement of the prostate gland (Fig. 39-11). It has been reported that more than 50% of men older than 60 years of age have BPH.44 The disorder is seen most frequently in Europe and the United States, and is seen least commonly in Asia.45 The prevalence of the disorder in the United States is higher among blacks than among whites.

Pathogenesis. The pathogenesis of BPH is not completely understood, but appears to involve an imbalance between cell proliferation and cell death that results in an overgrowth of the mucosal glands of the prostate. There is an increased number of epithelial cells and stromal components of the periurethral area of the prostate, but no clear evidence of increased epithelial cell proliferation. Instead, it has been proposed that the cause of the hyperplastic process is decreased cell death, resulting in an accumulation of senescent cells.14 The main androgen in the prostate is dihydrotestosterone (DHT), which is formed in the prostate from the conversion of testosterone by the enzyme 5α-reductase. It is thought that DHT-induced growth factors increase the proliferation of prostatic stromal cells and decrease the death of the epithelial cells. The discovery that DHT is the active factor in BPH provides the rationale for the use of 5α-reductase inhibitors in the treatment of the disorder.

Benign prostatic hyperplasia is characterized by the formation of large, discrete lesions in the periurethral region of the prostate rather than the peripheral zones, which commonly are affected by prostate cancer (Fig. 39-12). The anatomic location of the prostate at the bladder neck contributes to the obstructive properties of BPH and development of lower urinary tract symptoms. There are two distinct components of the obstruction: static and dynamic.44,45 The static component of BPH is related to an increase in prostatic size and gives rise to symptoms such as a weak urinary stream, postvoid dribbling, frequency of urination, and nocturia. The dynamic component of BPH is related to prostatic smooth muscle tone, which is mediated by α1-adrenergic receptors. The recognition of the role of α1-adrenergic receptors on neuromuscular function in the prostate is the basis for use of α1-adrenergic receptor blockers in treating BPH. A third component, detrusor instability and impaired bladder contractility, may contribute to the symptoms of BPH independent of the outlet obstruction created by an enlarged prostate (see Chapter 27). It has been suggested that some of the symptoms of BPH might be related to a decompensating or aging bladder rather than being primarily related to outflow obstruction. An example is the involuntary contraction that results in urgency and an attempt to void that occurs because of small bladder volume.45

Clinical Course. The clinical significance of BPH resides in its tendency to compress the urethra and cause partial or complete obstruction of urinary outflow. As the obstruction increases, acute retention of urine may occur with overdistention of the bladder. The residual urine in the bladder causes increased frequency of urination and a constant desire to empty the bladder, which becomes worse at night. With marked bladder
are readily infected. Back-pressure on the ureters and is completely emptied from them, these diverticula wall (see Chapter 27, Fig. 27-4). Because urine seldom develop as the herniations extend through the bladder and then herniations, or sacculations; finally, diverticula Initially, the hypertrophied fibers form trabeculations and changes in bladder wall structure develop in stages. destruction of the bladder resulting obstruction to urinary flow can give rise to urinary overflow incontinence may occur with the slightest increase in intra-abdominal pressure. The resulting obstruction to urinary flow can give rise to urinary tract infection, destructive changes of the bladder wall, hydroureter, and hydronephrosis. Hypertrophy and changes in bladder wall structure develop in stages. Initially, the hypertrophied fibers form trabeculations and then herniations, or sacculations; finally, diverticula develop as the herniations extend through the bladder wall (see Chapter 27, Fig. 27-4). Because urine seldom is completely emptied from them, these diverticula are readily infected. Back-pressure on the ureters and collecting system of the kidneys promotes hydroureter, hydronephrosis, and danger of eventual renal failure. Current practice suggests that the single most important factor in the evaluation and treatment of BPH is the man’s own experiences related to the disorder. The American Urological Association Symptom Index consists of seven questions about symptoms regarding incomplete emptying, frequency, intermittency, urgency, weak stream, straining, and nocturia.46

The diagnosis of BPH is based on history, physical examination, digital rectal examination, urinalysis, blood tests for serum creatinine and prostate-specific antigen (PSA), and urine flow rate. The digital rectal examination is used to examine the external surface and size of the prostate. An enlarged prostate found during a digital rectal examination does not always correlate with the degree of urinary obstruction. Some men can have greatly enlarged prostate glands with no urinary obstruction, but others may have severe symptoms without a palpable enlargement of the prostate. Urinalysis is done to detect bacteria, white blood cells, or microscopic hematuria in the presence of infection and inflammation. The serum creatinine test is used as an estimate of the glomerular filtration rate and renal function. The PSA test is used to screen for prostate cancer. These evaluation measures, along with the symptom index, are used to describe the extent of obstruction, determine if other diagnostic tests are needed, and establish the need for treatment.

Treatment of BPH is determined by the degree of symptoms that the condition produces and complications due to obstruction. When a man develops mild symptoms related to BPH, a “watchful waiting” stance often is taken.44–46 The condition does not always run a predictable course; it may remain stable or even improve. Until the 1980s, surgery was the mainstay of treatment to alleviate urinary obstruction due to BPH. Currently, there is an emphasis on less invasive methods of treatment, including use of pharmacologic agents. However, when more severe signs of obstruction develop, surgical treatment is indicated to provide comfort and avoid serious kidney damage.

Pharmacologic management includes the use of 5α-reductase inhibitors, α1-adrenergic blocking drugs, or a combination of the two drugs.44,45 The 5α-reductase inhibitors such as finasteride decrease prostate size by blocking the effect of androgens on the prostate. Finasteride causes atrophy of the prostate glandular epithelial cells, which results in a 20% to 30% reduction in volume. The onset is slow (3 to 6 months), but long-lasting. The presence of α-adrenergic receptors in prostatic smooth muscle has prompted the use of α1-adrenergic blocking drugs (e.g., prazosin, terazosin) to relieve prostatic obstruction and increase urine flow.

Herbal therapies have been used for many years by men for the treatment of BPH and lower urinary tract symptoms.44–46 Several studies have looked at the effects of these agents, including the extract of the saw palmetto berry. Improvements in peak urine flow rates and nocturia can occur compared with placebo, but the durability of these effects is unproven. The long-term toxicity and mechanism of action of these agents remain
unclear. Standardization of these products is also worrisome (as with all herbal therapies).

The surgical removal of an enlarged prostate can be accomplished by the transurethral, suprapubic, or perineal approach.44–46 Currently, transurethral prostatectomy (TURP) is the most commonly used technique. With this approach, an instrument is introduced through the urethra, and prostate tissue is removed using a resectoscope and electrocautery. Late complications of TURP include sexual dysfunction, incontinence, and bladder neck constriction. Many new and experimental techniques have also been used to treat BPH including transurethral incision of the prostate, laser surgery, transurethral vaporization, transurethral microwave therapy, and transurethral needle ablation. For men who have heart or lung disease or a condition that precludes major surgery, a stent may be used to widen and maintain the patency of the urethra. A stent is a device made of tubular mesh that is inserted under local or regional anesthesia. Within several months, the lining of the urethra grows to cover the inside of the stent.

Cancer of the Prostate

Globally, prostate cancer is the second most frequently diagnosed cancer in men. An estimated 900,000 new cases were projected to occur in 2008. Nearly three quarters of these cases were expected to be diagnosed in developed countries, with the highest rates being recorded in the United States (233,000 cases in 2014).47 The increase in diagnosed cases is thought to reflect earlier diagnosis because of widespread use of PSA testing since the early 1990s. African American men have the highest reported incidence rate for prostate cancer at all ages, and the cancer also tends to be diagnosed at a later stage.47,48 Asians and Native American men have the lowest rate. Prostate cancer also is a disease of aging. The incidence increases rapidly after 50 years of age; more than 85% of all prostate cancers are diagnosed in men older than 65 years of age.44

Etiology and Pathogenesis. The precise cause of prostate cancer is unclear. As with other cancers, it appears that the development of prostate cancer is a multistep process involving genes that control cell differentiation and growth. The incidence of prostate cancer appears to be higher in relatives of men with prostate cancer. It has been estimated that men who have an affected first-degree relative (e.g., father, brother) and an affected second-degree relative (e.g., grandfather, uncle) have an eightfold increase in risk.14,15,49 It has been suggested that dietary patterns, including increased dietary fats, may alter the production of sex hormones and growth factors and increase the risk of prostate cancer. Supporting the role of dietary fats as a risk factor for prostate cancer has been the observation that the diet of Japanese men, who have a low rate of prostate cancer, is much lower in fat content than that of U.S. men, who have a much higher incidence.

Several factors appear to be protective against the development of prostate cancer. These include dietary factors such as dietary fat reduction and supplementation with vitamins D and E and selenium.50 Dietary intake of soy, green tea, and tomato-rich products (lycopene) may also be important. Vitamin D is not technically a vitamin, but a steroid hormone that has a variety of antiproliferative and proapoptotic effects in prostatic as well as other cancer cell lines. Vitamin E, selenium, and lycopene are all antioxidants, thought to play an important role in cellular defenses to oxidative stress. The low incidence of prostate cancer in Asia has led to an interest in the study of soy and green tea, which are highly consumed in these nations.

In terms of hormonal influence, androgens are believed to play a role in the pathogenesis of prostate cancer.14 Evidence favoring a hormonal influence includes the presence of steroid receptors in the prostate, the requirement of sex hormones for normal growth and development of the prostate, and the fact that prostate cancer almost never develops in men who have been castrated. The response of prostate cancer to estrogen administration or androgen deprivation further supports a correlation between the disease and testosterone levels.14

Clinical Features. Prostatic adenocarcinomas, which account for most primary prostate cancers, are commonly multicentric and located in the peripheral zones of the prostate14,15 (see Fig. 39-12). The high frequency of invasion of the prostatic capsule by adenocarcinoma relates to its subcapsular location. Invasion of the urinary bladder is less frequent and occurs later in the clinical course. Metastasis to the lung reflects lymphatic spread through the thoracic duct and dissemination from the prostatic venous plexus to the inferior vena cava. Bony metastases, particularly to the vertebral column, ribs, and pelvis, produce pain that often presents as a first sign of the disease.

Most men with early-stage prostate cancer are asymptomatic.51 The presence of symptoms often suggests locally advanced or metastatic disease. Depending on the size and location in the prostate of the cancer at the time of diagnosis, there may be changes associated with the voiding pattern similar to those found in BPH. These include urgency, frequency, nocturia, hesitancy, dysuria, hematuria, or blood in the ejaculate.44 On digital rectal examination, the prostate can be nodular and fixed. Bone metastasis often is characterized by low back pain. Pathologic fractures can occur at the site of metastasis. Men with metastatic disease may experience weight loss, anemia, or shortness of breath.

Screening. Whether screening for prostate cancer results in a decrease in prostate cancer deaths is a subject of much debate.52,53 The screening tests currently available are digital rectal examination, PSA testing, and transrectal ultrasonography. Depending on the population studied, detection using digital rectal examination varies from 1.5% to 7%, with most cancers being far advanced when they are detected.53 Prostate-specific antigen is a glycoprotein secreted into the cytoplasm of benign and malignant prostatic cells that is not found in other normal tissues or tumors. However, a positive
PSA test indicates only the possible presence of prostate cancer. It also can be positive in cases of BPH and prostatitis. Thus, the test can result in a large number of men undergoing biopsy and being treated unnecessarily. Transrectal ultrasonography is not used for first-line detection because of its expense, but may benefit men who are at high risk for development of prostate cancer.

The U.S. Preventative Services Task Force (USPSTF) recommends against prostate-specific antigen (PSA)-based screening for prostate cancer. The American Cancer Society advocates that men aged 50 at average risk who are interested in PSA screening should discuss it with their health care provider. Before screening, they should understand the benefits and limitations of screening.

**Diagnosis.** The diagnosis of prostate cancer is based on history and physical examination and confirmed through biopsy methods. Transrectal ultrasonography is used to guide a biopsy needle and document the exact location of the sampled tissue. It also is used for providing staging information. Newly developed small probes for transrectal MRI have been shown to be effective in detecting the presence of cancer in the prostate. Radiologic examination of the bones of the skull, ribs, spine, and pelvis can be used to reveal metastases, although radionuclide bone scans are more sensitive.

Prostatic cancer, like other forms of cancer, is graded and staged (see Chapter 7). Prostate-specific antigen levels are important in the staging and management of prostate cancer. In untreated cases, the level of PSA correlates with the volume and stage of disease. A rising PSA after treatment is consistent with progressive disease, whether it is locally recurring or metastatic. Measurement of PSA is used to detect recurrence after total prostatectomy. Because the prostate is the source of PSA, levels should drop to zero after surgery; a rising PSA indicates recurring disease.

**Treatment.** Cancer of the prostate is treated by surgery, radiation therapy, and hormonal manipulations. Chemotherapy has shown limited effectiveness in the treatment of prostate cancer. Treatment decisions are based on tumor grade and stage and on the age and health of the man. Expectant therapy (watchful waiting) may be used if the tumor is not producing symptoms, is expected to grow slowly, and is small and contained in one area of the prostate. This approach is particularly suited for men who are elderly or have other health problems.

Radical prostatectomy involves complete removal of the seminal vesicles, prostate, and ampulla of the vas deferens. Refinements in surgical techniques (“nerve-sparing” prostatectomy) have allowed maintenance of continence in most men and erectile function in selected cases. Radiation therapy can be delivered by a variety of techniques, including external-beam radiation therapy and transperineal implantation of radioisotopes (brachytherapy).

Metastatic disease often is treated with androgen deprivation therapy. Androgen deprivation may be induced at several levels along the hypothalamic-pituitary-gonadal axis using a variety of methods or agents. Orchietomy or surgical removal of the testes eliminates the source of testosterone. The use of luteinizing hormone–releasing hormone (LHRH) agonists (e.g., leuprolide, goserelin), which act at the hypothalamic-pituitary level to achieve androgen deprivation without orchietomy or administration of diethylstilbestrol (a synthetic estrogenic compound), currently is the most common method of reducing testosterone levels. Although testosterone is the main circulating androgen, the adrenal gland also secretes androgens. Inhibitors of adrenal androgen synthesis (i.e., ketoconazole and amionoglutethimide) block the synthesis of adrenal androgens. Complete androgen blockade can be achieved by combining an antiandrogen with use of an LHRH agonist or orchietomy. The nonsteroidal antiandrogens (e.g., flutamide, bicalutamide) block the uptake and actions of androgens in the prostate cells. Abiraterone blocks the synthesis of androgens in the tumor as well as in the testes and adrenal glands. Patients treated with abiraterone are at risk for adrenal insufficiency and require concurrent steroid replacement therapy.

**SUMMARY CONCEPTS**

- Disorders of the male reproductive system include those that affect the penis, the scrotum and testes, and the prostate gland.
- Disorders of the penis include balanitis, an acute or chronic inflammation of the glans penis; and balanoposthitis, an inflammation of the glans and prepuce. Peyronie disease is characterized by the growth of a band of fibrous tissue on top of the penile shaft. Priapism is an abnormal, painful, sustained erection that can lead to ischemic damage of penile structures. It can occur at any age and is one of the possible complications of sickle cell disease.

**SUMMARY CONCEPTS**

- Disorders of the scrotum and testes include collection of fluid (hydrocele), blood (hematocele), or sperm (spermatocele) in the tunica vaginalis; varicosities of the veins in the pampiniform venous plexus (varicocele); and twisting of the spermatic cord with a resulting compromise of the blood supply to the testis (testicular torsion). Inflammatory conditions can involve the scrotal sac, epididymis, or testes.

- Tumors can arise in the scrotum or the testes. Scrotal cancers usually are associated with exposure to petroleum products such as tar, pitch, and soot. Testicular cancer is the most common cancer in 20- to 35-year-old males. With current treatment methods, a large percentage of men with these tumors can be cured.
Disorders in Childhood and Aging

Disorders of Childhood

Disorders of the male reproductive system that present in childhood include hypospadias, epispadias, phimosis and paraphimosis, and cryptorchidism.

Hypospadias and Epispadias

Hypospadias and epispadias are congenital disorders of the penis resulting from embryologic defects in the development of the urethral groove and penile urethra (Fig. 39-13). In hypospadias, which affects approximately 1 in 250 male infants, the termination of the urethra is on the ventral surface of the penis (the surface in contact with the scrotum). The testes are undescended (cryptorchidism) in 8% to 10% of boys born with hypospadias and chordee (i.e., ventral bowing of the penis), and inguinal hernia also may accompany the disorder. In the newborn with severe hypospadias and cryptorchidism, the differential diagnosis should consider ambiguous genitalia and masculinization that is seen in female infants with congenital adrenal hyperplasia (see Chapter 32). Because many chromosomal aberrations result in ambiguity of the external genitalia, chromosomal studies often are recommended for male infants with hypospadias and cryptorchidism.

Surgery is the treatment of choice for hypospadias. Circumcision is avoided because the foreskin is used for surgical repair. Factors that influence the timing of surgical repair include anesthetic risk, penile size, and the psychological effects of the surgery on the child. In mild cases, the surgery is done for cosmetic reasons only. In more severe cases, surgical repair becomes essential for normal sexual functioning and to prevent the psychological effects of having malformed genitalia. When indicated, surgical repair is usually done between the ages of 6 and 12 months.

Epispadias, in which the opening of the urethra is on the dorsal surface of the penis, is a less common defect, and is often associated with exstrophy of the bladder, a condition in which the abdominal wall fails to cover the bladder. The treatment depends on the extent of the developmental defect.

Phimosis and Paraphimosis

Embryologically, the foreskin begins to develop during the 8th week of gestation as a fold of skin at the distal edge of the penis that eventually grows forward over the base of the glans. By the 16th week of gestation, the prepuce and the glans are adherent. Only a small percentage of newborns have a fully retractable foreskin. With growth, a space develops between the glans and foreskin, and by 3 years of age, approximately 90% of male children have retractable foreskins.

Phimosis refers to a tightening of the prepuce or penile foreskin that prevents its retraction over the glans. In paraphimosis, the foreskin is so tight and constricted that it cannot cover the glans, a condition that can constrict the blood supply to the glans resulting in ischemia and necrosis.

Because the foreskin of many boys cannot be fully retracted in early childhood, it is important that the area be cleaned thoroughly. There is no need to retract the foreskin forcibly because this could lead to infection, scarring, or paraphimosis. As the child grows, the foreskin becomes retractable, and the glans and foreskin should be cleaned routinely. If symptomatic phimosis occurs after childhood, it can cause difficulty with voiding or sexual activity. Circumcision is then the treatment of choice.

Cryptorchidism

Cryptorchidism, or undescended testes, occurs when one or both of the testicles fail to move down into the scrotal sac. The condition is bilateral in 10% to...
of 2 years. However, orchiopexy does allow for earlier monal therapy, or late spontaneous descent after the age cancer is not significantly affected by orchiopexy, hor-
chological effects of an empty scrotum.

may produce morphologic changes in the contralateral undescended. When the disorder is unilateral, it also can be demonstrated at 6 to 12 months. The undescended testicle is normal at birth, but patho-
tics of the testes reflect intrinsic defects in the tes-
ticle or adverse effects of the extrascrotal environment. The undescended testes but rarely are symptomatic. Recognition of the condition and early treatment are important steps in pre-
venting adverse consequences. The risk of malignancy in the undescended testis is 4 to 10 times higher than in the general population. The increased risk of testicular cancer is not significantly affected by orchiopexy, hormonal therapy, or late spontaneous descent after the age of 2 years. However, orchiopexy does allow for earlier detection of a testicular malignancy by positioning the testis in a more easily palpable location.

As a group, men with unilateral or bilateral cryp-
orchidism usually have decreased sperm counts, poorer-
quality sperm, and lower fertility rates than do men whose testicles descend normally. The likelihood of decreased fertility increases when the condition is bilat-
eral. Early orchiopexy appears to provide some protec-
tion of fertility.

Diagnosis is based on careful examination of the genitalia in male infants. Undescended testes due to cryp-
orchidism should be differentiated from retractable testes that retract into the inguinal canal in response to an exaggerated cremaster muscle reflex. Retractable testes usually are palpable at birth but later become nonpal-
pable. They can be brought down with careful palpation in a warm room. Retractable testes usually assume a scrotal position during puberty. They have none of the complications associated with cryptorchidism.

Because imaging has not proven to be 100% reliable, laparoscopy has become standard practice for localization of nonpalpable testes.

The treatment goals for the child with cryptorchidism include measures to enhance future fertility potential, placement of the gonad in a favorable place for cancer detection, and improved cosmetic appearance. Surgical treatment is the cornerstone of therapy. Current information suggests that placement of the testes in the scrotum should be accomplished by 1 year of age to maximize the potential for fertility. Although hormonal treatment has been used in Europe, randomized clinical trials have not shown it to be effective in stimulating testicular descent.

Treatment of men with undescended testis should include lifelong follow-up, considering the sequela of testicular cancer and infertility. Parents need to be aware of the potential issues of infertility and increased risk of testicular cancer. On reaching puberty, boys should be instructed in the necessity of testicular self-examination.

**Changes Related to Aging**

Like other body systems, the male reproductive sys-

mum undergoes degenerative changes as a result of the aging process; it becomes less efficient with age. The declining physiologic efficiency of male reproductive function occurs gradually and involves the endocrine, circulatory, and neuromuscular systems. Compared with the marked physiologic change in aging women, the changes in the aging man are more gradual and less drastic. Gonadal and reproductive failures usually are not related directly to age because a man remains fertile into advanced age; 80- and 90-year-old men have been known to father children.

As the man ages, his reproductive system becomes measurably different in structure and function from that of the younger man. Male sex hormone lev-
el levels, particularly testosterone, decrease with age, with the decline starting later on average than in women.
The term andropause has been used to describe an ill-defined collection of symptoms in aging men, typically those older than 50 years, who may have a low androgen level.61

The sex hormones play a part in the structure and function of the reproductive system and other body systems from conception to old age: they affect protein synthesis, salt and water balance, bone growth, and cardiovascular function. Decreasing levels of testosterone affect sexual energy, muscle strength, and the genital tissues. The testes become smaller and lose their firmness. The seminiferous tubules, which produce spermatozoa, thicken and begin a degenerative process that finally inhibits sperm production, resulting in a decrease of viable spermatozoa. The prostate gland enlarges, and its contractions become weaker. The force of ejaculation also decreases because of a reduction in the volume and viscosity of the seminal fluid. The seminal vesicles change little from childhood to puberty. The pubertal increases in the fluid capacity of the gland remain throughout adulthood and decline after the age of 60 years. After age 60 years, the walls of the seminal vesicles thin, the epithelium decreases, and the muscle layer is replaced by connective tissue. Age-related changes in the penis consist of fibrotic changes in the trabeculae in the corpus spongiosum, with progressive sclerotic changes in arteries and veins. Sclerotic changes also follow in the corpora cavernosa, with the condition becoming generalized in 55- to 60-year-old men.

Erectile dysfunction in the elderly man often is directly related to the man’s general physical condition, including the presence of age-related diseases. Various cardiovascular, respiratory, hormonal, neurologic, and hematologic disorders can be responsible for secondary ED. For example, vascular disease affects male potency because it may impair blood flow to the pudendal arteries or their tributaries, resulting in loss of blood volume with subsequent poor distention of the vascular spaces of erectile tissue. Other diseases affecting potency include hypertension, diabetes, cardiac disease, and malignancies of the reproductive organs. In addition, certain medications can have an effect on sexual function.

Testosterone and other synthetic androgens may be used in older men with low androgen levels to improve muscle strength and vigor.62 Preliminary studies of androgen replacement in aging men with low androgen levels show an increase in lean body mass and a decrease in bone turnover. Before testosterone replacement therapy is initiated, all men should be screened for prostate cancer and other androgen-related diseases. Testosterone is available in an injectable form that is administered every 2 to 4 weeks (a formulation taken every 10 to 12 weeks is also available outside the United States), as a buccal tablet, or as a transdermal patch, gel, or solution (administered via the axilla). Side effects of replacement therapy may include acne, gynecomastia, and reduced high-density lipoprotein levels. It also may contribute to a worsening of sleep apnea in men who are troubled by this problem.

SUMMARY CONCEPTS

- Childhood disorders of the male reproductive system include congenital disorders in which the urethral opening is located on the ventral surface of the penis (hypospadias) or on the dorsal surface (epispadias). Phimosis is the condition in which the foreskin is too tight to permit retraction over the glans. Disorders of the scrotum and testes include cryptorchidism or undescended testicles. Early diagnosis and treatment are important to reduce the risk of malignancy and infertility.

- Like other body systems, the male reproductive system undergoes changes as a result of the aging process. The changes occur gradually and involve changes in endocrine, circulatory, and neuromuscular function. Testosterone levels decrease, the size and firmness of the testes decrease, sperm production declines, and the prostate gland enlarges. There often is a decrease in erectile function related to diseases that accompany the aging process.

REVIEW EXERCISES

1. A 64-year-old man presents to his family physician with erectile dysfunction. He is on multiple medications for “his heart disease.” An initial physical examination is unremarkable.
   A. What additional information should be obtained?
   B. Given his medical history, what are possible factors contributing to his problem?

2. A 23-year-old man presents in the emergency department in severe distress. His left testicle is large and tender and he has pain radiating to the inguinal area.
   A. What would be a tentative diagnosis for this man?
   B. Why would this problem necessitate immediate diagnosis and surgical intervention?

3. A 72-year-old man had a radical prostatectomy for localized prostate cancer. After surgery his PSA level was undetectable. He presents 5 years later having been “lost to follow-up.” He complains of pain in his hip and lower back. His PSA level is now markedly elevated.
   A. What initial investigations are warranted?
   B. What therapies are available for this complication?

Disorders of the female reproductive system have widespread effects on physical and psychological function, including general health status, sexuality, and reproductive potential. This chapter provides a review of the structure and function of the female reproductive system and a discussion of disorders of the external and internal female reproductive organs, menstrual disorders, and disorders of the breast.

**Structure and Function of the Female Reproductive System**

The female reproductive system consists of the external and internal genital structures. The external structures, or genitalia, are situated in the anterior part of the perineum, and the internal structures (vagina, uterus, fallopian tubes, and ovaries) are located in the pelvic cavity (Fig. 40-1).

**External Genitalia**

The external genitalia, which are collectively referred to as the vulva, include the mons pubis, labia majora, labia minora, clitoris, and perineal body (Fig. 40-2). Because of their location, the urethra and anus usually are considered in a discussion of the external genitalia. The mons pubis is a rounded, skin-covered fat pad located anterior to the symphysis pubis. Running posteriorly from the mons pubis are two elongated, hair-covered, fatty folds, the labia majora. The labia majora enclose the labia minora, which may be smaller than the labia majora and are composed of skin, fat, and some erectile tissue. The clitoris is located below the clitoral hood, which is formed by the joining of the two labia minora to form the prepuce. The clitoris is an erectile organ, rich in vascular and nervous supply. Analogous to the male penis, it is a highly sensitive organ that becomes engorged during sexual stimulation.
The area between the labia minora is called the vestibule. Located in the vestibule are the urethral and vaginal openings. The urethra is located posterior to the clitoris and usually is closer to the vaginal opening than to the clitoris. The vaginal orifice, commonly known as the introitus, is the opening between the external and internal genitalia. The ducts of the lesser vestibular (Skene) and greater vestibular (Bartholin) glands also open into the vestibule. Secretions from the Bartholin glands are responsible for sexually stimulated vaginal lubrication (see Fig. 40-2).

**Internal Genitalia**

The female internal genital organs include the vagina, uterus and cervix, and the paired fallopian tubes and ovaries.

**Vagina**

The vagina is a fibromuscular tube that connects the external and internal genitalia. It is located behind the urinary bladder and urethra and anterior to the rectum (Fig. 40-3). The uterine cervix projects into the vagina at its upper end, forming recesses called fornices. The vagina functions as a route for discharge of menses and other secretions, as well as an organ of sexual fulfillment and reproduction.

**Uterus and Cervix**

The uterus is a thick-walled muscular organ. This pear-shaped, hollow structure is located between the bladder and the rectum. The uterus can be divided into three parts: the upper portion above the insertion of the fallopian tubes, called the fundus; the central tapering
portion, called the body; and the inferior constricted part, called the cervix (see Fig. 40-3). The uterus is supported on both sides by four sets of ligaments: the broad ligaments, which run laterally from the body of the uterus to the pelvic side walls; the round ligaments, which run from the fundus laterally into each labium major; the uterosacral ligaments, which run from the uterocervical junction to the sacrum; and the cardinal or transverse cervical ligaments, which are attached to the side of the uterus (Fig. 40-4).

The wall of the uterus is composed of three layers: the perimetrium, the myometrium, and the endometrium. The perimetrium, or outer serosal layer, is derived from the abdominal peritoneum. This outer layer merges with the peritoneum that covers the broad ligaments. Anteriorly, the perimetrium is reflected over the bladder wall, forming the vesicouterine pouch; posteriorly, it extends to form the rectouterine pouch (see Fig. 40-1). Because of the proximity of the perimetrium to the urinary bladder, a bladder infection often causes uterine symptoms, particularly during pregnancy.

The myometrium, or middle muscle layer of smooth muscle fibers, forms the major portion of the uterine wall. It is continuous with the muscle layer of the uterine tubes and the vagina. The smooth muscle also extends into the ligaments connected to the uterus. The inner fibers of the myometrium run in various directions, giving it an interwoven appearance. Contractions of these muscle fibers help to expel menstrual flow and the products of conception during miscarriage or childbirth.

The endometrium, or inner mucosal layer of the uterus, is continuous with the epithelial lining of the uterine tubes and vagina. It is actively involved in the menstrual cycle, differing in structure with each stage of the cycle (to be discussed). If conception occurs, the products of conception are implanted in this layer; if conception does not occur, the inner surface of this layer is shed through menstruation.

The round cervix forms the neck of the uterus. The opening, or os, of the cervix forms a pathway between the vagina and the uterus. The vaginal opening is called the external os.
the external os, and the uterine opening, the internal os. The space between these two openings, which is called the endocervical (cervical) canal, provides a route for menstrual discharge and entry of sperm. Secretions from the columnar epithelium of the endocervix protect the uterus from infection, alter receptivity to sperm, and form a mucoid “plug” during pregnancy.

**Fallopian (Uterine) Tubes**

The fallopian, or uterine, tubes are slender cylindrical structures attached bilaterally to the uterus and supported by the upper folds of the broad ligament. They are formed by smooth muscle and lined with a ciliated, mucus-producing epithelial layer. The end of the fallopian tube nearest the ovary forms a funnel-like opening with fringed, fingerlike projections, called fimbriae, that pick up the oocyte (egg cell) after its release into the peritoneal cavity following ovulation (see Fig. 40-4). The beating of the cilia, along with contractile movements of the smooth muscle, propel the nonmobile oocyte toward the uterus. Besides providing a passageway for ova and sperm, the fallopian tubes permit drainage of tubal secretions into the uterus.

**Ovaries**

The ovaries are almond-shaped organs located on either side of the uterus below the ends of the two fallopian tubes. The ovaries are attached to the posterior surface of the broad ligament and to the uterus by the ovarian ligament (see Fig. 40-4). Structurally, the mature ovary is divided into a highly vascular inner medulla and an outer cortex. The medulla or medullary region is located in the central part of the ovary. It contains loose connective tissue, blood vessels, lymphatic vessels, and nerves. The ovarian cortex is composed of a connective tissue framework, the stroma (also known as the interstitial compartment), as well as ovarian follicles in various stages of development. The surface of the ovary is covered with a thin layer of surface epithelium that is continuous with the lining of the peritoneum. The integrity of this covering is periodically broken at the time of ovulation to allow for the release of the ovum, but then quickly repairs itself.

### The Menstrual Cycle

Between menarche (i.e., first menstrual bleeding) and menopause (i.e., cessation of menstrual bleeding), the female reproductive system undergoes cyclic changes called the menstrual cycle. This includes the maturation and release of oocytes from the ovary during ovulation and periodic vaginal bleeding resulting from the shedding of the endometrial lining. It is not necessary for a woman to ovulate to menstruate; anovulatory cycles do occur. The menstrual cycle produces changes in the breasts, uterus, skin, ovaries, and perhaps other unidentified tissues.

The menstrual cycle is regulated by a complex interaction between the hypothalamic-pituitary axis, the ovaries, and the uterus (Fig. 40-5). Although each part of the reproductive system is essential to normal function, the ovaries are primarily responsible for controlling the cyclic changes and the length of the menstrual cycle. In most women in the middle reproductive years, menstrual bleeding occurs every 25 to 35 days, with a median of 28 days.

**The Hypothalamic-Pituitary Axis**

The ovaries perform two interrelated functions—steroidogenesis, or production of the female sex hormones, and gametogenesis, or production of ova. Both of these functions are regulated by follicle-stimulating hormone.
(FSH) and luteinizing hormone (LH) from the anterior pituitary gland (Fig. 40-6). Because these hormones promote the growth of cells in the ovaries and testes as a means of stimulating the production of sex hormones, they are called the gonadotropic hormones. The secretion of LH and FSH is stimulated by gonadotropin-releasing hormone (GnRH) from the hypothalamus. These gonadotropins then trigger the ovary to release an oocyte that is capable of being fertilized. Concurrently, the ovary secretes hormones that act on the endometrial lining of the uterus to prepare for implantation. In addition, the ovarian hormones provide feedback to the hypothalamus and pituitary regarding the secretion of gonadotropins during the menstrual cycle.

In addition to LH and FSH, the anterior pituitary secretes a third reproductive hormone called prolactin. The primary function of prolactin is the stimulation of lactation in the postpartum period. During pregnancy, prolactin, along with other hormones such as estrogen, progesterone, insulin, and cortisol, contributes to breast development in preparation for lactation. Although prolactin does not appear to play a physiologic role in ovarian function, hyperprolactinemia can lead to hypogonadism. This may include an initial shortening of the luteal phase with subsequent absence of menstruation, scanty menstruation, infrequent menstruation (periods more than 35 days apart), and infertility. The hypothalamic control of prolactin secretion is primarily inhibitory, and dopamine is the most important inhibitory factor. Hyperprolactinemia may occur as an adverse effect of drug treatment using phenothiazine derivatives (i.e., antipsychotic drugs that block dopamine receptors).

**Ovarian Hormones**

The ovaries produce estrogens, progesterone, and androgens (e.g., testosterone). In the ovary, the main source of hormone production are the maturing follicles including the theca cells and granulosa cells (Fig. 40-7A), and the corpus luteum, the cell mass remaining in the ovary after the oocyte has been released (Fig. 40-7B). The theca cells produce androgens, the granulosa cells produce estrogen, and the corpus luteum produces progesterone. The other stromal cells that contribute to the production of androgens can be divided into two populations: the secondary interstitial cells (derived from the theca) and the cells of the hilum, the bridge of tissue through which blood vessels and nerves enter and exit the ovary (see Fig. 40-7B). These cells are the major ones involved in androgen production during menopause.

**Estrogens.** Estrogens are a family of structurally related female sex hormones synthesized and secreted by cells in the ovaries and, in small amounts, by cells in the adrenal cortex and other brain centers. Estrogens are transported in the blood bound to specific plasma globulins, inactivated and conjugated in the liver, and then excreted in the bile.

Estrogens are necessary for normal female development. They stimulate the development of the vagina, uterus, and uterine tubes in the embryo. They also stimulate the stromal development and ductal growth of the breasts at puberty, and are responsible for the accelerated pubertal skeletal growth phase and for closure of the epiphyses of the long bones, contribute to the growth of axillary and pubic hair, and alter the distribution of body fat to produce the typical female body contours. In concert with other hormones, estrogens provide for the reproductive processes of ovulation, implantation of the products of conception, pregnancy, parturition, and lactation by stimulating the development and maintaining the growth of the reproductive organs.

Estrogens also have a number of other important metabolic effects. They are responsible for maintaining the normal structure of skin and blood vessels in women. Estrogens decrease the rate of bone resorption by antagonizing the effects of calcitonin on bone; for this reason, osteoporosis is a common problem in estrogen-deficient postmenopausal women (see Chapter 44). In the liver, estrogens increase the synthesis of transport proteins for thyroxine, estrogen, testosterone, and other hormones. Estrogens also affect the composition of the plasma.
lipoproteins. They produce an increase in high-density lipoproteins (HDLs), a slight reduction in low-density lipoproteins (LDLs), and a reduction in cholesterol levels. Estrogens also increase plasma triglyceride levels, and they enhance the coagulability of blood by increasing the circulating levels of plasminogen and factors II, VII, IX, and X. Estrogens, which have a chemical structure similar to adrenal cortical hormones, can also cause sodium and water retention by the kidney. Most women retain sodium and water and gain weight just before menstruation. The actions of estrogens are summarized in Table 40-1.

Although the ovaries are the major source of estrogen, the biosynthesis of estrogens that occurs in adipose tissue may be a significant source of the hormone. There is evidence that a certain minimum body weight and fat content are necessary for menarche to occur and for the

</table>
menstrual cycle to be maintained. This is supported by the observation of amenorrhea in women with anorexia nervosa, chronic disease, and malnutrition and in those who are elite athletes. In these women, gonadotropin and estradiol secretion, including LH release and responsiveness to the hypothalamic GnRH, can revert to prepubertal levels. With resumption of weight gain and attainment of sufficient body mass, the normal hormonal pattern usually is reinstated. Obesity or significant weight gain also is associated with disruption of the menstrual cycle, including oligomenorrhea or amenorrhea and infertility, although the mechanism is not well understood.

**Progesterone.** Although the word progesterone literally means a substance that maintains pregnancy, progesterone is secreted as part of the normal menstrual cycle. The corpus luteum of the ovary secretes large amounts of progesterone after ovulation, and the adrenal cortex secretes small amounts. The hormone circulates in the blood attached to a specific plasma protein. It is metabolized in the liver and conjugated for excretion in the bile.

The local effects of progesterone on reproductive organs include the glandular development of the lobular and alveolar tissue of the breasts and the cyclic glandular development of the endometrium. Progesterone also can compete with aldosterone at the level of the renal tubule, causing a decrease in sodium reabsorption, with a resultant increase in secretion of aldosterone by the adrenal cortex (as occurs in pregnancy). Although the mechanism is uncertain, progesterone increases basal body temperature and is responsible for the increase in body temperature that occurs with ovulation. Smooth muscle relaxation under the influence of progesterone plays an important role in maintaining pregnancy by decreasing uterine contractions and is responsible for many of the common discomforts of pregnancy, such as edema, nausea, constipation, flatulence, and headaches. The increased progesterone present during pregnancy and the luteal phase of the menstrual cycle enhances the ventilatory response to carbon dioxide, leading to a measurable decrease in arterial and alveolar carbon dioxide (PCO₂) levels.

**Androgens.** Ovarian cells also secrete androgens. In the female, androgens contribute to normal hair growth at puberty and may have other important metabolic effects. Androgen production takes place in the stroma that surrounds the follicles. During the reproductive years, the ovaries are directly responsible for one third of testosterone production. The remaining two thirds comes from the periphery and adrenal precursors—mainly androstenedione, which is produced in equal proportions by the adrenal gland and ovary. The adrenal gland may directly secrete testosterone, but its main contribution is derived from precursor hormones.

**Ovarian Follicle Development and Ovulation**

Unlike the male gonads, which produce sperm throughout a man’s reproductive life, the female gonads contain a fixed number of ova at birth (1 to 2 million at birth—no further oocytes are produced). The process of oogenesis (generation of ova by mitotic division) begins during the 6th week of fetal life and proceeds to the development of the primary oocytes, which become surrounded by a single layer of granulosa cells. The primary oocytes with their surrounding granulosa cells are referred to as primordial follicles. Throughout childhood, the granulosa cells produce nourishment for the ovum and secrete an inhibiting factor that keeps it suspended in a primordial state.

Beginning at puberty, a cyclic rise in the anterior pituitary hormones FSH and LH stimulates the development of several mature (graafian) follicles. Follicles at all stages of development can be found in both ovaries, except in menopausal women (see Fig. 40-7). Most follicles exist as primary follicles, each of which consists of a round oocyte surrounded by a single layer of flattened epithelial cells called granulosa cells. The primary follicles constitute an inactive pool of follicles from which all the ovulating follicles develop. Under the influence of endocrine stimulation, 6 to 12 primary follicles develop into secondary follicles during every ovulatory cycle. The primary oocyte increases in size, and the granulosa cells proliferate to form a multilayered wall around it. During this time, a membrane called the zona pellucida develops and surrounds the oocyte and small pockets of fluid begin to appear between the granulosa cells.

As the follicles mature, FSH stimulates the development of the cell layers. Cells from the surrounding stromal tissue align themselves to form a sheath of connective tissue cells, known as the theca folliculi. The cells of the theca folliculi become differentiated into two layers: an inner layer of highly vascularized androgen-producing cells, called the theca interna, and an outer layer of connective tissue, called the theca externa. As the follicle enlarges, a single large cavity, or antrum, is formed, and a portion of the granulosa cells and the oocyte are displaced to one side of the follicle by the fluid that accumulates. The secondary oocyte remains surrounded by a crown of granulosa cells, the corona radiata. As the follicle matures, ovarian estrogen is produced by the granulosa cells.

Selection of a dominant follicle occurs with the conversion to an estrogen microenvironment. The lesser follicles, although continuing to produce some estrogen, degenerate or become atretic. The dominant preovulatory follicle accumulates a greater mass of granulosa cells, and the theca becomes richly vascular, giving the follicle a hyperemic appearance. High levels of estrogen exert a negative feedback effect on FSH, inhibiting the development of multiple follicles and causing an increase in LH levels. This represents the follicular stage of the menstrual cycle. As estrogen suppresses FSH, the actions of LH predominate, and the mature follicle (measuring approximately 20 mm) bursts; the oocyte, along with the corona radiata, is ejected from the follicle. The ovum normally is then picked up and transported through the fallopian tube toward the uterus.

After ovulation, the follicle collapses, and the luteal stage of the menstrual cycle begins. The granulosa cells are invaded by blood vessels and yellow lipochrome-bearing cells from the theca layer. A rapid
accumulation of blood and fluid forms a mass called the corpus luteum. Leakage of this blood onto the peritoneal surface that surrounds the ovary is thought to contribute to the mittelschmerz (“middle [or intermenstrual] pain”) of ovulation. During the luteal stage, progesterone is secreted from the corpus luteum. If fertilization does not take place, the corpus luteum atrophies and is replaced by white scar tissue called the corpus albicans; the hormonal support of the endometrium is withdrawn and menstruation occurs. In the event of fertilization, the multiplying cells produce a hormone called human chorionic gonadotropin. This hormone prevents luteal regression. As a result the corpus luteum remains functional for 3 months, producing hormonal support for pregnancy until the placenta is fully functional.

**Endometrial Changes**

The endometrium consists of two distinct layers, or zones, that are responsive to hormonal stimulation: a basal layer and a functional layer. The basal layer lies adjacent to the myometrium and is not sloughed during menstruation. The functional layer rises from the basal layer and undergoes proliferative changes and menstrual sloughing. It can be subdivided into two components: a thin, superficial compact layer, and a deeper spongiosa layer that makes up most of the secretory and fully developed endometrium.

The endometrial cycle can be divided into three phases: proliferative, secretory, and menstrual (see Fig. 40-5). The proliferative, or preovulatory, phase is the period during which the glands and stroma of the superficial layer grow rapidly under the influence of estrogen. The secretory, or postovulatory, phase is the period during which progesterone produces glandular dilatation and active mucus secretion and the endometrium becomes highly vascular and edematous. The menstrual phase is the period during which the superficial layer degenerates and sloughs off.

---

**SUMMARY CONCEPTS**

- The female reproductive system, which consists of the external and internal genitalia, has both sexual and reproductive functions. The external genitalia (labia majora, labia minora, clitoris, and vestibular glands) surround the openings of the urethra and vagina. The internal genitalia of the female reproductive system are specialized to participate in sexual intercourse (the vagina), produce and maintain the female egg cells (the ovaries), transport these cells to the site of fertilization (the fallopian tubes), provide a favorable environment for development of offspring (the uterus), and produce the female sex hormones (the ovaries).

---

**Disorders of the Female Reproductive Organs**

Disorders of the female reproductive system have widespread effects on physical, psychological, sexual, and reproductive function. Since the reproductive organs are located close to other pelvic structures, particularly those of the urinary system, disorders of the reproductive system may affect urinary function. This section of the chapter focuses on infections and benign and malignant disorders of the external and internal genitalia.

**Disorders of the External Genitalia**

The external genitalia, which are covered with stratified squamous epithelium, are subject to dermatologic conditions that affect skin elsewhere in the body. The discussion in this section of the chapter focuses on
Bartholin gland cysts and benign and malignant disorders of the vulva.

**Bartholin Gland Cyst and Abscess**

A Bartholin gland cyst is a fluid-filled sac located near the vaginal introitus that results from obstruction of the main duct of the gland (see Fig. 40-2). It may become large, up to 3 to 5 cm in diameter, and produce pain and local discomfort. Infection of a Bartholin cyst produces acute inflammation within the gland and may result in an abscess. Acute symptoms are usually the result of infection and include pain, tenderness, and dyspareunia.

The treatment of symptomatic Bartholin gland cysts consists of the administration of appropriate antibiotics, local application of moist heat, and incision and drainage. Cysts that are frequently are abscessed or are large enough to cause blockage of the introitus may require surgical intervention (i.e., marsupialization, a procedure that involves removal of a wedge of vulvar skin and the cyst wall). Because the Bartholin glands usually shrink during menopause, a vulvar growth in postmenopausal women should be evaluated for malignancy.

**Benign and Malignant Disorders of the Vulva**

Disorders of the vulva often present as white lesions of the vulvar skin and mucosa that may produce pruritus (itching) and scaling. Although commonly referred to as leukoplakia because of their plaquelike appearance, these lesions can represent a number of disorders including inflammatory dermatoses (e.g., psoriasis or chronic dermatitis, discussed in Chapter 46), non-neoplastic epithelial disorders, and premalignant and malignant lesions of the vulva.

**Non-neoplastic Epithelial Disorders.** The term non-neoplastic epithelial disorders refers to nonmalignant atrophic and hyperplastic changes of the vulvar skin and mucosa. Depending on clinical and histologic characteristics, the lesions can be further categorized as lichen sclerosus, lichen planus, and squamous cell hyperplasia (also known as lichen simplex chronicus).

*Lichen sclerosus* is an inflammatory disease of the vulva characterized by plaquelike areas that may progress to parchment-thin epithelium with focal areas of ecchymosis and superficial ulcerations secondary to scratching. Atrophy and contracture of the vulvar tissues with eventual stenosis of the introitus are common when this condition becomes chronic. Itching is common and dyspareunia (painful intercourse) is frequent. The condition develops insidiously and is progressive.

*Lichen planus*, while similar to lichen sclerosus, is an intensely inflammatory autoimmune disorder. Although the symptoms and sequelae are similar to lichen sclerosus, lichen planus may also involve the mucosal and keratinized skin of the oral, anl, and vulvovaginal mucosa. Erosive lichen planus is characterized erythematous erosions surrounded by white lacy edges called *Wickam's striae*. Unlike lichen sclerosus, which is usually limited to the vulva, up to 70% of women with erosive lichen planus have vaginal involvement.

**Squamous cell hyperplasia, or lichen simplex chronicus**, which usually presents as thickened, gray-white plaques with an irregular surface, is a nonspecific condition resulting from rubbing or scratching the skin to relieve pruritus. Presumed to be a response of the genital skin to some type of irritant, this diagnosis is used only when human papillomavirus (HPV) infection (see Chapter 41), fungal infections, or other known causative conditions have been excluded. Pruritus is the most common presenting complaint. Scaling is generally present, and excoriations due to recent scratching can often be seen. There is generally no increased predisposition to cancer, but similar lesions are often present at the margins of established cancer of the vulva.

Current treatment for lichen sclerosus, lichen planus, and squamous cell hyperplasia includes the use of topical corticosteroids. Lichen sclerosus frequently recurs, and lifetime maintenance therapy may be required. Hyperplastic areas that occur in the field of lichen sclerosus may be sites of malignant change and warrant close follow-up and possible biopsy.

**Premalignant and Malignant Neoplasms.** Carcinoma of the vulva is a relatively rare cancer that accounts for approximately 3% to 5% of all cancers of the female reproductive system in the United States, occurring most often in women 60 years of age or older. Approximately 85% to 95% of vulvar malignancies are squamous cell carcinomas. Less common forms of vulvar cancer include malignant melanomas, adenocarcinoma, basal cell carcinoma, and metastatic cancers from various other sites.

In terms of etiology, pathogenesis, and clinical presentation, vulvar carcinoma can be divided into two general groups: (1) basaloid and warty carcinomas, related to infection with oncogenic strains of HPV (about 30% of cases), and (2) keratinizing squamous cell carcinoma, not related to the human papillomavirus (HPV) infection (about 70% of cases). Invasive basaloid and warty-type carcinomas develop from a precancerous in situ lesion called *vulvar intraepithelial neoplasia* (VIN). This type of lesion occurs in reproductive-age women, and risk factors are similar to those for cancer in situ of the cervix. Spontaneous resolution of VIN lesions has occurred. The risk of progression to invasive cancer increases in older women and in women with suppressed immune function. The second form of vulvar cancer, which is seen more often in older women, is generally preceded by vulvar non-neoplastic disorders such as chronic vulvar irritation or lichen sclerosus. The etiology of this group of vulvar cancers is unclear, but they are not typically associated with HPV. Neoplastic changes may arise from lichen sclerosus lesions or hyperplasia, leading directly to invasion, or through an intermediate step involving cellular atypia.

Approximately 50% of women with vulvar cancer present with pruritus and a visible lesion. The lesion may appear as an inconspicuous thickening of the skin, a small raised area or lump, or an ulceration that fails to heal. It may be single or multiple and vary in color from white to velvety red or black. The lesions may resemble...
eczema or dermatitis and may produce few symptoms other than pruritus, local discomfort, and exudation. The lesion may become secondarily infected, causing pain and discomfort. The malignant lesion gradually spreads superficially or as a deep furrow involving all of one labial side. Because there are many lymph channels around the vulva, the cancer metastasizes freely to the regional lymph nodes, including those of the inguinal and femoral chains.

Early diagnosis is important in the treatment of vulvar carcinoma. Because malignant lesions can vary in appearance and commonly are mistaken for other conditions, biopsy and treatment are often delayed. Any vulvar lesion that is increasing in size or has an unusual wartlike appearance should be biopsied. Treatment is primarily wide surgical excision of the lesion for non-invasive cancer and radical excision or vulvectomy with node resection for invasive cancer.

**Vulvodynia**

Vulvodynia is a syndrome of unexplained vulvar pain, previously referred to as *vulvar pain syndrome* or *burning vulva syndrome*.\(^\text{12,13}\) The terminology and diagnostic criteria used for this chronic disorder remain in flux, but the most recent classification system of the International Society for the Study of Vulvovaginal Disorders (ISSVD) defines it as a condition characterized by a sensation of burning, stinging, irritation, soreness or rawness in the absence of relevant visible findings or a specific, clinically identifiable neurological disorder.\(^\text{12,14}\) Vulvodynia is further classified as localized or generalized, and as to whether it is provoked, unprovoked, or of mixed origin.

*Localized vulvodynia* or *vestibulodynia*, formerly referred to as *vulvar vestibulitis syndrome*, is characterized by pain at onset of intercourse, localized point tenderness near the vaginal opening, and sensitivity to tampon placement, tight-fitting pants, bicycling, or prolonged sitting. It is the leading cause of dyspareunia in women younger than 50 years of age. The pain can be primary (present from first contact) or secondary (developing after a period of comfortable sexual relations). The etiology is unknown, but the problem may evolve from chronic vulvar inflammation or trauma. Nerve fibers that supply the vestibular epithelium may become highly sensitized, causing neurons in the dorsal horn of the spinal cord to respond abnormally, thus transforming the sensation of touch in the vestibule into pain.

*Generalized vulvodynia*, formerly called *vulvar dysesthesia* or *essential vulvodynia*, involves severe, constant, widespread burning of the vulvar area that interferes with daily activities. No abnormalities are found on examination, but there is diffuse and variable hypersensitivity and altered sensation to light touch. The quality of this unprovoked pain shares many of the features of other neuropathic pain disorders, particularly complex regional pain syndrome (see Chapter 35) or pudendal neuralgia. Although the cause of the neuropathic pain is unknown, it has been suggested that it may result from myofascial restrictions affecting the sacral and pelvic floor nerves.\(^\text{12,13}\)

There are many proposed triggers for vulvodynia, including chronic recurrent vaginal infections; chemical irritation or drug effects, especially prolonged use of topical steroid creams; the irritating effects of elevated urinary levels of calcium oxalate; and immunoglobulin A deficiency or other disorders of immune regulation. Often it is multifactorial in origin.

Careful history taking and physical assessment are essential for differential diagnosis and treatment. *Vulvodynia* is a diagnosis of exclusion after ruling out infections, such as candidiasis and genital herpes; inflammatory conditions, such as squamous cell hyperplasia and lichen sclerosus; vulvar cancer; or neurologic disorders, such as herpes neuralgia or spinal nerve compression, as causes for the pain.

Treatment of vulvodynia is aimed at symptom relief, is frequently long term, and often needs to be managed from a multidimensional, chronic pain perspective.\(^\text{12,13}\) Local measures include avoidance of harsh soaps and perfumed products, use of sitz baths, and application of topical anesthetic agents (i.e., lidocaine gel). Because dermatologic conditions such as atopic dermatitis and candidiasis are responsible for many of the symptoms of vulvodynia, some health care providers recommend treatment with antihistamines and oral antifungal medications, as well as avoiding contact with potential irritants.\(^\text{14}\) Biofeedback and physical therapy may be used to reverse the changes in pelvic floor musculature and help women control the muscles, regaining strength and improving relaxation.\(^\text{14}\) Oral medications, including tricyclic antidepressants and other antidepressants, are often used to treat the neuropathic pain associated with vulvodynia. Botulinum toxin A injections block the cholinergic innervation of the target tissues and have been shown to be effective in some women with vulvodynia.\(^\text{14}\) Another treatment option for women with severe discomfort is surgical excision of the vestibule. It is commonly the last option and should be reserved for women with long-standing severe symptoms after all other management has yielded unsatisfactory results.\(^\text{14}\)

**Disorders of the Vagina**

The normal vaginal ecology depends on the delicate balance of hormones and bacterial flora. Normal estrogen levels maintain a thick, protective squamous epithelium that contains glycogen. Döderlein bacilli, part of the normal vaginal flora, metabolize glycogen, and in the process produce the lactic acid that normally maintains the vaginal pH of 3.8 to 4.5.\(^\text{15,16}\) Disruptions in these normal environmental conditions predispose to infection.

**Vaginitis**

Vaginitis represents an inflammation of the vagina that is characterized by vaginal discharge and burning, itching, redness, and swelling of vaginal tissues.\(^\text{15,16}\) Pain often occurs with urination and sexual intercourse. Vaginitis may be caused by chemical irritants, foreign bodies, or infectious agents. The causes of vaginitis differ in various age groups. In premenarchal girls, most vaginal infections have nonspecific causes, such as poor
hygiene, intestinal parasites, or the presence of foreign bodies. *Candida albicans, Trichomonas vaginalis,* and bacterial vaginosis are the most common causes of vaginitis in the childbearing years, and some organisms can be transmitted sexually15,16 (see Chapter 41).

The decrease in estrogen levels that occurs during perimenopause and post menopause can lead to an atrophic form of vaginitis. Estrogen deficiency results in a lack of regenerative growth of the vaginal epithelium and changes in the vaginal pH and flora, rendering these tissues more susceptible to infection and irritation. Döderlein bacilli disappear, and the vaginal secretions become less acidic. The symptoms of atrophic vaginitis include itching, burning, and dyspareunia. These symptoms can be reversed by local application of estrogen.

Every woman normally experiences vaginal discharge during the menstrual cycle, but it should not cause burning or itching or have an unpleasant odor. These symptoms suggest inflammation or infection. Because these symptoms are common to the different types of vaginitis, precise identification of the organism is essential for proper treatment. A careful history should include information about systemic disease conditions, the use of drugs such as antibiotics that foster the growth of yeast, dietary habits, stress, and other factors that alter the resistance of vaginal tissue to infections. A physical examination usually is done to evaluate the nature of the discharge and its effects on the genital structures. Microscopic examination of a saline wet-mount smear is the primary means of identifying the organism responsible for the infection. Culture methods and deoxyribonucleic acid (DNA) probe tests may be needed when the organism is not apparent on a wet-mount preparation.

**Cancer of the Vagina**

Primary cancers of the vagina are extremely rare, accounting for approximately 1% to 2% of all cancers of the female reproductive system.5,6,7,11 Like vulvar carcinoma, cancer of the vagina is largely a disease of older women, with a peak incidence between 60 and 70 years of age.7 Vaginal cancers may also result from local extension of cervical cancer, from exposure to sexually transmitted HPV, or rarely from local irritation such as occurs with prolonged use of a pessary. Smoking and human immunodeficiency virus (HIV) infection also increase the risk of vaginal cancer.

Approximately 70% of vaginal cancers are squamous cell carcinomas, with other less common types being adenocarcinomas (15%), malignant melanomas (9%), and sarcomas (up to 4%).17 Squamous cell carcinomas begin in the epithelium and progress over many years from precancerous lesions called vaginal intraepithelial neoplasia (VAIN). Not infrequently, squamous cell carcinoma develops some years after cervical or vulvar carcinoma, a sequence that supports the carcinogenic effect in the lower genital tract related to HPV infection.

The most common symptom of vaginal carcinoma is abnormal bleeding. Other signs or symptoms include an abnormal vaginal discharge, a palpable mass, or dyspareunia. Most women with preinvasive vaginal carcinoma are asymptomatic, with the cancer being discovered during a routine pelvic examination. The anatomic proximity of the vagina to other pelvic structures (urethra, bladder, and rectum) permits early spread to these areas. Pelvic pain, dysuria, and constipation are associated symptoms.

Since most preinvasive and early invasive cancers are silent, the routine use of vaginal cytology (Papanicolaou Pap) smear is the most effective method of detection. Diagnosis requires biopsy of suspect lesions or areas. Because vaginal cancer is rare, there is not standard treatment.11 Both radiation and surgical methods are used, with the treatment plan being determined by the cancer type, stage of the disease (i.e., size, location, and spread), and the woman’s age.11

**Disorders of the Uterine Cervix**

The cervix is composed of two types of epithelial tissue: stratified squamous and columnar epithelium. The exocervix, or visible portion, is covered with stratified squamous epithelium, which also lines the vagina. The endocervix, which is the canal that leads to the endometrial cavity, is lined with columnar epithelium that contains large, branched mucous-secreting glands. The amount and properties of the mucus secreted by the gland cells vary during the menstrual cycle. Blockage of the mucosal glands results in trapping of mucus in the deeper glands, leading to the formation of dilated cysts in the cervix called nabothian cysts. These benign cysts that require no treatment unless they become so numerous that they cause cervical enlargement.

The junction of the squamous epithelium of the exocervix and mucus-secreting columnar epithelium of the endocervix (i.e., squamocolumnar junction) appears at various locations on the cervix at different points in a woman’s life (Fig. 40-8). During childhood, the squamocolumnar junction is located just inside the external os. High levels of hormones which occur during puberty, first
pregnancy and prolonged oral contraceptive use cause the squamocolumnar junction to “roll out” or revert from its original position inside the external os to a position of enlarged cervical surface. Exposure of the columnar cells to low pH vaginal secretions, irritants, and a changing hormonal environment lead to a gradual transformation from columnar to squamous epithelium—a process called metaplasia (see Chapter 2). The area of dynamic change where metaplasia takes place is called the transformation zone. The transformation zone is a critical area for the development of cervical cancer.

Cervicitis

Cervicitis is an acute or chronic inflammation of the cervix. Acute cervicitis may result from the direct infection of the cervix or it may occur secondary to a vaginal or uterine infection. It may be caused by a variety of infective agents, particularly endogenous vaginal aerobes and anaerobes, Streptococcus, Staphylococcus, and Enterococcus. Other specific organisms include C. albicans and herpes simplex virus. Some agents are sexually transmitted, whereas others may be introduced by foreign objects such as tampons or pessaries.

With acute cervicitis, the cervix becomes reddened and edematous. Irritation from the infection results in copious mucopurulent drainage. Depending on the causative agent, acute cervicitis is treated with appropriate antibiotic therapy.

Chronic cervicitis represents a low-grade inflammatory process. It is seen most commonly in parous women and may be sequelae to minute lacerations that occur during childbirth, instrumentation, or other trauma. The organisms usually are nonspecific—often staphylococcal, streptococcal, or coliform bacilli. The symptoms of chronic cervicitis are well defined. The cervix may be ulcerated or normal in appearance; it may contain nabothian cysts; the cervical os may be distorted by old lacerations or everted to expose areas of columnar epithelium; and a mucopurulent drainage may be present.

Untreated cervicitis may extend to include the development of pelvic cellulitis, low back pain, dyspareunia, cervical stenosis, dysmenorrhea, and ascending infection of the uterus or fallopian tubes. Diagnosis of chronic cervicitis is based on vaginal examination, colposcopy, Pap smear cytology, and occasionally biopsy to exclude malignant changes. Treatment usually involves cryosurgery or cauteterization, which causes the tissues to slough and leads to eradication of the infection.

Premalignant Lesions and Cancer of the Cervix

Cervical cancer is one of the best-understood cancers and potentially one of the most preventable. In the 1950s cervical cancer was the leading cause of cancer deaths in women in the United States, but the death rate has declined steadily over the past several decades due to prevention and early detection by cancer screening. Worldwide, however, cervical cancer remains the second most common cancer in women.

Pathogenesis and Risk Factors. The pathogenesis of cervical cancer has been linked to HPV infection by a series of epidemiologic, pathologic, and molecular genetic studies. Of the approximate 100 types of HPV, about 40 affect the anogenital tract. About 15 of these types are associated with cancer and are known as high-risk groups, with subtypes 16 and 18 being the most important in terms of cervical cancer pathology (see Chapter 41). HPV 16 accounts for almost 60% of cervical cancer cases, and HPV 18 for another 10%. By contrast, low-risk types 6 and 11 are associated with genital warts (condylomatous acuminata).

Most cervical cancers begin their development in the squamous columnar cells of the transformation zone. The metaplastic cells within this zone represent the newest and least mature cells in the cervix. HPV infects immature basal cells of the squamous epithelium, but not mature superficial cells that cover the exocervix, vagina, or vulva, explaining the vulnerability of cells in the transformation zone to malignant transformation. Even though HPV has been firmly established as a causative factor in cervical cancer, the evidence does not implicate HPV as the only risk factor. Most HPV infections are transient, indicating the host’s defense system is able to eradicate the virus before it can cause neoplastic changes in cervical cells. Other factors such as cigarette smoking, dietary and nutritional factors, early age of first sexual intercourse, family history of cervical cancer, immunodeficiency (e.g., HIV infection), multiparity, and hormonal and other factors may play a role in determining whether a woman with HPV infection develops cervical cancer.

Two types of HPV vaccines are currently available to prevent HPV infection: a quadrivalent vaccine (Gardasil) to prevent infection by HPV subtypes 16, 18, 6, and 11, and a bivalent vaccine (Cervarix) to prevent infection by subtypes 16 and 18. The quadrivalent vaccine has been approved for females and males between the ages of 9 and 26 years, optimally before initiation of sexual activity. Human papillomavirus subtypes 6 and 11 cause the majority of venereal warts, while types 16 and 18 are responsible for over 80% of all cervical cancers. Because the bivalent vaccine does not protect against HPV subtypes 6 and 11, which are responsible for the majority of condyloma acuminata (genital warts), it is approved for females between the ages of 9 and 26 years, but not for males.

Premalignant and Malignant Lesions. One of the most important advances in the early diagnosis and treatment of cancer of the cervix was made possible by the observation that this cancer arises from precancerous lesions that begin with the development of atypical cervical cells. There are variations in cell size and shape and changes in the nuclear and cytoplasmic parts of the cell, commonly referred to as dysplasia (see Chapter 7). These precancerous changes represent a continuum of morphologic changes with indistinct boundaries that may gradually progress to cancer in situ and then to invasive cancer, or they may spontaneously regress.
The classification of cervical precancerous lesions has changed over time, and terms from different classification systems are currently used interchangeably. Precancerous cell epithelial lesions are often described as either atypical squamous cells (ASCs), low-grade intraepithelial lesions (LSILs), or high-grade intraepithelial lesions (HSILs), and cancerous lesions are termed invasive squamous carcinoma. Atypical squamous cells can be further divided into “ASC of undetermined significance” (ASC-US) and “ASC, cannot exclude HSIL.” Precancerous glandular lesions are classified in a similar manner as atypical glandular cells (AGC). Cancerous glandular lesions are classified as adenocarcinoma.

The atypical cellular changes that precede frank neoplastic changes consistent with cancer of the cervix can be recognized by a number of direct and microscopic techniques, including the cytology (Pap smear), colposcopy, and cervicography. The appropriate use of Pap smear cytology in cervical screening programs has been controversial. The American Cancer Society (ACS), the American College of Obstetricians and Gynecologists (ACOG), and the U.S. Preventative Services Task Force (USPSTF) have developed evidence-based guidelines for cancer screening. The ACOG guidelines recommend that screening begin at age 21 regardless of sexual history and be done every 3 years between the ages of 21 and 29 years. For women ages 30 to 65 the preferred approach is to be screened every 5 years with the combination HPV and Pap smear cytology. Women who prefer may continue to be screened every 3 years with Pap smear cytology. It is recommended that women discontinue screening after the age of 65 if they have had negative cytology results in the previous 10 years. Women who have had a total hysterectomy (removal of the uterus and cervix) for noncancerous reasons should discontinue cytology and HPV testing. For women who have had a total hysterectomy because of a cancer diagnosis, cytology and HPV testing may still be warranted. Women who have had a supra-cervical hysterectomy (the uterus is removed, but the cervix remains) should continue cytology and HPV testing as recommended by cervical cancer screening guidelines.

**Diagnosis and Treatment.** In its early stages, cervical cancer often manifests as a poorly defined lesion of the endocervix. Frequently, women with cervical cancer present with abnormal vaginal bleeding, spotting, and discharge. Although bleeding may assume any course, it is reported most frequently after intercourse. Women with more advanced disease may present with pelvic or back pain that may radiate down the leg, hematuria, fistulas (rectovaginal or vesicovaginal), or evidence of metastatic disease to supraclavicular or inguinal lymph node areas.

Diagnosis of cervical cancer requires pathologic confirmation. Pap smear cytology results demonstrating squamous intraepithelial lesions often require further evaluation by colposcopy, during which a biopsy sample may be obtained from suspect areas and examined microscopically. Diagnostic endocervical currettagge may also be done to determine the extent of endocervical involvement.

Early treatment of cervical cancer involves removal of the lesion by one of various techniques. Biopsy or local destruction of the affected cervical tissue may be therapeutic in and of itself. Electrocautery, cryosurgery, or carbon dioxide laser therapy may be used to treat moderate to severe dysplasia that is limited to the exocervix (i.e., squamocolumnar junction clearly visible). Therapeutic conization becomes necessary if the lesion extends into the endocervical canal and can be done surgically or with a large loop electrocautery procedure (LEEP) in the physician’s office.

Depending on the stage of involvement of the cervix, invasive cancer is treated with surgery, radiation therapy, chemoradiation, or chemotherapy. External-beam irradiation and intracavitary irradiation or brachytherapy (i.e., insertion of radioactive materials into the body) can be used in the treatment of cervical cancer. Intracavitary radiation provides direct access to the central lesion and increases the tolerance of the cervix and surrounding tissues, permitting curative levels of radiation to be used. External-beam radiation eliminates metastatic disease in pelvic lymph nodes and other structures, as well as shrinking the cervical lesion to optimize the effects of intracavitary radiation. Surgery can include extended hysterectomy (i.e., removal of the uterus, fallopian tubes, ovaries, and upper portion of the vagina) without pelvic lymph node dissection, and radical hysterectomy with pelvic lymph node dissection. The choice of treatment is influenced by the stage of the disease as well as the woman’s age and health.

**Disorders of the Uterus**

The uterus is subject to a number of disorders, the most common being infectious processes, endocrine imbalances, neoplasms, and defects in uterine support.

**Infectious Disorders of the Uterus and Pelvic Structures**

The uterus and pelvic structures are subject to infections by a number of agents, including the sexually transmitted organisms *N. gonorrhoeae* and *C. trachomatis*, as well as endogenous microorganisms such as anaerobes, *Haemophilus influenzae*, enteric gram-negative rods, and streptococci. Tuberculosis salpingitis is rare in the United States but more common in developing countries.

**Endometritis.** The endometrium and myometrium are relatively resistant to infections, primarily because the endocervix normally forms a barrier to ascending infections. Acute endometritis is uncommon and usually occurs after the cervical barrier is compromised by abortion, delivery, or instrumentation. Curettage (scraping of the uterine cavity) is diagnostic and often curative because it removes the necrotic tissue that has served as a site for microbial growth.

Chronic inflammation of the endometrium is associated with intrauterine devices (IUDs), pelvic inflammatory disease, and retained products of conception after delivery or abortion. The presence of plasma cells
(which are not present in the normal endometrium) is required for diagnosis. The clinical picture is variable, but often includes abnormal vaginal bleeding, mild to severe uterine tenderness, fever, malaise, and foul-smelling discharge. Treatment involves oral or intravenous antibiotic therapy, depending on the severity of the condition.

**Pelvic Inflammatory Disease.** Pelvic inflammatory disease (PID) is a polymicrobial infection of the upper reproductive tract (uterus, fallopian tubes, or ovaries) associated with sexually transmitted and endogenous organisms. The organisms ascend through the endocervical canal to the endometrial cavity, and then to the fallopian tubes and ovaries (Fig. 40-9). The endocervical canal is slightly dilated during menstruation, allowing bacteria to gain entrance to the uterus and other pelvic structures. After entering the upper reproductive tract, the organisms multiply rapidly in the favorable environment of the sloughing endometrium and ascend to the fallopian tube.

Factors that predispose women to the development of PID include an age younger than 25 years; young age at first intercourse (<15 years); use of nonbarrier contraception, especially IUD or oral contraception; history of new, multiple, or symptomatic sex partners; and previous history of PID or sexually transmitted infection.

The symptoms of PID include lower abdominal pain, which may start just after a menstrual period; dyspareunia; back pain; purulent cervical discharge; and the presence of lower abdominal tenderness and exquisitely painful cervix on bimanual pelvic examination. New-onset breakthrough bleeding in women who are on oral contraceptives or medroxyprogesterone contraceptive injection (Depo-Provera) has been associated with PID. Fever (>101°F), increased erythrocyte sedimentation rate, and an elevated white blood cell count (>10,000 cells/mL) commonly are seen, even though the woman may not appear acutely ill. Elevated C-reactive protein (CRP) levels equate with inflammation and can be used as another diagnostic tool. Laparoscopy, which allows for direct visualization of the ovaries, fallopian tubes, and uterus, is one of the most specific procedures for diagnosing PID, but is costly and carries the inherent risks of surgery and anesthesia. Minimal criteria for a presumptive diagnosis of PID require only the presence of lower abdominal pain, adnexal (area adjoining the uterus, fallopian tubes, and ovaries) tenderness, and cervical motion tenderness on bimanual examination with no other apparent cause.

Treatment may involve hospitalization with intravenous administration of antibiotics. If the condition is diagnosed early, outpatient antibiotic therapy may be sufficient. Treatment is aimed at preventing complications, which can include pelvic adhesions, infertility, ectopic pregnancy, chronic abdominal pain, and tubo-ovarian abscesses.

**Endometriosis**

Endometriosis is the condition in which functional endometrial tissue is found in ectopic sites outside the uterus. The site may be the ovaries, posterior broad ligaments, uterosacral ligaments, rectouterine pouch, pelvis, vagina, vulva, perineum, or intestines (Fig. 40-10). The cause of endometriosis is largely unknown. There appears to have been an increase in its incidence in developed Western countries during the past four
to five decades. Approximately 5% to 10% of reproductive-age women have some degree of endometriosis. Risk factors may include early menarche and late menopause; short menstrual cycles (<28 days), longer duration (>5 days) or heavier flow cycles; increased menstrual pain; and other first-degree relatives with the condition.

Several theories attempt to explain the origin of the dispersed endometrial lesions that occur in women with endometriosis. One theory, the regurgitation/implantation theory, suggests that menstrual blood containing fragments of endometrium is forced upward through the fallopian tubes into the peritoneal cavity. Retrograde menstruation is not an uncommon phenomenon, and it is unknown why endometrial cells implant and grow in some women but not in others. A second theory, the vascular or lymphatic theory, suggests that the endometrial tissue may metastasize through the lymphatics or vascular system. Another theory, the metaplastic theory, proposes that dormant, immature cellular elements, spread over a wide area during embryonic development, persist into adult life and then differentiate into endometrial tissue. Genetic and immune factors also have been studied as contributing factors to the development of endometriosis.

Endometriosis usually becomes apparent in the reproductive years when the lesions are stimulated by ovarian hormones in the same way as normal endometrium, becoming proliferative, then secretory, and finally undergoing menstrual breakdown. Bleeding into the surrounding structures can cause pain and the development of significant pelvic adhesions. Symptoms tend to be more severe premenstrually, subsiding after cessation of menstruation. Pelvic pain is the most common presenting symptom; other symptoms include back pain, dyspareunia, and pain on defecation and micturition. Endometriosis is associated with infertility because of adhesions that distort the pelvic anatomy and cause impaired ovum release and transport.

The gross pathologic changes that occur in endometriosis differ with location and duration. In the ovary, the endometrial tissue may form cysts (i.e., endometriomas filled with old blood that resembles chocolate syrup [chocolate cysts]). Rupture of these cysts can cause peritonitis and adhesions. Elsewhere in the pelvis, the tissue may take the form of small hemorrhagic lesions that may be black, bluish, red, clear, or opaque (Fig. 40-11). Some may be surrounded by scar tissue.

Endometriosis may be difficult to diagnose because its symptoms mimic those of other pelvic disorders and the severity of the symptoms does not always reflect the

---

**FIGURE 40-10.** Common locations of endometriosis in the pelvis and abdomen.

extent of the disease. Definitive diagnosis can be accomplished only through laparoscopy. This minimally invasive surgery allows direct visualization of pelvic organs to determine the presence and extent of endometrial lesions. Imaging techniques, including ultrasonography and magnetic resonance imaging (MRI), can be useful tools in evaluating endometriomas and deep endometriosis. Serum cancer antigen 125 (CA-125), which is known for its use in diagnosis and monitoring of ovarian cancer, may be elevated in the presence of endometriosis. It has limitations as a screening tool, but can be useful in monitoring response to therapy and recurrence.

Treatment modalities fall into three categories: pain relief, endometrial suppression, and surgery. In young women, simple observation and analgesics (nonsteroidal anti-inflammatory drugs [NSAIDs]) may be sufficient treatment. The use of hormones to induce physiologic amenorrhea is based on the observation that pregnancy and menopause afford pain relief by inducing atrophy of the endometrial tissue. This can be accomplished through administration of oral contraceptives, continuous progesterone therapy, androgenic agents (danazol), or long-acting GnRH analogs that inhibit the pituitary gonadotropins and suppress ovulation.

Surgery may offer more definitive therapy for women with large or symptomatic endometriomas (endometrial cysts) that do not respond to medical therapy because of the concentration of endometriosis within the cyst. Laparoscopic surgical options include the use of cautery, laser ablation, or excision techniques. Definitive surgical treatment involves total hysterectomy and bilateral salpingo-oophorectomy (removal of the uterus, ovaries, and fallopian tubes) when the symptoms are unbearable or the woman’s childbearing is completed.

**Adenomyosis**

Adenomyosis is the condition in which endometrial glands and stroma are found within the myometrium, interspersed between the smooth muscle fibers. In contrast to endometriosis, which usually is a problem in young, infertile women, adenomyosis typically is found in multiparous women in their late fourth or fifth decade. It is thought that events associated with repeated pregnancies, deliveries, and uterine involution may cause the endometrium to be displaced throughout the myometrium. Adenomyosis frequently coexists with uterine myomas or endometrial hyperplasia. Heavy, painful periods with clots and dyspareunia are common complaints. Adenomyosis resolves with menopause. Conservative therapy using oral contraceptives or GnRH agonists is usually the first choice of treatment. Hysterectomy (with preservation of the ovaries in premenopausal women) is considered when this approach fails.

**Endometrial Cancer**

Endometrial cancer is the most frequent invasive cancer of the female reproductive tract and accounts for 7% of all invasive cancers in women. It is typically a disease of postmenopausal women. Because endometrial cancer usually causes abnormal (postmenopausal) bleeding, early detection and cures are possible.

**Epidemiology and Pathogenesis.** Endometrial cancer occurs most frequently in postmenopausal women (peak age of 55 to 65 years) and is uncommon in women younger than 40 years of age. Two groups in which endometrial cancers arise are perimenopausal women with estrogen excess and older women with endometrial atrophy. Endometrial cancers that arise in women with estrogen excess are described as type I or endometrioid carcinoma, and those that arise in women with endometrial atrophy as type II or serous or clear-cell carcinoma.

The first group, or type I, is the most common type of endometrial cancer, accounting for 80% of cases. Most of these tumors are well differentiated and mimic proliferative endometrial glands, and as such are referred to as *endometrioid carcinoma*. Endometrioid carcinoma is associated with prolonged estrogen stimulation and mutations in PTEN, a tumor-suppressor gene. In addition to unopposed estrogen therapy, other risks for endometrioid carcinoma are obesity, diabetes, nulliparity (having borne no children), early menarche, and late menopause. Many of these risk factors are the same as those for endometrial hyperplasia. Obesity predisposes to insulin resistance, ovarian androgen excess, anovulation, and chronic progesterone deficiency. These hormonal changes stimulate endometrial cell proliferation, inhibit apoptosis, and promote angiogenesis. Progesterone counteracts the effects of estrogen. Pregnancy, with intense placental production of progesterins, protects against endometrial cancer. Thus, multiparity protects against endometrial cancer, whereas nulliparity increases risk, especially when infertility is also present. Diabetes mellitus, hypertension, and polycystic ovary syndrome are conditions that also alter estrogen metabolism and elevate estrogen levels. Type II endometrial cancers occur in a small subset of women who do not exhibit increased estrogen levels. These women usually acquire the disease at an older age and in a setting of endometrial atrophy rather than hyperplasia. This type of endometrial cancer usually is associated with a poorer prognosis than type I carcinomas.

**Clinical Features.** The major symptom of endometrial hyperplasia or overt endometrial cancer is abnormal, painless bleeding. Abnormal bleeding is an early warning sign of endometrial cancer in up to 90% of women, and because endometrial cancer tends to be slow growing in its early stages, the chances of cure are good if prompt medical care is sought. In menstruating women, this takes the form of bleeding between periods or excessive, prolonged menstrual flow. In postmenopausal women, any bleeding is abnormal and warrants investigation. Later signs of uterine cancer may include crampling, pelvic discomfort, postcoital bleeding, lower abdominal discomfort, and enlarged lymph nodes.

Although Pap smear cytology can identify a small percentage of endometrial cancers, it is not a good screening tool because endometrial cancer usually causes abnormal bleeding.
tool for the tumor. Endometrial biopsy is far more accurate. Direct visualization of the endometrium with hysteroscopy and dilatation of the cervix and curettage of the uterine cavity (D&C) is the definitive procedure for diagnosis because it provides a more thorough evaluation. Transvaginal ultrasonography may be used to determine the endometrial thickness as an indicator of hypertrophy and possible neoplastic change.

The prognosis for endometrial cancer depends on the clinical stage of the disease when it is diagnosed and its histologic grade and type. Surgery and radiation therapy are the most successful methods of treatment for endometrial cancer. With early diagnosis and treatment, the 5-year survival rate is approximately 80% to 85%.

**Uterine Leiomyomas**

Uterine leiomyomas (commonly called *fibroids*) are benign neoplasms of smooth muscle origin. They are the most common female reproductive tumor. Leiomyomas usually develop in the corpus of the uterus as intramural, subserosal, or submucosal growths (Fig. 40-12). Intramural *fibroids* are embedded in the myometrium. They are the most common type of *fibroid* and present as a symmetric enlargement of the nonpregnant uterus. Subserosal tumors are located beneath the perimetrium of the uterus. These tumors are recognized as irregular projections on the uterine surface; they may become pedunculated, displacing or impinging on other genitourinary structures and causing hydroureter or bladder problems. Submucosal *fibroids* displace endometrial tissue and are more likely to cause bleeding, necrosis, and infection than either of the other types.

Leiomyomas are asymptomatic approximately half of the time and may be discovered during routine pelvic examination, or they may cause menorrhagia (excessive menstrual bleeding), anemia, urinary frequency, rectal pressure/constipation, abdominal distention, and infrequently pain. Their rate of growth is variable, but they may increase in size during pregnancy or with exogenous estrogen stimulation (i.e., oral contraceptives or menopausal estrogen replacement therapy). Interference with pregnancy is rare unless the tumor is submucosal and interferes with implantation or obstructs the cervical outlet. These tumors may outgrow their blood supply, become infarcted, and undergo degenerative changes.

Most leiomyomas regress with menopause, but if bleeding, pressure on the bladder, pain, or other problems persist, hysterectomy may be indicated. Myomectomy (removal of just the tumors) can be done to preserve the uterus for future childbirth. Following myomectomy, cesarean section may be recommended for childbirth. Hypothalamic GnRH agonists may be used to suppress leiomyoma growth before surgery. Uterine artery embolization, which shrinks the *fibroids* by blocking the blood supply to the uterus, is a minimally invasive procedure for management of heavy bleeding and other symptoms. Uterine artery embolization is only used in women who have completed childbearing as there may not be enough circulation to the uterus to support a pregnancy.

**Disorders of Uterine Support**

The uterus and the pelvic structures are maintained in proper position by the uterosacral ligaments, round ligaments, broad ligament, and cardinal ligaments. The two cardinal ligaments maintain the cervix in its normal position (see Fig. 40-4A). The uterosacral ligaments hold the uterus in a forward position, and the broad ligaments suspend the uterus, fallopian tubes, and ovaries in the pelvis. The vagina is encased in the semirigid structure of the strong supporting fascia (Fig. 40-13A). The muscular floor of the pelvis is a strong, slinglike structure that supports the uterus, vagina, urinary bladder, and rectum (Fig. 40-14).
In the female anatomy, nature is faced with the problems of supporting the pelvic viscera against the force of gravity and the increases in intra-abdominal pressure associated with coughing, sneezing, defecation, and laughing, while at the same time allowing for urination, defecation, and normal reproductive tract function, especially the delivery of an infant.

Relaxation of the pelvic outlet usually comes about because of overstretching of the perineal supporting tissues during pregnancy and childbirth or years of prolonged straining with hard stools. Although the tissues are stretched only during these times, there may be no difficulty until later in life, such as in the fifth or sixth decade, when further loss of elasticity and muscle tone occurs. Even in a woman who has not borne children, the combination of aging and postmenopausal changes may give rise to problems related to relaxation of the pelvic support structures. The three most common conditions associated with this relaxation are cystocele, rectocele, and uterine prolapse. These may occur separately or together.

Cystocele is a herniation of the bladder into the vagina. It occurs when the normal muscle support for the bladder is weakened, and the bladder sags below the uterus. This causes the anterior vaginal wall to stretch and bulge downward, allowing the bladder to herniate into the vagina due to the force of gravity and pressures from coughing, lifting, or straining at stool (see Fig. 40-13B). The symptoms of cystocele include an annoying bearing-down sensation, difficulty
Disorders of the Ovaries

Disorders of the ovaries frequently cause menstrual and fertility problems. Benign conditions can present as primary lesions of the ovarian structures or as secondary disorders related to hypothalamic, pituitary, or adrenal dysfunction.

Cystic Lesions of the Ovaries

Cysts are the most common cause of enlarged ovaries. Many are benign. A follicular cyst is one that results from occlusion of the duct of the follicle. Each month, several follicles begin to develop and are blighted at various stages of development. These follicles form cavities that fill with fluid, producing a cyst. The dominant follicle normally ruptures to release the egg (i.e., ovulation) but occasionally persists and continues growing. Likewise, a luteal cyst is a persistent cystic enlargement of the corpus luteum that is formed after ovulation and does not regress in the absence of pregnancy. Functional cysts are asymptomatic unless there is substantial enlargement or bleeding into the cyst. This can cause considerable discomfort or a dull, aching sensation on the affected side. However, these cysts usually regress spontaneously. Occasionally, a cyst may become twisted or may rupture into the intra-abdominal cavity (Fig. 40-15).

Polycystic Ovary Syndrome

Polycystic ovary syndrome (PCOS) is a common endocrine disorder affecting 5% to 10% of women of reproductive age, and is a frequent source of chronic anovulation. The disorder is characterized by varying degrees of menstrual irregularity, signs of hyperandrogenism (acne and hirsutism or male-pattern hair loss), infertility, and hyperinsulinemia or insulin resistance. A substantial number of women who are diagnosed with PCOS are obese, and most have polycystic ovaries.

Chronic anovulation, causing amenorrhea or irregular menses, is now thought to be the underlying cause of the bilaterally enlarged “polycystic” ovaries. Hence, the polycystic ovary is a sign of the disease, not the cause of the disease. There is increasing evidence that the disorder may begin before adolescence and that many of the manifestations of PCOS begin to make their appearance at that time. Because many of the symptoms common to PCOS, such as hirsutism, acne, and obesity, can be detrimental to a teenage girl’s health and self-esteem, early detection and treatment of PCOS in adolescents are essential.

The underlying etiology of the disorder is unknown, although most women have altered gonadotropin levels. This is manifested by increased release of LH in relation to FSH release, with a resultant increase in production of androstenedione and testosterone by the theca cells of the ovary. Androstenedione, in turn, is converted to estrone within adipocytes. Although estrone is a weak estrogen, it stimulates LH release and suppresses FSH release. The resultant decrease in FSH levels allows for new follicular development, but full maturation is not attained and ovulation does not occur. The elevated LH levels result in increased androgen production, which in turn, prevents normal follicular development and contributes to a vicious cycle of anovulation and multiple cyst formation. Increased androgen levels also lead to the development of acne and hirsutism.

The typical woman with PCOS has hyperinsulinemia and many of the signs of the metabolic syndrome (see Chapter 33). It has been shown that the cause of hyperinsulinemia is insulin resistance. The frequency and degree of hyperinsulinemia in women with PCOS is often amplified by the presence of obesity. In addition to its clinical manifestations, long-term health problems linked to PCOS include cardiovascular disease and type 2 diabetes. Classic lipid abnormalities include elevated triglyceride levels, low HDL levels, and elevated LDL levels. Hypertension is also common in women with PCOS. There is also concern that women with PCOS who are anovulatory do not produce progesterone. This, in turn, may subject the endometrium to an unopposed estrogen environment, which is a significant risk factor for development of endometrial cancer.

The diagnosis of PCOS can be suspected from the clinical presentation. Although there is no consensus as to which tests should be used, laboratory evaluation to exclude hyperprolactinemia, late-onset adrenal hyperplasia, and androgen-secreting tumors of the ovary and adrenal gland are commonly done. Because of the high risk of insulin resistance, a fasting blood glucose, 2-hour oral glucose tolerance test, and insulin levels may be done to evaluate for hyperinsulinemia. Confirmation with ultrasonography or laparoscopic visualization of the ovaries is often done, but not required.

The overall goal of treatment of PCOS should be directed toward symptom relief, prevention of potential malignant endometrial sequelae, and reduction in risk for development of diabetes and cardiovascular disease. The preferred and most effective treatment for PCOS is lifestyle modification. Weight loss may be beneficial in restoring normal ovulation when obesity is present. Combined oral contraceptive agents ameliorate menstrual irregularities and improve hirsutism and acne. The addition of spironolactone, a mineralocorticoid antagonist that inhibits the production of androgens by the adrenal gland, may be beneficial to women with severe hirsutism.

Insulin-sensitizing agents (e.g., metformin) alone or with ovulation-inducing medications are emerging as an important component of PCOS treatment. In addition to expected improvements in insulin sensitivity and glucose metabolism, they have been associated with reductions in androgen and LH levels and are highly effective in restoring normal menstrual regularity and ovulatory cycles.

Ovarian Cancer

Ovarian cancer is the second most frequent gynecologic malignancy after endometrial cancer in the United States, and it carries the highest mortality rate of all genital cancers combined. The incidence of ovarian cancer and mortality rate increases with age, with most cases occurring in women older than 50 years of age. Malignant ovarian tumors are categorized according to cell type of origin—epithelial cell tumors, germ cell tumors, and gonadal stromal cell tumors (see Fig. 40-16). Approximately 90% of ovarian cancers are of epithelial cell origin. These tumors tend to occur in older women, are usually discovered late in the disease, and have a high mortality rate. The nonepithelial ovarian cancers, which include germ cell tumors and stromal cell tumors, tend to occur in a younger population of women. They typically present with earlier signs of disease and excellent survival potential when detected early.

The most significant risk factor for ovarian cancer appears to be ovulatory age—the length of time during a woman’s life when her ovarian cycle is not suppressed by pregnancy, lactation, or oral contraceptive use. The incidence of ovarian cancer is much lower in countries where women bear numerous children. Epithelial cancer of the ovaries derives from malignant transformation of the epithelium of the ovarian surface. When these epithelial cells are situated over developing follicles, they undergo metaplastic transformation whenever ovulation occurs. It follows that repeated stimulation of the epithelium of the ovarian surface, which occurs with uninterrupted ovulation, may predispose the epithelium to malignant transformation. Family history also is a significant risk factor for ovarian cancer. The breast cancer susceptibility genes, BRCA1 and BRCA2 mutations, which are tumor-suppressor genes, increase the susceptibility to ovarian cancer (see Chapter 7). The estimated lifetime risk of ovarian cancer in women bearing the BRCA1 and BRCA2 mutations is 23% to 54%. A high-fat Western diet and use of powders containing talc in the genital area are other factors that have been linked to the development of ovarian cancer.
Clinical Features. Until recently it was believed that most cancers of the ovary produce no symptoms. Several studies have now established that symptoms are often present and reported by women before diagnosis, but are nonspecific and therefore difficult to interpret. Symptoms that are believed to have a strong correlation to ovarian cancer include increased abdominal size, epigastric distress, early satiety, or bloating as the result of increased pressure from ascites (i.e., fluid in the peritoneal cavity) or involvement of the omentum. Occasionally, women with early-onset disease present with abdominal or pelvic pain, due to ovarian torsion, although most women with early-stage disease are asymptomatic. Because the gastrointestinal manifestations can occur for a variety of reasons, many women self-treat with antacids and other remedies for a time before seeking treatment, and health care providers may dismiss the woman’s complaints as being caused by other conditions, further delaying diagnosis and treatment. Recent onset (<12 months) and frequent occurrence (>12 times per month) of these symptoms should increase the index of suspicion for ovarian cancer and suggest the need for further evaluation. It is not fully understood why the initial symptoms of ovarian cancer are manifested as gastrointestinal disturbances. It is thought that biochemical changes in peritoneal fluids may irritate the bowel or that pain originating in the ovary may be referred to the abdomen and be interpreted as a gastrointestinal disturbance.

At present, no good screening tests or other early methods of detection exist for ovarian cancer. The serum tumor marker CA-125 is a cell surface antigen that can be used in monitoring therapy and recurrences when preoperative levels have been elevated. Despite its role in diagnostic evaluation and follow-up, CA-125 is not cancer or tissue specific for ovarian cancer. Levels are also elevated in the presence of endometriosis, uterine fibroids, pregnancy, liver disease, and other benign conditions and with cancers of the endometrium, cervix, fallopian tube, and pancreas. Transvaginal ultrasonography (TVS) has been used to evaluate ovarian masses for malignant potential. Although TVS has demonstrated high sensitivity and specificity as a screening tool, cost precludes its use as a universal screening method.

When ovarian cancer is suspected, surgical evaluation is required for diagnosis, complete and accurate staging, and cytoreduction and debulking procedures to reduce the size of the tumor. The most common surgery involves removal of the uterus, fallopian tubes, ovaries, and omentum. Recommendations regarding treatment beyond surgery and prognosis depend on the stage of the disease. Women with early-stage disease usually do not require adjuvant treatment; women with intermediate disease or advanced disease can often benefit from chemotherapy using a combination of a platinum compound (cisplatin or carboplatin) and a taxane (paclitaxel or docetaxel). When this combination therapy fails, salvage chemotherapy with newer drugs may prolong survival.
SUMMARY CONCEPTS

- The female external genitalia are affected by disorders that affect skin on other parts of the body. Bartholin cysts, which are the result of occluded ducts in Bartholin glands, are often painful and can become infected. Vulvodynia is a chronic vulvar pain syndrome with several classifications and variable treatment results. Cancer of the vulva, an uncommon malignant neoplasm, which accounts for 3% to 5% of all genital cancers in women.

- The normal vaginal ecology depends on a delicate balance of hormones and bacterial flora. Vaginitis or inflammation of the vagina is characterized by vaginal discharge and burning, itching, redness, and swelling of vaginal tissues. It may be caused by chemical irritants, foreign bodies, and infectious agents. Primary cancers of the vagina are uncommon, accounting for 1% of all cancers of the female reproductive system.

- Disorders of the cervix and uterus include inflammatory conditions such as cervicitis and endometritis. Endometriosis is a condition in which functional endometrial tissue is found in ectopic sites outside the uterus. Cervical cancer is caused by HPV and arises from precursor lesions that can be detected on Pap smear cytology, and if detected early, is the most easily cured of all the cancers of the female reproductive system. Endometrial cancer is the most common cancer of the female pelvis. Leiomyomas are benign neoplasms of the uterine wall.

- Pelvic inflammatory disease (PID) is an inflammatory condition of the upper reproductive tract that involves the uterus (endometritis), fallopian tubes (salpingitis), or ovaries (oophoritis).

- Disorders of uterine support result from weakness and relaxation of the pelvic floor muscles. Cystocele and rectocele involve herniation of the bladder or rectum into the vagina. Uterine prolapse occurs when the uterus bulges into the vagina.

- Disorders of the ovaries include cystic disorders, polycystic ovary syndrome (PCOS), and cancer of the ovary. Functional cysts usually are asymptomatic unless there is substantial enlargement or bleeding into the cyst or the cyst becomes twisted or ruptures. Polycystic ovary syndrome is a disorder characterized by various degrees of hirsutism, obesity, and infertility, and often is associated with hyperinsulinemia and insulin resistance. Cancer of the ovary is the second most common female genitourinary cancer and the most deadly. A family history of cancer, particularly breast and ovarian cancer, and nulliparity increase the risk of developing ovarian cancer, whereas oral contraceptive use, pregnancy, and lactation decrease the risk.

Menstrual Disorders

Between menarche (i.e., first menstrual bleeding) and menopause (i.e., cessation of menstruation), the female reproductive system undergoes cyclic changes called the menstrual cycle. This includes the maturation and release of oocytes from the ovary during ovulation and periodic vaginal bleeding resulting from the shedding of the endometrial lining. The menstrual cycle produces changes in the breasts, uterus, skin, ovaries, and perhaps other unidentified tissues.

Dysfunctional Menstrual Cycles

Dysfunctional menstrual cycles may take many forms, including dysfunctional bleeding, and amenorrhea (absence of menstruation) is failure to menstruate, hypomenorrhea (scanty menstruation), oligomenorrhea (infrequent menstruation, periods more than 35 days apart), polymenorrhea (frequent menstruation, periods <21 days apart), menorrhagia (excessive menstruation), or metrorrhagia (bleeding between periods). Menometorrhagia is heavy bleeding during and between menstrual periods.

Although unexplained bleeding can occur because of pregnancy, spontaneous abortion, neoplasms, or other reasons, the frequent cause in the nonpregnant woman is a condition commonly called dysfunctional bleeding. Dysfunctional bleeding is related to alterations in the hormones that support normal cyclic endometrial changes. Estrogen deprivation causes regression of a previously built-up endometrium and bleeding. Such bleeding often is irregular in amount and duration, with the flow varying with the time and degree of estrogen stimulation and with the degree of estrogen withdrawal. A lack of progesterone can cause abnormal menstrual bleeding. In its absence, estrogen induces development of a much thicker endometrial layer with a richer blood supply.

Periodic bleeding episodes alternating with amenorrhea are caused by variations in the number of functionally ovarian follicles present. When too many follicles are present and active, high levels of estrogen develop, causing the endometrium to proliferate for weeks or even months. In time, either of two events occurs that lead to an estrogen deficiency and bleeding: several follicles may
simultaneously degenerate, or the needs of an enlarged endometrial tissue mass may exceed the capabilities of the functioning follicles. Estrogen and progesterone deficiencies are associated with the absence of ovulation, hence the term anovulatory bleeding. Because the vasoconstriction and myometrial contractions that normally accompany menstruation are caused by progesterone, anovulatory bleeding seldom is accompanied by cramps, and the flow frequently is heavy. Anovulatory cycles are common among adolescents during the first several years after menarche, when ovarian function is becoming established, and among perimenopausal women, whose ovarian function is beginning to decline.

Dysfunctional bleeding can originate as a primary disorder of the ovaries or uterus or as a secondary defect in ovarian function related to hypothalamic-pituitary stimulation. The latter can be initiated by emotional stress, marked variation in weight (i.e., sudden gain or loss), or nonspecific endocrine or metabolic disturbances. Nonhormonal causes of irregular menstrual bleeding include endometrial polyps, submucosal myoma (i.e., fibroid), bleeding disorder (e.g., von Willebrand disease, platelet dysfunction), endometrial dysplasia, and cancer.

The treatment of dysfunctional bleeding depends on what is identified as the probable cause. The minimum evaluation should include a detailed history with emphasis on bleeding pattern and a physical examination. A pregnancy test is important to rule out any complications of pregnancy. Endocrine studies (e.g., FSH/LH ratio, prolactin, androgen levels), ultrasonography of the endometrium, and endometrial biopsy may be needed for diagnosis. Nonhormonal causes generally require surgical intervention. Dilatation of cervix and scraping of the endometrium (D&C) can be therapeutic as well as diagnostic. Endometrial ablation (destruction of the basal layer of the endometrium from which the monthly buildup generates) has become a primary treatment method for abnormal uterine bleeding. Various ablation devices are available; some use heat while others use cryotherapy. If nonhormonal problems have been excluded and alterations in hormone levels are the primary cause, treatment may include the use of oral contraceptives, cyclic progesterone therapy, or long-acting progesterone injections or implants.

Amenorrhea

There are two types of amenorrhea: primary and secondary. Primary amenorrhea is the failure to menstruate by 15 years of age, or by 13 years of age if failure to menstruate is accompanied by absence of secondary sex characteristics. Secondary amenorrhea is the cessation of menses for at least 6 months in a woman who has established normal menstrual cycles. Primary amenorrhea usually is caused by gonadal dysgenesis, congenital müllerian agenesis, testicular feminization, or a hypothalamic-pituitary-ovarian axis disorder. Causes of secondary amenorrhea include ovarian, pituitary, or hypothalamic dysfunction; intrauterine adhesions; infections (e.g., tuberculosis, syphilis); pituitary tumors; anorexia nervosa; or strenuous physical exercise, which can alter the critical body fat-to-muscle ratio needed for menses to occur.46

Diagnostic evaluation resembles that for dysfunctional uterine bleeding, with the possible addition of a computed tomographic scan or MRI to exclude a pituitary tumor. Treatment is based on correcting the underlying cause and inducing menstruation with cyclic progesterone or combined estrogen–progesterone regimens.

Dysmenorrhea

Dysmenorrhea is pain or discomfort with menstruation. Although not usually a serious medical problem, it causes some degree of monthly disability for a significant number of women. There are two forms of dysmenorrhea: primary and secondary. Primary dysmenorrhea is caused by the effects of excess prostaglandin production in the endometrium.47 Prostaglandins are potent smooth muscle stimulants that cause intense uterine contractions. Prostaglandin production in the uterus normally increases under the influence of progesterone, reaching a peak at or soon after the onset of menstruation. With onset of menstruation, formed prostaglandins are released from the shedding endometrium. Prostaglandins also cause contraction of smooth muscle elsewhere in the body. Severe dysmenorrhea may be associated with systemic symptoms such as headache, nausea, vomiting, and diarrhea. The pain of primary dysmenorrhea is often diffusely located in the lower abdomen or suprapubic area, radiating to the lower back. The pain is often described as cramping and spasmodic, or similar to labor pains. Secondary dysmenorrhea is menstrual pain caused by structural abnormalities or disease processes such as endometriosis, uterine fibroids, adenomyosis, pelvic adhesions, IUDs, or PID. In women with secondary dysmenorrhea, the pain often lasts longer than the menstrual period; it may begin before menstrual bleeding begins; and it may become worse during menstruation.

Treatment for primary dysmenorrhea is directed at symptom control.47 Women with primary dysmenorrhea generally experience dramatic pain relief with the nonsteroidal anti-inflammatory drugs (e.g., ibuprofen, naproxen, mefenamic acid), which are prostaglandin synthetase inhibitors. Ovulation suppression and symptomatic relief of dysmenorrhea can be instituted simultaneously with the use of hormonal contraceptives. Relief of secondary dysmenorrhea depends on identifying the cause of the problem. Medical or surgical intervention may be needed to eliminate the problem.

Premenstrual Syndrome Disorders

Premenstrual syndrome disorders are a group of physical, emotional, and behavioral changes that occur in a regular, cyclic relationship to the luteal phase of the menstrual cycle and that interfere with some aspect of
a woman’s life. The severity of this cyclic symptom complex can vary from premenstrual molimina on the mild end; through premenstrual syndrome (PMS), which is characterized by mild to moderate physical and psychological symptoms preceding menstruation and relieved by onset of the menses; to premenstrual dysphoric disorder (PMDD), which is the most severe form of premenstrual distress and generally is associated with mood disorders.

Up to 80% of women in the United States experience some emotional or physical symptoms during the luteal phase of their menstrual cycle, without experiencing a substantial impact on their daily functioning. The PMS disorder, which results in moderate disruptions in a woman’s life, occurs in 20% to 30% of premenstrual women and another 3% to 8% suffer from the extreme or severe symptoms of PMDD. The incidence of PMS and PMDD seems to increase with age. It is less common in women in their teens and twenties, and most women seeking help for the problem are in their mid-thirties. The disorder is not culturally distinct; it affects both Westerners and non-Westerners.

Physical symptoms of PMS include painful and swollen breasts, bloating, abdominal pain, headache, and backache. Psychologically, there may be depression, anxiety, irritability, and behavioral changes. In some cases, there are pulsing alterations in motor function, such as clumsiness and altered handwriting. Women with PMS may report one or several symptoms, with symptoms varying from woman to woman and from month to month in the same woman. The disorder can significantly affect a woman's ability to perform at normal levels. Family responsibilities and relationships may suffer and she may lose time from or function ineffectively at work.

Although the causes of PMS and PMDD are poorly documented, they probably are multifactorial. Like dysmenorrhea, it is only recently that PMS has been recognized as a bona fide disorder rather than merely a psychosomatic illness. Because there appear to be no measurable differences in hormone levels between women with and without PMS, it is presumed that normal cyclic variation in the hormones is the trigger for symptoms in vulnerable or predisposed women. Currently, data suggest a relationship between normal gonadal fluctuations and central neurotransmitter activity, particularly serotonin. It is unclear whether decreased levels of serotonin are present during the luteal phase and only susceptible women respond with varying degrees of premenstrual symptoms, or if women with PMDD have a neurotransmitter abnormality.

Diagnosis of PMS and PMDD focuses on documentation of the relationship of a woman’s symptoms to the luteal phase of the menstrual cycle. A complete history and physical examination are necessary to exclude other physical causes of the symptoms. Depending on the symptom pattern, blood studies, including thyroid hormones, glucose, and prolactin assays, may be done. Psychosocial evaluation is helpful to exclude emotional illness that is merely exacerbated premenstrually.

Management of PMS/PMDD has been largely symptomatic and includes education and support directed toward lifestyle changes for women with mild symptoms. An integrated program of personal assessment by diary, regular exercise, avoidance of caffeine, and a diet low in simple sugars and high in lean proteins is often beneficial. In addition to lifestyle changes. In addition to lifestyle changes, pharmacologic treatment includes the use of diuretics to reduce fluid retention, nonsteroidal anti-inflammatory agents for pain, and anxiolytic drugs to treat mood changes. Because symptoms are associated with ovulatory cycles, suppressing ovulation may be beneficial for some women with PMS and can be accomplished using hormonal contraceptives, danazol (a synthetic androgen), or GnRH agonists. Hormonal contraceptives can be used for women who also require contraception. However, some women find their symptoms worsen when taking contraceptives. The pharmacologic treatment of PMDD differs from that of PMS. Ovulation suppression does not seem to help women with PMDD. Although many medications have been studied, only three antidepressants (fluoxetine, sertraline, and paroxetine controlled release) and an oral contraceptive that contains drospirenone (a spironolactone derivative) have been approved for treatment of the emotional and physical symptoms of PMDD.

**Menopause and Aging Changes**

**Menopause** is the cessation of menstrual cycles. Like menarche, it is more of a process than a single event. Most women stop menstruating between 48 and 55 years of age. Perimenopause (the years immediately surrounding menopause) precedes menopause by approximately 4 years and is characterized by menstrual irregularity and other menopausal symptoms. Climacteric refers to the entire transition to the nonreproductive period of life. Premature ovarian failure describes the approximately 1% of women who experience menopause before the age of 40 years. A woman who has not menstruated for a full year or has an FSH level greater than 30 mIU/mL is considered menopausal.

Menopause results from the gradual cessation of ovarian function and the resultant diminished levels of estrogen. Although estrogens derived from the adrenal cortex continue to circulate in a woman’s body, they are insufficient to maintain the secondary sexual characteristics in the same manner as ovarian estrogens. As a result, breast tissue, body hair, skin elasticity, and subcutaneous fat decrease; the ovaries and uterus diminish in size; and the cervix and vagina become pale and friable. Problems that can arise as a result of this urogenital atrophy include vaginal dryness, urinary stress incontinence, urgency, nocturia, vaginitis, and urinary tract infection. The woman may find intercourse painful and traumatic, although some type of vaginal lubrication may be helpful.

Systemically, a woman may experience significant vasomotor instability secondary to the decrease in estrogens and the relative increase in other hormones, including FSH, LH, GnRH, dehydroepiandrosterone, and...
Menopausal hormonal therapy has come under scrutiny with the publication of the Women’s Health Initiative. Since the publication of these trials, there has been great interest in developing alternative doses, delivery systems, and medications for hormone therapy. Many products are now available, including vaginal estrogen preparations (transdermal delivery systems and lower-dose traditional hormone therapy). Selective estrogen receptor modulators (SERMs) may be used in place of estrogen to alleviate vulvovaginal atrophy and prevent osteoporosis.

Consequences of long-term estrogen deprivation include osteoporosis due to an imbalance in bone remodeling (see Chapter 44), and an increased risk for cardiovascular disease, which is the leading cause of death for women after menopause. With perimenopause, changes occur in the cardiovascular lipid profile: total cholesterol increases, HDL cholesterol decreases, and LDL cholesterol increases.

Menopausal hormonal therapy has come under scrutiny with the publication of the Women’s Health Initiative. Since the publication of these trials, there has been great interest in developing alternative doses, delivery systems, and medications for hormone therapy. Many products are now available, including transdermal delivery systems and lower-dose traditional hormone therapy. Vaginal estrogen preparations are available to treat symptoms related to vaginal atrophy. Selective estrogen receptor modulators (SERMs) may be used in place of estrogen to alleviate vulvovaginal atrophy and prevent osteoporosis.

Disorders of the Breast

Although anatomically separate, the breasts are functionally related to the female reproductive system in that they respond to the cyclic changes in sex hormones and produce milk for infant nourishment. The breasts are composed of specialized epithelium and stroma that may give rise to both benign and malignant lesions.

Breast Structures

The breasts, or mammary glands, are located between the third and seventh ribs of the anterior chest wall and are supported by the pectoral muscles and superficial fascia. They are specialized glandular structures that have an abundant shared nervous, vascular, and lymphatic supply (Fig. 40-17). Structurally the breast consists of fat, fibrous connective tissue, and glandular tissue. The superficial fibrous connective tissue is attached to the skin, a fact that is important in the visual observation of skin movement over the breast during breast self-examination. A nipple is located near the tip of the breast at about the level of the fourth intercostal space and is surrounded by an area of pigmented skin called the areola (Fig. 40-18). The areola contains sebaceous glands and modified sweat glands (glands of Montgomery). These glands have a structure intermediate between sweat glands and true mammary glands, and produce small elevations at the surface of the areola.

The breast mass is supported by the fascia of the pectoralis major and minor muscles and by the fibrous connective tissue of the breast. Fibrous tissue ligaments, called Cooper ligaments, extend from the outer boundaries of the breast to the nipple area in a radial manner, like the spokes on a wheel (see Fig. 40-17). These ligaments further support the breast and form septa that divide the breast into 15 to 20 lobes. Each lobe consists of grape-like clusters of glands (alveolar glands) and a duct (lactiferous duct) that lead to the nipple and opens to the outside (see Fig. 40-18). Two epithelial cell types line the...
ducts and alveolar glands of the lobules—myoepithelial and luminal epithelial cells. Contractile epithelial cells, which lie between the surface epithelium and the basement membrane, provide structural support for the lobules, and assist in milk ejection during lactation. The luminal epithelial cells, which are the only cells capable of producing milk, overlie the myoepithelial cells.

The structure of the breast changes with the menstrual cycle and pregnancy. Estrogen stimulates the growth of the ductal system, whereas progesterone stimulates the growth and development of the ductile and glandular secretory epithelium. Early in the menstrual cycle, the ducts appear as cords with little or no lumen. Under estrogen stimulation, at the time of ovulation, the secretory cells increase in size, lumina appear in the ducts as small amounts of secretions accumulate, and fluid collects in the connective tissue. This causes a feeling of breast fullness and discomfort. During pregnancy, placental estrogen and progesterone produce further changes in the mammary glands. Beginning at about the 5th week of pregnancy, the anterior pituitary releases increasing amounts of the hormone prolactin. The alveolar glands are lined with secretory cells capable of producing milk under the influence of prolactin. However, milk production does not occur until after birth. This is because placental hormones inhibit milk production. Following childbirth and expulsion of the placenta, the maternal concentration of placental hormones declines rapidly and the action of prolactin is no longer inhibited.

**Benign Disorders**

Breast disease may be described as benign or cancerous. Benign breast conditions are nonmalignant conditions of the breast. They include inflammatory disorders and benign epithelial disorders. Some benign disorders may increase the risk of malignant disease and others may present with signs that resemble malignant disease.

**Inflammatory Disorders**

Inflammatory diseases of the breast are uncommon, accounting for less than 1% of breast disorders. They include mastitis, mammary duct ectasia, and fat necrosis.

**Mastitis.** Mastitis is inflammation of the breast. It most frequently occurs during lactation but may also result from other disorders. In the lactating woman, inflammation results from an ascending infection that travels from the nipple to the ductal structures. The most common organisms isolated are *Staphylococcus aureus* and *Streptococcus*. The offending organisms often originate from the sucking infant’s nasopharynx or the mother’s hands. During the early weeks of nursing, the breast is particularly vulnerable to bacterial invasion because of minor cracks and fissures that occur with vigorous suckling. Infection and inflammation cause obstruction of the ductal system. The breast area becomes hard, inflamed, and tender if not treated early. Without treatment, the area becomes walled off and may abscess, requiring incision and drainage. It is
Mammary Duct Ectasia. Mammary duct ectasia refers to the presence of dilated breast ducts containing a thick pasty material, with accompanying periductal inflammation and fibrosis. The dilated ducts may rupture, resulting in grayish-green nipple discharge. Palpation of the breast increases the discharge. The disorder is usually unilateral, occurring after menopause, most often in elderly multiparous women. Women typically present with a poorly defined perialveolar mass that is often associated with thick, white nipple secretions and sometimes with nipple retraction. Pain and erythema are uncommon. Duct ectasia may be difficult to distinguish clinically from carcinoma and may require biopsy.

Fat Necrosis. Fat necrosis is a distinct clinical and histologic entity, resulting in either a localized or diffuse mass lesion of the breast. The majority of women have a history of trauma, surgery, or radiation therapy. Initially the lesion consists of necrotic adipocytes and hemorrhage, after which the inflammatory cells phagocytize the lipid debris. Macrophages may produce a granulomatous inflammatory response. Fibroblast proliferation and collagen deposition during healing may lead to scar tissue (fibrosis). As a result, an irregular fixed hard mass may form that clinically resembles breast cancer. Unlike a malignant mass, however, fat necrosis is typically very tender and has a specific mammographic appearance.

Benign Epithelial Disorders

A wide variety of benign alterations in ducts and lobules are observed in the breast. Most are detected by mammography or as incidental findings on surgical specimens. These lesions have been divided into three groups according to the subsequent risk of developing carcinoma: nonproliferative (fibrocystic) changes, proliferative breast disease without atypia, and proliferative breast disease with atypia.

Nonproliferative (Fibrocystic) Breast Changes. Formerly called fibrocystic disease, fibrocystic changes are the most frequent lesions of the breast. They encompass a wide variety of lesions and breast changes. Microscopically, fibrocystic changes refer to a constellation of morphologic changes manifested by (1) cystic dilation of terminal ducts, (2) relative increase in fibrous tissue, and (3) variable proliferation of terminal duct epithelial elements. They are most common in women 30 to 50 years of age and are rare in postmenopausal women not receiving hormone therapy.

Fibrocystic changes usually present as nodular (i.e., “shotty”), granular breast masses that are more prominent and painful during the luteal or progesterone-dominant portion of the menstrual cycle. Discomfort ranges from heaviness to exquisite tenderness, depending on the degree of vascular engorgement and cystic distention.

Although fibrocystic changes have been thought to increase the risk of breast cancer, only certain variants in which proliferation of the epithelial components is demonstrated represent a true risk. Fibrocystic changes with giant cysts and proliferative epithelial lesions with atypia are more common in women who are at increased risk for development of breast cancer. The nonproliferative form of fibrocystic changes that does not carry an increased risk for development of cancer is more common.

Diagnosis of fibrocystic changes is made by physical examination, mammography, ultrasonography, and biopsy (i.e., aspiration or tissue sample). Mammography may be helpful in establishing the diagnosis, but increased breast tissue density in women with fibrocystic changes may make an abnormal or cancerous mass difficult to discern among the other structures. Ultrasonography is useful in differentiating a cystic from a solid mass. Because a mass caused by fibrocystic changes may be indistinguishable from carcinoma on the basis of clinical findings, suspect lesions should undergo biopsy. Any discrete mass or lump on the breast should be viewed as possible carcinoma, and cancer should be excluded before instituting the conservative measures used to treat fibrocystic changes.

Treatment for fibrocystic changes is usually symptomatic. Mild analgesics (e.g., aspirin, acetaminophen, or NSAIDs), vitamin E, and local application of heat or cold may be used for pain relief. Prominent or persistent cysts may be aspirated and any fluid obtained sent to the laboratory for cytologic analysis. Women should be encouraged to wear a good supporting brassiere, and are advised to avoid foods that contain xanthines (e.g., coffee, cola, chocolate, and tea) in their daily diets, particularly premenstrually.

Proliferative Lesions without Atypia. Proliferative lesions without atypia, which are commonly detected as mammographic densities or calcifications, include epithelial hyperplasia, sclerosing adenosis, and intraductal papillomas. These lesions are characterized by proliferation of ductile or lobular epithelial cells and/or are stromal without the cytologic or structural changes suggestive of carcinoma in situ. If there is increased fibrosis within the lobule with distortion and compression of the epithelium, the lesion is termed sclerosing adenosis. Papillomas are intraductal growths composed of multiple fibrovascular cores, each having a connective tissue axis lined with epithelial cells. Solitary intraductal papillomas are found in the major lactiferous ducts of women, typically between the ages of 30 and 50 years. The papillomas, which can range in size from 2 mm to 5 cm, often present with serous or serosanguineous drainage.
Proliferative Lesions with Atypia. Proliferative disease with atypia includes atypical ductile hyperplasia and atypical lobular hyperplasia.\(^{57}\) The hyperplasia is accompanied by replacement of the normal epithelial cells lining the ducts or lobules with atypical cells resembling those of carcinoma in situ. The basement membrane remains intact and, therefore, the cells cannot metastasize.

There are two types of atypical hyperplasia: lobular and ductile.\(^{57}\) Atypical ductile hyperplasia is recognized by its histologic resemblance to ductile carcinoma in situ (DCIS). Atypical lobular hyperplasia is defined by proliferation of cells identical to those of lobular carcinoma in situ (LCIS), but the cells do not fill or distend more than 50% of the acini within the lobule. Management of LCIS consists of excisional biopsy. Women with DCIS are at increased risk for developing invasive cancer or recurrence of the DCIS lesion. For this reason, DCIS is evaluated with core-needle biopsy (to be discussed) followed by surgical biopsy or excision. Women with both types of lesions require careful follow-up to prevent and detect the presence of invasive cancer.

Breast Cancer

Cancer of the breast is the most common female cancer. Although the breast cancer mortality rate has shown a slight decline, it is second only to lung cancer as a cause of cancer-related deaths in women. The decline in the breast cancer mortality is due to a number of factors, especially improvements in screening and treatment.

Risk factors for breast cancer include increasing age, personal or family history of breast cancer (i.e., at highest risk are those with multiple affected first-order relatives), history of benign breast disease (i.e., primary “atypical” hyperplasia), and hormonal influences that promote breast maturation and may increase the chance of cell mutation (i.e., early menarche, late menopause, and no term pregnancies or first child after 30 years of age). Modifiable risk factors include obesity (particularly after menopause), physical inactivity, caffeine, moderate to heavy consumption of alcohol, cigarette smoking, and long-term use of postmenopausal hormone therapy (especially combined estrogen and progestin).\(^ {57}\) Most women with breast cancer have no identifiable risk factors.

Approximately 12% of all breast cancers are hereditary. The probability of a hereditary etiology increases with multiple affected first-degree relatives, with women who are affected before 50 years of age, and those who have multiple cancers.\(^ {57}\) Mutations in two breast cancer susceptibility genes—BRCA1 on chromosome 17 and BRCA2 on chromosome 13—may account for most inherited forms of breast cancer (see Chapter 7). BRCA1 is known to be involved in tumor suppression. A woman with known mutations in BRCA1 has a lifetime risk of approximately 57% for breast cancer and approximately 40% for ovarian cancer. BRCA2 is another susceptibility gene that elevates lifetime breast cancer risk to 49% and ovarian cancer risk to 18%.\(^ {59,60}\) Breast cancer risk reduction options available to known carriers of BRCA1 and BRCA2 mutations include surveillance and surgery. Breast evaluation using MRI, digital mammography, and breast ultrasound give the best sensitivity for detecting breast cancer. Prophylactic surgery, in the form of bilateral mastectomy, bilateral oophorectomy, or both, has been shown to decrease the risk of developing cancer. These controversial surgeries can have physical and psychological side effects that warrant careful consideration before proceeding.

Detection

Cancer of the breast may manifest clinically as a mass, a puckering, nipple retraction, or unusual discharge. Many cancers are found by women themselves—sometimes when only a thickening or subtle change in breast contour is noticed. The variety of symptoms and potential for self-discovery underscore the need for all women to have an awareness of what their normal breast appearance and texture are like.

Mammography is the only effective screening technique for the early detection of clinically apparent breast lesions. A generally slow-growing form of cancer, breast cancer may have been present for 2 to 9 years before it reaches 1 cm, the smallest mass normally detected by palpation. Mammography can disclose lesions as small as 1 mm and the clustering of calcifications that may warrant biopsy to exclude cancer.

In 2003, the American Cancer Society dropped its recommendation that all women perform regular, systematic breast self-examination (BSE). Research has indicated that most women who discover their own cancer do so at times other than scheduled BSE. The American Cancer Society screening guidelines now place primary emphasis for breast cancer diagnosis on clinical breast examination (CBE) by a trained health professional and mammography, while encouraging women in the area of self-awareness.\(^ {21}\) Between the ages of 20 and 39 years, average risk women should undergo CBE every 3 years, and after age 40 years CBE should take place annually, ideally prior to the woman’s annual mammogram.\(^ {21}\) There is no specific upper age at which mammogram should be discontinued. Instead it is suggested that decision to stop mammogram screening should be individualized based on the potential risks and benefits. As long as the woman is in good health and would be a candidate for cancer treatment, it is recommended that she continue to be screened with mammography.\(^ {21}\)

Diagnosis and Classification

Procedures used in the diagnosis of breast cancer include physical examination, mammography, ultrasonography, percutaneous needle aspiration, stereotactic needle biopsy (i.e., core biopsy), and excisional biopsy. Figure 40-19 illustrates the appearance of breast cancer on mammography. Breast cancer often manifests as a solitary, painless, firm, fixed lesion with poorly defined borders. It can be found anywhere in the breast but is most common in the upper outer quadrant. Because of the variability in presentation, any suspect change in breast tissue warrants further investigation.
use of mammography enables additional definition of the clinically suspect area (e.g., appearance, character, calcification). Placement of a wire marker under radiographic guidance can ensure accurate surgical biopsy of nonpalpable suspect areas. Ultrasonography is useful as a diagnostic adjunct to differentiate cystic from solid tissue in women with nonspecific thickening.

Fine needle aspiration is a simple in-office procedure that can be performed repeatedly in multiple sites and with minimal discomfort. It can be accomplished by stabilizing a palpable mass between two fingers or in conjunction with handheld sonography to define cystic masses or fibrocystic changes and to provide specimens for cytologic examination. Fine needle aspiration can identify the presence of malignant cells, but it cannot differentiate in situ from infiltrating cancers. Stereotactic needle biopsy is an outpatient procedure done with the guidance of a mammography machine. After the lesion is localized radiologically, a large-bore needle is mechanically thrust quickly into the area, removing a core of tissue. Cells are available for histologic evaluation with 96% accuracy in detecting cancer. This procedure is less costly than excisional biopsy. Excisional biopsy to remove the entire lump provides the only definitive diagnosis of breast cancer, and often is therapeutic without additional surgery. Magnetic resonance imaging, positron emission tomography (PET), and computer-based or digital mammography are available as additional diagnostic modalities for breast cancer, and may be recommended to supplement conventional mammography in women with radiographically dense breasts or a strong family history of cancer, or who are known carriers of BRCA1 or BRCA2.

Tumors are classified histologically according to tissue characteristics and staged clinically according to tumor size, nodal involvement, and presence of metastasis. It is recommended that estrogen and progesterone receptor analysis be performed on surgical specimens. Information about the presence or absence of estrogen and progesterone receptors can be used in predicting tumor responsiveness to hormonal manipulation. High levels of both receptors improve the prognosis and increase the likelihood of remission.

**Treatment**

The treatment methods for breast cancer include surgery, chemotherapy, radiation therapy, and hormonal manipulation. Radical mastectomy (i.e., removal of the entire breast, underlying muscles, and all axillary nodes) rarely is used today as a primary surgical therapy unless breast cancer is advanced at the time of diagnosis. Modified surgical techniques (i.e., mastectomy plus axillary dissection or lumpectomy for breast conservation) accompanied by chemotherapy or radiation therapy have achieved outcomes comparable with those obtained with radical surgical methods and constitute the preferred treatment methods.
The prognosis for women with breast cancer is related more to the extent of nodal involvement than to the extent of breast involvement. Greater nodal involvement requires more aggressive postsurgical treatment, and many cancer specialists believe that a diagnosis of breast cancer is not complete until dissection and testing of the axillary lymph nodes have been accomplished. A newer technique for evaluating lymph node involvement is a sentinel lymph node biopsy. A radioactive substance or dye is injected into the region of the tumor. In theory, the dye is carried to the first (sentinel) node to receive lymph from the tumor. This would therefore be the node most likely to contain cancer cells if the cancer has spread. If the sentinel node biopsy is positive, more nodes are tested. If it is negative, further lymph node evaluation may not be needed.

Systemic therapy refers to the administration of chemotherapy, biologic therapy, or hormonal therapy. Neoadjuvant therapy is given before surgery to shrink the tumor and make surgical removal more effective. Adjuvant therapy is given after surgery to women with and without detectable metastatic disease. The goal of this therapy depends on nodal involvement, menopausal status, and hormone receptor status. Systemic adjuvant therapy has been widely studied and has demonstrated benefits in reducing rates of recurrence and death from breast cancer. Biologic therapy, using the drug trastuzumab (Herceptin), is used to stop the growth of breast tumors that express the HER2/neu receptor on their cell surface. The HER2/neu receptor binds an epidermal growth factor that contributes to cancer cell growth. Trastuzumab is a recombinant DNA-derived monoclonal antibody that binds to the HER2/neu receptor, thereby inhibiting proliferation of tumor cells that overexpress the receptor gene.

Hormone therapy is used to block the effects of estrogen on the growth of breast cancer cells. Tamoxifen is a nonsteroidal antiestrogen that binds to estrogen receptors and blocks the effects of estrogens on the growth of malignant cells in the breast. Studies have shown decreased cancer recurrence, decreased mortality rates, and increased 5-year survival rates in women with estrogen receptor–positive tissue samples who have been treated with the drug. Aromatase inhibitors block the enzyme that converts androstenedione and testosterone to estrogen in the peripheral tissues. This reduces the circulating estrogen levels in postmenopausal women and is becoming the most effective adjuvant therapy for women with early-stage breast cancer. Autologous bone marrow transplantation and peripheral stem cell transplantation are experimental therapies that may be used for treatment of advanced disease or in women at increased risk for recurrence.

**Paget Disease**

Paget disease accounts for 1% of all breast cancers. The disease presents as an eczematoid lesion of the nipple and areola. Paget disease usually is associated with an infiltrating, intraductal carcinoma. When the lesion is limited to the nipple only, the rate of axillary metastasis is approximately 5%. Complete examination is required and includes a mammogram and biopsy. Treatment depends on the extent of spread.

**Summary Concepts**

- The breast contains alveolar glands and ducts that are lined with epithelial tissue that may give rise to benign and malignant lesions.
- Benign conditions include inflammatory disorders (mastitis, mammary duct dysplasia, and fat necrosis) and benign epithelial lesions (nonproliferative lesions, proliferative lesions without atypia, and proliferative lesions with atypia). Some benign conditions, such as proliferative lesions, may predispose to malignant disease, and others, such as fibrocystic changes and fat necrosis, may present with a mass and signs that resemble malignant disease.
- Breast cancer is a significant cause of death for women. Some inherited breast cancers are associated with mutations in breast cancer genes BRCA1 and BRCA2. The combination of clinical breast exam and mammography afford women the best opportunity for detection of breast cancer which allows for earlier treatment and improved outcomes. The choice of treatment, which includes surgical resection, radiation, and chemotherapy, depends on the stage of the disease.

**Review Exercises**

1. Most oral contraceptive agents use low doses of estrogen and progestin to prevent conception.
   A. Use Figures 40-5 and 40-6 to explain how these oral agents prevent ovulation and pregnancy.

2. A 32-year-old woman has been told that the report of her annual Pap test revealed the presence of mild cervical dysplasia.
   A. What questions should this woman ask to become informed about the significance of these findings?
   B. Cervical cancer is often referred to as a sexually transmitted disease. Explain.
   C. What type of follow-up care would be indicated?
3. A 30-year-old woman consults her gynecologist because of amenorrhea and inability to become pregnant. Physical examination reveals an obese woman with hirsutism. The physician tells her that she might have a condition known as polycystic ovary syndrome and that further laboratory tests are indicated.

A. Among tests ordered were a fasting blood glucose and serum LH, FSH, and dehydroepiandrosterone levels. What information can these tests provide that would help in establishing a diagnosis of polycystic ovary syndrome?

B. What is the probable cause of this woman’s amenorrhea, hirsutism, and failure to become pregnant?

C. What type of treatment might be used to help this woman become pregnant?

4. A 45-year-old woman makes an appointment to see her physician because of a painless lump in her breast that she has discovered.

A. What tests should be done to confirm the presence or absence of breast cancer?

B. During the removal of breast cancer, a sentinel node biopsy is often done to determine whether the cancer has spread to the lymph nodes. Explain how this procedure is done and its value in determining lymph node spread.

C. After surgical removal of breast cancer, tamoxifen may be used as an adjuvant systemic therapy for women without detectable metastatic disease. The presence or absence of estrogen receptors in the cytoplasm of tumor cells is important in determining the selection of an agent for use in adjuvant therapy. Explain.

sexually transmitted infections (STIs) encompass a broad range of infectious diseases that are spread by sexual contact. Although the incidence of syphilis and gonorrhea as reported in the professional literature and public health statistics has decreased slightly, the incidence of other STIs is increasing. The actual figures are probably much higher than those reported because many STIs are not reportable or not reported. The agents of infection include bacteria, viruses, fungi, and other microorganisms (see Chapter 14). The initial site of an STI may be the urethra, genitalia, rectum, or oral pharynx. The organisms that cause these infections tend to be short-lived outside the host, so they usually depend on person-to-person spread. The rates of many STIs are highest among adolescents; more common in persons who have more than one sexual partner; and it is not uncommon for a person to be concurrently infected with more than one type of STI.

Many factors contribute to the increased prevalence and the continued spread of STIs, including the fact that STIs are frequently asymptomatic, which promotes the spread of infection by persons who are unaware that they are carrying the infection. Furthermore, partners of infected persons are often difficult to notify and treat. Condoms could prevent the spread of many STIs, but they often are not used or are used improperly. In addition, there currently are no cures for viral STIs (e.g., human immunodeficiency virus [HIV], herpes simplex virus, and human papilloma virus [HPV]); although there are drugs available that may help to manage the infections, they do not entirely control the spread. Also, drug-resistant microorganisms are rapidly emerging, making treatment of many STIs more difficult.

This chapter discusses the manifestations of STIs in men and women in terms of infections of the external genitalia, vaginal infections, and infections that have genitourinary as well as systemic manifestations. HIV infection is presented in Chapter 16.
Infections of the External Genitalia

Sexually transmitted infections can selectively infect the mucocutaneous tissues of the external genitalia, rectum, and oral pharynx, or produce both genitourinary and systemic effects. These infections include condylomata acuminata, genital herpes, chancroid, and lymphogranuloma venereum.

Human Papillomavirus Infection and Genital Warts

Genital warts (condylomata acuminata) are caused by the human papillomavirus (HPV) that infects epithelial cells and can cause a number of benign and malignant growths. Although recognized for centuries, HPV-induced genital warts have become one of the fastest-growing STIs of the past decade. The Centers for Disease Control and Prevention (CDC) estimates that 360,000 million Americans are currently infected with the HPV.

Etiology and Pathogenesis

Transmission of HPV is usually through skin-to-skin contact, most often through penetration (oral–genital, manual–genital, and genital–genital contact). HPV can also be transmitted through nonsexual routes including mother to newborn (vertical transmission) and fomites (objects such as clothing, towels, or utensils that harbor the agent). Prevention of HPV transmission through condom use has not been adequately demonstrated. Most HPV infections are asymptomatic and transient, and resolve without treatment. In some cases, however, HPV infection results in genital warts, abnormal Papanicolaou (Pap) test abnormalities, or, rarely, cervical cancer.

Human papillomaviruses are nonenveloped double-stranded deoxyribonucleic acid (DNA) viruses that cause proliferative lesions of the squamous epithelium. Human papillomavirus is species specific, meaning it only affects humans. More than 100 distinct HPV subtypes have been identified, over 40 of which affect the anogenital area. These subtypes are routinely classified into low-risk and high-risk categories. Low-risk types such as HPV 6 and 11 are typically associated with genital warts. Types 16, 18, 31, 33, and 45 are considered to be high risk because of their association with cervical dysplasia and cervical cancer. Of the high-risk types, HPV 16 and 18 account for approximately two thirds of cervical cancer. Only a subset of women infected with HPV go on to develop cervical cancer, however, suggesting that even the most virulent HPV strains may vary in terms of their oncogenic potential. Cofactors that may increase the risk for cancer include smoking, immunosuppression, and exposure to hormonal alteration (e.g., pregnancy, oral contraceptives).

Human papillomavirus infection begins with viral inoculation into squamous epithelial cells, where infection stimulates replication of the squamous epithelium, producing the various HPV-proliferative lesions. The incubation period for HPV-induced genital warts ranges from 6 weeks to 8 months, with a mean of 2 to 3 months. Genital warts typically present as soft, raised, fleshy lesions on the external genitalia, including the penis (Fig. 41-1), vulva, scrotum, perineum, and perianal skin. External warts may appear as small bumps, or they may be flat, rough surfaced, or pedunculated. Less commonly, they can appear as smooth reddish or brown raised papules or as dome-shaped lesions on keratinized skin. Internal warts are cauliflower-shaped lesions that affect the mucous membranes of the vagina, urethra, anus, or mouth. They may cause discomfort, bleeding, or painful intercourse.

Although warts can be a disturbing clinical feature of HPV infection, subclinical infection is common. Approximately 70% of women with HPV become HPV DNA negative within 1 year, and as many as 91% of them become negative within 2 years. Many women with transient HPV infections develop atypical squamous cells of undetermined significance (ASC-US) or low-grade squamous intraepithelial lesions (LSILs) of the cervix as detected on a Pap test, colposcopy, or biopsy (see Chapter 40). In men, transient HPV infection may be associated with intraepithelial neoplasia of the penis and anus. Although many individuals will clear the virus and become negative within 1 to 2 years, it is unclear if development of an effective immune response completely clears the infection. In some individuals the virus may remain dormant for years and reactivate at a later time. While some of these later lesions may be reactivations, others may be re-infections from an affected partner.

Genital warts also may be removed using cryotherapy (i.e., freezing therapy) with liquid nitrogen or a cryoprobe, laser vaporization, electrocautery, or surgical excision. Cryotherapy and BCA or TCA are the recommended treatments for cervical HPV lesions. Laser surgery can be used to remove large or widespread lesions of the cervix, vagina, or vulva, or lesions that have failed to respond to other first-line methods of treatment. Electrocautery treatment has become more widespread for these types of lesions because it does not require suturing and is beneficial for persons who have a large number of warts.

Vaccination is currently regarded as one of the most effective strategies for controlling HPV-related diseases. Two vaccines are available to protect females against the type of HPV that causes cervical cancer—a quadrivalent vaccine (Gardasil) that protects against HPV types 6, 11, 16, and 18, and a bivalent vaccine (Cervarix) that protects against HPV types 16 and 18. The quadrivalent (Gardasil) vaccine can be given to males for protection from genital warts. There is no treatment, however, to eradicate the virus once a person has become infected.

**Genital Herpes**

Genital herpes is a common cause of genital ulcers, affecting more than 50 million people in the United States. Because herpesvirus infection is not reportable in all states, reliable data on its true incidence and prevalence are lacking.

**Etiology and Pathogenesis**

Genital herpes is caused by the herpes simplex virus (HSV), a large double-stranded DNA virus. Herpes simplex infections are highly contagious. There are eight types of HSV; however, only two are considered sexually transmitted. These are HSV-1 (usually associated with fever blisters and cold sores) and HSV-2 (usually associated with genital herpes). HSV-1 and HSV-2 are genetically similar; both cause a similar set of primary and recurrent infections; and both can cause oropharyngeal and genital lesions, but HSV-2 is most commonly found only in the genitals.

HSV-1 and HSV-2 are neurotropic viruses, meaning that they grow in neurons and share the biologic property of latency. Latency refers to the ability to maintain disease potential in the absence of clinical signs and symptoms. In genital herpes, the virus ascends through the peripheral nerves to the sacral dorsal root ganglia. The virus can remain dormant in the dorsal root ganglia, or it can reactivate, in which case the viral particles are transported back down the nerve root to the skin, where they multiply and cause a lesion to develop. During the dormant or latent period, the virus replicates in a different manner so that the immune system or available treatments have no effect on it. It is not known what reactivates the virus. It may be that the body’s defense mechanisms are altered. Numerous studies have shown that host responses to infection influence initial development of the disease, severity of
infection, development and maintenance of latency, and frequency of HSV recurrences.

Herpes simplex virus is transmitted by contact with infectious lesions, but may also be transmitted when no symptoms or lesions are present. Although most HSV genital infections were once caused by HSV-2, it is now increasingly common for infections to be caused by both HSV-1 and HSV-2, particularly among adolescents and young women. Persons infected with HSV-1 remain at risk for acquiring HSV-2. Most cases of HSV-2 infection are subclinical, manifesting as asymptomatic or symptomatic but unrecognized infections. These subclinical infections can occur in people who have never had a symptomatic outbreak or they can occur between recognized clinical recurrences. Up to 70% of genital herpes is spread through asymptomatic shedding by people who do not realize they have the infection. This “unknown” transmission of the virus to sex partners explains why this infection has reached epidemic proportions throughout the world.

The incubation period for HSV is 2 to 12 days. Genital HSV infection may manifest as a first-episode or recurrent infection. The initial symptoms of primary genital herpes infections include tingling, itching, and pain in the genital area, followed by eruption of small pustules and vesicles. These lesions rupture on approximately the 5th day to form wet ulcers that are excruciatingly painful to touch and can be associated with dysuria, dyspareunia, and urine retention. This period is followed by a 10- to 12-day interval during which the lesions crust over and gradually heal. Involvement of the cervix, vagina, urethra, and inguinal lymph nodes is common in women with primary infections. In men, the infection can cause urethritis and lesions of the penis and scrotum. Rectal and perianal infections are possible with anal contact. Systemic symptoms associated with primary infections include fever, headache, malaise, muscle ache, and lymphadenopathy. Primary infections may be debilitating enough to require hospitalization, particularly in women. First episodes of nonprimary infections (acquisition of HSV-2 in persons with preexisting antibodies to HSV-1 or, more rarely, acquisition of HSV-1 in persons with preexisting HSV-2 antibodies) are associated with fewer lesions, a shorter duration of disease, and a lower rate of complications than primary infections.

Recurrent HSV episodes are usually milder than the initial episode—there typically are fewer lesions, and viral shedding occurs at a lower concentration and for a shorter duration (about 3 days). However, the prodromal symptoms of itching, burning, and tingling at the lesion site are similar. Except for the greater tendency of HSV-2 to recur, the clinical manifestations of genital HSV-2 and HSV-1 infections are similar. The frequency and severity of recurrence vary from person to person. Numerous factors, including emotional stress, lack of sleep, overexertion, other infections, vigorous or prolonged coitus, and premenstrual or menstrual distress, have been identified as triggering mechanisms.

**Diagnosis and Treatment**

Diagnosis of genital herpes is based on symptoms, appearance of the lesions, and identification of the virus taken from the lesions. Viral culture can generally isolate the virus in 5 days, is relatively inexpensive, and is highly specific. However, it is not very sensitive, with false-negative results of 25% with primary infections and as high as 50% with recurrent infections. Polymerase chain reaction (PCR), which can detect single copies of viral DNA by amplifying the DNA many millions of times, has a higher sensitivity and has become the preferred method to confirm a diagnosis of genital HSV infection. In addition to identifying the virus from a sample taken from the herpes lesion, detection of type-specific antibodies to HSV-1 and HSV-2 from a blood sample also can help to establish the diagnosis. These tests yield false-negative results when used in the early stages of infection, since it takes approximately 22 days for the body to produce antibodies to the virus. Approximately 20% of patients may remain seronegative for 3 months, particularly if they have received antiviral medications. This type of testing may prove useful in confirming infection in persons with recurrent genital symptoms and negative HSV testing, or in establishing a clinical diagnosis of genital herpes in a partner of a person with genital herpes.

There is no known cure for genital herpes, and the methods of treatment are largely symptomatic. The oral antiviral drugs acyclovir, valacyclovir, and famciclovir have become the cornerstone for management of genital herpes. By interfering with viral DNA replication, these drugs decrease the frequency of recurrences, shorten the duration of active lesions, reduce the number of new lesions formed, and decrease viral shedding. Valacyclovir, the active component of acyclovir, and famciclovir have greater bioavailability, which enables improved dosing.
schedules and increased compliance. Episodic intervention reduces the duration of viral shedding and the healing time for recurrent lesions. For individuals who wish to prevent transmission to a susceptible partner or wish to prevent outbreaks, continuous antiviral suppressive therapy may be advised. These drugs are well tolerated, with few adverse effects. This long-term suppressive therapy does not limit latency, and reactivation of the disease frequently occurs after the drug is discontinued. In 2002, the FDA approved long-term suppressive therapy with valacyclovir and condon use for the prevention of HSV-2 transmission to an uninfected sexual partner. Infection with HSV-2 may predispose an individual to HIV infection and antiviral therapy does not reduce this risk.  

Maternal/Neonatal Transmission  
Herpes simplex virus may be transmitted from mother to child around the time of delivery causing potentially fatal disease in the newborn. Women who experience their first genital HSV infection in pregnancy are at highest risk of transmitting the disease to their newborn. Disseminated neonatal infection carries high mortality and morbidity rates. Because of the risk involved, many authorities recommend that recently acquired HSV infections in pregnant women be treated with antiviral drugs (e.g., aciclovir or valaciclovir).

Active infection during labor may necessitate cesarean delivery, ideally before membranes rupture, but this is not a guarantee that the infant will not acquire infection. Pregnant women with a known history of HSV-2 infection should be treated with antiviral therapy from 36 weeks until delivery. If there are no active lesions at the time of labor, vaginal delivery is preferred. Neonatal HSV is treated with systemic antiviral therapy.

Chancroid  
Chancroid is a disease of the external genitalia and lymph nodes caused by the gram-negative bacterium *Haemophilus ducreyi*. The disease is most common in tropical and subtropical regions. It is one of the most common causes of genital ulcers in less developed countries, especially in Africa and parts of Asia, where it probably serves as an important cofactor in the transmission of HIV infection. This STI has become uncommon in the United States. However, recent evidence suggests that chancroid may be underdiagnosed because many STI clinics do not have the facilities to test for *H. ducreyi*.

Chancroid is highly infectious and is usually transmitted by sexual intercourse or through skin and mucous membrane abrasions. Autoinoculation may lead to multiple chancrees. Lesions begin as macules, progress to pustules, and then rupture. On physical examination, lesions and regional lymphadenopathy (i.e., buboes) may be found. Secondary infection may cause significant tissue destruction.

Diagnosis usually is made clinically, but may be confirmed through culture. Gram stain rarely is used today because it is insensitive and nonspecific. There are no FDA approved PCR tests for *H. ducreyi*. The organism has shown resistance to treatment with sulfamethoxazole alone and to tetracycline.

**Lymphogranuloma Venereum**  
Lymphogranuloma venereum (LGV) is an acute and chronic venereal disease caused by *Chlamydia trachomatis* types L1, L2, and L3. The disease, although found worldwide, has a low incidence outside the tropics. Most cases reported in the United States are in men. There appears to be a new variant of L2 that is causing a resurgence of LGV in Europe and the United States, particularly in men who have sex with men.

The lesions of LGV can incubate for a few days to several weeks and thereafter cause small, painless papules or vesicles that may go undetected. An important characteristic of the infection is the early (1 to 4 weeks later) development of large, tender, and sometimes fluctuant lymph nodes called buboes. There may be febrile symptoms with joint pain, rash, weight loss, pneumonitis, tachycardia, splenomegaly, and proctitis. In later stages of the disease, a small percentage of affected persons develop elephantiasis (hypertrophy, edema, and fibrosis of the skin and subcutaneous tissues) of the external genitalia, caused by lymphatic obstruction or fibrous strictures of the rectum or urethra from inflammation and scarring. Urethral involvement may cause pyuria and dysuria. Cervicitis is a common manifestation of primary LGV in women, and could extend to perimetritis or salpingitis, which are known to occur in other chlamydial infections. Anorectal structures may be compromised to the point of incontinence. Complications of LGV may be minor or extensive, involving compromise of whole systems or progression to a cancerous state.

Diagnosis usually is accomplished by a complement fixation test for LGV-specific *Chlamydia* antibodies. High titers for this antibody differentiate this group from other chlamydial subgroups. PCR techniques, when more widely available, will provide a more practical, cost-effective tool for diagnosis. Treatment involves 3 weeks of doxycycline, tetracycline, or erythromycin. Because doxycycline is contraindicated in pregnancy, erythromycin should be used. Surgery may be required to correct sequelae such as strictures or fistulas or to drain fluctuant lymph nodes.

**SUMMARY CONCEPTS**

- Sexually transmitted infections (STIs) are spread by sexual contact and involve both male and female partners. Ports of entry include the mouth, genitalia, urinary meatus, rectum, and skin. All STIs are more common in persons who have more than one sexual partner, and it is not uncommon for a person to be concurrently infected with more than one type of STI.
SUMMARY CONCEPTS (continued)

- Genital warts (condylomata acuminata) are caused by the human papillomavirus (HPV) that infects epithelial cells. Of particular concern is the relation between HPV infections and the development of genital neoplasms. Over 100 types of HPV have been identified, including subtypes 6 and 11, which are typically associated with genital warts, and subtypes 16 and 18, which account for approximately two thirds of cervical dysplasia and cervical cancer.

- Genital herpes is an ulcerative disorder caused by the highly contagious herpes simplex virus (HSV). Both HSV-1 and HSV-2 are neurotrophic viruses that produce acute primary infections and latent recurrent episodes. During the primary infection, the HSV ascends through peripheral nerves to a sacral dorsal root ganglia. Recurrences occur when the virus is reactivated and travels down the nerve root to the affected area. There is no permanent cure for herpes infections.

- Chancroid and lymphogranuloma venereum (LGV) produce external genital lesions with various degrees of inguinal lymph node involvement. These diseases are uncommon in the United States.

Vaginal Infections

Candidiasis, trichomoniasis, and bacterial vaginosis are vaginal infections that can be associated with sexual activity. Trichomoniasis is the only form of vaginitis that is known to be sexually transmitted and requires partner treatment. A male partner usually is asymptomatic. However, candidiasis requires a favorable environment for growth of the organism. Studies have documented the presence of Candida on the penis of male partners of women with vulvovaginal candidiasis, but few men develop balanoposthitis that requires treatment. The gastrointestinal tract also serves as a reservoir for this organism, and candidiasis can develop through autoinoculation in women who are not sexually active.

Reported risk factors for the overgrowth of C. albicans include recent antibiotic therapy, which suppresses the normal protective bacterial flora; high hormone levels owing to pregnancy or the use of oral contraceptives, which cause an increase in vaginal glycogen stores; and uncontrolled diabetes mellitus, HIV infection, or other diseases, which compromise the immune system. Women with vulvovaginal candidiasis commonly complain of vulvovaginal pruritus accompanied by irritation, erythema, swelling, dysuria, and dyspareunia. The characteristic discharge, when present, is usually thick, white, and odorless. In obese persons, Candida may grow in skin folds underneath the breast tissue, the abdominal flap, and the inguinal folds.

Accurate diagnosis is made by identification of budding yeast filaments (i.e., hyphae) or spores on a wet-mount slide using 10% potassium hydroxide (Fig. 41-3A). The pH of the discharge, which is checked with litmus paper, typically is less than 4.5. When the wet-mount technique is negative but the clinical manifestations are suggestive of candidiasis, a culture may be necessary.

For treatment purposes, vulvovaginitis is commonly classified as uncomplicated or complicated. Current choice of therapeutic agents is for the most part limited to the azole medications, fungistatic drugs that inhibit cell wall metabolism. Some of these antifungal medications (e.g., clotrimazole, miconazole) are available as topical preparations (creams or suppositories) that can be obtained without a prescription for treatment in women with uncomplicated cases of candidiasis. Topical terconazole and oral fluconazole are also available with prescription. Because of ease of use, oral fluconazole has become a preferred method for most women, but

Candidiasis

Vulvovaginal candidiasis, also referred to as a yeast infection, thrush, or moniliasis, is one of the most frequent reasons that women visit a health care provider. Candida albicans is the most commonly identified organism in vaginal yeast infections, but other Candida species, such as Candida glabrata and Candida tropicalis, may also be present. These organisms are present in 20% to 55% of healthy women without causing symptoms. Although vulvovaginal candidiasis usually is not transmitted sexually, it is included in the CDC STI treatment guidelines because it often is diagnosed in women being evaluated for STIs. The possibility of sexual transmission has been recognized for many years;
usually requires a medical appointment to confirm the presence of vaginal candidiasis. Recurrent vulvovaginal candidiasis, defined as four or more mycologically confirmed episodes within 1 year, affects approximately 5% of women and is difficult to manage. Maintenance therapy with oral fluconazole often is required for long-term management of this problem.16–18

**Trichomoniasis**

Trichomoniasis affects an estimated 120 million people in the United States and is the most prevalent nonviral sexually transmitted infection worldwide.4 Trichomoniasis vaginalis infections are commonly associated with other STIs and are therefore a marker for high-risk sexual behavior. Although the infection is commonly transmitted by sexual contact, it can occur via fomites and the organism has been shown to survive in swimming pools and hot tubs.2

The manifestations of infection with *T. vaginalis*, the causative agent of trichomoniasis, are primarily observed in women, and range from asymptomatic presentation to a copious, frothy, malodorous green or yellow discharge.19–21 There often is erythema and edema of the affected mucosa, with occasional itching and irritation. Sometimes, small hemorrhagic punctations, called strawberry spots, appear on the cervix. Men can present with urethritis, prostatitis, and discharge, but most men are largely asymptomatic.21

*Trichomoniasis vaginalis* is an anaerobic protozoan that is shaped like a turp and has three or four anterior flagella (see Fig. 41-3B, C). Trichomonads can reside in the paraurethral glands of both sexes. This extracellular parasite feeds on the vaginal mucosa and ingests bacteria and leukocytes. Trichomonads attach easily to mucous membranes. It may reduce the choioamnionic membrane strength and predispose pregnant women to premature rupture of membranes and premature birth.19

*Trichomoniasis vaginalis* infection has emerged as a cofactor for HIV transmission. Potential mechanisms for increased susceptibility include recruitment of HIV target cells, weakening of structural integrity of epithelial cells and their defense against HIV invasion, and creation of punctate microhemorrhages in mucosal genital tissue that serve as a portal of HIV entry.19,20 Trichomonads may serve as vectors for the spread of other organisms, carrying pathogens attached to their surface into the fallopian tubes; infection has been associated with acute salpingitis and postpartum endometrial infection.21 In men, it is a common cause of nongonococcal urethritis and is a risk factor for infertility, altering sperm motility and viability. It has also been associated with chronic prostatitis.

Diagnosis is made microscopically by identification of the motile protozoan on a wet-mount slide preparation. The pH of the discharge usually is greater than 6.0. Newer point-of-care tests include an antigen-based diagnostic test (OSOM *Trichomonas* Rapid Test), a DNA probe test (Afirma VP III), and a PCR-based test. The OSOM and DNA probes have greater sensitivity than a vaginal mount and results can be available in less than an hour.4,19 Because the organism resides in other urogenital structures besides the vagina, systemic treatment is recommended. Metronidazole and tinidazole, which are the treatments of choice against anaerobic protozoans, can cure *T. vaginalis*.19 Systemic treatment is preferred over topical application to achieve adequate drug concentrations in nonvaginal sites.19 Because the organism responds to only one class of medication, mild drug resistance has been noted against metronidazole but not tinidazole.24 Although metronidazole is considered safe for use during pregnancy, data on tinidazole use in pregnancy are limited. Sexual partners should be treated to avoid reinfection, and abstinence is recommended until the full course of therapy is completed.

**Bacterial Vaginosis**

Bacterial vaginosis is a polymicrobial infection characterized by lack of hydrogen peroxide–producing lactobacilli and an overgrowth of anaerobic organisms. It is the most prevalent vaginal disorder in women of reproductive age.2 Bacterial vaginosis is associated with multiple male or female sex partners, a new sex partner, lack of condom use, and douching.2,22–24 Sexual activity is believed to be a catalyst rather than a primary mode of transmission, and endogenous factors may play a role in the development of symptoms.

The predominant symptom of bacterial vaginosis is a thin, grayish-white discharge that has a foul, fishy odor. Burning, itching, and erythema usually are absent because the bacteria have only minimal inflammatory potential. Because of the lack of inflammation, the term vaginosis rather than vaginitis is used to describe the condition. The organisms associated with bacterial vaginosis may be carried asymptptomatically by men and women.

The pathogenesis of bacterial vaginosis remains poorly understood. It is a complex disorder characterized by a shift in the vaginal flora from one dominated by hydrogen peroxide–producing lactobacilli to one with greatly reduced numbers of *Lactobacillus* species and an overgrowth of facultative anaerobic organisms, including *Gardnerella vaginalis*, *Mobiluncus* species, and *Mycoplasma hominis*.2,22,24 The massive overgrowth of vaginal anaerobes is associated with the production of proteolytic enzymes that break down vaginal amines, which become volatile and malodorous in a high pH. The amines are associated with increased vaginal secretions and squamous epithelial cell exfoliation, creating the typical discharge. In conditions of elevated pH, the vaginal anaerobes more efficiently adhere to the exfoliating epithelial cells, creating what are called clue cells (Fig. 41-4).

In addition to causing bothersome symptoms, bacterial vaginosis is associated with an increased risk of pelvic inflammatory disease (PID), adverse pregnancy outcomes including premature rupture of membranes, preterm labor, preterm birth, and postpartum endometritis linked to the organisms associated with bacterial vaginosis. Postoperative infections, including postabortion...
and postcesarean endometritis, have been shown to be associated with asymptomatic bacterial vaginosis. It has also been associated with increased risk of acquisition of HIV and HSV infection.

The diagnosis of bacterial vaginosis is made when at least three of the following signs or symptoms are present: abnormal gray discharge, vaginal pH above 4.5 (usually 5.0 to 6.0), positive fishy odor of vaginal discharge on addition of 10% potassium hydroxide, and appearance of characteristic “clue cells” on wet-mount microscopic studies. Because *G. vaginalis* can be a part of the normal vaginal flora, cultures should not be done routinely.

Bacterial vaginosis may be treated with oral or topical metronidazole or clindamycin and oral tinidazole. Symptomatic pregnant women can also be treated with metronidazole or clindamycin. Some studies have shown that screening for and treating bacterial vaginosis may reduce the incidence of adverse pregnancy outcomes. However, studies do not confirm a benefit from universal testing of low- and medium-risk pregnant women.

**Vaginal-Urogenital-Systemic Infections**

Some STIs infect male and female genital and extragenital structures. Among the infections of this type are chlamydial infections, gonorrhea, and syphilis. Many of these infections also pose a risk to infants born to infected mothers. Some infections, such as syphilis, may be spread to the unborn infant while in utero, whereas others, such as chlamydial and gonorrheal infections, can be spread to the infant during the birth process.

**Chlamydial Infections**

Chlamydial infection is the most frequently reported bacterial STI in the United States, with an incidence estimated to be more than twice that of gonorrhea. According to the Centers for Disease Control and Prevention (CDC), an estimated 2.86 million infections occur annually. A large number of cases go unreported because most people with chlamydia are asymptomatic and do not seek testing. If untreated, chlamydial infections can lead to serious complications including pelvic inflammatory disease, infertility, ectopic pregnancy, and chronic pelvic pain.

**Etiology and Pathogenesis**

*Chlamydia trachomatis* is an obligate intracellular bacterial pathogen that is closely related to gram-negative bacteria. It resembles a virus in that it requires tissue culture for isolation, but like bacteria, it has both DNA and RNA and is susceptible to some antimicrobial agents. Chlamydial infection exists in two morphologically distinct forms during its unique life—a small infectious elementary body and a large noninfectious reticulate body. Much like a spore, the **elementary body**

---

**FIGURE 41-4.** Clue cells. Clue cells are epithelial cells with clumps of bacteria clustered on their surface. Clue cells indicate the presence of bacterial vaginosis. (From the Centers for Disease Control and Prevention Public Health Image Library. No. 3720. Courtesy of M. Rein.)
is metabolically inactive and can survive outside the cell. It does not replicate. The reticulate body is metabolically active and cannot survive outside the cell. The 48-hour growth cycle starts with attachment of the elementary body to the susceptible host cell, after which it is ingested by a process that resembles phagocytosis (Fig. 41-5). Once inside the cell, the elementary body transforms into the larger reticulate body, which then commandeers the host cell’s metabolic machinery to fuel its replication. The reticulate body divides repeatedly for up to 36 hours, forming new elementary bodies that are released when the infected cell bursts. Necrotic debris elicits inflammatory and immune processes that further damage infected tissue.

The signs and symptoms of chlamydial infection resemble those produced by gonorrhea. The most significant difference between chlamydial and gonococcal salpingitis is that chlamydial infections may be asymptomatic or clinically nonspecific. In women, chlamydial infections may cause urinary frequency, dysuria, and vaginal discharge. The most common symptom is a mucopurulent cervical discharge. The cervix itself frequently hypertrophies and becomes erythematous, edematous, and extremely friable. This can lead to fallopian tube damage and increase the reservoir for further chlamydial infections. In men, chlamydial infections cause urethritis, including meatal erythema and tenderness, urethral discharge, dysuria, and urethral itching. Prostatitis and epididymitis with subsequent infertility may develop. The most serious complication of untreated chlamydial infection in men is the development of Reiter syndrome, a reactive arthritis that includes the triad of urethritis, conjunctivitis, and painless mucocutaneous lesions (see Chapter 44).

**Diagnosis and Treatment**

The CDC recommends annual screening of women who are sexually active and younger than 25 years; men who have sex with men and have receptive anal sex; and all HIV-infected individuals who participate in receptive anal sex. Heterosexual individuals and men who have sex with men or have multiple and/or anonymous sex partners should be tested more frequently. A health care provider may choose to screen more frequently depending on a person’s sexual risks. All pregnant women should be tested early in pregnancy; for women with increased risk factors, third-trimester screening is also recommended.

Diagnosis of chlamydial infections takes several forms. The identification of polymorphonuclear leukocytes on Gram stain of penile discharge in the man or cervical discharge in the woman provides presumptive evidence. The direct fluorescent antibody test and the enzyme-linked immunosorbent assay, which use antibodies against an antigen in the *Chlamydia* cell wall, are rapid tests that are highly sensitive and specific. The positive predictive value of these tests is excellent among high-risk groups, but false-positive results occur more often in low-risk groups. The methodological challenges of culturing this organism have led to the development of non–culture-based tests that amplify and detect *C. trachomatis*–specific DNA and RNA sequences. One of the newer sets of nonculture techniques, the nucleic acid amplification tests (NAATs), do not require viable organisms for detection, and can produce a positive signal from as little as a single copy of the target DNA or RNA. These amplification methods are highly sensitive and, if properly monitored, very specific. Because NAATs can be performed on urine and self-collected swab specimens from the distal vagina as well as the traditional endocervical and urethral specimens, this easy, convenient means of accurate detection has become the diagnostic method of choice. Detection rates (specificity) for chlamydiae in urine and vaginal samples are nearly identical to those for cervical and urethral samples.

---

**FIGURE 41-5.** Chlamydial growth cycle. EB, elementary body; RB, reticulate body. (From Thompson SE, Washington AE. Epidemiology of sexually transmitted Chlamydia trachomatis infections. Epidemiol Rev. 1983;5:96–123.)
The CDC recommends the use of azithromycin or doxycycline in the treatment of chlamydial infection; penicillin is ineffective. Azithromycin or amoxicillin is the preferred choice in pregnancy. Simultaneous antibi-otic treatment of both sexual partners is recommended. Abstinence from sexual activity is encouraged to facilitate cure. With the exception of women who are pregnant, a test of cure 3 to 4 weeks after treatment is no longer recommended unless therapeutic compliance is in question.

**Gonorrhea**

Gonorrhea is one of the oldest and still one of the most common STIs. Currently, it is the second most commonly reported communicable disease in the United States, with greater than 300,000 cases being reported in 2011. The infection disproportionately affects vulnerable populations such as minorities, who are marginalized because of race, ethnicity, or sexual orientation.

**Etiology and Pathogenesis**

The gonococcus is a pyogenic (i.e., pus-forming), gram-negative diplococcus that evokes inflammatory reactions characterized by purulent exudates. Humans are the only natural host for *N. gonorrhoeae*. The organism grows best in warm, mucus-secreting epithelia. The portal of entry can be the genitourinary tract, eyes, oropharynx, anorectum, or skin. Transmission usually is by intercourse. Autoinoculation of the organism to the conjunctiva is possible. Neonates born to infected mothers can acquire the infection during passage through the birth canal and are in danger of developing gonorrheal conjunctivitis, with resultant blindness, unless treated promptly. Genital gonorrhea in young children should raise the possibility of sexual abuse.

Gonococcal infection commonly manifests 3 to 5 days after exposure, but asymptomatic infections are common in both men and women. Gonorrhea typically begins in the anterior urethra, accessory urethral glands, Bartholin or Skene glands, and cervix. If untreated, gonorrhea spreads from its initial sites upward into the genital tract. In males, it spreads to the prostate and epididymis; in females, it commonly moves to the fallopian tubes (Fig. 41-6). Pharyngitis may follow oral–genital contact. The organism also can invade the bloodstream (i.e., disseminated gonococcal infection), causing serious sequelae such as bacteremic involvement of joint spaces, heart valves, meninges, and other body organs and tissues.

Persons with gonorrhea may be asymptomatic and may unwittingly spread the disease to their sexual partners. Men are more likely to be symptomatic than women. In men, the initial symptoms include urethral pain and a creamy yellow, sometimes bloody, penile discharge (Fig. 41-7). The disorder may become chronic and affect the prostate, epididymis, and periurethral glands. Rectal infections are common in men who have sex with men. In women, recognizable symptoms include unusual genital or urinary discharge, dysuria, dyspareunia, pelvic pain or tenderness, unusual vaginal bleeding (including bleeding after intercourse), fever, and proctitis. Symptoms may occur or increase during or immediately after menses because the bacterium is an intracellular diplococcus that thrives in menstrual blood but cannot survive long outside the human body. There may be infections of the uterus and development of acute or chronic infection of the fallopian tubes (i.e., salpingitis), with ultimate scarring and sterility.

**FIGURE 41-7.** Purulent penile discharge due to gonorrhea with overlying pyodermal lesions. (From the Centers for Disease Control and Prevention Public Health Image Library. No. 4065.)
Diagnosis and Treatment

Diagnosis is based on the history of sexual exposure and symptoms. The presence of *N. gonorrhoea* may be confirmed by identification of the organism on a gram stain or culture, but more rapid testing that can be done from a urine sample is becoming preferred. While culture remains the gold standard, detection by NAATs is possible using urine and urethral swab specimens. The sensitivity of these tests is similar to that of culture, and they are cost effective in high-risk populations.

Updated recommendations from the U.S. Preventive Services Task Force (USPSTF) suggest that clinicians screen for gonorrhea in all sexually active men and women who are at increased risk for infection (i.e., younger than 25 years of age, new or multiple sexual partners, inconsistent condom use, sex work, men who have sex with men, or drug use). Testing for other STIs, particularly syphilis and chlamydial infection, is suggested at the time of examination. Pregnant women are routinely screened at the time of their first prenatal visit; high-risk populations should have repeat cultures during the third trimester. Neonates are routinely treated with various antibacterial agents applied to the conjunctiva within 1 hour of birth to protect against undiagnosed gonorrhea and other diseases.

Strains of *N. gonorrhoeae* that are resistant to penicillin, tetracycline, and quinolone are prevalent worldwide, and strains with other kinds of antibiotic resistance continue to evolve and spread. The current treatment recommendation to combat penicillin- and tetracycline-resistant strains is ceftriaxone or cefixime in a single injection. While a single injection of cefixime is still the standard treatment, some strains of *N. gonorrhoeae* have begun to show resistance to this dose. At this time the organism is responding to higher dosing (up to 1 gm) of cefixime. Because gonorrhea and chlamydia frequently occur together, treatment of cefixime should be followed with azithromycin or doxycycline for chlamydia. All sex partners within 60 days prior to discovery of the infection should be contacted, tested, and treated. Test of cure is not required with observed single-dose therapy. Patients are instructed to refrain from intercourse until therapy is completed and symptoms are no longer present.

**Syphilis**

After declining every year from 1990 to 2000, the rates of primary and secondary syphilis have been increasing. The CDC estimates that 55,400 people in the United States develop syphilis each year. Increased rates were primarily in men, with men who have sex with men being particularly affected. There has also been an increase in congenital syphilis.

**Etiology and Pathogenesis**

Syphilis is caused by a spirochete, *Treponema pallidum*. *T. pallidum* is spread by direct contact with an infectious moist lesion, usually through sexual intercourse. Bacterial-laden secretions may transfer the organism during kissing or intimate contact. Skin abrasions provide another possible portal of entry. There is rapid transplacental transmission of the organism from the mother to the fetus after 16 weeks’ gestation, so that active infection in the mother during pregnancy can produce congenital syphilis in the fetus. Untreated syphilis can cause prematurity, stillbirth, and congenital defects and active infection in the infant (Fig. 41-8). Because the manifestations of maternal syphilis may be subtle, testing for syphilis is mandatory in all pregnancies. Once treated for syphilis, a pregnant woman usually is followed throughout pregnancy by repeat testing of serum titers.

The clinical disease is divided into three stages: primary, secondary, and tertiary. Primary syphilis is characterized by the appearance of a chancre at the site of exposure. Chancre typically appear within 3 weeks of exposure but may incubate for 1 to 3 months. The primary chancre begins as a single, indurated, buttonlike papule up to several centimeters in diameter that erodes to create a round or oval clean-based ulcerated lesion on an elevated base. These lesions usually are painless and located at the site of sexual contact. Primary syphilis is readily apparent in the male, where the lesion is on the scrotum or penis (Fig. 41-9). Although chancres can develop on the external genitalia in females, they are more common on the vagina or cervix, and primary syphilis therefore may go untreated. There usually is an accompanying regional lymphadenopathy. The infection is highly
contagious at this stage, but because the symptoms are mild, it frequently goes unnoticed. The chancre usually heals within 3 to 12 weeks, with or without treatment.

The timing of the second stage of syphilis varies even more than that of the first, lasting from 1 week to 6 months. The symptoms of a rash (especially on the palms [Fig. 41-10] and soles), fever, sore throat, stomatitis, nausea, loss of appetite, and inflamed eyes may come and go for a year but usually last for 3 to 6 months. Secondary manifestations may include alopecia and genital lesions called condylomata lata. These elevated 2- to 3-cm red-brown lesions, which contain many spirocetes and are highly infectious, may ulcerate and produce a foul discharge.

After the second stage, syphilis frequently enters a latent phase that may last the lifetime of the person or progress to tertiary syphilis at some point. Persons can be infective during the first 1 to 2 years of latency.

Tertiary syphilis is a delayed response to the untreated disease. Approximately one third of people with untreated syphilis develop syphilis after a latent period of 5 years or more. When syphilis does progress to the symptomatic tertiary stage, it commonly develops into one of three forms: localized destructive lesions called gummas, central nervous system lesions, or cardiovascular manifestations. The syphilitic gumma is a peculiar, rubbery, necrotic lesion that is caused by noninflammatory tissue necrosis. Gummas can occur singly or multiply and vary in size from microscopic lesions to large, tumorous masses. They most commonly are found in the liver, testes, and bone. Central nervous system lesions can produce dementia, blindness, or injury to the spinal cord, with ataxia and sensory loss (i.e., tabes dorsalis). Cardiovascular manifestations usually result from scarring of the medial layer of the thoracic aorta with aneurysm formation. These aneurysms produce enlargement of the aortic valve ring with aortic valve insufficiency.

**Diagnosis and Treatment**

The diagnosis of syphilis can be made rapidly by dark-field microscopic examination of the exudate from skin lesions. However, the test is reliable only when a specimen with actively motile $T. pallidum$ is examined immediately by a trained microscopist. $Treponema pallidum$ does not survive transport to a laboratory and it cannot be cultured. It does, however, evoke a humoral immune response and production of antibodies that provide the basis for serologic tests.

Although PCR tests have been developed for syphilis, serology tests remain the mainstay for diagnosis. Two general types of serology tests are available: nonspecific (nontreponemal) tests and the specific treponemal tests. The *nontreponemal tests* measure immunoglobulin (Ig) G and IgM antibodies developed against molecules released from damaged cells during the early stages of the infection and present on the cell surface of treponemas. These antibodies are detected by tests such as the
Venereal Disease Research Laboratory (VDRL) or the rapid plasma reagin (RPR) tests. The tests, which are easy to perform, rapid, and inexpensive, are frequently used as screening tests for syphilis. Because these tests are nonspecific, positive results can occur for diseases other than syphilis. Results become positive 4 to 6 weeks after infection or 1 to 3 weeks after the appearance of the primary lesion. The disease’s incubation period may delay test sensitivity; therefore, serologic tests usually are repeated after 6 weeks if the initial test results were negative.

The specific treponemal tests measure antibodies capable of reacting with T. pallidum antigens. These tests are used to determine whether a positive result on a nonspecific test such as the VDRL is attributable to syphilis. Some clinical laboratories and blood banks have begun to screen samples using automated treponemal tests, the enzyme-linked immunosorbent (EIA) or chemiluminescence (CIA) assays, and then follow-up with a nontreponemal test (VDRL or RPR). The CDC recommends that persons with a positive screening test should have a standard nontreponemal titer performed by the laboratory. If the test is negative, it is recommended that the laboratory perform a different test using a different antigen.

The treatment of choice for syphilis is penicillin. Because of the spirochete’s long generation time, effective tissue levels of penicillin must be maintained for several weeks. Long-acting injectable forms of penicillin are used. Tetracycline or doxycycline is used for several weeks. Long-acting injectable forms of penicillin, antibiotics cannot be used in pregnancy.

**SUMMARY CONCEPTS**

- The vaginal-urogenital systemic STIs—chlamydial infections, gonorrhea, and syphilis—can severely affect the genital structures and manifest as systemic infections.
- Gonorrheal and chlamydial infections can cause a wide variety of genitourinary complications in men and women, and both can cause ocular disease and blindness in neonates born to infected mothers.
- Syphilis is caused by a spirochete, T. pallidum. It can produce widespread systemic effects and is transferred to the fetus of infected mothers through the placenta.

**REVIEW EXERCISES**

1. A 25-year-old woman has been told that her Pap test indicates infection with HPV type 16.
   - A. What are the possible implications of infection with HPV 16?
   - B. How might she have acquired this infection?
   - C. What treatments are currently available for treatment of this infection?

2. A 35-year-old woman presents with vulvar pruritus, dysuria, dyspareunia, and an odorless, thick, cheesy vaginal discharge. She has diabetes mellitus and has recently recovered from a respiratory tract infection, which required antibiotic treatment.
   - A. Given that these manifestations are consistent with a *Candida* infection, what tests might be used to confirm the diagnosis?
   - B. What risk factors does this woman have that predispose her to this type of vaginitis?
   - C. How might this infection be treated?

Without the skeletal system, movement in the external environment would not be possible. The bones of the skeletal system serve as a framework for skeletal muscle attachment and movement; protect and maintain vital structures in their proper position, provide stability for the body, and maintain the body's shape. The skeletal system also serves as a reservoir for ions such as calcium, phosphorous, and magnesium, and it houses the hematopoietic connective tissue in which blood cells are formed.

**Structures of the Skeletal System**

The skeletal system can be divided into two functional parts—the axial and appendicular skeletons (Fig. 42-1). The **axial skeleton**, which is composed of the bones of the skull, thorax, and vertebral column, forms the axis of the body. The **appendicular skeleton** consists of the bones of the upper and lower extremities, including those of the shoulder and hip girdles. In addition to bones, the skeletal system includes cartilage and ligaments that join bones together at joints, giving the body flexibility and allowing movement to occur.

Two types of connective tissue are found in the skeletal system: **cartilage** and **bone**. They both have living cells that secrete the extracellular matrix in which their cells are housed. The extracellular matrix in cartilage is firm but also somewhat pliable, providing the resilience needed for cushioning of bony structures. In contrast
to cartilage, the extracellular matrix of bone is mineralized, producing a hard tissue capable of providing support for the body and protection for its vital structures.

**Cartilage**

Cartilage is an avascular tissue that consists of cells, called chondrocytes, and an extensive extracellular matrix composed of fibers and ground substance. The chondrocytes are sparse, but are essential to the production and maintenance of the matrix. A connective tissue sheath, called the perichondrium, overlies the free surfaces of most cartilage. The perichondrium is vascular and its blood vessels supply nutrients to the chondrocytes. In areas where the cartilage has no perichondrium, such as the articular surfaces of moving joints, the chondrocytes receive their nourishment from the synovial fluid that bathes the joint surfaces.

**Types of Cartilage**

There are three types of cartilage, each exhibiting variations in matrix composition: elastic, fibrocartilage, and hyaline. Elastic cartilage has a dense network of elastic fibers scattered throughout its matrix. It is found in areas where flexibility is important, such as in the auricle of the ear, the auditory canal, the epiglottis, and the larynx. Fibrocartilage is characterized by a matrix containing a combination of chondrocytes and dense fibrous tissue. It is found in areas subjected to pulling forces such as attachments of ligaments to the cartilaginous surface of bones, the symphysis pubis, and intervertebral disks.

Hyaline cartilage is the most abundant and the best studied of the three types. It forms the articulating surfaces of the moveable joints in the body, costal cartilages that join the ribs to the sternum and vertebrae, and many of the cartilages of the respiratory tract. Hyaline cartilage is also essential for growth before and after birth. In the embryo, most of the axial and appendicular skeleton is formed first as a cartilage model and then is replaced by bone. In postnatal life, hyaline cartilage continues to play an essential role in the growth of long bones and persists as articular cartilage in the adult.

The matrix of hyaline cartilage is composed of collagen fibers embedded in a firm, hydrated gel of structural glycoproteins and proteoglycans, which have a high affinity for water. This high degree of hydration in the cartilage matrix contributes to the weight-bearing properties of cartilage and allows the cartilage matrix to respond to varying pressure loads. The multiadhesive glycoproteins influence interactions between the chondrocytes and matrix molecules and have clinical value as markers of cartilage turnover and degeneration.

**Repair of Hyaline Cartilage**

Hyaline cartilage can tolerate considerable amounts of intense and repetitive stress, but manifests a striking inability to heal from even the most minor injuries. This lack of response to injury is attributable to the avascular nature of cartilage, the immobility of chondrocytes, and the limited ability of chondrocytes to proliferate. Some repair can occur, but only if the defect involves the perichondrium, in which case chondrogenic cells from the perichondrium enter the defect and form new cartilage. If the defect is large, the cells form dense connective tissue to repair the injury. Hyaline cartilage is also subject to calcification, a process in which calcium phosphate crystals become embedded in the cartilage matrix. In most situations, given sufficient time, cartilage that calcifies will be replaced by bone. Chondrocytes normally derive all of their nutrients and dispose of waste materials through the extracellular matrix. When the matrix becomes heavily calcified, diffusion is impeded and the chondrocytes swell and die. The ultimate consequence of this event is removal of the calcified matrix and its replacement by bone.

**Bones and Bone Structure**

Bones are the major component of the skeletal system. Besides contributing to body shape and form, bones perform several other important functions. They provide the hard framework that supports the body and provides protection for its delicate soft tissues and organs. For example, the bones of lower limbs act as pillars to support the body trunk when we stand, and
the fused bones of the skull provide protection for the brain. Skeletal muscles, which are attached to bones by tendons, use bones as levers to move the body and its parts. Bones also serve as reservoirs for storage of minerals such as calcium and phosphate; and the bulk of blood cells are formed within the marrow cavities of certain bones.

**Classification of Bones**

Bones can be classified according to type: compact (dense) or spongy (cancellous). They can also be classified according to their shape, and the effect that bone shape has on the location of compact and spongy bone.

**Compact and Spongy Bone.** If a bone is cut, two distinct structural arrangements of bone tissue can be recognized—a dense layer of compact bone that forms the outside of the bone and a spongelike meshwork consisting of trabeculae (thin, anastomosing spicules of bone tissue) that forms the interior of bone (Fig. 42-2). Spongy bone is relatively light, but its structure is such that it has considerable tensile strength and weight-bearing properties. Although bones contain both compact and spongy elements, their proportions vary in different bones throughout the body and in different parts of the same bone, depending on the relative needs for strength and lightness.

**Classification of Bones by Shape.** Bones are classified by shape as long, short, flat, and irregular. Long bones are found in the upper and lower extremities. Short bones are irregularly shaped bones located in the ankle and the wrist. Except for their surface, which is compact bone, these bones are spongy throughout. Flat bones are composed of a layer of spongy bone between two layers of compact bone. They are found in areas where extensive protection of underlying structures is needed such as the skull and rib cage, or where a broad surface for muscle attachment is needed, as in the scapula. Irregular bones, because of their shapes, cannot be classified in any of the previous groups. This group includes bones such as the vertebrae and the bones of the jaw.

**Parts of a Long Bone**

A typical long bone has a shaft, or diaphysis, and two ends, called epiphyses (Fig. 42-3). Long bones usually are narrow in the midportion and broad at the ends so that the weight they bear can be distributed over a wider surface. The shaft of a long bone is formed mainly of compact bone roughly hollowed out to form a marrow-filled medullary canal. The ends of long bones are covered with articular cartilage.

In growing bones, the part of the bone shaft that funnels out as it approaches the epiphysis is called the metaphysis. It is composed of bony trabeculae that have cores of cartilage. In the child, the epiphysis is separated from the metaphysis by the cartilaginous growth plate. After puberty, the metaphysis and epiphysis merge, and the growth plate is obliterated.

Bones are covered, except at their articular ends, by a membrane called the periosteum (see Fig. 42-2A). The periosteum consists of an outer layer of connective tissue
and an inner, more cellular layer of osteoprogenitor cells which can differentiate into osteoblasts (bone-forming cells, to be discussed). The periosteum contains blood vessels and acts as an anchorage point for blood vessels as they enter and leave the bone. The endosteum is the membrane that lines the spaces of spongy bone, the marrow cavities, and the haversian canals of compact bone. It is considerably thinner than the periosteum and is composed of a single layer of flattened osteoprogenitor cells and small amounts of connective tissue. The principal functions of the periosteum and endosteum are the nutrition of bone tissue and continuous supply of new osteoblasts for repair and growth of bone.

**Bone marrow** occupies the medullary cavities of the long bones (see Fig. 42-2C) throughout the skeleton and the cavities of spongy bone in the vertebrae, ribs, sternum, and flat bones of the pelvis. The cellular composition of the bone marrow varies with age and skeletal location. Red bone marrow contains developing red blood cells and is the site of blood cell formation. Yellow bone marrow is composed largely of adipose cells. At birth, nearly all of the marrow is red and hematopoietically active. As the need for red blood cell production decreases during postnatal life, red marrow is gradually replaced with yellow bone marrow in most of the bones. In the adult, red marrow persists in the vertebrae, ribs, sternum, and ilia.

**Bone Tissue**

Bone, or osseous, tissue is perhaps one of the most distinctive tissues in the body. It is typical of other connective tissue in that it consists of cells, fibers, and an extracellular matrix. However, its extracellular components are hard and calcified, a feature that enables it to serve both supportive and protective functions. The extracellular bone matrix can be divided into two parts: the organic matrix and inorganic mineral matrix.

The organic matrix of bone and other connective tissues is a composite of collagenous fibers and an amorphous mixture of protein and polysaccharides called *ground substance*. The ground substance provides support and adhesion between cellular and fibrous elements and serves an active role in many metabolic functions necessary for bone growth, repair, and remodeling.

The inorganic mineral matrix of bone is composed largely of calcium phosphate in the form of hydroxyapatite crystals. It comprises about 25% of the bones’ volume, but because of its high density, it is responsible for about half its weight. In addition to calcium and phosphate, bone contains considerable amounts of the body’s content of carbonate, magnesium, and sodium. Bone may also take up lead and other heavy metals, thereby removing these toxic substances from the circulation.

**Laminar and Woven Bone.** There are two distinct types of bone tissue based on their stage of development: laminar (mature) and woven (immature).

**Laminar** or mature bone is composed largely of cylinder-shaped units of calcified matrix, called *osteons*, that are oriented parallel to the long axis of the bone. Functionally, osteons can be thought of as tiny weight-bearing pillars.

Running through the core of each osteon is a central canal, called a *haversian canal*, which contains the blood vessels and nerves that supply the osteon (Fig. 42-4A). Canals of a second type called *perforating*, or *Volkmann canals*, lie at right angles to the long axis of the bone, connecting the vascular and nerve supplies of the periosteum and medullary cavity. Spider-shaped osteocytes (mature bone cells) occupy small cavities, or lacunae, at the junctions of the lamellae (Fig. 42-4B). In compact bone (e.g., diaphysis of long bones), the lamellae exhibit a characteristic organization of outer circumferential lamellae, inner circumferential lamellae, and interstitial lamellae. The *outer circumferential lamellae* are located just beneath the periosteum and the *inner circumferential lamellae* are arranged concentrically around a central haversian canal. Between the two circumferential lamellae are the irregularly shaped *interstitial lamellae*. These are the remnants of haversian systems that have been destroyed during bone growth or remodeling. *Trabecular lamellar bone* forms the coarse spongy bone of the medullary cavity. It exhibits plates of lamellar bone perforated by marrow spaces.

In contrast to compact bone, *immature or woven bone*, consisting of trabeculae, looks like poorly organized bone. It is deposited more rapidly than lamellar bone, has low tensile strength, and serves as temporary scaffolding for support. It is found in the developing fetus, in areas surrounding tumors and infections, and as part of a healing fracture.

**Blood Supply**

Bones are richly supplied with blood from nutrient and perforating arteries (see Fig. 42-2C). The nutrient arteries enter the bone through a nutrient foramen and supply the marrow space and the internal half of the cortex. The perforating arteries are small arteries that extend inward from the periosteal arteries on the external surface of the periosteum and anastomose in the cortex with branches of the nutrient arteries coming from the bone marrow. The distribution of blood in the cortex occurs through the haversian and Volkmann canals (see Fig. 42-4A). Veins accompany arteries through the nutrient foramina. Many large veins also leave through openings near the articulating ends of bones. Bones containing red bone marrow have numerous large veins.

**Bone Cells**

Five types of cells participate in the formation and maintenance of bone tissue: osteoprogenitor cells, osteoblasts, osteocytes, osteoclasts, and bone-lining cells (Table 42-1). With the exception of the osteoclast, each type of bone cell originates from the same basic cell type, undergoing transformation as it matures.

**Osteoprogenitor Cells.** Osteoprogenitor cells are undifferentiated or resting cells that are found in the periosteum, endosteum, and epiphyseal plate of growing bone. Derived from stem cells in the bone marrow, they have the potential to differentiate into many different cell types, including adipocytes, fibroblasts, and osteoblasts.
When appropriately stimulated by bone morphogenic proteins (BMPs) and transforming growth factors, they undergo cell division and differentiate into osteoblasts.

**Osteoblasts.** Osteoblasts are cells that secrete bone matrix. Bone formation occurs in two stages: ossification and calcification. Ossification involves the formation of the initial unmineralized bone, or osteoid (also called prebone). Osteoblasts secrete both type I collagen (which constitutes 90% of the protein of bone) and bone matrix proteins, forming the osteoid. They also are responsible for calcification of the bone matrix. The calcification process appears to be initiated by the osteoblast through the secretion of the enzyme *alkaline phosphatase*, which is thought to act locally in bone tissue to raise calcium and phosphate levels to the point at which precipitation occurs. The activity of the osteoblasts undoubtedly contributes to the increase in serum levels of alkaline phosphatase that follows bone injury and fractures.

**Osteocytes.** Osteocytes are mature bone cells, derived from osteoblasts, which are housed in *lacunae* within the calcified bony matrix (see Fig. 42-4B). Extracellular fluid-filled passageways permeate the calcified matrix and connect with the lacunae of adjacent osteocytes. These passageways are called *canaliculi*. Because diffusion does not occur through the calcified matrix of bone, the canaliculi serve as communicating channels for the exchange of nutrients and metabolites between the osteocytes and the blood vessels on the surface of the bone layer.

Osteocytes are the cells responsible for maintaining the bone matrix. They can synthesize new matrix, as well as participate in matrix degradation. Death of osteocytes through trauma, cell senescence, or apoptosis, results in resorption of the bone matrix by osteoclasts, followed by repair or remodeling of the bone tissue by osteoblasts.

**Osteoclasts.** Osteoclasts are large multinucleated “bone-chewing” cells that function in the resorption of bone, removing its mineral content and organic matrix. They are derived from the same mononuclear hematopoietic progenitor cells that give rise to blood monocytes and tissue macrophages. Osteoclast formation occurs in close association with the stromal cells of the bone marrow. These cells secrete essential cytokines that promote

---

**FIGURE 42-4.** (A) Haversian systems as seen in a wedge of compact bone tissue. The periosteum has been peeled back to show a blood vessel entering a Volkmann canal. (B) Osteocytes lying within lacunae; canaliculi permit interstitial fluid to reach each lacuna.
the differentiation of both osteoclasts and macrophages. These cytokines function either by stimulating osteoclast progenitor cells or by participating in a paracrine system in which osteoblasts and marrow cells play a central role. Recent studies indicate that substances promoting osteoclast differentiation act through the RANK–RANKL signaling pathway (to be discussed).

Newly formed osteoclasts undergo activation to become bone-resorbing cells. Once activated, they bind to the bone surface, where they form an underlying resorption pit. They then remove the bone mineral by generating an acidic environment and digest the organic bone matrix by releasing proteolytic enzymes.

**Bone-Lining Cells.** Bone-lining cells cover bone at sites where remodeling is not occurring. They are flat cells with an enlarged cytoplasm and a limited number of organelles. Bone-lining cells on external bone surfaces are called periosteal cells, and those lining the internal bone surfaces, endosteal cells. They represent a population of cells that are derived from osteoblasts and are thought to function in the maintenance and nutritional support of the osteocytes embedded in the underlying bone matrix and in the regulation of calcium and phosphate movement into and out of bone.

**Bone Formation, Growth, and Remodeling**

The development of skeletal structures begins in utero and continues to change throughout life. During childhood, skeletal structures grow in length and diameter, resulting in a bone having adult form and shape. Once skeletal growth has ceased, the process of bone remodeling is responsible for skeletal maintenance.

---

**BONE GROWTH IN CHILDHOOD**

During the first two decades of life, the skeleton undergoes general overall growth. The long bones of the skeleton, which grow at a relatively rapid rate, are provided with a specialized structure called the epiphyseal growth plate. As long bones grow in length, the deeper layers of cartilage cells in the growth plate multiply and enlarge, pushing the articular cartilage farther away from the metaphysis and diaphysis of the bone. As this occurs, the mature and enlarged cartilage cells at the metaphyseal end of the plate become metabolically inactive and are replaced by bone cells. This process allows bone growth to proceed without changing the shape of the bone or causing disruption of the articular cartilage. The cells in the growth plate stop dividing at puberty, at which time the epiphysis and metaphysis fuse.

Several factors can influence the growth of cells in the epiphyseal growth plate. Epiphyseal separation can occur in children as the result of trauma. The separation usually occurs in the zone of the mature enlarged cartilage cells, which is the weakest part of the growth plate. The blood vessels that nourish the epiphysis pass through the growth plate. These vessels are ruptured when the growth plate separates. This can cause cessation of growth and a shortened extremity. The growth plate also is sensitive to nutritional and metabolic changes. Scurvy (i.e., vitamin C deficiency) impairs the formation of the organic matrix of bone, causing slowing of growth at the epiphyseal plate and cessation of diaphyseal growth. In rickets (i.e., vitamin D deficiency), calcification of the newly developed bone on the metaphyseal side of the growth plate is impaired. Thyroid and growth hormones are required for normal growth. Alterations in these and other hormones can also affect bone growth (see Chapter 31).

Growth in the diameter of bones occurs as new bone is added to the outer surface of existing bone along with an accompanying resorption of bone on the endosteal or inner surface. Such oppositional growth allows for widening of the marrow cavity while preventing the cortex from becoming too thick and heavy. In this way, the shape of the bone is maintained. As a bone grows in diameter, concentric rings are added to the bone surface, much as rings are added to a tree trunk. These rings form the lamellar structure of mature bone. Osteocytes, which develop from osteoblasts, become buried in the rings.

**Bone Remodeling**

Peak bone mass is achieved during early adulthood. It is determined by a number of factors, including the type of vitamin D receptor inherited, nutrition, level of physical activity, age, and hormonal status. Once skeletal growth has attained its adult size, the breakdown and renewal of bone that is responsible for skeletal maintenance is initiated at sites that require replacement or repair. This process is called bone remodeling.

In bone remodeling, the processes of bone formation and resorption are tightly coupled, and their balance
determines skeletal mass at any given time. The sequence of bone resorption and bone formation begins with osteoclastic resorption of existing bone, during which the organic (protein matrix) and the inorganic (mineral) components are removed. The sequence proceeds to the formation of new bone by osteoblasts. In the adult, the length of one sequence (i.e., bone resorption and formation) is approximately 4 months. Ideally, the replaced bone should equal the absorbed bone. If it does not, there is a net loss of bone. In the elderly, for example, bone resorption and formation no longer are perfectly coupled, and bone mass is lost.

Recently, significant progress has been made in understanding the phenomenon of bone remodeling as it relates to the coupling of bone resorption with bone formation. The pivotal paracrine pathway linking these two processes consists of three factors: RANKL (for receptor activator of nuclear factor-κB ligand); its receptor, RANK; and a soluble inhibitor receptor for RANK called osteoprotegerin (OPG). RANKL is expressed by osteoblasts and their immature precursors and is necessary for osteoclast differentiation and function. RANKL activates its receptor, RANK, which is expressed on osteoclasts and their precursors, thus promoting osteoclast differentiation and activation and prolonging osteoclast survival by suppressing apoptosis. The fact that RANKL is expressed on osteoblasts indicates that bone resorption and bone formation are linked through RANKL. The effects of RANKL are blocked by OPG, a soluble receptor protein, which acts as a decoy receptor that binds RANKL and prevents it from binding with RANK on osteoclasts.

It is now believed that dysregulation of the RANKL/RANK/OPG pathway plays a prominent role in the pathogenesis of bone diseases such as osteoporosis (low bone density). For example, it has been shown that postmenopausal women express higher levels of RANKL on their marrow stromal cells and lymphocytes than premenopausal women or postmenopausal women taking estrogen. It has also been shown that estrogen and the selective estrogen receptor modulator, raloxifene, stimulate OPG production in osteoblasts. Glucocorticoid exposure, which can contribute to steroid osteoporosis, enhances RANKL expression and suppresses OPG levels, thus elevating the RANKL-to-OPG ratio. There is also evidence linking the pathogenesis of inflammatory conditions such as rheumatoid arthritis to dysregulation of the RANKL/OPG system.

### Hormonal Control of Bone Formation and Metabolism

The process of bone formation and mineral metabolism is complex. It involves the interplay among the actions of parathyroid hormone (PTH), calcitonin, and vitamin D (Table 42-2). Other hormones, such as corticosteroid hormone, growth hormone, thyroid hormone, and the sex hormones, also influence bone formation directly or indirectly.

**Parathyroid Hormone.** Parathyroid hormone, which is produced by the parathyroid glands embedded in the thyroid gland, is one of the important regulators of calcium and phosphate levels in the blood. Parathyroid hormone prevents serum calcium levels from falling below and serum phosphate levels from rising above normal physiologic concentrations (see Chapter 8). The secretion of PTH is regulated through negative feedback related to serum levels of ionized calcium, with decreased levels stimulating PTH release and increased levels inhibiting its release. Parathyroid hormone maintains serum calcium levels by promoting bone resorption, conserving calcium by the kidney, enhancing intestinal absorption of calcium through activation of vitamin D, and reducing serum phosphate levels (Fig. 42-5). Parathyroid hormone also increases the movement of calcium and phosphate from bone into the extracellular fluid. In the kidney, PTH stimulates tubular reabsorption of calcium while reducing the reabsorption of phosphate. The latter effect ensures that the increased release of phosphate from bone during mobilization of calcium does not produce an elevation in serum phosphate levels. This is important because an increase in calcium and phosphate levels could lead to crystallization in soft tissues. Parathyroid hormone also stimulates the activation of vitamin D by the kidney, thereby increasing the absorption of calcium from the intestine.

Bone remodeling constitutes a process of skeletal maintenance once skeletal growth is complete. It takes place in the (1) osteons of mature bone and consists of a cycle of (2) bone resorption by osteoclasts, (3) followed by bone formation by osteoblasts. Bone remodeling is (4) controlled by cytokines and growth factors that interact with a paracrine system consisting of the RANK ligand (RANKL), the RANK receptor, and osteoprotegerin.

**Bone Remodeling Cycle.** Mature bone is made up of osteons or units of concentric lamellae (bone layers) and the haversian canal they surround. Bone remodeling consists of a sequence of bone resorption within an osteon by osteoclasts, followed by new bone formation by osteoblasts. In the adult, the length of one sequence (i.e., bone resorption and formation) is approximately 4 months. Ideally, the replaced bone should equal the resorbed bone. If it does not, there is net loss of bone. In the elderly, for example, bone resorption and formation no longer are perfectly coupled, and bone mass is lost.

**Bone Resorption.** The osteoclasts, which are bone-resorbing cells derived from monocyte/macrophage precursors, are the cells involved in the initiation of bone remodeling. The sequence of bone resorption and bone formation is activated by many stimuli, including the action of parathyroid hormone and calcitonin. It begins with osteoclastic resorption of existing bone, during which the organic (protein matrix) and inorganic (mineral) components are removed, creating a tunnel-like space in the osteon. Soluble factors released during resorption aid in the recruitment of osteoblasts to the site, thereby linking bone resorption to bone formation.
Bone Formation. After osteoclastic activity has ceased, osteoblasts begin to deposit the organic matrix (osteoid) on the wall of the osteon canal. As successive lamellae of bone are deposited, the canal ultimately attains the relative proportions of the original osteon. In the formation and maintenance of bone, osteoblasts provide much of the local control because not only do they produce new bone matrix, they play an essential role in mediating osteoclast activity. Many of the primary stimulators of bone resorption, such as parathyroid hormone, have minimal or no direct effects on osteoclasts. Once the osteoblast, which has receptors for these substances, receives the appropriate signal, it releases a soluble mediator called RANKL that induces osteoclast activity.

Control of Bone Metabolism and Remodeling. The pivotal pathway linking osteoclast-mediated bone resorption with osteoblast-mediated bone formation consists of a paracrine system that includes RANKL, its receptor RANK, and a soluble protein called osteoprotegerin (OPG). RANKL, which is produced by osteoblasts and their precursors, binds to RANK, promoting osteoclast differentiation and proliferation. The soluble OPG molecule, which is produced by a number of tissues, acts as a decoy receptor to block the action of RANKL. This system ensures the tight coupling of bone formation and resorption, and provides a means whereby a wide variety of biologic mediators (e.g., hormones, cytokines, growth factors) influence the homeostasis of bone.
Calcitonin. Whereas PTH increases blood calcium levels, the hormone calcitonin lowers blood calcium levels. Calcitonin, sometimes called thyrocalcitonin, is secreted by the parafollicular, or C, cells of the thyroid gland. Calcitonin inhibits the release of calcium from bone into the extracellular fluid. It is thought to act by causing calcium to become sequestered in bone cells and by inhibiting osteoclast activity. Calcitonin also reduces the renal tubular reabsorption of calcium and phosphate; the decrease in serum calcium level that follows administration of pharmacologic doses of calcitonin may be related to this action.

The major stimulus for calcitonin synthesis and release is an increase in serum calcium. The role of calcitonin in overall mineral homeostasis is uncertain. There are no clearly definable syndromes of calcitonin deficiency or excess, which suggests that calcitonin does not directly alter calcium metabolism. It has been suggested that the physiologic actions of calcitonin are related to the postprandial handling and processing of dietary calcium. This theory proposes that after meals, calcitonin maintains PTH secretion at a time when it normally would be reduced by calcium entering the blood from the digestive tract. Although excess or deficiency states associated with alterations in physiologic levels of calcitonin have not been observed, it has been shown that pharmacologic doses of the hormone reduce osteoclast activity. Because of this action, calcitonin has proved effective in the treatment of Paget disease (see Chapter 45). The hormone is also used to reduce serum calcium levels during hypercalcemic crises.

Vitamin D. Vitamin D and its metabolites are not true vitamins but steroid hormones. There are two forms of vitamin D: vitamin D\(_2\) (ergocalciferol) and vitamin D\(_3\) (cholecalciferol). The two forms differ by the presence of a double bond, but they have identical biologic activity. Therefore, the term vitamin D is often used to indicate both forms.

Vitamin D has little or no activity until it has been converted to its physiologically active form by the kidney. Figure 42-6 depicts sources of vitamin D and pathways for activation. The first step of the activation process occurs in the liver, where vitamin D is hydroxylated to form the metabolite 25-hydroxyvitamin D\(_3\) [25-(OH)D\(_3\)]. From the liver, 25-(OH)D\(_3\) is transported to the kidneys, where it undergoes conversion to 1,25-dihydroxyvitamin D\(_3\) [1,25-(OH)\(_2\)D\(_3\)] or 24,25 hydroxyvitamin D\(_3\) [24,25-(OH)\(_2\)D\(_3\)].

There are two sources of vitamin D: intestinal absorption and skin production. Intestinal absorption occurs mainly in the jejunum and includes vitamin D\(_2\) and vitamin D\(_3\). The most important dietary sources of vitamin D are fish, liver, and irradiated milk. Because vitamin D is fat soluble, its absorption is mediated by bile salts and occurs by means of the lymphatic vessels. In the skin, ultraviolet radiation from sunlight spontaneously converts 7-dehydrocholesterol D\(_3\) to vitamin D\(_3\). A circulating vitamin D-binding protein provides a mechanism to remove vitamin D from the skin and make it available to the rest of the body.

![FIGURE 42-5. Regulation and actions of parathyroid hormone.](image1)

![FIGURE 42-6. Sources and pathways for activation of vitamin D.](image2)
With adequate exposure to sunlight, the amount of vitamin D that can be produced by the skin is usually sufficient to meet physiologic requirements. Modern conditions of dress, lifestyle, and recommendations regarding sun screens and avoidance of sun exposure to reduce skin cancer risk may prevent a large proportion of the population from producing adequate amounts of vitamin D. Elderly persons who are housebound or institutionalized frequently have low vitamin D levels. The deficiency often goes undetected until there are problems such as pseudo fractures or electrolyte imbalances. Seasonal variations in vitamin D levels probably reflect changes in sunlight exposure.

The most potent of the vitamin D metabolites is 1,25-(OH)$_2$D$_3$. This metabolite increases intestinal absorption of calcium and promotes the actions of PTH on resorption of calcium and phosphate from bone. Bone resorption by the osteoclasts is increased and bone formation by the osteoblasts is decreased; there is also an increase in acid phosphatase and a decrease in alkaline phosphatase. Intestinal absorption and bone resorption increase the amount of calcium and phosphorus available to the mineralizing surface of the bone. The role of 24,25-(OH)$_3$D$_3$ is less clear. There is evidence that 24,25-(OH)$_3$D$_3$ in conjunction with 1,25-(OH)$_2$D$_3$ may be involved in normal bone mineralization.

The regulation of vitamin D activity is influenced by several hormones. PTH and prolactin stimulate 1,25-(OH)$_2$D$_3$ production by the kidney. States of hyperparathyroidism are associated with increased levels of 1,25-(OH)$_2$D$_3$, and hypoparathyroidism leads to lowered levels of this metabolite. Prolactin may have an ancillary role in regulating vitamin D metabolism during pregnancy and lactation. Calcitonin inhibits 1,25-(OH)$_2$D$_3$ production by the kidney. In addition to hormonal influences, changes in the concentration of ions such as calcium, phosphate, hydrogen, and potassium exert an effect on 1,25-(OH)$_2$D$_3$ and 24,25-(OH)$_3$D$_3$ production. Under conditions of phosphate and calcium deprivation, 1,25-(OH)$_2$D$_3$ levels are increased, whereas hyperphosphatemia and hypercalcemia decrease the levels of metabolite.

**SUMMARY CONCEPTS**

- The skeletal system consists of the bones of the skull, thorax, and vertebral column, which form the axial skeleton, and the bones of the upper and lower extremities, which form the appendicular skeleton.

- Two types of connective tissue are found in the skeletal system: (1) cartilage, a semirigid and slightly flexible tissue that plays an essential role in prenatal and childhood development of the skeleton and serves as a surface for the articulating ends of skeletal joints; and (2) bone, which provides the firm structure of the skeleton and serves as a reservoir for calcium and phosphate storage.

- Bone tissue is classified as either spongy or compact according to the relative amount of solid matter and number and size of the spaces they contain. Spongy bone, which forms the interior of bones, is composed of spicules or trabeculae that form a latticelike pattern. Compact bone, which forms the outer shell of a bone, has a densely calcified intercellular matrix that makes it more rigid than spongy bone.

- Bone matrix is maintained by five types of cells: osteoprogenitor cells, which are resting cells that differentiate into osteoblasts; osteoblasts, which function as bone-building cells during bone remodeling; osteocytes, or mature bone cells; osteoclasts, which function as bone resorption cells during bone remodeling; and bone-lining cells, which cover the outer and inner surfaces of bone where remodeling is not occurring.

- The process of bone formation and mineral metabolism involves the interplay among the actions of parathyroid hormone (PTH), calcitonin, and vitamin D. PTH acts to maintain serum levels of ionized calcium by increasing the release of calcium and phosphate from bone, conserving calcium and increasing phosphate elimination by the kidney, and enhancing intestinal reabsorption of calcium through vitamin D. Calcitonin inhibits the release of calcium from bone and increases renal elimination of calcium and phosphate, thereby serving to lower serum calcium levels. Vitamin D, which functions as a hormone in regulating body calcium, increases absorption of calcium from the intestine and promotes the actions of PTH on bone.

**Joints**

Joints, or articulations, are places where adjacent bones or cartilages meet. Joints vary in the type and extent of movements they allow. Some joints have no movement; others allow only slight movement; and some such as the shoulder joint are freely moveable. There are three classes of joints based on their structure and function: fibrous (synarthroses), cartilaginous (amphiarthroses), and synovial (diarthroses).
Fibrous Joints (Synarthroses)

Fibrous joints, or synarthroses, are joints in which the bones are joined by dense fibrous tissue. They have little or no movement, depending on the length of the fibers connecting the articulating bone. The sutures of the skull are examples of fibrous joints. In children and young adults the bones of the skull are joined by dense connective tissue; and in older persons, by bone. Another type of fibrous joint that is partially moveable unites bones with a sheet of fibrous tissue, either a ligament or fibrous membrane. The interosseous membrane that joins the radius and the ulna of the forearm is an example of this type of joint. A unique type of fibrous joint is the one between the root of a tooth and the alveolar processes of the jaw. The fibrous tissue between the tooth and alveolar bone of the tooth socket is called the periodental ligament.

Cartilaginous Joints (Amphiarthroses)

Cartilaginous joints, or amphiarthroses, are connected by hyaline cartilage or fibrocartilage and have limited motion. In primary cartilaginous joints, the bones are joined by hyaline cartilage, which permits slight bending during early childhood. Primary cartilaginous joints are usually temporary articulations, such as those present during early development, where the epiphysis and the shaft are joined by cartilage or growth plate. Secondary cartilaginous joints are strong, slightly moveable joints united by fibrocartilage. The fibrocartilaginous intervertebral disks between the vertebrae consist of connective tissue that holds the vertebrae together. These joints provide strength and shock absorption as well as considerable flexibility.

Synovial Joints (Diarthroses)

Synovial joints, or diarthroses, are freely moveable joints in which the articulating bone ends are separated by a joint cavity containing synovial fluid. Most joints in the body are of this type. Although as a group they are classified as freely moveable, synovial joints include planar joints, which allow almost no movement (e.g., vertebrocostal joint), and hinge joints, which allow angular movement in one plane (e.g., interphalangeal, knee, and ankle joints). Only the ball-and-socket joints permit movement in all directions (e.g., shoulder and hip joint).

All synovial joints are covered with articular cartilage, a feature that allows the surfaces of these joints to slide freely past each other during movement. The articular cartilage, which is typically hyaline cartilage, is unique in that its free surface is not covered with perichondrium. It has only a peripheral rim of perichondrium, and calcification of the portion of cartilage abutting the bone may limit or preclude diffusion from blood vessels supplying the subchondral bone. Regeneration of most cartilage is slow; it is accomplished primarily by growth that requires the activity of perichondrial cells.

In synovial joints, the articulating ends of the bones are not connected directly but are indirectly linked by a strong fibrous capsule (i.e., joint capsule) that surrounds the joint and is continuous with the periosteum (Fig. 42-7). The joint capsule consists of two layers: an outer fibrous layer and an inner synovial membrane. The outer fibrous layer of the capsule supports the joint and helps to hold the bones in place. Additional support is provided by ligaments that extend between the bones and by tendons that attach to muscles supplying the joint. The synovium secretes a slippery fluid with the consistency of egg white called synovial fluid. In addition to supplying nutrients and oxygen to the chondrocytes in the articular cartilage, this fluid serves as a lubricant for the joint. Moreover, macrophages in the synovial fluid act to phagocytize debris in the joint space.

The collagen fibers in the articular surface cartilage are arranged to evenly distribute the forces generated by pressure to this tissue. The proteoglycan molecules of the cartilage, found isolated or aggregated in a network, contain large amounts of water. These matrix components, rich in hydrophylic glycosaminoglycans, function as a mechanical spring. When pressure is applied, water is forced out of the cartilage matrix into the synovial fluid. When the pressure is released, water is attracted back into the collagen matrix. These water movements, which are brought about by the use of a joint, are essential for the delivery of nutrients and the exchange of carbon dioxide, oxygen, and other molecules between the synovial fluid and articular cartilage.

Ligaments and Tendons

Ligaments and tendons are dense connective tissue structures that connect muscles and bone and support synovial joint structures. The dense connective tissue found in tendons and ligaments has a limited blood supply and is composed largely of intercellular bundles of collagen fibers arranged in the same direction and plane. Collagen is an inelastic and insoluble fibrous protein. Because of its molecular configuration, collagen has great tensile strength; the breaking point of collagenous fibers found in human tendons is reached with a force of several hundred kilograms per square centimeter.
Ligaments are fibrous thickenings of the articular capsule that join one bone to its articulating mate. They vary in size and shape depending on their specific role. Although most ligaments are considered inelastic, they are pliable enough to permit movement at the joints. However, ligaments tear rather than stretch when exposed to excess stress. Torn ligaments are extremely painful and accompanied by local swelling.

Tendons, which attach skeletal muscles to bone, are relatively inextensible because of their richness in collagen fibers. The intercellular bands of collagen fibers aggregate into bundles that are enveloped by loose connective tissue, blood vessels, and nerves. Tendons that may rub against bone or other friction-generating surfaces are enclosed in double-layered sheaths. An outer connective tissue tube is attached to the structures surrounding the tendon, and an inner sheath encloses the tendon and is attached to it. The space between the inner and outer sheath is filled with a fluid similar to synovial fluid. Overuse can result in tendonitis or inflammation of the tendon.

Joint Vasculature and Innervation

All the tissues of synovial joints, except the surfaces of the articulating cartilage, receive nourishment either directly or indirectly from blood vessels. The articulating areas are nourished indirectly by the synovial fluid that is distributed over the surface of the articular cartilage.

The blood supply to a joint arises from blood vessels that enter the subchondral bone at or near the attachment of the joint capsule and form an arterial circle around the joint. The synovial membrane has a rich blood supply, and constituents of plasma diffuse rapidly between these vessels and the joint cavity. Because many of the capillaries are near the surface of the synovium, blood may escape into the synovial fluid after relatively minor injuries. Healing and repair of the synovial membrane usually are rapid and complete. This is important because synovial tissue is injured in many surgical procedures that involve the joint.

The nerve supply to joints is provided by the same nerve trunks that supply the muscles that move the joints. These nerve trunks also supply the skin over the joints. As a rule, all the joints of an extremity are innervated by the same peripheral nerves as they travel down an extremity. This helps to explain the referral of pain from one joint to another. For example, hip pain may be perceived as pain in the knee.

The synovial membrane is innervated only by autonomic nerve fibers that control blood flow. It is relatively free of pain fibers, as evidenced by the fact that surgical procedures on the joint are often done under local anesthesia. The joint capsule and the ligaments have pain receptors; these receptors are more easily stimulated by stretching and twisting than are other joint structures. Pain arising from the capsule tends to be diffuse and poorly localized.

The tendons and ligaments of the joint capsule are sensitive to position and movement, particularly stretching and twisting. These structures are supplied by the large sensory nerve fibers that form proprioceptor endings for the deep tendon reflex (see Chapter 36). The proprioceptors function reflexively to adjust the tension of the muscles that support the joint and are particularly important in maintaining muscular support for the joint. For example, when a weight is lifted, there is a proprioceptor-mediated reflex contraction and relaxation of appropriate muscle groups to support the joint and protect the joint capsule and other joint structures. Loss of proprioception and reflex control of muscular support leads to destructive changes in the joint.

Bursae and Tendon Sheaths

In some synovial joints, the synovial membrane forms a closed sac that is not part of the joint. These sacs, called bursae, contain synovial fluid. Their purpose is to prevent friction on a tendon. Bursae occur in areas such as the knee where pressure is exerted because of close approximation of joint structures (Fig. 42-8).

**FIGURE 42-8.** Sagittal section of knee joint, showing prepatellar and suprapatellar bursa.
Such conditions occur when tendons are deflected over bone or where skin must move freely over bony tissue. Bursae may become injured or inflamed, causing discomfort, swelling, and limitation in movement of the involved area.

In addition to bursae, structures called tendon sheaths also reduce friction at joints. Tendon sheaths are tubelike bursae that wrap around tendons where there is considerable friction. This occurs where tendons pass through synovial cavities, such as the tendon of the biceps brachi muscle at the shoulder joint. Similar areas of friction are found at the wrist and ankle, where many tendons come together in a confined space and may be torn as the result of an injury (see Chapter 44).

**SUMMARY CONCEPTS**

- Joints (or articulations) are areas where two or more bones are joined together by fibrous tissue, cartilage, or bone. In fibrous joints, or synarthroses, such as those of the skull, the bones are joined by fibrous tissue. In cartilaginous joints, or amphiarthroses, bones are joined by hyaline cartilage (as in the epiphyseal plate during childhood and early adolescence). In fibrocartilaginous joints (as in those that join the vertebrae and intervertebral disks) the articular surface is covered with hyaline cartilage, which in turn is fused to an intervening pad of fibrocartilage.

- Synovial joints or diarthroses are freely moveable joints in which the surfaces of the articulating ends of bones are enclosed in a fibrous joint capsule. The joint capsule consists of two layers: an outer fibrous layer and an inner synovial membrane (or synovium). The synovial fluid, which is secreted by the synovium into the joint capsule, acts as a lubricant and facilitates movement of the joint’s articulating surfaces. The articulating surfaces of synovial joints are covered with a layer of avascular cartilage that relies on oxygen and nutrients contained in the synovial fluid.

- Tendons and ligaments are dense connective tissue structures that connect the muscles and bones of diarthroidal joints. Bursae, which are closed sacs containing synovial fluid, prevent friction in areas where tendons are deflected over bone or where skin must move freely over bony tissue.

**REVIEW EXERCISES**

1. Hyaline cartilage degenerates when the chondrocytes become metabolically inactive and die, causing the matrix to calcify and be replaced by bone.
   
   A. Explain how this process can contribute to normal skeletal growth during childhood and adolescence, but cause joint pain and immobility when it occurs during adulthood.

2. Persons with end-stage kidney disease have a deficiency of activated vitamin D.
   
   A. Explain why this occurs, and what effect it would have on the persons’ bones.
   
   B. How might this deficiency be treated?

3. Recent studies have revealed that estrogen deficiency as well as normal aging may produce a decrease in osteoblast activity.
   
   A. Explain how this would contribute to a disruption in bone remodeling and the development of osteoporosis.

4. Often pain from injury to the knee is experienced as pain in the hip.
   
   A. Explain why this might occur.

The musculoskeletal system includes the bones, joints, and muscles of the body together with associated structures such as ligaments and tendons. This system, which constitutes more than 70% of the body, is subject to a large number of disorders causing pain and disability in people of all ages. The main discussion in this chapter focuses on injuries, infections, necrosis, and neoplasms of the musculoskeletal system. At the end of the chapter, disorders of skeletal growth and development in children are discussed.

Injury and Trauma of Musculoskeletal Structures

A broad spectrum of musculoskeletal injuries results from numerous physical forces, including blunt tissue trauma, disruption of tendons and ligaments, and fractures of bony structures. Many of the forces that cause these injuries are typical for a particular age group, activity, or environmental setting. The most common causes of childhood injuries are falls, bicycle-related injuries, and sports injuries. Trauma resulting from motor vehicle accidents is ranked as the number one killer of adults younger than 45 years of age. Falls are the most common cause of injury in people 65 years of age and older, with fractures of the hip and proximal humerus particularly common in this age group.
Sports-Related Injuries

Sports and athletic activities are particularly common causes of acute and overuse injuries of the musculoskeletal system. Acute injuries are caused by sudden trauma and include injuries to soft tissues (contusion, strains, and sprains) and to bone (fractures).

Overuse injuries have been described as chronic injuries, including tendinopathies, stress fractures, compartment syndrome, and shin splints, that result from constant high levels of physiologic stress without sufficient recovery time.2–4 They commonly occur in the elbow (“little league elbow” or “tennis elbow”) and in tissue where tendons attach to the bone, such as the heel, knee, hip, and shoulder.

Factors that increase the likelihood of sports injuries include intrinsic and extrinsic risk factors.4 Intrinsic risk factors are those that are unique to the individual that increase the likelihood of sustaining an injury, such as maturation status. Contact sports pose a greater threat for injury to the neck, spine, and growth plates in children and adolescents, who have not yet reached maturity. Extrinsic risk factors are those that, when applied to the athlete, may increase the risk of injury. They may include training methods, or equipment, and environment that may have an effect on the magnitude, stress, or force applied to the body. They include factors such as athletic activity that is repeated so often that areas of the body do not have enough time to heal between efforts. Injuries can often be prevented by proper training, use of safety equipment, and limiting the level of competition according to skill and size rather than chronologic age. Adequate warm-up time, hydration, and proper nutrition are also key factors in injury prevention.

Soft Tissue Injuries

Most skeletal injuries are accompanied by soft tissue (muscle, tendon, or ligament) injuries. These injuries include contusions and hematomas.

A contusion is an injury, or bruise, that results from direct trauma and is usually caused by striking a body part against a hard object.5 Although the resulting disability is usually minor, some contusions can be quite painful. Muscle bruises are common in all athletic events, even the so-called noncontact sports. The thigh and the arm are the most commonly involved. In contusions, the skin overlying the injury remains intact while the injured tissue undergoes a well-defined sequence of events including microscopic rupture of blood vessels and damage to muscle cells, swelling, and inflammation. The area often becomes ecchymotic (i.e., black and blue) because of local hemorrhage; later, the discoloration gradually changes to brown and then to yellow as the blood is reabsorbed.

A large area of local hemorrhage is called a hematoma. Hematomas cause pain as blood accumulates and exerts pressure on nerve endings. The pain increases with movement or when pressure is applied to the area. The pain and swelling of a hematoma take longer to subside than those accompanying a contusion.

The treatment for a contusion and a hematoma consists of elevating the affected part and applying cold for the first 24 hours to reduce the bleeding into the area. A compression wrapping is sometimes helpful in the early stages. Reinjury is avoided by appropriately protecting the area and allowing for complete healing to occur before returning to activities.

Joint (Musculotendinous) Injuries

Joints, or articulations, are sites where two or more bones meet. Joints (i.e., diarthrodial) are supported by tough bundles of collagenous fibers called ligaments that attach to the joint capsule and hold the articular ends of bones together and by tendons that join muscles to the periosteum of the articulating bones (see Chapter 42). Joint injuries usually involve mechanical overloading or forcible twisting or stretching.

Strains and Sprains

Strains and sprains are both musculoskeletal injuries, but they differ in terms of the tissue that is affected.5 Strains involve muscles, or more precisely the muscle–tendon unit. Sprains involve the supporting ligaments of a joint.

A strain is a stretching or partial tear in a muscle or a muscle–tendon unit. Strains commonly result from sudden stretch of a muscle that is actively contracting. Although there usually is no external evidence of a specific injury, an inflammatory response develops at the injured site, followed by fibrous tissue replacement of the damaged muscle fibers. Muscle strains are usually characterized by pain, stiffness, swelling, and local tenderness. Pain is increased with stretching of the muscle group. Strains can occur at any age but are more common in middle-aged and older adults. With aging, the collagen fibers in the muscle–tendon unit change; as a result, muscles have decreased elasticity and are more susceptible to injury. Common sites of muscle strains are the lower back and the cervical region of the spine. The elbow and the shoulder are also supported by muscle–tendon units that are subject to strains. Strains of muscle units around the hip, hamstring, and quadriceps are commonly associated with athletic activities. Proper warm-up exercises increase the flexibility of muscle–tendon units and help prevent these types of injuries.

A sprain, which involves the joint ligaments or capsule surrounding the joint, resembles a strain, but the pain and swelling subside more slowly. It usually is caused by abnormal or excessive movement of a joint. With a sprain, the ligaments may be incompletely torn or, in a severe sprain, completely torn or ruptured (Fig. 43-1). The signs of sprain are pain, rapid swelling, discoloration, and limitation of function. Any joint may be sprained, but the ankle joint is most commonly involved, especially in high-risk sports such as basketball. Most ankle sprains occur in the lateral ankle when the foot is turned inward under a person, forcing the ankle into inversion beyond its structural limits. Other common sites of sprain are the knee (the collateral...
sprains involves rest, ice, compression, and elevation tissue injury. An MRI is the most sensitive test for evaluation of a soft tissue injury that surrounds the tendon.

The treatment of muscle strains and ligamentous sprains involves rest, ice, compression, and elevation (RICE). For an injured extremity such as the ankle, elevation of the injured body part followed by local application of cold may be sufficient. Compression, accomplished through the use of adhesive wraps, helps to reduce swelling and provide support. For a muscle strain, the affected joint is immobilized until the pain and swelling have subsided. In a sprain, the affected joint is immobilized for several weeks. Immobilization may be followed by graded active exercises. Early diagnosis, treatment, and rehabilitation are essential in preventing chronic ligamentous instability.

Healing of the dense connective tissues in tendons and ligaments is similar to that of other soft tissues. If properly treated, injuries usually heal with the restoration of the original tensile strength. Repair is accomplished by fibroblasts from the inner tendon sheath or, if the tendon has no sheath, from the loose connective tissue that surrounds the tendon. Capillaries infiltrate the injured area during the initial healing process and supply the fibroblasts with the materials they need to produce large amounts of collagen. Formation of the long collagen bundles occurs within the first 2 weeks, and although tensile strength increases steadily thereafter, it is not sufficient to permit strong tendon pulls for 6 to 8 weeks. During the healing process, there is a danger that muscle contraction will pull the injured ends apart, causing the tendon to heal in the lengthened position. There is also a danger that adhesions will develop in areas where tendons pass through fibrous channels, such as in the distal palm of the hands, rendering the tendon useless.

**Dislocations**

A dislocation is the abnormal displacement of the articulating surfaces of a joint such that surfaces are not in contact. It usually follows a severe trauma that disrupts the holding ligaments. Dislocations are seen most often in the shoulder and acromioclavicular joints. A subluxation is a partial dislocation in which the bone ends in the joint are still in partial contact with each other.

Dislocations can be congenital, traumatic, or pathologic. Congenital dislocations occur in the hip or knee. Traumatic dislocations occur after falls, blows, or rotational injuries. For example, auto accidents often cause dislocations of the hip and accompanying acetabular fractures because of the direction of impact. In the shoulder and patella, dislocations may become recurrent, especially in athletes. They recur with the same motion but require less and less force each time. Less common sites of dislocation, seen mainly in young adults, are the wrist and midtarsal region. They usually are the result of direct force, such as a fall on an outstretched hand. Pathologic dislocation in the hip is a late complication of infection, rheumatoid arthritis, paralysis, and neuromuscular diseases.

Diagnosis of a dislocation is based on history, physical examination, and radiologic findings. The symptoms are pain, deformity, and limited movement. The treatment depends on the site, mechanism of injury, and associated injuries such as fractures. Dislocations that do not reduce spontaneously usually require manipulation or surgical repair. Immobilization is necessary for several weeks after reduction of a dislocation to allow healing of the joint structures. In dislocations affecting the knee, alternatives to surgery are isometric quadriceps-strengthening exercises and a temporary brace.

**Shoulder and Rotator Cuff Injuries**

The shoulder is a complex series of joints that produces extraordinary range of motion but lacks stability. This instability, combined with its relatively exposed position, makes the shoulder extremely vulnerable to injuries including fractures, dislocations, and degenerative processes such as rotator cuff disorders.

The shoulder is composed of three bones: the scapula, the clavicle, and the humerus (Fig. 43-2). The scapula is a thin bone that articulates widely and closely with the chest wall. It also articulates with the humerus by way of its small, shallow glenoid cavity and with the clavicle at the acromion process. The clavicle, which is held firmly in place by ligaments at the sternum and acromion, forms the only bony connection between the axial skeleton and the upper extremity. Clavicle fractures
Disorders of the rotator cuff, such as tendinitis, subacromial bursitis, and partial and complete tears, account for a substantial majority of shoulder problems (see Fig. 43-2). Rotator cuff injuries can result from excessive use, a direct blow, or stretch injury, usually involving throwing or swinging, as with baseball pitchers or tennis players. While rotator cuff injuries sometimes occur with acute injury, most result from a combination of factors, including altered blood supply to the tendons, repeated mechanical insult as the tendon passes under the coracoacromial arch, and age-related degeneration. Repetitive overhead throwing, which produces significant stress on the glenohumeral complex of the rotator cuff, is a common cause of rotator cuff tendinitis. Full-thickness tears are more common in persons older than 40 years of age, although they can occur in athletes. Tears generally originate in the supraspinous tendon and may progress posteriorly and anteriorly.

The major clinical features of rotator cuff disorders are pain (especially at night), tenderness, and occasionally muscle atrophy. Pain and impingement may be noted when motions of the arm squeeze and pinch cuff tendons between the humerus and the overlying arch. With rotator cuff tears, there may be difficulty abducting and rotating the arm.

Several physical examination maneuvers, including assessment of active and passive range of motion, are used to define shoulder pathology. The history and mechanism of injury are important. In addition to standard radiographs, an arthrogram or magnetic resonance imaging (MRI) scan may be obtained. Arthroscopic examination under anesthesia may be done for diagnostic purposes. Conservative treatment with anti-inflammatory agents, corticosteroid injections, and physical therapy often is used. A period of rest is followed by a customized exercise and rehabilitation program to improve strength, flexibility, and endurance. Surgical repair may be considered for persons with an acute traumatic rotator cuff tear or those with significant symptoms and failed rehabilitation.

Knee Injuries

The knee is a common site of injury, particularly sports-related injuries in which the knee is subjected to abnormal twisting and compression forces. These forces can result in injury to the ligaments and menisci, patellar subluxation and dislocation, and the patellofemoral pain syndrome. Many knee injuries can predispose to osteoarthritis in later life.

The knee joint consists of lateral and medial femoral condyles, the lateral and medial femotibial condyles, and the patella (Fig. 43-3). It is essentially a round bone (femoral condyles) sitting on a flat bone (tibial condyles) with no intrinsic bony stability and depends on its ligaments and menisci for support. The most important ligaments are the medial and lateral collateral ligaments along with their associated posterior capsular structures.
The menisci play a major role in load bearing and shock by the coronary and transverse ligaments of the knee. They are located in the intercondylar area of the tibia and are supported by their ends to the intercondylar area of the tibia and are supported by the coronary and transverse ligaments of the knee. The menisci play a major role in load bearing and shock absorption. They also help to stabilize the knee by deepening the tibial socket and maintaining the femur and tibia in proper position. In addition, the meniscus assists in joint lubrication and serves as a source of nutrition for articular cartilage in the knee.

Meniscus injury commonly occurs as the result of a rotational injury from a sudden or sharp pivot or a direct blow to the knee, as in hockey, basketball, or football. It is often associated with other injuries, such as a torn ACL. The type and location of the meniscal tear are determined by the magnitude and direction of the force that acts on the knee and the position of the knee at the time of injury. Meniscus tears can be described by their appearance (e.g., parrot-beak, bucket handle) or their location (e.g., posterior horn, anterior horn). The injured knee is edematous and painful, especially with hyperflexion and hyperextension. A loose fragment may cause knee instability and locking.

Diagnosis is made by examination and confirmed by MRI. A regular radiograph may be needed to rule out osteoarthritis. Initial treatment of meniscal injuries may be conservative. The knee may be placed in a removable knee immobilizer. Isometric quadriceps exercises may be prescribed. Activity usually is restricted until complete motion is recovered. Arthroscopic meniscectomy may be performed when there is recurrent or persistent locking, recurrent effusion, or disabling pain.

There is evidence that loss of meniscal function is associated with progressive deterioration of knee function and osteoarthritic changes. Damaged articular cartilage has a limited capacity to heal because of its avascular nature and inadequate mobilization of regenerative cells. Meniscal reconstruction procedures have been developed to preserve these functions before significant degenerative changes develop, thus preventing the need for a total joint replacement later in life.

Patellar Subluxation and Dislocations. Recurrent subluxation and dislocation of the patella are common in young adults. Sports such as skiing or tennis involve external rotation of the foot and leg with knee flexion, a position that exerts rotational stresses on the knee. Congenital knee variations are also a predisposing factor. There is often a sensation of the patella “popping out” when the dislocation occurs. Other complaints include the knee giving out, swelling, crepitus, stiffness, and loss of range of motion. Treatment measures include immobilization with the knee extended, bracing, administration of anti-inflammatory agents, and isometric quadriceps-strengthening exercises. Surgical intervention often is necessary.

Patellofemoral Pain Syndrome. Patellofemoral pain syndrome is the most common cause of anterior knee pain. It is caused by imbalances in the forces controlling movement of the patella during knee flexion and extension, particularly with overloading of the joint. The patellofemoral joint is composed of the patella and the central groove in the proximal femur, which is referred to as the patellar groove or femoral trochlea (see Fig. 43-3). Stability of the joint involves dynamic and
static stabilizers, which control patellar tracking; that is, the movement of the patella within the femoral trochlea. The disorder, also called “runner’s knee,” occurs most frequently in young adults and is often associated with jogging, volleyball, and basketball. Persons with this disorder typically complain of pain, particularly when climbing stairs or sitting with the knees bent. The pain is usually difficult to localize, and swelling of the knee is not characteristic of the disorder. Occasionally, the person experiences weakness of the knee.

Diagnosis is usually based on history and physical examination. Radiography may be used as an adjunct to the history and physical. Treatment consists of relative rest and physical therapy. Reduction of loading of the patellofemoral joint and surrounding tissues is the first step to reduce pain. Inappropriate or excessively worn footwear may contribute to the problem and need to be replaced. Although a variety of braces, sleeves, and straps have been used in treatment of the disorder, studies have found no significant benefit from their use.

**Hip Injuries**

The hip is a ball-and-socket joint in which the femoral head articulates deeply in the acetabulum. The proximal part of the femur consists of a head, neck, and greater trochanter. The vascular anatomy of the femoral head, which receives its main blood supply from the femoral head and avascular necrosis may result. To prevent this complication, early reduction is indicated. Weight bearing is usually limited after reduction to prevent the dislocation from reoccurring and allow healing to occur.

**Fractures of the Hip.** Hip fracture is a major public health problem in the Western world, particularly among the elderly. It results in hospitalization, disability, and loss of independence. Risk factors for hip fracture include physical inactivity, excessive consumption of alcohol, use of certain psychotropic drugs, residence in an institution, visual impairment, and dementia. Osteoporosis is an important contributing factor.

Most hip fractures result from falls. Occasionally, the person may actually fracture the hip before falling, the fracture representing the completion of an incomplete break. The characteristics of the fall (the direction, site of impact, and protective response) and environmental factors are recognized as important influences for the risk of hip fracture from a fall.

A hip fracture usually involves the proximal femur. Such fractures are commonly categorized according to the anatomic site in which they occur. Femoral neck fractures are located in the area distal to the femoral head but proximal to the greater and lesser trochanters and are considered intracapsular because they are located...
within the capsule of the hip joint. Intertrochanteric fractures occur in the metaphyseal region between the greater and lesser trochanter. Subtrochanteric fractures are those that occur just below the greater trochanter.

The location of a hip fracture is important in terms of blood flow to the femoral head, which receives its blood supply from vessels that course proximally up the femoral neck (see Fig. 43-4). Subtrochanteric and intertrochanteric fractures that occur distal to these vessels do not usually disturb the blood supply to the femoral head, whereas femoral neck fractures, particularly those involving marked displacement, often disrupt the blood supply to the femoral head and are therefore associated with an increased incidence of complications (nonunion and avascular necrosis).

Most hip fractures are diagnosed based on clinical findings and standard radiographs. A bone scan or MRI may be done when the radiograph is negative, but the clinical findings support the diagnosis of hip fracture.

The primary goal of treatment for a hip fracture is a return to the preinjury level of function as soon as possible. Undisplaced or impacted fractures have a better prognosis in terms of healing and are often treated nonoperatively or by simple internal fixation to provide stability. Displaced intracapsular fractures in the elderly are usually best treated by surgical hip replacement and early mobilization. Young, healthy people are treated by reduction of the fracture (if needed) and internal fixation. This method allows for preservation of the femoral head, which in this age group is desirable because the long-term results are better than with prosthetic replacement. Intertrochanteric fractures are usually treated with open reduction and internal fixation. This allows for early ambulation by eliminating pain at the fracture site.

Fractures

A fracture represents a disruption in the continuity of a bone. Normal bone can withstand considerable compression and shearing forces and, to a lesser extent, tension forces. A fracture occurs when more stress is placed on the bone than it is able to absorb. Grouped according to cause, fractures can be divided into three major categories: (1) fractures caused by sudden injury, (2) fatigue stress fractures, and (3) pathologic stress fractures. The most common fractures are those resulting from sudden injury. The force causing the fracture may be direct, such as a fall or blow, or indirect, such as a massive muscle contraction or trauma transmitted along the bone. For example, the head of the radius or clavicle can be fractured by the indirect forces that result from sudden injury. The force causing the fracture may be direct, such as a fall or blow, or indirect, such as a massive muscle contraction or trauma transmitted along the bone. For example, the head of the radius or clavicle can be fractured by the indirect forces that result from sudden injury. The force causing the fracture may be direct, such as a fall or blow, or indirect, such as a massive muscle contraction or trauma transmitted along the bone. For example, the head of the radius or clavicle can be fractured by the indirect forces that result from sudden injury. The force causing the fracture may be direct, such as a fall or blow, or indirect, such as a massive muscle contraction or trauma transmitted along the bone. For example, the head of the radius or clavicle can be fractured by the indirect forces that result from sudden injury. The force causing the fracture may be direct, such as a fall or blow, or indirect, such as a massive muscle contraction or trauma transmitted along the bone. For example, the head of the radius or clavicle can be fractured by the indirect forces that result from sudden injury. The force causing the fracture may be direct, such as a fall or blow, or indirect, such as a massive muscle contraction or trauma transmitted along the bone. For example, the head of the radius or clavicle can be fractured by the indirect forces that result from sudden injury. The degree of a fracture is described in terms of a complete or incomplete break in the continuity of bone. A greenstick fracture, which is seen in children, is an example of a partial break in bone continuity and resembles that seen when a young sapling is broken. This kind of break occurs because children’s bones, especially until approximately 10 years of age, are more resilient than the bones of adults.

The character of the fracture pieces may also be used to describe a fracture. A comminuted fracture has more than two pieces. A compression fracture, as occurs in the vertebral body, involves two bones that are crushed or squeezed together. A fracture is called impacted when the fracture fragments are wedged together. This type usually occurs in the humerus, often is less serious, and usually is treated without surgery.

The direction of the trauma or mechanism of injury produces a certain configuration or pattern of fracture. Reduction is the restoration of a fractured bone to its normal anatomic position. The pattern of a fracture indicates the nature of the trauma and provides information about the easiest method for reduction. Transverse fractures are caused by simple angulatory forces. A spiral fracture results from a twisting motion, or torque. A transverse fracture is not likely to become displaced or lose its position after it is reduced. On the other hand, spiral, oblique, and comminuted fractures often are unstable and may change position after reduction.

Manifestations

The signs and symptoms of a fracture include pain, tenderness at the site of bone disruption, swelling, loss of function, deformity of the affected part, and abnormal mobility. The deformity varies according to the type of force applied, the area of the bone involved, the type of fracture produced, and the strength and balance of the surrounding muscles.

In long bones, three types of deformities—angulation, shortening, and rotation—are seen. Severely angulated fracture fragments may be felt at the fracture site and often push up against the soft tissue to cause a tenting effect on the skin. Bending forces and unequal muscle pulls cause angulation. Shortening of the extremity occurs as the bone fragments slide and override each other because of the pull of the muscles on the long axis of the extremity (Fig. 43-6). Rotational deformity occurs when the fracture fragments rotate out of their normal longitudinal axis; this can result from rotational strain produced by the fracture or unequal pull by the muscles that are attached to the fracture fragments. A crepitus, or grating sound, may be heard as the bone fragments rub against each other. In the case of an open fracture, there is bleeding from the wound where the bone protrudes. Blood loss from a pelvic fracture or multiple long bone fractures can cause hypovolemic shock in a trauma victim.

Shortly after the fracture has occurred, nerve function at the fracture site may be temporarily lost. The area may become numb, and the surrounding muscles may become flaccid. This condition has been called local shock. During this period, which may last for a few minutes to half an hour, fractured bones may be reduced with little or no pain. After this brief period, the pain sensation returns, and with it muscle spasms and contractions of the surrounding muscles.

Diagnosis and Treatment

Diagnosis is the first step in the care of fractures and is based on history and physical manifestations. X-ray examination is used to confirm the diagnosis and direct the treatment. The ease of diagnosis varies with the location and severity of the fracture. In the trauma patient, the presence of other, more serious injuries may make diagnosis more difficult.

Treatment depends on the general condition of the person, the presence of associated injuries, the location of the fracture and its displacement, and whether the fracture is open or closed. A splint is a device for immobilizing the movable fragments of a fracture. When a fracture is suspected, the injured part always should be splinted before it is moved. This is essential for preventing further injury.

There are three objectives for treatment of fractures: (1) reduction of the fracture, (2) immobilization, and (3) preservation and restoration of the function of the injured part. Reduction of a fracture is directed toward manipulating the bone fragments to as near-normal an anatomic position as possible. This can be accomplished by closed or surgical (open) reduction. Closed reduction uses methods such as manual pressure and traction. Fractures are then held in place by external or internal fixation devices. Surgical reduction involves the use of various types of hardware to accomplish internal fixation of the fracture fragments.

Immobilization prevents movement of the injured parts and is the single most important element in obtaining union of the fracture fragments. Immobilization can be accomplished through the use of external devices, such as splints, casts, external fixation devices, or traction, or by means of internal fixation devices inserted during surgical reduction of the fracture. Preservation and restoration of the function of muscles and joints is an ongoing process in the unaffected and affected extremities during the period of immobilization required for fracture healing. Exercises designed to preserve function, maintain muscle strength, and reduce joint stiffness should be started early.

Bone Healing

Bone healing occurs in a manner similar to soft tissue healing. However, it is a more complex process and takes longer. There are essentially four stages...
A fracture, which is any break in a bone, undergoes a healing process to reestablish bone continuity and strength. The repair of simple fractures is commonly divided into four phases: (1) hematoma formation, (2) fibrocartilaginous callus formation, (3) bony callus formation, and (4) remodeling.

1. **Hematoma Formation.** When a bone breaks, blood vessels in the bone and surrounding tissues are torn and bleed into and around the fragments of the fractured bone, forming a blood clot, or hematoma. The hematoma facilitates the formation of the fibrin meshwork that seals off the fracture site and serves as a framework for the influx of inflammatory cells, the ingrowth of fibroblasts, and the development of new capillary buds (vessels). It is also the source of signaling molecules that initiate the cellular events that are critical to the healing process.

2. **Fibrocartilaginous Callus Formation.** As new capillaries infiltrate the hematoma at the fracture site, it becomes organized into a form of granulation tissue, called procallus. Fibroblasts from the periosteum, endosteum, and red bone marrow proliferate and invade the procallus. The fibroblasts produce a fibrocartilaginous soft callus bridge that connects the bone fragments. Although this repair tissue usually reaches its maximum girth at the end of the 2nd or 3rd week, it is not strong enough for weight bearing.
Bony Callus Formation. Ossification represents the conversion of the fibrocartilaginous cartilage to bony callus. In areas close to well-vascularized bone tissue, osteogenic cells develop into osteoblasts, or bone-building cells, which produce spongy bone trabeculae. The newly formed osteoblasts first deposit bone on the outer surface of the bone some distance from the fracture site. The formation of bone progresses toward the fracture site until a new bony sheath covers the fibrocartilaginous callus. In time, the fibrocartilage is converted to spongy bone, and the callus is then referred to as bony callus. Gradually, the bony callus calcifies and is replaced by mature bone. Bony callus formation begins 3 to 4 weeks after injury and continues until a firm bony union is formed months later.

Remodeling. During remodeling of the bony callus, dead portions of the bone are gradually removed by osteoclasts. Compact bone replaces spongy bone around the periphery of the fracture, and there is reorganization of mineralized bone along the lines of mechanical stress. During this period, the excess material on the outside of the bone shaft and within the medullary cavity is removed and compact bone is laid down to reconstruct the shaft. The final structure of the remodeled area resembles that of the original unbroken bone; however, a thickened area on the surface of the bone may remain as evidence of a healed fracture.
The condition of the fracture fragments, hematoma bone usually appears as it did before the injury. Of the bone is also restored. After this is completed, the bone have been reestablished. The medullary cavity the callus is reduced in size until the shape and outline of are not stressed are resorbed. It is in this manner that and transmits weight-bearing forces, the portions that external aspect of the fracture site. As the callus matures callus that develops in the marrow space and encircles the usually safe to remove the cast.

The next event in fracture healing is formation of granulation tissue or soft tissue callus. During this stage of bone healing, fibroblasts and osteoblasts migrate into the fracture site from the nearby periosteal and endosteal membranes and begin reconstruction of bone. The fibroblasts produce collagen that spans the break and connects the broken bone ends, and some differentiate into chondrocytes that secrete collagen matrix. At about the same time, osteoblasts begin depositing bone into this matrix. After a few days, a fibrocartilage “collar” becomes evident around the fracture site. The collar edges on either side of the fracture eventually unite to form a bridge, which connects the bone fragments. The earliest bone, in the form of woven bone, begins its formation sometime after the 1st week. In an uncomplicated fracture, the repair tissue reaches its maximum girth at the end of the 2nd to 3rd week, which helps stabilize the fracture, but it is not yet strong enough for weight bearing.

Ossification represents the deposition of mineral salts into the callus. This stage usually begins during the 3rd to 4th week of fracture healing. During this stage, mature bone gradually replaces the fibrocartilaginous callus, and the excess callus is gradually resorbed by the osteoclasts. The fracture site feels firm and immovable and appears united on the radiograph. At this point, it is usually safe to remove the cast.

Remodeling involves resorption of the excess bony callus that develops in the marrow space and encircles the external aspect of the fracture site. As the callus matures and transmits weight-bearing forces, the portions that are not stressed are resorbed. It is in this manner that the callus is reduced in size until the shape and outline of the bone have been reestablished. The medullary cavity of the bone is also restored. After this is completed, the bone usually appears as it did before the injury.

Healing time depends on the site of the fracture, the condition of the fracture fragments, hematoma formation, and other local and host factors. In children, fractures usually heal within 4 to 6 weeks; in adolescents, they heal within 6 to 8 weeks; and in adults, they heal within 10 to 18 weeks. The increased rate of healing among children compared with adults may be related to the increased cellularity and vascularity of the child’s periosteum. In general, fractures of long bones, displaced fractures, and fractures with less surface area heal more slowly. Function usually returns within 6 months after union is complete. However, return to complete function may take longer.

Impaired Bone Healing. Factors that influence bone healing are specific to the person, the type of injury sustained, and local factors that disrupt healing. Individual factors that may delay bone healing are the patient’s age; current medications; debilitating diseases, such as diabetes and rheumatoid arthritis; local stress around the fracture site; circulatory problems and coagulation disorders; and poor nutrition.

Malunion is healing with deformity, angulation, or rotation that is visible on x-ray films. Early and aggressive treatment, especially of the hand, can help prevent malunion and result in earlier alignment and return of function. Delayed union is the failure of a fracture to unite within the normal period (e.g., 20 weeks for a fracture of the tibia or femur in an adult). Intra-articular fractures (i.e., those through a joint) may heal more slowly and may eventually produce arthritis. Nonunion is failure to produce union and cessation of the processes of bone repair. It is seen most often in the tibia, especially with open fractures or crushing injuries. It is characterized by mobility of the fracture site and pain on weight bearing. Muscular atrophy and loss of range of motion may occur. Nonunion usually is established 6 to 12 months after the time of the fracture. The complications of fracture healing are summarized in Table 43-1.

Treatment methods for impaired bone healing encompass surgical interventions, including bone grafts, bracing, external fixation, or electrical stimulation of the bone ends. Electrical stimulation is thought to stimulate the osteoblasts to lay down a network of bone. Three types of commercial bone growth stimulators are available: a noninvasive model, which is placed outside the cast; a semi-invasive model, in which pins are inserted around the fracture site; and a totally implantable type, in which a cathode coil is wound around the bone at the fracture site and operated by a battery pack implanted under the skin.

Complications of Fractures and Other Injuries

The complications of fractures and other orthopedic injuries are associated with loss of skeletal continuity, injury from bone fragments, pressure from swelling and hemorrhage (e.g., fracture blisters, compartment syndrome), or development of fat emboli. The complex regional pain syndrome or reflex sympathetic dystrophy, caused by involvement of nerve fibers, is discussed in Chapter 35.
**Fracture Blister**s. Fracture blisters are skin bullae and blisters representing areas of epidermal necrosis with separation of the epidermis from the underlying dermis by edema fluid. They are seen with more severe, twisting types of injuries (e.g., motor vehicle accidents and falls from heights) but can also occur after excessive joint manipulation, dependent positioning, and heat application, or from peripheral vascular disease. They can be solitary, multiple, or massive, depending on the extent of injury. Most fracture blisters occur in the ankle, elbow, foot, knee, or areas where there is little soft tissue between the bone and the skin. The development of fracture blisters reportedly is reduced by early surgical intervention in persons requiring operative repair. This probably reflects the early operative release of the fracture hematoma, reapproximation of the disrupted soft tissues, ligation of bleeding vessels, and fixation of bleeding fracture surfaces. Prevention of fracture blisters is important because they pose an additional risk of infection.

**Compartment Syndrome.** The compartment syndrome has been described as a condition of increased pressure within a limited space (e.g., abdominal and limb compartments) that compromises the circulation and function of the tissues within the space. The abdominal compartment syndrome alters cardiovascular hemodynamics, respiratory mechanics, and renal function. The discussion in this chapter is limited to the limb compartment syndromes.

The muscles and nerves of an extremity are enclosed in a tough, inelastic fascial envelope called a muscle compartment (Fig. 43-7). If the pressure in the compartment is sufficiently high, tissue circulation is compromised, causing death of nerve and muscle cells. Permanent loss of function may occur. Intracompartmental pressures greater than 30 mm Hg (normal is approximately 6 mm Hg) are considered sufficient to impair capillary blood flow; however, the amount of pressure required to produce a compartment syndrome depends on many factors.5

Compartment syndrome can result from a decrease in compartment size, an increase in the volume of its contents, or a combination of the two factors. Among the causes of decreased compartment size are constrictive dressings and casts, closure of fascial defects, and burns. In persons with circumferential third-degree burns, the inelastic and constricting eschar (thick coagulated crust or slough) decreases the size of the underlying compartments. An increase in compartment volume can be caused by trauma, including contusions and soft tissue injury,
as well as a fracture, crushing injury, or bone surgery, when excessive swelling around the site of injury results in increased pressure in a closed compartment. Vascular injury and bleeding, and venous obstruction can also increase compartment volume. Exertional compartment syndrome is associated with walking or running. Symptoms usually develop gradually with exercise, but resolve within 30 minutes of cessation of activity.

The hallmark symptom of an acute compartment syndrome is severe pain that is out of proportion to the original injury or physical findings. Nerve compression may cause changes in sensation (e.g., paresthesias such as burning or tingling or loss of sensation), diminished reflexes, and eventually the loss of motor function. Symptoms usually begin within a few hours but can be delayed.

Because muscle necrosis can occur in as little as 4 to 8 hours, it is important that persons at risk for compartment syndrome be identified and proper treatment instituted. Assessment should include pain, sensory function (i.e., light touch and two-point discrimination), motor function (i.e., movement and muscle strength), passive stretch, and palpation of the muscle compartments. Direct measurements of tissue pressure can be obtained using a needle or wick catheter inserted into the muscle compartment.

Treatment consists of reducing compartmental pressures. This entails cast splitting or removal of restrictive dressings. These procedures often are sufficient to relieve most of the underlying pressure and symptoms. Elevating the extremity on pillows can help to reduce edema. However, excessive elevation should be avoided because the effects of gravity can lower arterial pressure in the limb, thereby decreasing compartmental perfusion. When compartment syndrome cannot be relieved by conservative measures, a fasciotomy may become necessary. During this procedure, the fascia is incised longitudinally and separated so that the compartment volume can expand and blood flow can be reestablished. Because of potential problems with wound infection and closure, this procedure is usually performed as a last resort.

**Fat Embolism Syndrome.** The fat embolism syndrome (FES) refers to a constellation of clinical manifestations resulting from the presence of fat droplets in the small blood vessels of the lung or other organs after a long bone fracture or other major trauma. The fat emboli are thought to be released from the bone marrow or adipose tissue at the fracture site into the venous system through torn veins. It is important to point out that FES is not synonymous with fat embolization, which involves the presence of fat particles in the circulation. Although fat embolization occurs in many persons with fractures or operative fixation of fractures, FES occurs in only a small percentage of cases, supporting the hypothesis that factors other than fat embolization may be necessary in the development of FES.

The main clinical features of FES are respiratory failure, cerebral dysfunction, and skin and mucosal petechiae. Cerebral manifestations include encephalopathy, seizures, and focal neurologic deficits unrelated to head injury. Initial symptoms begin within a few hours to 3 to 4 days after injury and include a subtle change in behavior and signs of disorientation resulting from emboli in the cerebral circulation combined with respiratory depression. There may be complaints of substernal chest pain and dyspnea accompanied by tachycardia and a low-grade fever. Diaphoresis, pallor, and cyanosis become evident as respiratory function deteriorates. A petechial rash that does not blanch with pressure often occurs 2 to 3 days after the onset of symptoms. It is thought to be related to embolization of the skin capillaries or thrombocytopenia.

Three degrees of severity are seen: subclinical, overt clinical, and fulminating. Although the subclinical and overt clinical forms of FES respond well to treatment, the fulminating form often is fatal. Early diagnosis is critical. Arterial blood gases should be assayed immediately after recognition of clinical manifestations. Treatment is directed toward correcting hypoxemia and maintaining adequate fluid balance. Mechanical ventilation may be required. Corticosteroid drugs are administered to decrease the inflammatory response of lung tissues, decrease edema, stabilize the lipid membranes to reduce lipolysis, and combat bronchospasm. Corticosteroids are also given prophylactically to high-risk persons. The only preventive approach to FES is early stabilization of the fracture.

**SUMMARY CONCEPTS**

- Many external physical agents can cause trauma to the musculoskeletal system. Some soft tissue injuries such as contusions, hematomas, and lacerations are relatively minor and easily treated. Muscle strains and ligamentous sprains are caused by mechanical overload on the connective tissue. They heal more slowly than the minor soft tissue injuries and require some degree of immobilization.

- The shoulder and knee are common sites for injuries in athletes. Shoulder dislocations and rotator cuff injuries are common. Knee injuries include torn ligaments and menisci, patellar subluxation and dislocation, and patellofemoral pain syndrome. Hip dislocation is also common.

- Fractures occur when more stress is placed on a bone than the bone can absorb. Healing of fractures is a complex process that takes place in four stages: hematoma formation, fibrocartilaginous callus formation, ossification, and remodeling. For satisfactory healing to take place, the affected bone has to be reduced and immobilized. This is accomplished with external fixation devices (e.g., splints, casts, or traction) or surgically implanted internal fixation devices.
Bone Infections and Osteonecrosis

Bone like other body tissues is susceptible to infection due to invasion by microorganisms. It also is susceptible to osteonecrosis (bone death) when it loses its blood supply.

Infections—Osteomyelitis

Osteomyelitis represents an acute or chronic infection of the bone and marrow. Despite the common use of antibiotics, bone infections remain difficult to treat and eradicate. All types of organisms, including parasites, viruses, bacteria, and fungi, can cause osteomyelitis, but certain pyogenic bacteria and mycobacteria are the most common.

Pyogenic Osteomyelitis

Pyogenic osteomyelitis is almost always caused by bacteria. Organisms may reach the bone by seeding through the bloodstream (hematogenous spread), direct penetration or contamination of an open fracture or wound (exogenous origin), or extension from a contiguous site.

The specific agents isolated in pyogenic bacterial osteomyelitis are often associated with the age of the person or the inciting condition (e.g., trauma or surgery). *Staphylococcus aureus* is the most common cause, but organisms such as *Escherichia coli*, *Neisseria gonorrhoeae*, *Haemophilus influenzae*, and *Salmonella* species are also seen. *Staphylococcus aureus* has two characteristics that favor its ability to produce osteomyelitis: (1) it has the ability to produce a collagen-binding adhesion molecule that allows it to adhere to the connective tissue elements of bone, and (2) it has the ability to evade host defenses, attack host cells, and colonize bone persistently. Also, infection caused by methicillin-resistant *S. aureus* is becoming an increasingly common problem.

Hematogenous Osteomyelitis. Hematogenous osteomyelitis originates with infectious organisms that reach the bone through the bloodstream. Acute hematogenous osteomyelitis occurs predominantly in children. In adults, it is seen most commonly in debilitated persons and in those with a history of chronic skin infections, chronic urinary tract infections, and intravenous drug use and in those who are immunologically suppressed. Intravenous drug users are especially at risk for infections with *Streptococcus* and *Pseudomonas*.

The pathogenesis of hematogenous osteomyelitis differs in children and adults. In children, the infection usually affects the long bones of the appendicular skeleton. It starts in the metaphyseal region close to the growth plate, where termination of nutrient blood vessels and sluggish blood flow favor the attachment of blood-borne bacteria (Fig. 43-8). With advancement of the infection, purulent exudate collects in the rigidly enclosed bony tissue. Because of the bone’s rigid structure, there is little room for swelling and the purulent exudate finds its way beneath the periosteum, shearing off the perforating arteries that supply the cortex with blood, thereby leading to necrosis of cortical bone. The necrotic bone that is formed may separate from the viable surrounding bone

**FIGURE 43-8.** Hematogenous osteomyelitis. (A) Infectious organisms reach the metaphysis through a nutrient blood vessel. (B) Bacterial growth results in bone destruction and abscess formation. From the abscess cavity, the infection spreads between the trabeculae into the medullary cavity of compact bone and then through the cortex to the outside. (C) The purulent exudate finds its way beneath the periosteum, shearing off the perforating arteries that supply the cortex with blood, thereby leading to necrosis of cortical bone and formation of devascularized fragments, called sequestra.
to form devascularized fragments, called sequestra.18,19 Eventually, the purulent drainage may penetrate the periosteum and skin to form a draining sinus. In children 1 year of age and younger, the adjacent joint is often involved because the periosteum is not firmly attached to the cortex.18,19 From 1 year of age to puberty, subperiosteal abscesses are more common. As the process continues, periosteal new bone formation and reactive bone formation in the marrow tend to wall off the infection.

In adults, the long bone microvasculature no longer favors seeding, and hematogenous infection rarely affects the appendicular skeleton. Instead, vertebral, sternoclavicular and sacroiliac joints, and the symphysis pubis are involved. Infection typically first involves subchondral bone, then spreads to the joint space. With vertebral osteomyelitis, this causes sequential destruction of the endplate, adjoining disk, and contiguous vertebral body. Infection less commonly begins in the joint and spreads to the adjacent bone.

The signs and symptoms of acute hematogenous osteomyelitis are those of bacteremia accompanied by symptoms referable to the site of the bone lesion. Bacteremia is characterized by chills, fever, and malaise. There often is pain on movement of the affected extremity, loss of movement, and local tenderness followed by redness and swelling. X-ray studies may appear normal initially, but they show evidence of periosteal elevation and increased osteoclastic activity after an abscess has formed. Radiographic bone scans and MRI can usually detect subtle changes at an earlier stage.

The treatment of hematogenous osteomyelitis begins with identification of the causative organism through blood and bone aspiration cultures. Antimicrobial agents are given first parenterally and then orally. The length of time the affected limb needs to be rested and the pain control measures used are based on the person’s symptoms. Débridement and surgical drainage also may be necessary.

**Chronic Osteomyelitis.** Chronic osteomyelitis usually occurs in adults and is secondary to an open wound, most often to the bone or surrounding tissue. It may be the result of delayed or inadequate treatment of acute hematogenous osteomyelitis or osteomyelitis caused by direct contamination of bone by exogenous organisms. Chronic osteomyelitis can persist for years; it may appear spontaneously following a minor trauma, or when resistance is lowered.

The hallmark feature of chronic osteomyelitis is the presence of infected dead bone, a sequestrum, that has separated from the living bone.18,19 A sheath of new bone, called the involucrum, forms around the dead bone. Radiologic techniques such as x-ray films, bone scans, and sinograms are used to identify the infected site. Chronic osteomyelitis or infection around a total joint prosthesis can be difficult to diagnose because the classic signs of infection are not apparent and the blood leukocyte count may not be elevated. A subclinical infection may exist for years. Bone scans are used with bone biopsy for a definitive diagnosis.

The treatment of chronic bone infections begins with wound cultures to identify the microorganism and its sensitivity to antibiotic therapy.31-33 Initial antibiotic therapy is often followed by surgery to remove foreign bodies (e.g., metal plates, screws) or sequestra and by long-term antibiotic therapy. Immobilization of the affected part usually is necessary, with restriction of weight bearing on a lower extremity. External fixation devices are sometimes used.

**Direct Penetration and Contiguous Spread Osteomyelitis.** Direct penetration or extension of bacteria from an outside (exogenous) source is now the most common cause of osteomyelitis in the United States.19 Bacteria may be introduced directly into the bone by a penetrating wound, an open fracture, or surgery. In persons with vascular insufficiency or poorly controlled diabetes, osteomyelitis may develop from a skin lesion.

Iatrogenic bone infections are those inadvertently brought about by surgery or other treatments. These complications include pin tract infection in skeletal traction, septic (infected) joints in joint replacement surgery, and wound infections after surgery. Risk factors for the development of a surgical site infection include both host factors and those related to the procedure.34 Delays in wound healing, infection and failure of surgical implants cause greater morbidity and possibly the need for subsequent revision surgery.

Osteomyelitis after trauma or bone surgery usually is associated with persistent or recurrent fever, increased pain at the operative or trauma site, and poor incisional healing, which often is accompanied by continued wound drainage and wound separation. Prosthetic joint infections often present with joint pain, fever, and cutaneous drainage.

Treatment includes the use of antibiotics and selective use of surgical interventions. The choice of agents and method of administration depend on the microorganisms causing the infection. In acute osteomyelitis that does not respond to antibiotic therapy, surgical decompression is used to release intramedullary pressure and remove drainage from the periosteal area. Prosthesis removal may be necessary in cases of an infected prosthetic joint. The joint is left out while a 2- to 6-week course of therapy is given, after which another joint is implanted.32

**Tuberculosis Osteomyelitis**

A resurgence of tuberculosis osteomyelitis is occurring in industrialized countries of the world, attributed to the influx of immigrants from developing countries and the greater numbers of immunocompromised people.19 Tuberculosis can spread from one part of the body, such as the lungs or the lymph nodes, to the musculoskeletal system. Any bone, joint, or bursa may be affected, but the spine is the most common site, followed by the knees and hips.18,19,35 Tubercular osteomyelitis tends to be more destructive and difficult to control than pyogenic osteomyelitis. The infection spreads through large areas of the medullary cavity and causes extensive necrosis. In tuberculosis of the spine, also known as Pott disease, the infection spreads through the intervertebral disks to involve multiple vertebrae and extends into the soft tissue, forming abscesses.
Local symptoms include pain, immobility, and muscle atrophy; joint swelling, mild fever, and leukocytosis also may occur. The most feared complication of spinal tuberculosis is neurologic compromise due to spinal deformity and epidural abscess formation. Because there are no specific radiographic findings in tubercular osteomyelitis, the diagnosis is usually made by tissue biopsy or culture findings. In spinal tuberculosis, a computed tomography (CT)-guided biopsy is often used. The mainstay of treatment for tubercular osteomyelitis remains the appropriate three- or four-drug antimicrobial therapy based on current guidelines.\textsuperscript{35} Conservative treatment is usually as effective as surgery, especially for earlier and milder cases.

### Osteonecrosis

Osteonecrosis, also known as avascular necrosis, is an aseptic destruction of a segment of bone that is due to an interruption in blood flow rather than an infection.\textsuperscript{18,19,36,37} It is relatively common and can occur in the medullary cavity of the metaphysis and the subchondral region of the epiphysis, especially in the hips, knees, shoulders, and ankles. Destruction of bone frequently is severe enough to require joint replacement surgery.

Bone has a rich blood supply that varies from site to site. The flow in the medullary portion of bone originates in nutrient vessels from an interconnecting plexus that supplies the marrow, trabecular bone, and endosteal half of the cortex. The outer cortex receives its blood supply from periosteal, muscular, metaphyseal, and epiphyseal vessels that surround the bone. Some bony sites, such as the head of the femur, have only limited collateral circulation so that interruption of the flow, such as with a hip fracture, can cause necrosis and irreversible damage to a substantial portion of medullary and cortical bone.

Although bone necrosis results from ischemia, the mechanisms producing the ischemia are varied and include mechanical interruption such as occurs with a fracture; thrombosis and embolism (e.g., sickle cell disease, nitrogen bubbles caused by inadequate decompression during deep sea diving); vessel injury (e.g., vasculitis, radiation therapy); and increased intraosseous pressure with vascular compression. Chart 43-1 lists some of the causes of osteonecrosis. Other than vessel injury and obstruction, the most common known cause is prior corticosteroid therapy.\textsuperscript{38,39} Despite numerous studies, the mechanism of steroid-induced osteonecrosis remains unclear. The condition may develop after the administration of very high, short-term doses; during long-term treatment; or even from intra-articular injection. Although the risk increases with the dose and duration of treatment, it is difficult to predict who will be affected. Of recent concern is the development of osteonecrosis of the jaw with long-term use of bisphosphonates, drugs that are widely used for the treatment of postmenopausal osteoporosis, Paget disease of the bone, and cancer-related conditions.\textsuperscript{40} The pathogenesis of bisphosphonate-associated osteonecrosis of the jaw remains largely unknown. The complication has mainly been reported in patients receiving the drugs intravenously for treatment of malignancies.

The pathologic features of bone necrosis are the same, regardless of cause. The site of the lesion is related to the vessels involved. There is necrosis of cancellous bone and marrow. The cortex usually is not involved because of collateral blood flow. In persons with subchondral infarcts (i.e., ischemia below the cartilage), a triangular or wedge-shaped segment of tissue that has the subchondral bone plate as its base and the center of the epiphysis as its apex undergoes necrosis (Fig. 43-9). In cases where medullary infarcts occur in fatty marrow, death of bone results in the release of calcium and necrosis of fat cells results in the release of free fatty acids.

**FIGURE 43-9**  Osteonecrosis of the head of the femur.

The calcium and free fatty acids form lesions composed of an insoluble "soap." Because bone lacks mechanisms for resolving the infarct, the lesions remain for life.

The symptoms associated with osteonecrosis are varied and depend on the site and extent of infarction. Typically, subchondral infarcts cause chronic pain that is initially associated with activity but that gradually becomes more progressive until it is experienced at rest. Subchondral infarcts often collapse and predispose the patient to severe secondary osteoarthritis.

Diagnosis of osteonecrosis is based on history, physical findings, radiographic findings, and the results of special imaging studies, including CT scans and technetium-99 m bone scans. Treatment depends on the underlying pathologic process. In some cases, only short-term immobilization, nonsteroidal anti-inflammatory drugs, exercises, and limitation in weight bearing are used. Osteonecrosis of the hip is particularly difficult to treat. In persons with early disease, limitation of weight bearing through the use of a walker may allow the condition to stabilize. Although several surgical approaches have been used, the most definitive treatment of advanced osteonecrosis of the knee or hip is total joint replacement.

Neoplasms

Neoplasms of the skeletal system, often referred to as bone tumors, may be benign or malignant, and in the case of malignant neoplasms, may represent a primary tumor or secondary metastatic lesion. Benign tumors greatly outnumber their malignant counterparts and occur with the greatest frequency in the first three decades of life, whereas in the elderly a bone tumor is more likely to be malignant.

Both benign and malignant tumors can develop from the cartilage (chondrogenic), bone (osteogenic), and supporting (fibrogenic) elements of bone, and bone tumors are generally classified according to their tissue counterpart. As a group, these tumors affect all age groups and arise in virtually every bone. Most develop during the first several decades of life and have a propensity to originate in the long bones of the extremities; however, certain types of tumors target specific age groups and anatomic sites. Thus, the location of the tumor provides important diagnostic information.

There are three major manifestations of bone tumors: pain, presence of a mass, and impairment of function. Although benign tumors are frequently asymptomatic and are detected as an incidental finding, malignant tumors are associated with constant, deep aching pain that does not go away with rest and is present at night. However, certain benign tumors also cause night pain. A mass or hard lump may be the first sign of a bone tumor. A malignant tumor is suspected when a painful mass exists that is enlarging or eroding the cortex of the bone. The ease of discovery of a mass depends on the location of the tumor; a small lump arising on the surface of the tibia is easy to detect, whereas a tumor that is deep in the medial portion of the femur may grow to a considerable size before it is noticed. Benign and malignant tumors may cause the bone to erode to the point where it cannot withstand the strain of ordinary use. A sudden increase in pain followed by trivial trauma that is preceded by a history of mild, dull aching pain is suggestive of a pathologic fracture. A tumor also may produce pressure on a peripheral nerve, causing a decreased sensation, numbness, a limp, or limitation in movement.

The diagnosis of bone tumors relies on the history and physical examination, as well radiography, computed tomography, and MRI. Radiographs give the most general diagnostic information, such as malignant versus benign and primary versus metastatic status. The radiograph demonstrates the region of bone involvement, extent of destruction, and amount of reactive bone formed. CT scans further aid diagnosis and anatomic localization and can identify small pulmonary metastases not seen by conventional radiographs. Magnetic resonance imaging is the most accurate method of evaluating the intramedullary extent of bone tumor and can demarcate the soft structures in relation to neurovascular structures without the use of contrast media. It is best used in conjunction with a CT scan. Radionuclide bone scans are used to assess for metastasis. A biopsy may be done to determine the histologic characteristics of the tumor.
Benign Bone Tumors

Benign bone tumors usually are limited to the confines of the bone, have well-demarcated edges, and are surrounded by a thin rim of sclerotic bone. The most common benign tumors are of either fibrous or cartilaginous tissue origin. Benign fibrous tumors of the bone are common in growing bones. They are usually asymptomatic, resolve in 2 to 3 years, and do not require treatment.

Common cartilaginous tumors include chondromas and osteochondromas. Giant cell tumors, which contain mononuclear and osteoclast-type giant cells, are often classified as “intermediate” in nature between malignant and benign.

Chondromas are benign tumors of hyaline cartilage that usually occur in bones of endochondral origin. They can arise within the medullary cavity, where they are known as endochondromas, or on the surface of bone, where they are called subperiosteal or juxtacortical chondromas. They are usually solitary lesions of and are most commonly found in short tubular bones of hands and feet. Most endochondromas are asymptomatic and detected incidentally. Occasionally they are painful and cause fractures. Treatment is usually simple observation, with surgical intervention reserved for cases in which pain or danger of fracture is present.

An osteochondroma, also known as an exostosis, is a benign cartilage-capped tumor that is attached to the underlying bone by a bony stalk. It is the most common benign bone tumor, about 85% of which occur as solitary tumors. The remaining tumors are seen as part of a multiple hereditary exostosis syndrome, which is inherited as an autosomal dominant disorder. Solitary exostoses are usually first diagnosed in late adolescence or early adulthood, but multiple exostoses become apparent in childhood. Exostoses develop only in bones of endochondral origin, arising from the metaphysis near the growth plate of tubular bones, especially about the knee. Clinically, osteochondromas present as slow-growing masses, which can be painful if they impinge on a nerve or if the stalk is fractured. In many cases they are discovered incidentally. In multiple hereditary exostosis, the underlying bone may be bowed and shortened, reflecting an associated disturbance in epiphyseal growth. Osteochondromas usually stop growing at the time of growth plate closure. Malignant changes are rare, and excision of the tumor is done only when necessary.

A giant cell tumor, or osteoclastoma, is an aggressive tumor that often behaves like a malignant tumor, metastasizing through the bloodstream and recurring locally after excision. The tumor is a mixture of mononuclear and multinucleated osteoclast-type giant cells. The mononuclear cells in the tumor express RANKL, and the giant osteoclast-like cells are believed to form via the RANK/RANKL signaling pathway (see Chapter 42).

Giant cell tumors usually arise in people in their thirties or forties. The majority of tumors arise around the knee (distal femur and proximal tibia), but virtually any bone can be involved. The tumor begins in the metaphyseal region, grows into the epiphysis, and may extend into the joint surface. Pathologic fractures are common because the tumor destroys the bone substance.

Clinically, pain may occur at the tumor site, with gradually increasing swelling. X-ray films show destruction of the bone with expansion of the cortex. The biologic unpredictability of these tumors complicates their management. Conservative surgery such as curettage is associated with a 40% to 60% recurrence rate; up to 4% metastasize to the lungs.

Malignant Bone Tumors

In contrast to benign tumors, primary malignant tumors tend to be ill defined, lack sharp borders, and extend beyond the confines of the bone. Primary malignant bone tumors occur in all age groups and may arise in any part of the skeleton. However, certain types of tumors tend to target certain age groups and anatomic sites (Fig. 43-10). For example, most osteosarcomas occur in adolescents and are particularly common around the knee joint. Also, people with certain conditions such as Paget disease are at increased risk for development of bone cancer.
Osteosarcoma

Osteosarcoma is an aggressive and highly malignant bone tumor. It is the most common malignant bone tumor, representing one-fifth of all primary bone tumors. The tumor has a bimodal distribution, with 75% occurring in persons younger than 20 years of age. A second peak occurs in the elderly with predisposing factors such as Paget disease, bone infarcts, or prior irradiation. Overall, men are more commonly affected than women.

The cause of osteosarcoma is unknown. The correlation of age and location of most of the tumors with the period of maximum growth suggests some relation to increased osteoblastic activity. In younger persons, the primary tumor most often is located at the anatomic sites associated with maximum growth velocity—the distal femur, proximal tibia, and proximal humerus. Bone tumors in the elderly are more common in the humerus, pelvis, and proximal femur. There are known genetic factors associated with osteosarcoma. Mutations in two genes are reported to increase susceptibility: the retinoblastoma gene (RB), a critical cell cycle generator; and the p53 gene, which regulates deoxyribonucleic acid (DNA) repair and certain aspects of cellular metabolism (see Chapter 7).

Osteosarcomas are aggressive tumors that grow rapidly in a circular, ball-like mass in the bone tissue. They often are eccentrically placed in the bone and move from the metaphysis of the bone out into the periosteal surface, with subsequent spread to adjacent soft tissues (Fig. 43-11). These tumors spread through the bloodstream; most often, the tumor cells exit the primary tumor through the venous end of the capillary, and early metastasis to the lung is common. Lung metastases, even if massive, usually are relatively asymptomatic. The prognosis for a person with osteosarcoma depends on the aggressiveness of the disease, presence or absence of pathologic fractures, size of the tumor, and rapidity of tumor growth.

The primary clinical feature of osteosarcoma is deep, localized pain with nighttime awakening and swelling in the affected bone. Because the pain is often of sudden onset, patients and their families often associate the symptoms with recent trauma. The skin overlying the tumor may be warm, shiny, and stretched, with prominent superficial veins. The range of motion of the adjacent joint may be restricted.

The treatment of osteosarcoma is surgery in combination with multiagent chemotherapy, both before and after surgery. In the past, treatment usually entailed amputation above the level of the tumor. Limb salvage surgical procedures, using a metal prosthesis or cadaver allograft, are now a standard alternative. In younger children who undergo arthroplasty, an expandable internal prosthesis is used to allow for bone growth. Amputation is another surgical option. It involves either the removal of expendable bones such as the fibula, toes, or ulna, or the complete removal of the tumor and the affected limb.

Chondrosarcoma

Chondrosarcoma consists of malignant tumors of cartilaginous lineage and is commonly subclassified according to site of origin as central (intramedullary) or peripheral (juxtacortical and surface). Chondrosarcomas can arise as a primary tumor from preexisting benign cartilage tumors such as osteochondroma or chondroblastoma. They commonly arise in the central portions of the skeleton, including the pelvis, shoulder, and ribs. Chondrosarcomas develop about half as frequently as osteosarcomas. They occur primarily in middle or later life; however, there are chondromas that occur in younger persons. Chondrosarcomas are slow growing and metastasize late, and often are painless. They can remain hidden in an area such as the pelvis for a long period of time. This type of tumor, like many primary malignancies, tends to destroy bone and extend into the soft tissues beyond the confines of the bone of origin.

Early diagnosis is important because chondrosarcomas respond well to early radical surgical excision. It usually is resistant to radiation therapy and available chemotherapeutic agents. Not infrequently, these tumors transform into a highly malignant tumor, mesenchymal chondrosarcoma, which requires a more aggressive treatment, including combination chemotherapy.

Ewing Sarcoma

Ewing sarcoma is a member of a family of tumors that includes primitive neuroectodermal tumor (PNET). Both tumors are characterized by densely packed, regularly shaped, small cells with round or oval nuclei; and both share a specific reciprocal translocation of chromosomes 11 and 31, or variants thereof.
Ewing sarcoma is primarily a disease of children and young adults and is rarely seen in older adults. Males are affected slightly more frequently than females, and white children have an approximately ninefold higher incidence rate than black children. The most frequent site of Ewing sarcoma is the femur, usually in the diaphysis (see Fig. 43-10). The pelvis represents the second most common site; other sites include the pubis, sacrum, humerus, vertebrae, ribs, skull, and other flat bones. Manifestations of Ewing tumor include bone pain, limitation of movement, and tenderness over the involved bone or soft tissue. It often is accompanied by systemic manifestations such as fever or weight loss, which may serve to confuse the diagnosis. There may be a delay in diagnosis when the pain and swelling associated with the tumor are attributed to a sports injury, or when the tumor is located in the pelvis and the pain is not localized and the mass is not apparent. Pathologic fractures are common because of bone destruction. The most common sites of metastasis are the lungs, bone marrow, and other bones. Because Ewing sarcoma is a difficult diagnosis to establish, the diagnostic biopsy is very important.

Treatment methods incorporate a combination of multiagent chemotherapy, surgery, and radiation therapy. Multiagent chemotherapy can shrink the tumor rapidly, and is generally given before local control measures are initiated. Ewing sarcoma is considered to be a radiosensitive tumor, and local control may be achieved through radiation or surgery. Patients with small, nonmetastatic, distally located tumors generally have the best prognosis.

**Metastatic Bone Disease**

Skeletal metastases are the most common malignancy of osseous tissue. Approximately half of all people with cancer have bone metastasis at some point in their disease. Metastatic lesions are seen most often in the spine, femur, pelvis, ribs, sternum, proximal humerus, and skull, and are less common in anatomic sites more distant from the trunk of the body. Tumors that frequently spread to the skeletal system are those of the breast, lung, prostate, kidney, and thyroid, although any cancer can ultimately involve the skeleton.

The major symptom of bone metastasis is pain with evidence of an impending pathologic fracture. It usually develops gradually, over weeks, and is more severe at night. Pain is caused by stretching of the periosteum of the involved bone or by nerve entrapment, as when the nerve roots of the spinal cord are compressed by the vertebral body. Symptoms of hypercalcemia may occur in cases of bony destruction.

Radiographic examinations are used along with CT or bone scans to detect, diagnose, and localize metastatic bone lesions. A bone biopsy usually is done when there is a question regarding the diagnosis or treatment. Serum levels of alkaline phosphatase and calcium often are elevated in persons with metastatic bone disease.

The primary goals in treatment of metastatic bone disease are to prevent pathologic fractures and promote survival with maximum functioning, allowing the person to maintain as much mobility and pain control as possible. Standard treatment methods include chemotherapy, irradiation, and surgical stabilization. Radiation therapy is primarily used as a palliative treatment to alleviate pain and prevent pathologic fractures. After a pathologic fracture has occurred, bracing, intramedullary nailing of the femur, or spine stabilization may be done. Because adequate fixation often is difficult, bone cement often is used with internal fixation devices to stabilize the bone.

Recent research has focused on the role of osteoclastic and osteoblastic activity in the pathogenesis of metastatic bone disease and on the use of the bisphosphonates (e.g., pamidronate disodium, zoledronic acid) for its treatment. The bisphosphonates, which are now well-established agents for the prevention and treatment of osteoporosis, have recently been shown to decrease symptoms associated with bone metastasis secondary to breast and prostate cancer. These agents bind preferentially to bone at sites of active bone metabolism, are released from the bone matrix during bone resorption, and potentially inhibit osteoclast activity and survival, thereby reducing osteoclast-mediated bone resorption. Recent studies suggest that besides their strong antiosteoclastic activity, these agents may also have some direct antitumor effects.

**SUMMARY CONCEPTS**

- Both benign and malignant tumors can develop from the cartilage (chondrogenic), bone (osteogenic), and supporting (fibrogenic) elements of bone, and bone tumors are generally classified according to their tissue counterpart.
- Benign bone tumors grow slowly and usually do not destroy the surrounding tissues. Malignant tumors can be primary or metastatic. Primary bone tumors are rare, grow rapidly, metastasize to the lungs and other parts of the body through the bloodstream. They include osteosarcoma, which begins in osteogenic cells of the bone and is the most common type of bone cancer; chondrosarcoma, which has its origin in the cartilaginous elements of bone; and Ewing sarcoma, which is characterized by small round cell tumors of bone and soft tissue origin.
- Metastatic bone tumors usually are multiple in occurrence, originating primarily from cancers of the breast, lung, and prostate. A primary goal in metastatic bone disease is the prevention of pathologic fractures.
Angular and Torsional Deformities

All infants and toddlers have lax ligaments that become tighter with age and assumption of the weight-bearing posture. The hypermobility that accompanies joint laxity coupled with the torsional, or twisting, forces exerted on the limbs during growth are responsible for a number of variants seen in young children. Torsional forces caused by intrauterine positions or sleeping and sitting patterns twist the growing bones and can produce deformities as a child grows and develops.

In infants, the femur normally is rotated to an antverted or forward position with the femoral head and neck rotated anteriorly with respect to the femoral condyles. Normally this angle is approximately 40 degrees at birth and declines to 15 to 29 degrees by 8 to 10 years of age. A second source of rotation is found in the tibia. Infants can have 30 degrees of medial rotation of the tibia, and by maturity the rotation is between 5 degrees of medial rotation and 15 degrees of lateral rotation. Abnormalities of rotation may include excessive adduction (turning in or toward the body) or abduction (turning out or away from the body).

Intoeing and Outtoeing. The foot progression angle describes the angle between the axis of the foot and the line of progression. It is determined by watching the child walking and running, although it is usually less noticeable when the child is running or barefoot. Figure 43-13 illustrates the position of the foot in intoeing and outtoeing. Inward rotation of the foot is assigned a negative value and outward rotation is assigned a positive value. The normal value in children and adolescents is 10 degrees (range −3 to 20 degrees).

Variations of Normal Growth and Development

Infants and children undergo changes in muscle tone and joint motion during growth and development. Intoeing, outtoeing, bowlegs, and knock-knees occur frequently in infancy and childhood. They usually cause few problems and are corrected during normal growth processes. The normal folded position of the fetus in utero causes physiologic flexion contractures of the hips and a froglike appearance of the lower extremities (Fig. 43-12). The hips are externally rotated and the patellae point outward, whereas the feet appear to point forward because of the internal pulling force of the tibiae. During the 1st year of life, the lower extremities begin to straighten out in preparation for walking. Internal and external rotations become equal, and the hips extend.

Musculoskeletal assessment of the newborn is important to identify abnormalities that require early intervention, facilitate treatment, establish baselines for future reference, and educate and counsel parents. There are many clinical deviations that are easily correctable in a newborn. Many others correct spontaneously as the child grows.
The foot progression value serves only to define whether there is an intoeing or outtoeing gait. Intoeing may be secondary to foot deformities or may be due to inward rotation of the femur or tibia, or a combination of the two. Increased internal torsion of the femur (femoral anteversion) is the most common finding. In many cases intoeing is a variation of normal development. Outtoeing is a common problem in children and is caused by external femoral torsion. Because the femoral torsion persists when a child habitually sleeps in the prone position, an external tibial torsion also may develop. External tibial torsion rarely causes outtoeing; it only intensifies the condition. Outtoeing usually corrects itself as the child becomes proficient in walking.

Intoeing due to a condition called metatarsus adductus is a common congenital deformity characterized by forefoot adduction with a normal hindfoot, giving the foot a kidney-shaped appearance (Fig. 43-14). It may occur in one foot or both feet. Diagnostic methods include examination of the plantar aspect of the foot, noting the overall shape of the foot and the presence or absence of an arch. The severity of the deformity can be determined by assessing the flexibility of the foot and using a heel bissection line. Normally, a line bisecting the heel crosses the forefoot between the second and third toes. In mild metatarsus adductus, the foot is flexible and can be passively manipulated and the line crosses the third toe; in a moderate deformity, the foot is less flexible and the line falls between the third and fourth toes; and in a severe deformity, the foot is more rigid and the line crosses between the fourth and fifth toes. Most infants do not require treatment, although parents are advised to avoid positioning the infant in the prone position. When needed, treatment consists of serial long leg casting or a brace that pushes the metatarsals (not the hindfoot) into abduction.

Femoral Torsion. Femoral torsion refers to abnormal variations in hip rotation. Hip rotation is measured at the pelvic level with the child in the prone position and the knees flexed at a 90-degree angle (Fig. 43-15A).

In this position, the hip is in a neutral position. Rotating the lower leg outward produces internal or medial femoral rotation; rotating it inward produces external or lateral rotation. During measurement of hip rotation, the legs are allowed to fall to full internal rotation by gravity alone; lateral rotation is measured by allowing the legs to fall inward and cross. Hip rotation in flexion and extension also can be measured with CT.

Excessive internal femoral anteverision is a normal variant commonly seen during the first 6 years of life, especially in 3- and 4-year-old girls. Characteristically, there is 80 to 90 degrees of internal rotation of the hip in the prone position. The condition is thought to be related to increased laxity of the anterior capsule of the hip such that it does not provide the stable pressure needed to correct the anteverision that is present at birth. Children are most comfortable sitting in the "W" position, with their hips between their knees. It is believed that this position allows the lower leg to act as a lever, producing torsional changes in the femur. When the child stands, the knees turn in and the feet appear to point straight ahead, and when the child walks, the

FIGURE 43-14. Shape of foot. The left foot is normal, whereas the right foot has metatarsus adductus.
Tibial Torsion is a rotation of the tibia that makes the feet appear to turn inward. It is the most common cause of intoeing. Infants normally have a mean angle of 5 degrees at birth, which increases to about 10 degrees at 15 degrees at maturity. Tibial torsion improves naturally with growth, but this may take several years.

External or lateral tibial torsion is a much less common disorder. It is usually seen between 4 and 7 years of age, and is often unilateral. The natural growth rotates the tibia externally, and hence external tibial rotation can become worse with time. Clinically, the patella faces outward when the foot is straight. There may be associated patellofemoral instability with knee pain. Although some correction may occur with growth, extremely symptomatic children may require surgical correction, which is usually done after 10 years of age.

Genu Varum and Genu Valgum

Genu varum and genu valgum are common pediatric deformities of the knee. As children grow, lower limb alignment usually follows a predictable pattern (Fig. 43-17). Genu varum, or bowlegs, is an outward bowing of the knees greater than 1 inch when the medial malleoli of the ankles are touching. Most infants and toddlers have some bowing of their legs up to 18 months of age. If there is a large separation between the knees (>15 degrees) after 2 years of age, the child may require bracing. Genu varum can cause gait awkwardness and increased risk for sprains and fractures. The child also should be evaluated for diseases such as rickets or tibia vara (i.e., Blount disease, to be discussed).

Genu valgum, or knock-knees, is a deformity in which there is decreased space between the knees. The medial malleoli in the ankles cannot be brought in contact with each other when the knees are touching. Valgum normally develops after age 24 months and is most apparent between 3 and 4 years of age (see Fig. 43-17). By 7 years of age, the lower limb is in slight valgum and changes very little thereafter. Genu valgum can be ignored up to 7 years of age, unless it is more than 15 degrees, unilateral, or associated with short stature. It usually resolves spontaneously and rarely requires treatment. Uncorrected genu valgum may cause subluxation and recurrent dislocation of the patella, with a predisposition to chondromalacia and joint pain and fatigue. If genu varum or genu valgum persists and is uncorrected, osteoarthritis may develop in adulthood as a result of abnormal intra-articular stress.
bilateral. It has been classified into three types: infantile (1 to 3 years of age), juvenile (4 to 10 years of age), and adolescent (11 years or older). The juvenile and adolescent forms are commonly combined as late-onset tibia vara.

The infantile form of tibia vara, which is commonly bilateral, is the most common. Untreated infantile tibia vara is almost always progressive, with evidence of outward angulation, flexion, internal rotation, and abnormal lateral knee laxity. There is radiographic evidence of progressive depression of the medial metaphysis, the growth plate, and the epiphysis. Fusion of the metaphysis to the epiphysis may occur in severe cases. Night-brace treatment is used for mild early-onset disease. Valgum rotational osteotomy of the tibia is usually indicated if angulation persists beyond 3 years of age.

Persistent tibia vara leads to early degenerative changes of the knee.

Late-onset Blount disease is more common in obese boys who are of normal or greater-than-normal height. The condition may be bilateral or unilateral and characterized by pain rather than deformity as the primary initial complaint. Radiography shows medial femoral and tibial bowing. Bracing is not practical in obese adolescents. Treatment includes osteotomy to realign the limb or lateral growth plate closure to allow growth to “catch up” medially.

**Congenital Disorders**

Congenital skeletal deformities can be caused by many factors, including hereditary influences, external agents that injure the fetus (e.g., radiation, alcohol, drugs, viruses), and intrauterine environmental factors. They range in severity from mild limb deformities, which are relatively common, to major limb malformations, which are relatively rare. The most common anomaly of the toes or fingers is polydactyly; or the presence of an extra digit on the hand or foot. There may also be a simple webbing of the fingers or toes (syndactyly) or the absence of a bone such as the phalanx, rib, or clavicle. Joint contractures and dislocations produce more severe deformity, as does the absence of entire bones, joints, or limbs.

**Osteogenesis Imperfecta**

Osteogenesis imperfecta, or brittle bone disease, is a hereditary disorder caused by deficiencies in the synthesis of type I collagen. Although it is usually transmitted as an autosomal trait, a distinctive form of the disorder with multiple lethal defects is thought to be transmitted as an autosomal recessive trait. In some cases, the disorder is caused by a spontaneous mutation.
The clinical manifestations of osteogenesis imperfecta include a spectrum of disorders marked by extreme skeletal fragility. Four major subtypes of the disorder have been identified (Table 43-2). The disorder is characterized by thin and poorly developed bones that are prone to multiple fractures. These children have short limbs and a soft, thin cranium with bifrontal prominences that give a triangular appearance to the face. Other problems associated with defective connective tissue synthesis include thin skin, blue or gray sclera, abnormal tooth development, hypotonic muscles, loose-jointedness, scoliosis, and a tendency toward hernia formation. Hearing loss due to otosclerosis of the tiny bones in the middle ear is common in affected adults.

The most serious defects occur when the disorder is inherited as a recessive trait (type II). Severely affected fetuses have multiple intrauterine fractures and bowing and shortening of the extremities. Many of these infants are stillborn or die during infancy. Less severe forms occur when the disorder is inherited as a dominant trait. The skeletal system is not as weakened, and fractures often do not appear until the child becomes active and starts to walk, or even later in childhood. These fractures heal rapidly, although with a poor-quality callus. In some cases, parents may be suspected of child abuse when the child is admitted to the health care facility with multiple fractures. There also is an increased incidence of complications such as hernias and congenital heart abnormalities.

There is no definitive treatment for correction of the defective collagen synthesis that is characteristic of osteogenesis imperfecta. However, a short course of treatment with bisphosphonates has been shown to produce an increase in cortical bone width and cancellous bone volume, as well as increased bone strength and mineral content. In children treated with intravenous pamidronate, this has led to a decrease in fractures, improvements in mobility, and less pain. Prevention and treatment of fractures is important. Precise alignment is necessary to prevent deformities. Nonunion is common, especially with repeated fractures. Surgical intervention often is needed to stabilize fractures and correct deformities (e.g., internal fixation of long bones may be done with an intramedullary rod that “grows” with the child).

### Developmental Dysplasia of the Hip

Developmental dysplasia of the hip (DDH), formerly known as congenital dislocation of the hip, is an abnormality in hip development that leads to a wide spectrum of hip problems in infants and children, including hips that are unstable, malformed, subluxated, or dislocated. In less-severe cases, the hip joint may be unstable, with excessive laxity of the joint capsule, or subluxated, so that the joint surfaces are separated and there is a partial dislocation (Fig. 43-19). With dislocated hips, the head of the femur is located outside of the acetabulum.

The results of newborn screening programs have shown that 1 of 250 infants have some evidence of hip instability, whereas actual dislocation of the hip is less common, being found in 1 to 1.5 of every 1000 live births. The left hip is involved more frequently than the right hip because of the left occipital intrauterine positioning of most infants. The disorder occurs most frequently in first-born children and is six times more common in female than in male infants. The cause of DDH is multifactorial, with heredity, environmental, and mechanical factors playing a role. A positive family history and generalized laxity of the ligaments are related. The increased frequency in girls is thought to result from their susceptibility to maternal estrogens and other hormones associated with pelvic relaxation. Dislocation also may result from environmental factors such as fetal position, a tight uterus that prevents fetal movement, and breech delivery. The presence of other congenital abnormalities is associated with an increased incidence.
of DDH. Thus, the hips of children presenting with congenital abnormalities should be examined carefully.

Early diagnosis of DDH is important because treatment is easiest and most effective if begun during the first 6 months of life. Also, repeated dislocations cause damage to the femoral head and the acetabulum. In infants, signs of DDH include asymmetry of the hip or gluteal folds, shortening of the thigh so that one knee (on the affected side) is higher than the other knee, and limited abduction of the affected hip(63–67) (Fig. 43-20). The asymmetry of gluteal folds is not definitive but indicates the need for further evaluation. Physical examination remains the key to the diagnosis of DDH. However, the U.S. Preventive Services Task Force (USPSTF) recently concluded that evidence was insufficient to recommend routine screening of asymptomatic infants as a means of preventing adverse outcomes.(66) This recommendation applies only to infants who do not have obvious hip dislocation or other abnormalities evident without screening.

Several examination techniques can be used to screen for a dislocatable hip. Two provocative dynamic tests for assessing hip stability in the newborn are the Ortolani maneuver (for reducible dislocation) and the Barlow maneuver (for the dislocatable hip)(8,63–65) (Fig. 43-21). The Galeazzi test is a measurement of the length of the femurs that is done by comparing the height at the knees while they are flexed at 90 degrees. An inequality in the height of the knees is a positive Galeazzi sign and is usually caused by hip dislocation or congenital femoral shortening. This test is not useful in detecting bilateral DDH because both leg lengths will be equal. In an older child, instability of the hip may produce a delay in standing or walking and eventually cause a characteristic waddling gait. When the thumbs are placed over the anterior iliac crest and the hands are placed over the lateral pelvis in examination, the levels of the thumbs are not even; the child is unable to elevate the opposite side of the pelvis (positive Trendelenburg test).

Diagnosis of DDH is confirmed by ultrasonography or radiography. Ultrasonography is used in infants with high-risk factors (e.g., female infants born in the breech position) or an abnormal result on examination.(63–67) Radiographs of newborns with suspected DDH are of limited value because the femoral heads do not ossify until 4 to 6 months of age. After 6 months of age, the increasing ossification of the femur renders ultrasonography less reliable, and radiographs are preferred.

Treatment of DDH should be individualized and depends on whether the hip is subluxated or dislocated. Subluxation of the hip at birth often resolves without treatment and should be observed for 2 weeks. When subluxation persists beyond this time, treatment may be indicated and referral is recommended. The best results are obtained if the treatment is begun before changes in the hip structure (e.g., 2 to 3 months) prevent it from being reduced by gentle manipulation or abduction devices. The Pavlik harness is used on newborns (up to 6 months) to maintain the femoral head in the acetabulum. (63) The
principal goals for treatment of children 6 months to 2 years of age are to obtain and maintain reduction of the hip without damaging the femoral head. Closed reduction is often performed under general anesthesia, followed by several months of immobilization in a hip spica cast, plaster splints, or an abduction splint. Surgical treatment may be required for children who fail to maintain a stable hip with closed reduction methods. The most serious complication of any treatment is avascular necrosis of the femoral head as a result of the forced abduction. This most often occurs as a complication of a closed or open reduction in an older child. In addition, hyperflexion has the potential to cause femoral nerve palsies.

### Congenital Clubfoot

Clubfoot, or talipes, is one of the most common pediatric orthopedic conditions. The clubfoot deformity may be positional, congenital, or associated with a variety of other underlying congenital conditions. The positional clubfoot is a normal foot that has been held in a deformed position in utero and is found to be flexible on examination in the nursery. The congenital clubfoot involves a spectrum of severity, while the clubfoot associated with other congenital conditions is typically rigid and difficult to treat.

Congenital clubfoot has an incidence of approximately 1 to 2 cases per 1000 live births, is bilateral in about 50% of cases, and affects boys more often than girls. Like developmental dysplasia of the hip, its occurrence follows a multifactorial inheritance pattern. Clubfoot may be associated with chromosomal abnormalities or congenital syndromes that are transmitted by mendelian inheritance patterns. However, it is most commonly idiopathic and found in normal infants in whom no genetic or chromosomal abnormality or other extrinsic cause can be found.

In forefoot adduction, which accounts for approximately 95% of idiopathic cases, the foot is planter flexed and inverted or twisted toward the midline of the leg. This is the so-called equinovarus type of clubfoot. The other 5% of cases are of the equinovalgus type, or reverse clubfoot, in which the foot is dorsiflexed and everted. Reverse clubfoot can occur as an isolated condition or in association with multiple congenital defects. At birth, the feet of many infants assume one of these two positions, but they can be passively overcorrected or brought back into the opposite position. If the foot cannot be overcorrected, some type of correction may be necessary.

Treatment of clubfoot is begun as soon as the diagnosis is made. When treatment is initiated during the first few weeks of life, a nonoperative procedure may be effective. Serial manipulations and casting are used to gently correct each component of the deformity. One method, called the Ponseti method, involves weekly gentle stretching and manipulation of the misaligned bones followed by application of a well-molded long leg plaster cast with the knee held at a right angle. The cast maintains the correction and allows for further relaxation of tight structures in anticipation of the next week’s casting. Correction of the deformity is usually obtained within 6 to 8 weeks. Frequently, a percutaneous Achilles tendon lengthening is performed using a topical anesthetic cream before application of the final cast to allow for complete correction of the equinus deformity. The correction is maintained by wearing a brace full time for 3 months and part-time wear during napping and at night for approximately 2 to 3 years. Surgery may be required for severe deformities or when nonoperative treatment methods are unsuccessful. It is performed most commonly between 6 and 12 months of age.

### Juvenile Osteochondroses

Juvenile osteochondroses are a group of children’s diseases in which one or more growth ossification centers undergo a period of degeneration, necrosis, or inactivity that is followed by regeneration and usually deformity. The osteochondroses are separated into two groups according to their causes. The first group consists of the true osteonecrotic osteochondroses, so called because the diseases are caused by localized osteonecrosis of an apophyseal or epiphyseal center (e.g., Legg-Calvé-Perthes disease, Freiberg infraction, Panner disease, Kienböck disease). The second group of juvenile osteochondroses is caused by abnormalities in ossification of cartilaginous tissue resulting from a genetically determined normal variation or from trauma (e.g., Osgood-Schlatter disease, Blount disease, Sever disease, Scheuermann disease). The discussion in this section focuses on Legg-Calvé-Perthes disease and Osgood-Schlatter disease.

#### Legg-Calvé-Perthes Disease

Legg-Calvé-Perthes disease is an idiopathic osteonecrotic disease of the proximal (capital) femoral epiphysis with later reabsorption. The disorder usually
(but not exclusively) affects children between the ages of 4 and 8 years. Boys are affected four to five times as often as girls and 10% to 15% of all cases are bilateral. Although no definite genetic pattern has been established, it occasionally affects more than one family member.

The cause of Legg-Calvé-Perthes disease is unknown. The disorder usually is insidious in onset and occurs in otherwise healthy children. It may, however, be associated with acute trauma. Affected children usually have a shorter stature. Recent evidence suggests that some cases may be caused by a subclinical hypercoagulable state such as deficiency in antithrombotic factors S or C or a decrease in fibrinolysis. When girls are affected, they usually have a poorer prognosis than boys because they are skeletally more mature and have a shorter period for growth and remodeling than boys of the same age.

The primary pathologic feature of Legg-Calvé-Perthes disease is an avascular necrosis of the bone and marrow involving the epiphyseal growth center in the femoral head. The disorder may be confined to part of the epiphysis, or it may involve the entire epiphysis. In severe cases, there is a disturbance in the growth pattern that leads to a broad, short femoral neck. The necrosis is followed by slow absorption of the dead bone over 2 to 3 years. Although the necrotic trabeculae eventually are replaced by healthy new bone, the epiphysis rarely regains its normal shape.

The main symptoms of Legg-Calvé-Perthes disease are pain in the groin, thigh, or knee and difficulty in walking. The child may have a painless limp with limited abduction and internal rotation and a flexion contracture of the affected hip. The age of onset is important because young children have a greater capability for remodeling of the femoral head and acetabulum, and thus less flattening of the femoral head occurs. Early diagnosis is important and is based on correlating physical symptoms with radiographic findings that are related to the stage of the disease.

The goal of treatment is to reduce deformity and preserve the integrity of the femoral head. Conservative and surgical interventions are used in the treatment of Legg-Calvé-Perthes disease. Children younger than 4 years of age with little or no involvement of the femoral head may require only periodic observation. In other children, some intervention is needed to relieve the force of weight bearing, muscular tension, and subluxation of the femoral head. It is important to maintain the femur in a well-seated position in the concave acetabulum to prevent deformity. This is done by keeping the hip in abduction and mild internal rotation. Treatment involves periods of rest, use of assistive devices for walking, non-weight-bearing, and abduction braces to keep the legs separated in abduction with mild internal rotation. The Atlanta Scottish Rite brace, which does not extend below the knee, is the most widely used orthosis because it provides containment while allowing free knee motion and ambulation without crutches or external support (Fig. 43-23). Surgery may be done to contain the femoral head in the acetabulum. This treatment usually is reserved for children older than 6 years of age who at the time of diagnosis have more serious involvement of the femoral head. The best surgical results are obtained when surgery is done early, before the epiphysis becomes necrotic.

**FIGURE 43-23.** Scottish Rite brace for Legg-Calvé-Perthes disease produces containment for abduction and allows free knee motion. (From Crocetti M, Barone MA. Oski’s Essential Pediatrics. 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2004:679.)

**Osgood-Schlatter Disease**

Osgood-Schlatter disease involves microfractures in the area where the patellar tendon inserts into the tibial tubercle. This area, which is an extension of the proximal tibial epiphysis, is particularly vulnerable to injury caused by sudden or continued strain from the patellar tendon during periods of growth. It occurs most frequently in boys between the ages of 10 and 15 years and in girls about 2 years before that in boys.

The disorder is characterized by pain in the front of the knee that is associated with inflammation and thickening of the patellar tendon. The pain usually is associated with specific activities such as kneeling, running, bicycle riding, or stair climbing. There is swelling, tenderness, and increased prominence of the tibial tubercle.

The symptoms usually are self-limiting. They may recur during growth periods, but usually resolve after closure of the tibial growth plate.

Treatment consists of rest, restriction of activities, and occasionally a knee immobilizer. Complete resolution of symptoms through healing (physical closure) of the tibial tubercle usually requires 12 to 24 months. Occasionally, minor symptoms or an increased prominence of the tibial tubercle may continue into adulthood.

**Slipped Capital Femoral Epiphysis**

Slipped capital femoral epiphysis, or coxa vara, is a disorder of the growth plate that occurs near the age of skeletal maturity. It involves a three-dimensional displacement of the epiphysis (posteriorly, medially, inferiorly),
meaning that the femur is rotated externally from under the epiphysis. It is considered the most common hip disorder of adolescence with an increased prevalence among males, most often between 11 and 16 years of age.72 The cause of slipped capital femoral epiphysis is obscure, but it may be related to the child’s susceptibility to stress on the femoral neck as a result of genetics or structural abnormalities. Affected children often are overweight with poorly developed secondary sex characteristics, or, in some instances, are extremely tall and thin. In many cases, there is a history of rapid skeletal growth preceding displacement of the epiphysis. The condition also may be affected by nutritional deficiencies or endocrine disorders such as hypothyroidism, hypopituitarism, and hypogonadism.

Children with the condition often complain of referred knee pain accompanied by difficulty in walking, fatigue, and stiffness. The diagnosis is confirmed by radiographic studies in which the degree of slipping is determined and graded according to severity.72 Early treatment is imperative to prevent further slippage and permanent deformity. Avoidance of weight bearing on the femur and bed rest are essential parts of the treatment. Traction or gentle manipulation under anesthesia is used to reduce the slip. Surgical insertion of pins to keep the femoral neck and head of the femur aligned is a common method of treatment for children with moderate or severe slips. Crutches are used for several months after surgical correction to prevent full weight bearing until the growth plate closes.

Children with the disorder must be followed closely until the epiphyseal plate closes. Long-term prognosis depends on the amount of displacement that occurs. Complications include avascular necrosis, leg shortening, malunion, and problems with internal fixation. Degenerative arthritis may develop, requiring joint replacement later in life.

Scoliosis

Scoliosis is a lateral curvature of the spine in the upright position. Scoliosis is classified as postural or structural. With postural scoliosis, there is a small curve that corrects with bending. It can be corrected with passive and active exercises. Structural scoliosis does not correct with bending. It is a fixed deformity classified according to the cause: congenital, neuromuscular, or idiopathic.75–79

Types of Scoliosis

Congenital scoliosis is caused by disturbances in vertebral development during the sixth to eighth week of embryologic development.75–79 It may involve failures of formation or failures of segmentation. Failures of formation indicate the absence of a portion of the vertebra, such as hemivertebra (absence of a whole side of the vertebra) and wedge vertebra (missing only a portion of the vertebra). Failure of segmentation is the absence of the normal separation between the vertebrae. The child may have other anomalies and neurologic complications if the spine is involved. Early diagnosis and treatment of progressive curves are essential for children with congenital scoliosis. Surgical intervention is the treatment of choice for progressive congenital scoliosis.

In neuromuscular scoliosis, there is often a long, C-shaped curve from the cervical to the sacral region. It is seen in children with cerebral palsy, in whom severe deformity may make treatment difficult. It also develops in children with Duchenne muscular dystrophy and usually is not severe.

Idiopathic scoliosis is a structural spinal curvature for which no cause has been established. It occurs in healthy, neurologically normal children. Although the incidence is only slightly greater in girls than boys, it is more likely to progress and require treatment in girls.8,77–79 It seems likely that heredity is involved because mother–daughter pairings are common, but identical twins are not uniformly affected, and the magnitude of the curvature in an affected individual is not related to magnitude of curvature in relatives. A recent study of the melatonin receptor 1B (MTNR1B) gene in persons with adolescent idiopathic scoliosis suggests that the MTNR1B gene may serve as a susceptibility gene.81

Idiopathic scoliosis usually appears clinically between the age of 10 and skeletal maturity, but may be seen at any age. By definition, the curve must be greater than 10 degrees—this has historically been used because 10 degrees is the limit that can be detected by physical examination.8 Although the curve may be present in any area of the spine, the most common curve is a right thoracic curve.

Manifestations

Scoliosis usually is first noticed because of the deformity it causes. A high shoulder, prominent hip, or projecting scapula may be noticed by a parent or in a school-based screening program (Fig. 43-24). Idiopathic scoliosis is usually not painful. However, as the curve increases, there may be referred knee pain accompanied by difficulty in walking, fatigue, and stiffness. The diagnosis is confirmed by radiographic studies in which the degree of slipping is determined and graded according to severity.72 Early treatment is imperative to prevent further slippage and permanent deformity. Avoidance of weight bearing on the femur and bed rest are essential parts of the treatment. Traction or gentle manipulation under anesthesia is used to reduce the slip. Surgical insertion of pins to keep the femoral neck and head of the femur aligned is a common method of treatment for children with moderate or severe slips. Crutches are used for several months after surgical correction to prevent full weight bearing until the growth plate closes.

Children with the disorder must be followed closely until the epiphyseal plate closes. Long-term prognosis depends on the amount of displacement that occurs. Complications include avascular necrosis, leg shortening, malunion, and problems with internal fixation. Degenerative arthritis may develop, requiring joint replacement later in life.

FIGURE 43-24. Scoliosis: Abnormalities to be determined at initial screening examination.
Diagnostic Imaging

Early diagnosis of scoliosis can be important in the prevention of severe spinal deformity. The cardinal signs of scoliosis are uneven shoulders or iliac crest, prominent scapula on the convex side of the curve, misalignment of the spinous processes, asymmetry of the flanks, asymmetry of the thoracic cage, and rib hump or paraspinal muscle prominence when bending forward (see Fig. 43-24).

A complete physical examination is necessary for children with scoliosis because the deformity may be indicative of other, underlying pathologic processes.

Diagnosis of scoliosis is made by physical examination and confirmed by radiography. A scoliometer is used at the apex of the curvature to quantify a prominence; a scoliometer reading of greater than 10 degrees requires referral to a physician. The curve is measured by determining the amount of lateral deviation present on radiographs and is labeled “right” or “left” for the convex portion of the curve. Other radiographic procedures may be done, including CT scanning, MRI, and myelography.

Although school screening continues to be mandated in a number of states, the USPSTF recommends against the routine screening of asymptomatic adolescents for idiopathic scoliosis, indicating that the potential harms from screening include unnecessary follow-up visits and evaluations due to false-positive results, and adverse psychological effects, especially related to brace wear. It is recommended, however, that health care professionals be prepared to evaluate idiopathic scoliosis when it is discovered incidentally or when an adolescent or parent expresses concern about scoliosis.

The treatment of scoliosis depends on the severity of the deformity and the likelihood of curve progression. The three determinants of progression are gender, the curve magnitude at the time of diagnosis, and skeletal growth potential. In all cases, girls have a risk progression 10 times greater than that of boys. Larger curves are more likely to progress. Age of presentation also is important. Curves that are detected before menarche are more likely to progress than those detected after menarche. For persons with lesser degrees of curvature (10 to 20 degrees), the trend has been away from aggressive treatment and toward a “wait and see” approach, taking advantage of the more sophisticated diagnostic methods that now are available. Treatment is considered for physically immature patients with curves between 20 and 30 degrees. Curves between 30 and 40 degrees usually are considered for bracing, and those greater than 40 to 45 degrees are considered for surgery.

A brace may be used to control the progression of the curve and maintain the spine in the corrected position. Several methods of instrumentation (i.e., rods that attach to the vertebral column and posterior fusion) are used. Combined anterior and posterior surgery is used for more severe curves. The newer systems provide better sagittal control and more stable fixation, which allows earlier mobility. Despite great advances in spinal surgery, no one method seems to be the best for all cases. There is recent interest in growth modulation approaches using minimally invasive techniques, which will result in curve correction while preserving spinal motion and intervertebral disk viability.

SUMMARY CONCEPTS

- Skeletal disorders can result from congenital or hereditary influences or from factors that occur during normal periods of skeletal growth and development. Newborn infants undergo normal changes in muscle tone and joint motion, causing torsional conditions of the femur or tibia. Many of these conditions are corrected as skeletal growth and development take place.
- Osteogenesis imperfecta is a rare autosomal hereditary disorder characterized by defective synthesis of connective tissue, including bone matrix. It results in poorly developed bones that fracture easily.
- Disorders such as developmental dysplasia of the hip and congenital clubfoot are present at birth. Both of these disorders are best treated during infancy. Regular examinations during the first year of life are recommended as a means of achieving early diagnosis.
- Other childhood skeletal disorders, such as the juvenile osteochondroses and slipped capital femoral epiphysis, are not corrected by the growth process. These disorders are progressive, can cause permanent disability, and require treatment.

(continued)
SUMMARY CONCEPTS (continued)

- Scoliosis is a lateral curvature of the spine. It is classified as congenital, which results from defects in vertebral development; neuromuscular, which is caused by diseases such as cerebral palsy; and idiopathic, which is the most common form. Idiopathic scoliosis affects girls more often than boys and usually becomes evident between age 10 years and skeletal maturity. The treatment of scoliosis depends on the severity of the deformity and the likelihood of curve progression. Curves between 30 and 40 degrees usually are considered for bracing, and those greater than 40 to 45 degrees are considered for surgery.

REVIEW EXERCISES

1. A 34-year-old football player dislocates his hip during a game.
   
   A. Explain the need for immediate reduction of the dislocation based on the vascular anatomy of the hip.

2. A 39-year-old man is in intensive care after a motorcycle accident in which he skidded across the pavement on his right side. He has fractures of his right femur, pelvis, and several ribs on the right side. His right leg was crushed beneath the motorcycle, and he is beginning to lose movement in that leg.
   
   A. What are the priorities in treating his orthopedic injuries? What are the available options for stabilizing his leg?
   B. What risk factors for complications of fractures are present?
   C. What are the symptoms of compartment syndrome, and how is it treated?

3. A 73-year-old woman with a history of breast cancer sustained a comminuted fracture in the mid-diaphysis of her left humerus when her husband lifted her up in bed. She has multiple lucent lesions scattered throughout her proximal humerus, radius, and ulna. She was recently hospitalized for confusion and found to have diffuse bone metastases.
   
   A. What would you consider to be the most likely cause of her fracture?
   B. What are the most common sites for bone metastasis?
   C. Explain the treatment goals for persons with pathologic fractures.

4. A 14-year-old boy complains of recent pain and swelling of the knee, with some restriction in movement. Although he thinks he may have injured his knee playing football, his mother insists that he be seen by an orthopedic specialist and raises the possibility that the boy may have an osteosarcoma.
   
   A. Use the information that osteosarcoma originates in sites of maximal growth velocity to explain the site of this boy’s possible tumor.
   B. What diagnostic tests could be used to establish a diagnosis of osteosarcoma?
   C. The boy and his family are concerned that the boy will require radical surgery with amputation of the leg. How would you go about explaining possible treatment options to him?

5. A newborn girl was found to have developmental dysplasia of the hip during a routine screening examination.
   
   A. Describe the anatomic abnormalities that are present in the disorder.
   B. Explain the need for early treatment of developmental dysplasia of the hip.

Chapter 44

Disorders of the Skeletal System: Metabolic and Rheumatic Disorders

The skeletal system plays an essential role in mineral homeostasis and mobility. The bones of the skeletal system provide the basic framework that supports the body, protects its organs, and provides for movement. Joints hold the bones of the skeleton together, making movement possible. Bone is also one of the few tissues that normally undergo mineralization. It is a storehouse for 99% of the body’s calcium and 85% of its phosphorus. This chapter focuses on two types of skeletal disorders: metabolic bone diseases, which produce a decrease in bone mass and mineralization, and joint disorders, which disrupt mobility.

Metabolic Bone Disease

Metabolic bone disease represents disorders of bone metabolism that result in structural effects on the skeleton, including decreased bone density and diminished bone strength. The strength of bone is determined by its composition and structure. It must be rigid enough to support the body, yet flexible enough to absorb energy by deforming, to shorten and widen when compressed, and to lengthen and narrow under tension without cracking.

There are two types of bone: cortical and trabecular. Cortical or compact bone is composed of densely packed layers of mineralized collagen; it provides rigidity and is the major component of tubular bones (see Chapter 42, Fig. 42-1). Trabecular or cancellous bone is spongy on cross-section; it provides strength and elasticity, and constitutes the major part of axial skeletal structures such as the vertebrae. Disorders in which cortical bone is defective or reduced in mass lead to fractures of the long bones, whereas those of cancellous bone lead preferentially to vertebral fractures.
Osteopenia

Osteopenia is a condition that is common to all metabolic bone diseases. It is characterized by a reduction in bone mineral density greater than expected for age, race, or gender, and occurs because of a decrease in bone formation, inadequate bone mineralization, or excessive bone deossification. Osteopenia is not a diagnosis but a term used to describe an apparent loss of bone density seen on x-ray studies. Approximately 60% of bone is mineral content, approximately 30% is organic matrix, and the remainder is living bone cells. Osteopenia can involve a decrease in bone matrix due to an imbalance between bone formation and destruction, or a decrease in mineralization. The major causes of osteopenia are osteoporosis, osteomalacia, malignancies such as multiple myeloma, and endocrine disorders such as hyperparathyroidism and hyperthyroidism.

Osteoporosis

Osteoporosis is a metabolic bone disease characterized by decreased bone density (i.e., increased porosity) and strength in which both the bone matrix and mineralization are decreased. The World Health Organization has defined osteoporosis as a bone mineral density (BMD) value greater than 2.5 standard deviations (SD) below the mean for a young adult reference population. The most useful methods of estimating fracture risk are BMD testing and consideration of clinical risk factors for fracture. Fracture risk assessment tests, such as the International Osteoporosis Foundation one-minute osteoporosis risk test, are available online to estimate the fracture probability.

Osteoporosis can occur as the result of a number of disorders, but is most often associated with the aging process. In the United States alone, osteoporosis affects approximately 10 million persons aged 50 years or older, and an additional 34 million have low bone mass (osteopenia) and are potentially at risk for development of osteoporosis and its complications.

Etiology and Pathogenesis

The cause of osteoporosis remains largely unknown, but most data suggest an imbalance between bone resorption and formation such that bone resorption exceeds bone formation. Although both of these factors play a role in most cases of osteoporosis, their relative contribution to bone loss may vary depending on age, gender, genetic predisposition, activity level, and nutritional status.

Under normal conditions, bone mass increases steadily during childhood, reaching a peak in the young adult years. The peak bone mass, or BMD, is an important determinant of the subsequent risk for osteoporosis. It is determined in part by genetic factors, hormone (estrogen) levels, exercise, calcium intake and absorption, and environmental factors (Chart 44-1). Genetic factors are linked, in largest part, to the maximal amount of bone in a given person, referred to as peak bone mass. Race is a key determinant of BMD and the risk of fractures. Incidence rates obtained from studies among racial and ethnic groups demonstrate that although women have higher fracture rates compared with men overall, these differences vary by race and age. White and Asian women had higher rates for all age groups older than 50 years. The highest BMD values and lowest fracture rates have been reported for black women. Body size is another factor affecting the risk of osteoporosis and risk of fractures. Women with smaller body builds are at increased risk of hip fracture because of lower hip BMD.

Hormonal factors play a significant role in the development of osteoporosis, particularly in postmenopausal women. Postmenopausal osteoporosis, which is caused by an estrogen deficiency, is manifested by a loss of cancellous bone and a predisposition to fractures of the vertebrae and distal radius. The loss of bone mass is greatest during early menopause, when estrogen levels are withdrawing. Several factors appear to influence the increased loss of bone mass associated with an estrogen deficiency, including an increased secretion of cytokines by monocytes and bone marrow cells. These cytokines stimulate osteoclast recruitment and activity by increasing the levels of RANK ligand (RANKL) while...
diminishing the expression of osteoprotegerin (OPG) (see Chapter 42, Understanding Bone Remodeling). Compensatory osteoblastic activity and new bone formation occurs, but does not keep pace with the bone that is lost.

Male sex hormone deficiency may contribute to age-related bone loss in men, although the effect is not of the same magnitude as that caused by estrogen deficiency. Unlike women, men do not have a midlife loss of sex hormone production. Another factor that provides relative protection for men is the fact that they achieve 8% to 10% more peak bone mass than women. Although androgens have long been assumed to be critical for growth and maintenance of the male skeleton, it has recently been suggested that estrogens obtained from peripheral conversion of testicular and adrenal hormone precursors may be even more important than androgens in the maintenance of bone mass in men.

Age-related changes in bone density occur in all individuals and contribute to the development of osteoporosis in both sexes. Age-related changes in bone cells and matrix have a strong impact on bone metabolism. Osteoblasts from elderly persons have reduced replicative and biosynthetic potential compared with those of younger persons. Growth factors that stimulate osteoblastic activity also lose their potential over time. The end result is a skeleton that has decreased ability to make bone. Reduced physical activity increases the rate of bone loss because mechanical forces are important stimuli for normal bone remodeling. Thus, the decreased physical activity that often accompanies aging may also contribute to the loss of bone mass in the elderly.

Secondary osteoporosis is associated with many conditions, including endocrine disorders, malabsorption disorders, malignancies, alcoholism, and certain medications. Persons with endocrine disorders such as hyperthyroidism, hyperparathyroidism, Cushing syndrome, or diabetes mellitus are at high risk for development of osteoporosis. Hyperthyroidism causes an acceleration of bone turnover. Some malignancies (e.g., multiple myeloma) secrete osteoclast-activating factor, causing significant bone loss. Alcohol is a direct inhibitor of osteoblasts and may also inhibit calcium absorption. Corticosteroid use is the most common cause of drug-related osteoporosis, and long-term corticosteroid use in the treatment of disorders such as rheumatoid arthritis and chronic obstructive lung disease is associated with a high rate of fractures. The prolonged use of aluminum-containing antacids, which increase calcium excretion, and anticonvulsants, which impair vitamin D production, may also contribute to bone loss. Persons with human immunodeficiency virus (HIV) infection or acquired immunodeficiency syndrome (AIDS) who are being treated with antiretroviral therapy may develop a decrease in bone density and signs of osteopenia and osteoporosis.

Several groups of children and adolescents are at particular risk for decreased bone mass, including premature infants and those with low birth weight who have lower-than-expected bone mass in the early weeks of life, and children who require treatment with corticosteroid drugs (e.g., those with childhood inflammatory diseases and transplant recipients). Children with cystic fibrosis often have impaired gastrointestinal function that reduces the absorption of calcium and other nutrients, and many also require the frequent use of corticosteroid drugs.

Premature osteoporosis is increasingly being seen in female athletes due to an increased prevalence of eating disorders and amenorrhea. It most frequently affects women engaged in endurance sports, such as running and swimming; in activities where appearance is important, such as figure skating, diving, and gymnastics; or in sports with weight restrictions, such as horse racing, martial arts, and rowing. The \textit{female athlete triad} refers to a pattern of disordered eating that leads to amenorrhea and eventually osteoporosis. Poor nutrition, combined with intense training, can decrease the critical body fat–to–muscle ratio needed for normal menses and estrogen production by the ovary. The decreased levels of estrogen combined with the lack of calcium and vitamin D from dietary deficiencies result in a loss of bone density and increased risk for fractures. There is a concern that athletes with low BMD will be at increased risk for fractures during their competitive years. It is unclear whether osteoporosis induced by amenorrhea is reversible. Data are emerging that even having only one or two elements of the triad greatly increases the risk of these women for long-term morbidity.

**Clinical Features**

Osteoporotic changes occur in the diaphysis and metaphysis of bone. There is loss of trabeculae from cancellous bone and thinning of the cortex to such an extent that minimal stress causes fractures. The changes that occur with osteoporosis have been explained by two distinct disease processes: postmenopausal, or age-related, osteoporosis. In postmenopausal women, the increase in osteoclastic activity affects mainly bones or portions of bone that have increased surface area, such as the cancellous compartment of the vertebral bodies. The osteoporotic trabeculae become thinned and lose their interconnections, leading to microfractures and eventual vertebral collapse. In senile osteoporosis, the osteoporotic cortex is thinned by subperiosteal and endosteal resorption and the haversian systems are widened. In severe cases, the haversian systems are so enlarged that the cortex resembles cancellous bone (Fig. 44-1). Hip fractures, which are seen later in life, are more commonly associated with senile osteoporosis.

**Clinical Manifestations.** Osteoporosis is usually a silent disorder. Often, the first manifestations of the disorder are those that accompany a skeletal fracture—a vertebral compression fracture or fracture of the hip, pelvis, humerus, or other bones (Fig. 44-2). Fractures are typically sudden in onset and may be caused by a fall, sudden movement, lifting, jumping, or even coughing. Hip fractures occur mainly in persons over age 65. Wedging and collapse of vertebral cause a loss of height in the vertebral column and kyphosis, a condition
commonly referred to as dowager hump. Usually, there is no generalized bone tenderness. When pain occurs, it usually is related to fractures. Systemic symptoms such as weakness and weight loss suggest that the osteoporosis may be caused by underlying disease.

**Diagnosis and Treatment.** An important advance in diagnostic methods used for the identification of osteoporosis has been the use of BMD assessment. The clinical method of choice for BMD studies is dual-energy x-ray absorptiometry (DEXA) of the spine and hip. Measurement of serial heights in older adults is another simple way to screen for osteoporosis. A further advance in the diagnosis of osteoporosis is the refinement of risk factors, permitting better analysis of risk pertaining to particular persons. The U.S. Preventive Services Task Force (USPSTF) recommends a screening DEXA of all women 65 years of age and older, as well as women 60 to 64 years of age who have an increased fracture risk. Although there are no USPSTF guidelines for BMD testing in men, the National Osteoporosis Foundation (NOF) recommends screening for all men 70 years of age and older and men 50 to 69 years of age with risk factors.

Prevention and early detection of osteoporosis are essential to the prevention of associated deformities and fractures. It is important to identify persons in high-risk groups so that preventive measures can begin early (see Chart 44-1). Regular exercise and adequate calcium and vitamin D intake are important factors in preventing osteoporosis. Weight-bearing exercises such as walking, jogging, rowing, and weight lifting are important in the maintenance of bone mass. Studies have indicated that premenopausal women need more than 1000 mg/day of calcium, and postmenopausal women need at least 1200 mg of calcium daily. Because most older American women do not consume a sufficient quantity of dairy products to meet their calcium needs, calcium supplementation is recommended. A daily intake of 800 to 1000 IU of vitamin D is recommended for adults age 50 years and older. Many elderly persons are at high risk for vitamin D deficiency, especially those with chronic illness, malabsorption disorders (e.g., celiac disease), and limited exposure to sunlight. It is recommended that serum vitamin D levels be obtained for persons at risk of a deficiency and that supplemental vitamin D be prescribed for persons with low serum levels.

There are five main types of drugs used in the treatment of osteoporosis: bisphosphonates, selective estrogen receptor modulators (SERMs), calcitomin, recombinant parathyroid hormone, and the RANKL inhibitor denosumab. Bisphosphonates are effective inhibitors of bone resorption and the most effective agents for prevention and treatment of osteoporosis. The bisphosphonates (e.g., alendronate, risedronate, ibandronate, zoledronate) are analogs of endogenous inorganic pyrophosphate that the body cannot break down. In bone, they bind to hydroxyapatite and prevent
bone resorption by inhibiting osteoclast activity. The most dramatic impact has been in the reduction of multiple spine fractures, showing that treatment can decrease progression of the disease. These drugs are effective in men as well women and for various causes of osteoporosis.24

Raloxifene, a selective estrogen receptor modulator (SERM) that acts only on specific estrogen receptors, has been approved for prevention and treatment of osteoporosis in postmenopausal women. Although hormone therapy (i.e., estrogen with or without progesterone) has been shown to slightly reduce the risk of hip and vertebral fractures in postmenopausal women, the use of hormone therapy has come under scrutiny after the release of data from the Women’s Health Initiative, which linked hormone replacement therapy to an increased risk of stroke, venous thromboembolism, coronary heart disease, and breast cancer.25 Raloxifene does not prevent hot flashes associated with menopause and it imposes the same risk of venous thrombosis as estrogen.24

Calcitonin is an endogenous peptide that partially inhibits osteoclastic activity. Nasal calcitonin has been approved for the treatment of postmenopausal osteoporosis. It has been shown to decrease the occurrence of vertebral fractures, but not nonvertebral or hip fractures. Because more effective drugs are available, it is not usually considered first-line treatment for osteoporosis.

Teriparatide, a recombinant human parathyroid hormone, stimulates bone remodeling by increasing osteoblast-mediated bone formation. Unlike the fluoride, this bone appears structurally normal and is associated with substantial reduction in the incidence of fractures. Teriparatide is given by injection and is approved for only 2 years of use.24

Denosumab, the RANKL inhibitor, has recently been approved for treatment of postmenopausal osteoporosis.24 It is given subcutaneously every 6 months. Like the bisphosphonates it suppresses bone resorption and secondary bone formation. Denosumab reduces the risk of both vertebral and nonvertebral fractures with comparable effectiveness to the potent bisphosphonates.24

To reduce their fracture risk, persons with osteoporosis should correct conditions in their homes that pre-dispose them to falls. They should follow their health care provider’s prescribed diet and program of physical activity. In treating fractures, it is important to minimize immobility. Surgical interventions are used to provide stable fixation of lower extremity fractures and allow for early weight bearing and restoration of mobility and function. Vertebral fractures are treated symptomatically. Conservative treatment with bracing is most often seen, especially in fractures of the thoracic vertebra.

Osteomalacia and Rickets

In contrast to osteoporosis, which causes a loss of total bone mass and results in brittle bones, osteomalacia and rickets produce a softening of the bones resulting from an inadequate mineralization of newly formed bone matrix.2 The term rickets refers to the disorder in children in which changes in bone growth produce characteristic skeletal abnormalities, and osteomalacia is used in adults because the bone that forms during the remodeling process is undermineralized.4

Osteomalacia

Osteomalacia is a generalized bone condition in which there is inadequate mineralization of bone.3,4,15 There are two main causes of osteomalacia: (1) insufficient calcium absorption from the intestine because of a lack of dietary calcium or a deficiency of or resistance to the action of vitamin D and (2) phosphate deficiency caused by increased renal losses or decreased intestinal absorption. Vitamin D is ingested in the diet and synthesized in the skin from 7-dehydrocholesterol under the influence of ultraviolet B (UVB) sunlight. The vitamin is first hydroxylated in the liver to form its major metabolite, 25-hydroxyvitamin D. It is then hydroxylated in the kidney to produce the active hormone 1,25(OH)2D (see Chapter 42). There are many causes of vitamin D deficiency including reduced skin synthesis, inadequate dietary intake, diminished intestinal absorption, and heritable and acquired disorders of vitamin D metabolism and responsiveness.26,27

The incidence of osteomalacia is high among the elderly because of diets deficient in calcium and vitamin D, a problem often compounded by the intestinal malabsorption that accompanies aging. Melanin is extremely efficient in absorbing UVB radiation; thus, decreased skin pigmentation markedly reduces vitamin D synthesis, as does the use of sunscreens. Osteomalacia also may occur in persons on long-term treatment with medications such as anticonvulsants (e.g., phenytoin, carbamazepine, valproate) that decrease the activation of vitamin D in the liver. There also is a greater incidence of osteomalacia in the colder regions of the world, particularly during the winter months when UVB radiation is inadequate to allow skin synthesis of vitamin D.

A form of osteomalacia called renal rickets occurs in persons with chronic renal failure. It is caused by the inability of the kidney to activate vitamin D and excrete phosphate and is accompanied by hyperparathyroidism, increased bone turnover, and increased bone resorption (see Chapter 26). Another form of osteomalacia results from renal tubular defects that cause excessive phosphate losses. This form of osteomalacia is commonly referred to as vitamin D–resistant rickets, and often is a familial disorder.4 It is inherited as an X-linked dominant gene passed by mothers to one half of their children and by fathers to their daughters only. This form of osteomalacia affects boys more severely than girls. Long-standing primary hyperparathyroidism causes increased calcium resorption from bone and hypophosphatemia, which can lead to rickets in children and osteomalacia in adults.

The clinical manifestations of osteomalacia are bone pain, tenderness, and fractures as the disease progresses. In severe cases, muscle weakness often is an early sign. Osteomalacia predisposes a person to pathologic
fractures in the weakened bones, especially those in the distal radius and the proximal femur. In contrast to osteoporosis, it is not a significant cause of hip fractures. There may be delayed healing and poor retention of internal fixation devices. Osteomalacia usually is accompanied by a compensatory or secondary hyperparathyroidism stimulated by low serum calcium levels. Parathyroid hormone reduces renal absorption of phosphate and removes calcium from the bone. Serum calcium levels are only slightly reduced in osteomalacia.

Diagnostic measures are directed toward identifying osteomalacia and establishing its cause. Diagnostic methods include x-ray studies, laboratory tests, bone scan, and bone biopsy. X-ray findings typical of osteomalacia are the development of transverse lines or pseudofractures called Looser zones. These apparently are caused by stress fractures that are inadequately healed or by the mechanical inadequacy of penetrating nutrient vessels. A bone biopsy may be done to confirm the diagnosis of osteomalacia in a person with nonspecific osteopenia who shows no improvement after treatment with exercise, vitamin D, and calcium.

The treatment of osteomalacia is directed at the underlying cause. If the problem is nutritional, restoring adequate amounts of calcium and vitamin D to the diet may be sufficient. The elderly and persons with an inadequate dietary intake or sunlight exposure may require supplemental vitamin D. Supplemental vitamin D is specific for vitamin D-resistant rickets, but large doses usually are needed to overcome the resistance to calcium absorption action and to prevent renal loss of phosphate. The biologically active forms of vitamin D, 25-OH vitamin D (calciferol) or 1,25-(OH)2 vitamin D (calcitriol), are available for use in the treatment of osteomalacia resistant to vitamin D (i.e., osteomalacia resulting from chronic liver disease and kidney failure). If osteomalacia is caused by malabsorption, the treatment is directed toward correcting the primary disease. For example, adequate replacement of pancreatic enzymes is of paramount importance in pancreatic insufficiency. In renal tubular disorders, the treatment is directed at the altered renal physiology.

Rickets

Rickets is a metabolic bone disorder characterized by a failure or delay in calcification of the cartilaginous growth plate in children whose epiphyses have not yet fused.28-30 It is also manifested by widening and deformation of the metaphyseal regions of long bones and a delay in the mineralization of trabecular, endosteal, and periosteal bone surfaces. Rickets is not a reportable disease; however, case reports and hospital records suggest that, in the United States, its incidence has been rising during the past three decades.31

There are several forms of rickets, including nutritional rickets, vitamin D–dependent rickets, and vitamin D–resistant rickets. As with osteomalacia in the adult, rickets can result from kidney failure; malabsorptive syndromes such as celiac disease and cystic fibrosis; and medications such as anticonvulsants, which impair the activation of vitamin D in the liver; and aluminum-containing antacids, which bind phosphorus and prevent its absorption.

Etiology and Pathogenesis. Nutritional rickets results from inadequate sunlight exposure or inadequate intake of vitamin D, calcium, or phosphate. Although uncommon in developed countries of the world, rickets still can occur, particularly when an infant is solely breast fed, is dark skinned, or has limited exposure to sunlight. Modern conditions of dress, lifestyle, and recommendations regarding sun avoidance to reduce skin cancer risk may prevent a large proportion of the population from producing adequate amounts of vitamin D. In 2003, the American Academy of Pediatrics recommended a vitamin D supplement for breast-fed infants who do not consume at least 500 mL/day of vitamin D–fortified formula/beverages and non–breast-fed infants who do not consume greater than 500 mL of vitamin D–fortified beverages.31 The supplementation should start during the first 2 months of life and continue throughout childhood and adolescence.

Vitamin D–dependent rickets can result from abnormalities in the gene coding for the enzyme that converts inactive vitamin D to the active form of vitamin D, or from an autosomal disorder caused by mutations in the vitamin D receptor.29 Vitamin D–resistant rickets involves hypophosphatemia or a decrease in serum phosphate levels, the most common form being caused by mutations of the phosphate-regulating gene on the X chromosome.29 The gene mutation causes renal wasting of phosphate at the proximal tubular level of the kidney.

Clinical Features. Rickets is characterized by changes in the growing bones of children with overgrowth of the epiphyseal cartilage due to inadequate provisional calcification and failure of the cartilage cells to disintegrate. Bones become deformed; ossification at the epiphyseal plates is delayed and disordered, resulting in widening of the epiphyseal cartilage plate. Any new bone that does grow is unmineralized. The conformation of the gross skeletal changes depends on the severity and duration of the rachitic process, and in particular on the stresses to which the individual bones are subjected. During the nonmobile stage of infancy, the head and chest undergo the greatest stresses. The skull is enlarged and soft, closure of the fontanel is delayed, and the teeth are slow to develop. When an ambulating child develops rickets, deformities are likely to affect the spine, pelvis, and long bones (i.e., tibia), causing, most notably, lumbar lordosis and bowing of the legs (Fig. 44-3). The ends of long bones and ribs are enlarged. The thorax may be abnormally shaped, with prominent rib cartilage (i.e., rachitic rosary). The child usually has stunted growth, with a height sometimes far below the normal range. Weight often is not affected so that the children, many of whom present with a protruding abdomen (i.e., rachitic potbelly), have been described as presenting a Buddha-like appearance when sitting.
Nutritional rickets is treated with a balanced diet sufficient in calcium, phosphorus, and vitamin D. Exposure to sunlight also is important, especially for premature infants and those on artificial milk feedings. Supplemental vitamin D in excess of normal requirements is given for several months. Children with vitamin D–resistant rickets are treated with calcitriol, the active form of vitamin D. Vitamin D–resistant forms of rickets are treated with oral phosphorus or oral phosphorus and calcitriol. Maintenance of good posture, positioning, and bracing in older children are used to prevent deformities. After the disease is controlled, deformities may have to be surgically corrected as the child grows.

**Paget Disease**

Paget disease (i.e., osteitis deformans) is the second most common bone disease after osteoporosis,1,3,4,32,33 The disease, which has been described as a “collage of matrix madness,” is characterized by focal areas of excessive osteoclast-mediated bone resorption preceding disorganized osteoblast-mediated bone repair. Paget disease usually begins during mid-adulthood and becomes progressively more common with increasing age, affecting about 5% of women and 8% of men by the eighth decade of life.32 It is more common in people of Northern European heritage and is rare in Africans, people of the Indian subcontinent, and Asians.32

**Etiology and Pathogenesis**

Although the pathogenesis of Paget disease remains unclear, there is evidence of both genetic and environmental influences. It has been reported that 15% of persons with the disease have a positive family history32 and numerous studies have described extended family members with the disease.31 There is increasing evidence that Paget disease and some related diseases are caused by mutations in genes encoding proteins in the RANK signaling pathways.3,4 Other evidence presents a probable association with a virus, possibly a paramyxovirus, suggesting that a viral infection may serve as a trigger for development of Paget disease in genetically predisposed individuals.4,32 The incidence and severity of Paget disease of bone have decreased in recent years, possibly as a result of improved nutrition, reduced exposure to infections, and a more sedentary lifestyle, which has had the effect of reducing mechanical loading of the skeleton.32

Paget disease is a focal process with considerable variation in its stage of development in separate skeletal sites.33 At the onset, the disease is marked by regions of furious osteoclastic bone resorption, followed by a period of hectic bone formation with increased numbers of osteoblasts rapidly depositing bone in a chaotic fashion such that the newly formed bone is of poor quality and is disorganized rather than lamellar. The poor quality of bone accounts for the bowing and fractures that occur in bones affected by the disease. The bone marrow adjacent to the bone-forming surface is replaced by loose connective tissue that contains osteoprogenitor cells and numerous blood vessels, which transport blood to and from these metabolically active sites. The lesions of Paget disease may be solitary or may occur in multiple sites. They tend to localize to the bones of the axial skeleton, including the skull, spine, and pelvis. The proximal femur and tibia may be involved in more widespread forms of the disease. Histologically, Paget lesions show increased vascularity and bone marrow fibrosis with intense cellular activity. Numerous osteoclasts, large active osteoblasts, and peritrabular fibrosis are encountered. The rapid remodeling leads to disruption of bone architecture. The bone has a somewhat mosaic-like pattern resembling pieces of jigsaw puzzle, separated by prominent areas of density, called cement lines5 (Fig. 44-4).

**Clinical Features**

The clinical manifestations of Paget disease are extremely variable and depend on the extent and site of the disease (see Fig. 44-4). The disease is usually asymptomatic and discovered as an incidental radiograph finding.12 Skeletal expansion and distortion may be obvious if the disease affects the skull, jaw, clavicle, or long bones of the leg. Involvement of the skull causes headaches, intermittent tinnitus, vertigo, and eventual hearing loss. The vertebræ of the spine may enlarge, weaken, and collapse, causing kyphosis of the thoracic spine and

**FIGURE 44-3.** A child suffering from nutritional rickets. Note the bowed legs, protruding abdomen, and enlarged left wrist. (From the Centers for Disease Control and Prevention Public Health Images Library. No. 2435.)
nerve compression. Weight bearing may cause anterior bowings of the femur and tibia. Softening of the femoral neck can cause coxa vara (i.e., reduced angle of the femoral neck), which in combination with involvement of the pelvis can cause a waddling gait and secondary osteoarthritis. Mild to moderate deep, aching pain characteristically begins late in the course of the disease, persists throughout the day and at rest, and becomes worse at night. In some persons, the early hypervascularity of the pagetic bone produces warmth of the overlying skin and subcutaneous tissue. In persons with extensive disease, blood flow to the bones and subcutaneous tissue can increase remarkably, leading to high-output heart failure or exacerbation of underlying cardiac disease.

A variety of tumor and tumorlike conditions develop in pagetic bone, the most dreaded of which is sarcoma. Osteogenic sarcomas occur in 5% to 10% of persons with extensive disease. The bones most often affected, in order of frequency, are the femur, pelvis, and humerus.

**Diagnosis and Treatment.** Diagnosis of Paget disease is based on characteristic bone deformities and x-ray changes. Elevated levels of serum alkaline phosphatase and urinary hydroxyproline support the diagnosis, and continued surveillance of these levels may be used to monitor the effectiveness of treatment. Bone scans are used to detect the rapid bone turnover indicative of active disease and to monitor the response to treatment.

The scan cannot identify bone activity resulting from malignant lesions. Bone biopsy may be done to differentiate the lesion from osteomyelitis or a primary or metastatic bone tumor.

The treatment of Paget disease is based on the degree of pain and the extent of the disease. Pain can be reduced with nonsteroidal or other anti-inflammatory agents. Suppressive agents such as the bisphosphonates and calcitonin are used to prevent further progress of the disease. Persons with Paget disease should receive adequate doses of calcium and vitamin D. Orthopedic surgery may be required for the management of pseudofractures, pathologic fractures, and spinal stenosis.

---

**SUMMARY CONCEPTS**

- Metabolic bone disorders have their origin in the bone remodeling process that involves an orderly sequence of osteoclastic bone reabsorption, the formation of new bone by the osteoblasts, and mineralization of the newly formed osteoid tissue.

- Osteopenia is a condition that is common to all metabolic bone diseases. It is characterized by a reduction in bone mineral density greater than expected for age, race, or gender, and it occurs because of a decrease in bone formation, inadequate bone mineralization, or excessive bone deossification.

- Osteoporosis represents an increased loss of total bone mass due to an imbalance between bone absorption and bone formation that results in a decrease in bone density and diminished bone strength and is associated with an increase in bone fragility and susceptibility to fractures. Although the disease can occur as the result of a number of disorders, the most common causes are age-related changes in bone metabolism and a relative absence of estrogen in postmenopausal women.

- Osteomalacia and rickets represent a softening of bone due to inadequate mineralization of the bone matrix caused by a deficiency of calcium or phosphate. Osteomalacia is a disorder of adults and is caused by insufficient calcium absorption from the intestine because of lack of dietary vitamin D, resistance to the action of the vitamin, or a phosphate deficiency.

- Rickets, which affects children, is characterized by failure or delay in calcification of the cartilaginous growth plate, widening and deformation of the metaphyseal regions in long bones, and a delay in mineralization of trabecular, endosteal, and periosteal bone surfaces.
Rheumatic Disorders

Arthritis is a descriptive term applied to more than 100 rheumatic disorders, ranging from localized, self-limiting conditions to those that are systemic immune-mediated processes. The term, which is used to describe any disorder that affects the joints, oversimplifies the nature of the varied disease processes, the difficulty in differentiating one form of arthritis from another, and the complexity of treatment of these usually chronic conditions. These diverse rheumatic conditions share inflammation of the joint as a prominent or accompanying symptom. In the systemic rheumatic diseases, such as rheumatoid arthritis, the inflammation is primary, resulting from an immune response, probably autoimmune in origin. In rheumatic conditions limited to a single or few diarthrodial joints, such as osteoarthritis, the inflammation is secondary, resulting from the degenerative process and joint irregularities.

Systemic Autoimmune Rheumatic Diseases

Systemic autoimmune rheumatic diseases are a group of chronic disorders characterized by diffuse inflammatory vascular lesions and degenerative changes in connective tissue that share clinical features and may affect many of the same tissues and organs. They include rheumatoid arthritis, systemic lupus erythematosus, and systemic sclerosis, all of which share an immune-mediated pathogenesis.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a chronic autoimmune systemic disease that affects all ethnic groups throughout the world, with women being affected more frequently than men. The onset of the disease can occur at any age, but its peak incidence is between 50 and 75 years of age.\(^\text{34}\)

Etiology. Although the cause of RA remains uncertain, evidence points to a genetic predisposition and the development of joint inflammation that is immunologically mediated.\(^\text{3,4,35}\) It has been suggested that the disease is initiated in a genetically predisposed individual by the activation of a T-cell–mediated response to an immunologic trigger, such as a microbial agent (Fig. 44-5). The importance of genetic factors in the pathogenesis of RA is supported by the increased frequency of the disease among first-degree relatives and monozygotic twins.\(^\text{4}\) In addition, specific major histocompatibility complex (MHC) alleles or human leukocyte antigen (HLA) types have been associated with RA (see Chapter 15). An increased prevalence of RA has been associated with specific HLA DR alleles that share a sequence of amino acids located in the antigen-binding site of the DR molecule. This location is presumably the specific binding site of the immunologic trigger.\(^\text{3}\) Cigarette smoking is a strong risk factor for the development of RA and may also influence the severity of the disease, especially in those with the shared epitope (HLA-DR4 marker) and a positive anti-citrullinated peptide antibody (ACPA) test, to be discussed.\(^\text{35,36}\)

Pathogenesis. The pathogenesis of RA can be viewed as an aberrant immune response that leads to synovial inflammation and destruction of the joint architecture. It has been suggested that the disease is initiated by the activation of CD4\(^+\) helper T cells, the local release of inflammatory mediators and cytokines (e.g., tumor necrosis factor [TNF], interleukin [IL]-1) that destroy the joint, and formation of antibodies directed against joint-specific and systemic autoantigens. Approximately

![Figure 44-5. Disease process in rheumatoid arthritis. IL, interleukin; TNF, tumor necrosis factor.](image-url)
70% to 80% of persons with the disease have a substance called the *rheumatoid factor* (RF), which is an antibody that reacts with a fragment of immunoglobulin G (IgG) to form immune complexes. Although persons with RA may be seronegative (not have Ig RF in their serum), the presence of a high RF titer is frequently associated with severe and unremitting disease, mainly systemic complications. Anti-cyclic citrullinated peptide antibodies (ACPA) are another key antibody system in RA. Citrulline is a nonnaturally occurring amino acid that is generated by the enzymatic digestion of arginine on proteins. Research suggests that citruline-containing proteins may be present years before clinical disease and elevated ACPA levels can predict the severity of disease.

The role of the autoimmune process in the joint destruction of RA remains obscure. At the cellular level, neutrophils, macrophages, and lymphocytes are attracted to the area. The neutrophils and macrophages phagocytize the immune complexes and, in the process, release lysosomal enzymes capable of causing destructive changes in the joint cartilage (see Fig. 44-5). The inflammatory response that follows attracts additional inflammatory cells, setting into motion a chain of events that perpetuates the process. As the inflammatory process progresses, synovial cells and subsynovial tissues undergo reactive hyperplasia. The joint swelling that occurs is the result of increased blood flow and capillary permeability that accompanies the inflammatory process.

Characteristic of RA is the development of an extensive network of new blood vessels in the synovial membrane that contributes to the advancement of the rheumatoid synovitis. This destructive vascular granulation tissue, which is called pannus, extends from the synovium to involve the “bare area,” a region of unprotected bone at the junction between cartilage and subchondral bone (Fig. 44-6B). Pannus is a feature of RA that differentiates it from other forms of inflammatory arthritis. The inflammatory cells found in the pannus have a destructive effect on the adjacent cartilage and bone. Eventually, pannus develops between the joint margins, leading to reduced joint motion and the possibility of eventual ankylosis (joint fusion). With progression of the disease, joint inflammation and the resulting structural changes lead to joint instability, muscle atrophy from disuse, stretching of the ligaments, and involvement of the tendons and muscles. The effect of the pathologic changes on joint structure and function is related to the degree of disease activity, which can change at any time. Unfortunately, the destructive changes are irreversible.

Rheumatoid arthritis often is associated with articular as well as extra-articular (i.e., systemic) manifestations (see Fig. 44-6). It usually has an insidious onset marked by systemic manifestations such as fatigue, weakness, and generalized aching and stiffness. The disease, which is characterized by exacerbations and remissions, may involve only a few joints for brief durations, or it may become relentlessly progressive and debilitating.

**Articular Manifestations.** Joint involvement usually is symmetric and polyarticular. Any diarthrodial joint can be involved. The person may complain of joint pain and stiffness that lasts for 30 minutes and frequently for several hours. The limitation of joint motion that occurs early in the disease usually is because of pain; later, it is because of fibrosis. In early disease, the wrists, metacarpophalangeal (MCP) joints, proximal interphalangeal (PIP) joints of the fingers, interphalangeal joints of the thumb, and metatarsophalangeal (MTP) joints are most commonly affected. Pain in the ball of the foot upon arising from bed and widening of the forefoot necessitating an increase in shoe size are frequently reported due to inflammation of the metatarsophalangeal joints. Pain with turning door knobs, opening jars, and buttoning shirts is commonly reported due to swelling of the wrists and small joints of the hand. As the disease progresses, larger joints such as the ankles, knees, elbows, and shoulders become affected. Spinal involvement usually is limited to the cervical region.

Progressive joint destruction may lead to subluxation (i.e., a partial dislocation of the joint resulting in misalignment of the bone ends) with instability and limitation of movement. Swelling and thickening of the synovium can result in stretching of the joint capsule and ligaments. When this occurs, muscle and tendon imbalances develop, and mechanical forces applied to the joints through daily activities produce joint deformities. In the MCP joints, the extensor tendons can slip to the ulnar side of the metacarpal head, causing ulnar deviation of the fingers (see Fig. 44-6A). Hyperextension of the PIP joint and partial flexion of the distal interphalangeal (DIP) joint is called a *swan neck deformity*. After this condition becomes fixed, severe loss of function occurs because the person can no longer make a fist.

The knee is one of the most commonly affected joints and is responsible for much of the disability associated with the disease. Active synovitis may be apparent as visible swelling that obliterates the normal contour over the medial and lateral aspects of the patella. Joint contractures, instability, and genu valgus (knock-knee) deformity are other possible manifestations. Severe atrophy of the quadriceps muscles can contribute to the disability. A *Baker cyst* may develop in the popliteal area behind the knee. This is caused by enlargement of the bursa but does not usually cause symptoms unless the cyst ruptures, in which case symptoms mimicking thrombophlebitis appear. Ankle involvement can limit flexion and extension, which can create difficulty in walking. Involvement of the metatarsophalangeal joints can cause subluxation, hallux valgus, and hammertoe deformities. Neck pain and stiffness occur later in the disease.

**Extra-Articular Manifestations.** In addition to articular manifestations, persons with early RA frequently have constitutional symptoms such as fatigue, weakness, anorexia, and weight loss that are due to systemic inflammation. The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), which commonly are elevated during inflammatory processes, have been
found to correlate with the amount of disease activity. A moderate hypochromic anemia is common.

Extra-articular involvement occurring in long-standing disease include the development of rheumatic nodules (Fig. 44-6A). These granulomatous lesions have a central core of fibrinoid necrosis that is made up of a mixture of fibrin and other proteins such as degraded collagen. The nodules may be tender or nontender, movable or immovable, and small or large. Typically, they are found over pressure points such as the extensor surfaces of the ulna. The nodules may resolve spontaneously or be surgically removed.

Vasculitis, or inflammation of small and medium-sized arteries, is an uncommon manifestation that produces ischemic areas in the nail fold and digital pulp that appear as brown spots. Ulcerations may occur in the lower extremities, particularly around the malleolar areas. In some cases, neuropathy may be the only
symptom of vasculitis. The visceral organs, such as the heart, lungs, and gastrointestinal tract, also may be affected.

Dryness of the eyes, mouth, and other mucous membranes may occur, especially in advanced disease. Ocular manifestations include episcleritis, scleritis, and scleromalacia, which is due to scleral nodules. Additional extra-articular manifestations of RA include pulmonary fibrosis and pericarditis. A small number of persons have splenomegaly and lymph node enlargement.

**Diagnosis.** The diagnosis of RA is based on findings of the history, physical examination, and laboratory tests. In 2010, the American College of Rheumatology/European League Against Rheumatism collaborated to develop new classification criteria for RA \(^3\) (Chart 44-2). The new criteria are aimed at diagnosing RA earlier in persons who meet the 1987 classification criteria.

Because changes in joint structure usually are not visible early in the disease, diagnosis is often difficult. On physical examination, the affected joints show signs of inflammation, swelling, tenderness, and possibly warmth and reduced motion. The joints have a soft, spongy feeling because of the synovial thickening and inflammation. Body movements may be guarded to prevent pain.

The combined serologic presence of the RF and ACPA are findings that are sensitive and fairly specific for RA. \(^3\) The presence of ACPA, which are often detected very early in RA, appear to be a good prognostic marker for the disease and discriminates between erosive and nonerosive forms of the disease. Disease severity and activity tend to correlate with RF levels; patients with high RF levels tend to have a significantly higher frequency of extra-articular involvement (e.g., rheumatoid nodules, vasculitis, neuropathy). Synovial fluid analysis can be helpful in the diagnostic process. The synovial fluid has a cloudy appearance, the white blood cell count is elevated as a result of inflammation, and the complement components are decreased. Radiologic findings provide the most specific evidence of joint changes in RA, but are often normal during the early stages of the disorder.

**Treatment.** The treatment goals for a person with RA are to reduce pain, minimize stiffness and swelling, maintain mobility, and become an informed health care consumer. The treatment plan includes education about the disease and its treatment, physical rest, therapeutic exercises, and medications. Because of the chronicity of the disease and the need for continuous, long-term adherence to the prescribed treatment modalities, it is important that the treatment be integrated with the person's lifestyle.

Both physical rest and therapeutic exercises are important aspects of care. \(^3\) Physical rest reduces joint stress. Rest of specific joints is recommended to relieve pain. For example, sitting reduces the weight on an inflamed knee, and the use of lightweight splints reduces undue movement of the hand or wrist. Although rest is essential, therapeutic exercises also are important in maintaining joint motion and muscle strength. \(^3\)

In addition to those that meet these criteria, which are best suited to persons with newly presenting disease, the following patients are classified as having RA:

- Persons with erosive disease typical of RA with a history compatible with prior fulfillment of the criteria
- Persons with long-standing disease, including those with inactive disease (with or without treatment) who have previously fulfilled these criteria upon retrospectively available data

*Classification of definite RA based upon the presence of synovitis in at least one joint, the absence of an alternative diagnosis that better explains the synovitis, and the achievement of a total score of at least 6 (of a possible 10) from the individual scores in four domains. The highest score achieved in a given domain is used for this calculation. These domains and their values are:

- ACPA, anti-cyclic citrullinated peptide antibodies; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; RF, rheumatoid factor.

Proper posture, positioning, body mechanics, and the use of supportive shoes can provide further comfort. There often is a need for information about the
principles of joint protection and work simplification. Some persons need assistive devices to reduce pain and improve their ability to perform activities of daily living. Instruction in the safe use of heat and cold modalities to relieve discomfort and in the use of relaxation techniques are also important.

The classes of drugs used in the treatment of RA include nonsteroidal anti-inflammatory drugs (NSAIDs) and selective cyclooxygenase (COX)-2 inhibitors; disease-modifying antirheumatic drugs (DMARDs); corticosteroids; and biologic agents. The NSAIDs inhibit COX-mediated synthesis of prostaglandins, which have a damaging effect on joint structures (see Chapter 3, Fig. 3-4).

Corticosteroid drugs interrupt the inflammatory and immune cascade at several levels, such as interfering with inflammatory cell adhesion and migration, impairing prostaglandin synthesis, and inhibiting neutrophil superoxide production. To avoid long-term side effects, they are used only in specific situations for short-term therapy at a low dose level. The corticosteroids do not modify the disease and are unable to prevent joint destruction. Intra-articular corticosteroid injections can provide rapid relief of acute or subacute inflammatory synovitis (after infection is excluded) in a few joints. They should not be repeated more than a few times each year.

The DMARDs are a diverse group of therapeutic drugs that reduce the signs and symptoms of RA as well as retard progression of the disease. The DMARDs include hydroxychloroquine, sulfasalazine, methotrexate, and leflunomide. Methotrexate has become the drug of choice because of its potency, and it is relatively fast acting (i.e., improvement is seen in 1 month) compared with the slower-acting DMARDs, which can take 3 to 4 months to work. Methotrexate is thought to interfere with purine metabolism, leading to the release of adenosine, a potent anti-inflammatory compound. Leflunomide is a pyrimidine synthesis inhibitor that blocks the proliferation of T cells. All of the DMARDs can be toxic and require close monitoring for adverse effects, especially those related to bone marrow suppression.

The biologic agents are structurally engineered versions of natural molecules (e.g., monoclonal antibodies) designed to target specific pathogenic mediators of joint inflammation and damage. Etanercept, infliximab, adalimumab, certolizumab, and golimumab are biologic response-modifying agents that block tumor necrosis factor (TNF)-α, one of the key proinflammatory cytokines in RA. Abatacept is a recombiant protein that prevents the co-stimulatory signal that results in full T-cell activation. Rituximab is a chimeric antibody that causes B-cell depletion. Tocilizumab prevents IL-6 from interacting with its receptor and activating cells. The newest drug used in the treatment of RA is tofacitinib, a janus kinase 3 inhibitor which interrupts the signal from the cytokine receptors to the nucleus where inflammatory molecules are made.

Surgery also may be a part of the treatment of RA. Synovectomy may be indicated to reduce pain and joint damage when synovitis does not respond to medical treatment. The most common soft tissue surgery is tenosynovectomy (i.e., repair of damaged tendons) of the hand to release nerve entrapments. Total joint replacements (i.e., arthroplasty) may be indicated to reduce pain and increase motion. Arthrodesis (i.e., joint fusion) is indicated only in extreme cases when there is so much soft tissue damage and scarring or infection that a replacement is impossible.

**Systemic Lupus Erythematous**

Systemic lupus erythematosus (SLE) is a chronic inflammatory disease that can affect virtually any organ system, including the musculoskeletal system. It is a major rheumatic disease, with a prevalence of approximately 1 case per 2000 persons. Systemic lupus erythematosus is primarily a disease of young women, with a peak incidence between the ages of 15 and 40 years. It is more common in African Americans, Hispanics, and Asians than whites, and the incidence in some families is higher than in others.

**Etiology and Pathogenesis.** The cause of SLE is largely unknown. It is characterized by the formation of autoantibodies and immune complexes (type III hypersensitivity; see Chapter 16). Persons with SLE appear to have defective elimination of self-reactive B cells with a resultant increase in production of antibodies that can cause tissue damage. Autoantibodies have been identified against an array of self-molecules found in the plasma, cytoplasm, or on the surface of cells, but those directed against components of the cell nucleus (antinuclear antibodies [ANAs]) are the most characteristic. Antibodies to double-stranded DNA and a nuclear antigen called Sm is found in almost all persons with SLE and are part of the serologic classification of the disease.

The development of autoantibodies can result from a combination of genetic, hormonal, and environmental factors. Genetic predisposition is evidenced by the occurrence of familial cases of SLE, especially among identical twins, and the increased incidence among African Americans compared with whites. As many as four genes may be involved in the expression of SLE. Studies also suggest that an imbalance in sex hormone levels may play a role in the development of the disease, especially because the disease is so prevalent among women. Possible environmental triggers include ultraviolet (UV) light, certain foods, infectious agents, and toxic chemicals, including some drugs. Photosensitivity frequently occurs in SLE. Photosensitive persons may report a worsening of systemic disease symptoms such as fatigue and joint pain following sun exposure. Certain drugs may also provoke a lupus-like disorder in susceptible persons, particularly in the elderly. The most common of these drugs are hydralazine and procainamide.

**Clinical Manifestations.** Systemic lupus erythematosus can manifest in a variety of ways. The disease has been called the "great imitator" because it has the capacity to affect many different body systems, including the musculoskeletal system, skin, cardiovascular system, lungs, kidneys, central nervous system (CNS), and red
blood cells and platelets. The onset may be acute or insidious, and the course of the disease is characterized by exacerbations and remissions.

Arthralgias and arthritis, the most common manifestations of SLE, are present in up to 90% of persons at some point during the course of their disease. Although the arthritis can affect any joint, it is most often symmetric with involvement of the small joints of the hands, wrists, and knees. Ligaments, tendons, and the joint capsule may be involved, causing varied deformities. Other musculoskeletal manifestations of SLE include tenosynovitis, rupture of the intrapatellar and Achilles tendons, and avascular necrosis, frequently of the femoral head.

Skin manifestations can vary greatly and may be classified as acute, subacute, or chronic. The acute skin lesions include the classic malar or “butterfly” rash on the nose and cheeks (see Fig. 44-7). Other skin lesions that may occur include hives or livedo reticularis (i.e., reticular cyanotic discoloration of the skin, often precipitated by cold), and fingertip lesions. Hair loss is common. Mucous membrane lesions tend to occur during periods of exacerbation. Sun sensitivity may occur in SLE even after mild exposure.

Renal involvement is common in SLE and a significant cause of morbidity and mortality. Several forms of renal involvement may occur, including glomerulonephritis, tubulointerstitial nephritis, and vascular disease (see Chapter 25). The clinical manifestations of renal involvement range from asymptomatic hematuria and/or proteinuria to frank nephrotic syndrome with progressive loss of renal function. Nephrotic syndrome causes proteinuria with resultant edema in the legs and abdomen, and around the eyes. Kidney biopsy is the best determinant of renal damage and the type of treatment needed.

Pulmonary involvement is manifested primarily by pleural effusions and/or pleuritis. Pleural effusions are typically small, bilateral, and exudative. Up to 50% of persons with SLE develop pleuritis, which is manifested by pleuritic chest pain. The presence of pleuritis usually corresponds to active SLE in other organ systems.

Cardiovascular disease is a frequent complication of SLE. It can involve the pericardium, myocardium, or coronary arteries. Pericarditis, with or without effusion, is the most common cardiac manifestation in SLE, occurring in 50% of persons with SLE at some point during the course of their disease. Coronary heart disease is also increased in persons with SLE. Hypertension may be associated with lupus nephritis and long-term corticosteroid use. Hematologic disorders may manifest as hemolytic anemia, leukopenia, lymphopenia, or thrombocytopenia.

The nervous system is involved in persons with SLE. Involvement of both the central (CNS) and peripheral (PNS) nervous systems occurs. Central nervous system disorders range from diffuse processes such as headache, psychosis, and mood disorders to more focal processes such as seizures. Headaches are reported in more than 50% of persons with SLE, with both migrainous and tension-type headaches being described. Psychotic manifestations include depression and unnatural euphoria, as well as decreased cognitive functioning, and confusion.

Chronic discoid cutaneous lupus is a disease characterized by plaquelike lesions on the head, scalp, and neck. These lesions first appear as red, swollen patches of skin, and later there can be scarring, depigmentation, and plugging of hair follicles. The disease is usually confined to the skin, but after many years 5% to 10% of persons with the disorder may develop multisystem manifestations.

Subacute cutaneous lupus erythematosus is a less-severe form of lupus that presents with skin lesions resembling psoriasis on sun-exposed areas such as the face, chest, upper back, and arms. Most persons have mild systemic manifestations of SLE, which usually are limited to joint and muscle pains. There is also a low incidence of lupus nephritis.

**Diagnosis and Treatment.** The diagnosis of SLE is based on a complete history, physical examination, and
analysis of bloodwork. The most common laboratory test performed is the immunofluorescence test for ANA. The ANA test is not specific for SLE, and positive ANA results may be found in healthy persons or may be associated with other disorders. Other serum tests may reveal moderate to severe anemia, thrombocytopenia, and leukocytosis or leukopenia.

Treatment of SLE focuses on managing the acute and chronic symptoms of the disease. Persons with photosensitivity should be cautioned against sun exposure and should apply a protective lotion when outdoors. Skin lesions often respond to local application of corticosteroids and minor joint symptoms are usually relieved by rest and NSAIDs.

An antimalarial drug (e.g., hydroxychloroquine) may be helpful in treating mucocutaneous manifestations, pleuritis, arthritis, and fatigue. Corticosteroids are used to treat more significant symptoms of SLE, such as renal and CNS disorders. High-dose corticosteroid treatment is used for acute symptoms, and the drug is tapered to the lowest therapeutic dose as soon as possible to minimize the adverse effects. Immunosuppressive drugs, such as azathioprine and cyclophosphamide, may be used in cases resistant to corticosteroids. Biologics, such as rituximab and belimumab, target B cells and are used for refractory symptoms.

**Systemic Sclerosis/Scleroderma**

Systemic sclerosis, commonly called scleroderma, is an autoimmune disease of connective tissues that causes extensive fibrosis throughout the body. The disease affects women four times as frequently as men, with a peak incidence in the 35- to 50-year-old age group.

The cause of systemic sclerosis is poorly understood, although there is evidence of both humoral and cellular immune system abnormalities. Fibroblast activation with excessive fibrosis is a hallmark of the disease. Skin involvement is the usual presenting symptom, but it is the involvement of organs such as the gastrointestinal tract, heart, lungs, and kidneys that produces the major morbidity and mortality. Microvascular disease is also present early in the disease, with repeated cycles of endothelial damage followed by platelet activation and release of platelet factors that lead to fibrosis and narrowing of the microvasculature and tissue ischemia.

**Clinical Manifestations.** Scleroderma presents as two major clinical subsets: limited and diffuse scleroderma. The most common subset, which accounts for about half of the cases, is limited cutaneous scleroderma in which the skin changes are limited to the fingers, forearms, and face. Some persons with limited involvement also develop a condition called the CREST syndrome, characterized by a combination of calcinosis (i.e., calcium deposits in the subcutaneous tissue that erupt through the skin), Raynaud phenomenon (a vascular disorder characterized by reversible vasospasm of the arteries supplying the fingers [see Chapter 18]), esophageal dysmotility, sclerodactyly (localized scleroderma of the fingers), and telangiectasia (dilated skin capillaries).

Diffuse scleroderma, which accounts for approximately 35% of persons with scleroderma, is characterized by severe, widespread, and progressive skin involvement and early onset of organ involvement. The typical person has a “stone facies” due to tightening of the facial skin with restricted motion of the mouth. Other cutaneous manifestations include hair loss on the involved skin and telangiectasia on the face, buccal mucosa, chest, and hands. Almost all persons with diffuse scleroderma develop Raynaud phenomenon. Musculoskeletal involvement is common. Puffy hands with arthralgia and myalgia may lead to difficulty forming a fist. There are palpable or audible friction rubs over the extensor and flexor tendons of the hands, knees, and ankles. Involvement of the esophagus that leads to difficulty swallowing is common, and malabsorption may develop if the disease affects the intestine. Pulmonary involvement leads to dyspnea and eventually respiratory failure. Vascular involvement of the kidneys is responsible for malignant hypertension and progressive renal insufficiency. Cardiac problems include pericarditis, heart block, and myocardial fibrosis.

**Treatment.** Treatment of systemic sclerosis is largely symptomatic and supportive. Advances in treatment, primarily the use of angiotensin-converting enzyme (ACE) inhibitors in renal involvement, have led to a substantial decrease in the mortality from hypertensive renal disease. Cardiopulmonary manifestations of scleroderma, specifically pulmonary hypertension, can be treated with prostanooids (or endothelial receptor antagonists [bosentan]). Disease modifying agents such as methotrexate, cyclophosphamide, azathioprine, and mycophenolate mofetil have been reported effective in limited case series or randomized controlled trials. These agents can be used in early diffuse disease.

**Seronegative Spondyloarthopathies**

The spondyloarthopathies are an interrelated group of multisystem inflammatory disorders that primarily affect the axial skeleton, particularly the spine. Sacroiliitis is a pathologic hallmark of the disorders. Typically, the inflammation begins at sites, called entheses, where tendons and ligaments insert into bone rather than the synovium. There may also be inflammation and involvement of the peripheral joints, in which case the signs and symptoms overlap with other inflammatory types of arthritis.

The spondyloarthopathies are grouped into two subtypes: the axial spondyloarthropathies, which include ankylosing spondylitis; and the peripheral spondyloarthropathies, which include psoriatic arthritis, reactive arthritis, inflammatory bowel disease-associated arthritis, and undifferentiated peripheral spondyloarthritides. Although they differ in terms of factors such as age and type of onset and extent of joint involvement, there is clinical evidence of overlap between the various disorders.
Ankylosing Spondylitis

Ankylosing spondylitis is a chronic, systemic inflammatory disease of the joints of the axial skeleton manifested by pain and progressive stiffening of the spine. The disease usually begins in late adolescence or early adulthood. The incidence is greater in men than in women, and symptoms are generally more prominent in men.

Pathogenesis. Although the pathogenesis of ankylosing spondylitis has not been established, the presence of mononuclear cells in the acutely involved tissue suggests an immune response. Epidemiologic findings indicate that genetic and environmental factors play a role in the pathogenesis of the disease. The HLA-B27 allele remains one of the best-known examples of an association between a disease and a hereditary marker. Approximately 90% of those with ankylosing spondylitis possess the HLA-B27 allele, which also is present in approximately 5% to 15% of the normal population.

Several theories have been advanced to account for the association between HLA-B27 and ankylosing spondylitis. One possibility is that it predisposes to ankylosing spondylitis by influencing the body’s endogenous flora.

Clinical Manifestations. The typical musculoskeletal lesion associated with ankylosing spondylitis is inflammation, or enthesitis, at sites where tendons and ligaments attach to bones. Typically, the disease process begins with bilateral involvement of the sacroiliac joints and then moves to the smaller joints of the posterior elements of the spine (Fig. 44-8). The result is ultimate destruction of these joints with ankylosis or posterior fusion of the spine. The vertebrae take on a squared appearance and bone bridges fuse one vertebral body to the next across the intervertebral disks.

Progressive spinal changes usually begin with the sacroiliac area and then move up the spine to involve the costovertebral joints and cervical spine. Occasionally, large synovial joints (i.e., hips, knees, and shoulders) may be involved. The disease spectrum ranges from an asymptomatic sacroiliitis to a progressive disease that can affect many body systems.

The usual presenting symptom is back pain that may be persistent or intermittent. The pain, which becomes worse when resting, particularly when lying in bed, may also involve the buttocks and hip areas, and can radiate to the thigh in a manner similar to that of sciatic pain. Mild physical activity or a hot shower helps reduce pain and stiffness. Sleep patterns frequently are interrupted because of these manifestations. Walking or exercise may be needed to provide the comfort needed to return to sleep. The most common extraskeletal involvement is anterior uveitis (iritis), which occurs in approximately 30% of persons sometime in the course of their disease. Systemic features of weight loss, fever, and fatigue may be apparent.

Osteoporosis may occur, especially in the spine, which contributes to the risk of spinal fracture. Loss of motion in the spinal column is characteristic of the disease (see Fig. 44-8). Loss of lumbar lordosis occurs as the disease progresses, and this is followed by kyphosis of the thoracic spine and extension of the neck. A spine fused in the flexed position is the end result of severe ankylosing spondylitis. A kyphotic spine makes it difficult for the patient to look ahead and to maintain balance while walking. The image is one of a person bent over looking at the floor and unable to straighten up. X-ray films show a rigid, bamboolike spine. The heart and lungs are constricted in the chest cavity. Abnormal weight bearing can lead to degeneration and destruction of the hip joint, necessitating joint replacement procedures. Peripheral arthritis is more common in the hips and shoulders.

Diagnosis and Treatment. The diagnosis of ankylosing spondylitis is based on history, physical examination, and x-ray examination. The history and physical examination should include measures of physical function, pain, spinal mobility, duration of morning stiffness, involvement of peripheral joints and entheses, and fatigue. Laboratory findings frequently include an...
Reactive arthritis is an inflammatory joint disorder that arises after certain inciting gastrointestinal or genitourinary tract infections and manifests as a sterile oligoarthritis, typically of the lower extremities. Most cases of reactive arthritis develop after either a gastrointestinal infection (Salmonella, Shigella, Campylobacter, or Yersinia) or sexually transmitted infection (Chlamydia trachomatis). The infecting agents cannot be cultured and are not viable after reaching the joints. A clinically indistinguishable syndrome can occur without antecedent infection, suggesting that subclinical infection or some other unrecognized agent can precipitate reactive arthritis. Reiter syndrome is a form of reactive arthritis defined by a triad of arthritis, nongonococcal urethritis or cervicitis, and conjunctivitis. Enteropathic arthritis is a reactive arthritis that is associated with inflammatory bowel disease (i.e., Crohn disease and ulcerative colitis) or triggered by enterogenic bacteria.

Clinical Manifestations. Reactive arthritis is most commonly asymmetric and frequently involves the lower extremities. Symptoms typically start within 1 to 4 weeks of the initial infection. Hip disease is uncommon and involvement of the upper extremities is rare. The joints are typically warm, swollen, and tender. Systemic manifestations including fever and weight loss are common at the onset. Enthesitis is a common feature of reactive arthritis. The Achilles tendon and plantar fascia are the most common sites of involvement, but pain in the iliac crests, ischial tuberosities, and back may occur. This aspect of the disease can be disabling, with marked restriction in weight bearing and ambulation. Extra-articular lesions are common and include circinate balanitis (shallow ulcers on the glans or shaft of the penis), stomatitis (e.g., painless oral ulcers on the hard palate or tongue), and keratoderma blennorrhagicum (a papulosquamous rash most commonly affecting the palms of the hands and soles of the feet [Fig. 44-9]). While most of the signs and symptoms disappear within days or weeks, the arthritis may persist for several months, and in a small number of cases, it may follow a continuous and unremitting course.

Treatment. The treatment is largely symptomatic. NSAIDs are used in treating the arthritic symptoms. Vigorous treatment of possible triggering infections is thought to prevent relapses of reactive arthritis, but in many cases the triggering infection passes unnoticed or unreported.

Reactive Arthritis

Reactive arthritis is an inflammatory joint disorder that arises after certain inciting gastrointestinal or genitourinary tract infections and manifests as a sterile oligoarthritis, typically of the lower extremities. Most cases of reactive arthritis develop after either a gastrointestinal infection (Salmonella, Shigella, Campylobacter, or Yersinia) or sexually transmitted infection (Chlamydia trachomatis). The infecting agents cannot be cultured and are not viable after reaching the joints. A clinically indistinguishable syndrome can occur without antecedent infection, suggesting that subclinical infection or some other unrecognized agent can precipitate reactive arthritis. Reiter syndrome is a form of reactive arthritis defined by a triad of arthritis, nongonococcal urethritis or cervicitis, and conjunctivitis. Enteropathic arthritis is a reactive arthritis that is associated with inflammatory bowel disease (i.e., Crohn disease and ulcerative colitis) or triggered by enterogenic bacteria.

Clinical Manifestations. Reactive arthritis is most commonly asymmetric and frequently involves the lower extremities. Symptoms typically start within 1 to 4 weeks of the initial infection. Hip disease is uncommon and involvement of the upper extremities is rare. The joints are typically warm, swollen, and tender. Systemic manifestations including fever and weight loss are common at the onset. Enthesitis is a common feature of reactive arthritis. The Achilles tendon and plantar fascia are the most common sites of involvement, but pain in the iliac crests, ischial tuberosities, and back may occur. This aspect of the disease can be disabling, with marked restriction in weight bearing and ambulation. Extra-articular lesions are common and include circinate balanitis (shallow ulcers on the glans or shaft of the penis), stomatitis (e.g., painless oral ulcers on the hard palate or tongue), and keratoderma blennorrhagicum (a papulosquamous rash most commonly affecting the palms of the hands and soles of the feet [Fig. 44-9]). While most of the signs and symptoms disappear within days or weeks, the arthritis may persist for several months, and in a small number of cases, it may follow a continuous and unremitting course.

Treatment. The treatment is largely symptomatic. NSAIDs are used in treating the arthritic symptoms. Vigorous treatment of possible triggering infections is thought to prevent relapses of reactive arthritis, but in many cases the triggering infection passes unnoticed or unreported.
is mild, and the person seeks medical care only with the onset of definite arthritis. Short antibiotic courses at this time are not effective.

Psoriatic Arthritis

Psoriatic arthritis is a seronegative inflammatory arthropathy that occurs with variable frequency in people with psoriasis. It is a disease with various and similar features of the spondyloarthropathies in some persons, in whom an asymmetric sacroiliitis and spinal involvement predominate. In others, the disease is polyarticular and resembles RA, and in some, features of both disorders coexist. Although the arthritis can antedate a detectable skin rash, the definitive diagnosis of psoriatic arthritis cannot be made without evidence of skin or nail changes typical of psoriasis (see Chapter 46).

The etiology of psoriasis and psoriatic arthritis is unknown. Genetic, environmental, and immunologic factors appear to affect susceptibility and play a role in expression of the psoriatic skin disease and the arthritis. Environmental factors that may play a role in the pathogenesis of the disorder include infectious agents and physical trauma. T-cell–mediated immune responses seem to play an important role in the skin and joint manifestations of the disease, as indicated by the observation that there is improvement in disease status after treatment with immunosuppressant agents such as cyclosporine.

Psoriatic arthritis falls into five subgroups: (1) an oligoarticular form affecting four or fewer joints; (2) a spondylitis form in which sacroiliitis and spinal involvement predominate; (3) a polyarticular, or symmetric, form that resembles RA; (4) a form in which the distal interphalangeal joints are primarily affected; and (5) arthritis mutilans, a very destructive form of arthritis. The joint involvement of peripheral psoriatic arthritis is inflammatory in nature, presenting with swelling and stiffness of the affected joints. Early in the disease, the arthritis tends to be oligoarticular, but may become polyarticular over time. The affected joints of persons with psoriatic arthritis are often less tender than those of persons with RA. Thus, persons with psoriatic arthritis may present with deformity and joint damage, not having perceived any pain during the inflammatory phase of the disease. Sacroiliac involvement, when it occurs, tends to be asymmetric, involving only one sacroiliac joint and sparing the other or with different degrees of radiologic involvement. Likewise, spinal involvement tends to be asymmetric, with skin lesions. Dactylitis, or sausage digit, is a typical feature of distal interphalangeal joint disease and reflects inflammation of the entire digit.

Basic management is similar to the treatment of RA. Suppression of the skin disease may be important in helping control the arthritis. Often, affected joints are surprisingly functional and only minimally symptomatic. The biologic response modifiers, specifically the TNF inhibitors (e.g., etanercept, infliximab, and adalimumab), have been found to be beneficial in controlling the arthritis as well as the psoriasis in patients with psoriatic arthritis.

Osteoarthritis

Osteoarthritis (OA), also called degenerative joint disease, is the most prevalent type of joint disease and is one of the 10 most disabling conditions in developing nations. The disorder, which is characterized by degenerative changes of the articular cartilage, can affect any one of 200 or so synovial joints in the body, and can occur as a primary idiopathic disorder or as a secondary disorder. In most instances, OA appears insidiously, without an apparent initiating cause, as an aging phenomenon (idiopathic or primary OA). In these cases the disorder is usually oligoarticular, but may be generalized. Secondary OA has a known underlying cause such as congenital or acquired defects of joint structures, trauma, metabolic disorders, or inflammatory diseases.

Joint changes associated with OA include a gradual loss of articular cartilage, combined with thickening of the subchondral bone, bony outgrowths (osteophytes) at joint margins, and mild synovial inflammation. These changes are accompanied by joint pain, stiffness, and limitation of motion, and in some cases by joint instability and deformity.

Etiology and Pathogenesis

Osteoarthritis is a multifactorial disease that has genetic and environmental risk factors. Studies of families and twins suggest that the risk of OA is related to the net impact of multiple genes, each with a small effect. Age, gender, and race interact to influence the time of onset and the pattern of joint involvement in OA. Age is one of the strongest risk factors for OA of all joints. The increase in incidence and prevalence with age probably is the consequence of cumulative exposure to the various risk factors and biologic changes that occur in a lifetime. Women are more likely to have OA than men, and they tend to have more severe OA as well. The prevalence of OA and pattern of joint involvement vary among racial and ethnic groups. Hand OA is more likely to affect white women, whereas knee OA is more common in black women. The incidence of hip OA is lower among the Chinese than Europeans, perhaps representing the influence of other factors such as occupation, obesity, or heredity. Bone mass may also influence the risk of developing OA. In theory, thinner subchondral bone mass may provide a greater shock-absorbing function than denser bone, allowing less direct trauma to the cartilage. Obesity is a particular risk factor for OA of the knee in women and a contributory biomechanical factor in the pathogenesis of the disease. Weight loss reduces the risk of developing symptomatic arthritis of the knee.

The pathogenesis of OA resides in the homeostatic mechanisms that maintain the articular cartilage. Articular cartilage plays two essential mechanical roles in joint physiology. First, it serves as a remarkably smooth weight-bearing surface. In combination with synovial fluid, the articular cartilage provides extremely low friction during movement of the joint. Second, the cartilage transmits the load down to the bone, dissipating...
Thus, the subchondral bone protects the overlying articular cartilage, providing it with a pliable bed and absorbing the energy of the force (Fig. 44-10). Articular cartilage has two major components: an extracellular matrix, which is rich in proteoglycan and collagen fibers, and a limited number of chondrocytes, which produce the matrix.

Popularly known as wear-and-tear arthritis, OA is characterized by significant changes in both the composition and mechanical properties of cartilage. The articular cartilage injury is thought to result from chondrocyte injury and release of cytokines such as interleukin (IL)-1 and TNF (Fig. 44-11). These chemical messengers stimulate the production and release of proteases (enzymes) that are destructive to joint structures. The resulting damage predisposes the chondrocytes to additional injury and impairs their ability to maintain cartilage synthesis and repair the damage. The combined effects of inadequate repair mechanisms and imbalances between the proteases and their inhibitors contribute further to disease progression.

The earliest structural changes in OA include enlargement and reorganization of the chondrocytes in the superficial part of the articular cartilage. This is accompanied by edematous changes in the cartilaginous matrix, principally the intermediate layer. The cartilage loses its smooth aspect and surface cracks or microfractures occur, allowing synovial fluid to enter and widen the crack. As the crack deepens, vertical clefts form and eventually extend through the full thickness of the articular surface and into the subchondral bone. Portions of the articular cartilage eventually become completely eroded and the exposed surface of the subchondral bone becomes thickened to an ivory-like consistency (eburnation). Fragments of cartilage and bone often become dislodged, creating free-floating osteocartilaginous bodies (“joint mice”) that enter the joint cavity. Synovial fluid may leak through the defects in the residual cartilage to form cysts within the bone (Fig. 44-12). As the disease progresses, the underlying subchondral bone becomes sclerotic and thickened in response to increased pressure on the surface of the joint, rendering it less effective as a shock absorber. Sclerosis, or formation of new bone and cysts, usually occurs at the joint margins, forming abnormal bony outgrowths called osteophytes, or spurs (see Fig. 44-12). As the joint begins to lose its integrity, there is trauma to the synovial membrane, which results in nonspecific inflammation. Compared with RA, however, the inflammatory
Typically, OA presents with joint pain. Generally, pain may be described as aching and may be somewhat difficult to localize. It usually worsens with use or activity and is relieved by rest. A common phenomenon, often referred to as “gelling,” involves difficulty initiating joint movement after inactivity, epitomized by the problems older people with OA have in “getting started” after sitting down for a while. In later stages of disease activity, night pain may be experienced during rest. Cracking of joints (audible crepitus) and joint locking may occur when the joint is moved. As the disease advances, even minimal activity may cause pain.

The most frequently affected joints are the hips, knees, lumbar and cervical spine, proximal and distal joints of the hands, the first carpometacarpal joint, and the first metatarsophalangeal joints of the feet. Table 44-1 identifies the joints that commonly are affected by OA and the common clinical features correlated with the disease activity of each particular joint. A single joint or several may be affected. Although a single weight-bearing joint may be involved initially, other joints often become affected because of the additional stress placed on them while trying to protect the initial joint. It is not unusual for a person having a knee replacement to discover soon after the surgery is done that the second knee also needs to be replaced. Other clinical features are limitations of joint motion and joint instability. Joint enlargement usually results from new bone formation; the joint feels hard, in contrast to the soft, spongy feeling characteristic of the joint in RA. Sometimes, mild synovitis or increased synovial fluid can cause joint enlargement.

**Clinical Features**

Typically, OA presents with joint pain. Initially, pain may be described as aching and may be somewhat difficult to localize. It usually worsens with use or activity and is relieved by rest. A common phenomenon, often referred to as “gelling,” involves difficulty initiating joint movement after inactivity, epitomized by the problems older people with OA have in “getting started” after sitting down for a while. In later stages of disease activity, night pain may be experienced during rest. Cracking of joints (audible crepitus) and joint locking may occur when the joint is moved. As the disease advances, even minimal activity may cause pain.

The most frequently affected joints are the hips, knees, lumbar and cervical spine, proximal and distal joints of the hands, the first carpometacarpal joint, and the first metatarsophalangeal joints of the feet. Table 44-1 identifies the joints that commonly are affected by OA and the common clinical features correlated with the disease activity of each particular joint. A single joint or several may be affected. Although a single weight-bearing joint may be involved initially, other joints often become affected because of the additional stress placed on them while trying to protect the initial joint. It is not unusual for a person having a knee replacement to discover soon after the surgery is done that the second knee also needs to be replaced. Other clinical features are limitations of joint motion and joint instability. Joint enlargement usually results from new bone formation; the joint feels hard, in contrast to the soft, spongy feeling characteristic of the joint in RA. Sometimes, mild synovitis or increased synovial fluid can cause joint enlargement.

**Diagnosis and Treatment.** The diagnosis of OA usually is determined by history and physical examination, x-ray studies, and laboratory findings that exclude other diseases. Although OA often is contrasted with RA for diagnostic purposes, the differences are not always readily apparent. Other rheumatic diseases may be superimposed on OA. Psychological factors, severity of joint disease, and educational level affect the expression of symptoms.

Because there is no cure, the treatment of OA is symptomatic and includes physical rehabilitative, pharmacologic, and surgical measures. Physical measures are aimed at improving the supporting structures of the joint and strengthening opposing muscle groups involved in cushioning weight-bearing forces. This includes a balance of rest and exercise, use of splints to protect and rest the joint, use of heat and cold to relieve pain and muscle spasm, and adjusting the activities of daily living. Weight reduction is helpful when the knee is involved. The involved joint should not be further abused, and steps should be taken to protect and rest it. These include weight reduction (when weight-bearing surfaces are involved) and the use of a cane or walker if

**TABLE 44-1 Clinical Features of Osteoarthritis**

<table>
<thead>
<tr>
<th>Joint</th>
<th>Clinical Features</th>
</tr>
</thead>
<tbody>
<tr>
<td>Cervical spine</td>
<td>Localized stiffness; radicular or nonradicular pain; posterior osteophyte formation may cause vascular compression</td>
</tr>
<tr>
<td>Lumbar spine</td>
<td>Low back pain and stiffness; muscle spasm; decreased back motion; nerve root compression causing radicular pain; spinal stenosis</td>
</tr>
<tr>
<td>Hip</td>
<td>Most common in older men; characterized by insidious onset of pain, localized to groin region or inner aspect of the thigh; may be referred to buttocks, sciatic region, or knee; reduced hip motion; leg may be held in external rotation with hip flexed and adducted; limp or shuffling gait; difficulty getting in and out of chairs</td>
</tr>
<tr>
<td>Knee</td>
<td>Localized discomfort with pain on motion; limitation of motion; crepitus; quadriceps atrophy due to lack of use; joint instability; genu varus or valgus; joint effusion</td>
</tr>
<tr>
<td>First carpometacarpal joint</td>
<td>Tenderness at base of thumb; squared appearance to joint</td>
</tr>
<tr>
<td>Proximal interphalangeal joint—Bouchard nodes</td>
<td>Same as for distal interphalangeal joint disease</td>

the hips and knees are involved. Muscle-strengthening exercises may help protect the joint and reduce pain.

Several dietary supplements are available and advertised as beneficial for OA, but few have undergone rigorous testing. The most widely used supplements for OA are glucosamine and chondroitin sulfate. A recent multicenter trial funded by the National Institutes of Health found that glucosamine and chondroitin (alone or in combination) were no better than placebo in reducing pain in the total group of persons with knee pain, but that the combination may be effective in those with moderate to severe pain.63 Topical capsaicin may have some pain-relieving effect in osteoarthritic knees and hands.

Oral medications are aimed at reducing inflammation or providing analgesia. The mainstay of treatment for mild osteoarthritis is acetaminophen. When acetaminophen fails to control symptoms, or if the symptoms are moderate to severe, NSAID therapy is recommended. Intra-articular corticosteroid injections may be used when other treatment measures have been unsuccessful in adequately relieving symptoms.60,61 They are especially helpful in persons who have an effusion of the joint. Injections are usually limited to no more than three times a year in the same joint because their use is thought to accelerate joint destruction. Viscosupplementation is based on the hypothesis that joint lubrication is abnormal in OA.64 Hyaluronate is injected into the joint weekly for 3 to 5 weeks.

Surgery is considered when the person is having severe pain and joint function is severely reduced.60 Procedures include arthroscopic lavage and débridement, bunion resections, osteotomies to change alignment of the knee and hip joints, and decompression of the spinal roots in osteoarthritic vertebral stenosis. Total hip replacements have provided effective relief of symptoms and improved range of motion for many persons, as have total knee replacements, although the latter procedure has produced less-consistent results. Joint replacement is available for the first carpometacarpal joint. Arthrodesis (surgical stiffening of a joint) is used in advanced disease to reduce pain; however, this results in loss of motion.

Crystal-Induced Arthropathies

Crystal deposition in joints produces arthritis. In gout, monosodium urate or uric acid crystals are found in the joint cavity. Another condition in which calcium pyrophosphate dihydrate crystals are found in the joints sometimes is referred to as pseudogout or chondrocalcinosis. A brief discussion of pseudogout is found in the section on rheumatic diseases in the elderly.

Gout

Gout is actually a group of diseases known as the gout syndrome.66–68 It includes acute gouty arthritis with recurrent attacks of severe articular and periarticular inflammation; tophi or the accumulation of crystalline deposits in articular surfaces, bones, soft tissue, and cartilage; gouty nephropathy or renal impairment; and uric acid kidney stones.

The term primary gout is used to designate cases in which the cause of the disorder is unknown or an inborn error in metabolism and is characterized primarily by hyperuricemia and gout. Primary gout is predominantly a disease of men, with a peak incidence in the fourth to sixth decade. In secondary gout, the cause of the hyperuricemia is known but the gout is not the main disorder. Asymptomatic hyperuricemia is a laboratory finding and not a disease. Most persons with hyperuricemia do not develop gout.

Pathogenesis. The pathogenesis of gout resides in an elevation of serum uric acid levels. Uric acid is the end product of purine (adenine and guanine from DNA and RNA) metabolism.3,4 The elevation of uric acid and the subsequent development of gout can result from overproduction of purines, decreased salvage of free purine bases, augmented breakdown of nucleic acids as a result of increased cell turnover, or decreased urinary excretion of uric acid. Primary gout, which constitutes 90% of cases,3 may be a consequence of enzyme defects that result in an overproduction of uric acid, inadequate elimination of uric acid by the kidney, or a combination of the two. In most cases, the reason is unknown. In secondary gout, hyperuricemia may be caused by increased breakdown of nucleic acids, as occurs with rapid tumor cell lysis during treatment for lymphoma or leukemia. Other cases of secondary gout result from chronic kidney disease. Some of the diuretics, including the thiazides, can interfere with the excretion of uric acid.

An attack of gout occurs when monosodium urate crystals precipitate in the joint and initiate an inflammatory response. Synovial fluid is a poorer solvent for uric acid than plasma. Moreover, uric acid crystals are even less soluble at temperatures below 37°C, and typically are deposited in peripheral areas of the body, such as the great toe, where the temperatures are cooler than other parts of the body.3 With prolonged hyperuricemia, crystals and microtophi (i.e., small, hard nodules with irregular surfaces that contain crystalline deposits of monosodium urate) accumulate in the synovial lining cells and in the joint cartilage. The released crystals are chemotactic to leukocytes and also activate complement. Phagocytosis of urate crystals by polymorphonuclear leukocytes occurs and leads to polymorphonuclear cell death with the release of lysosomal enzymes. As this process continues, the inflammation causes destruction of the cartilage and subchondral bone.

Repeated attacks of acute arthritis eventually lead to chronic arthritis and the formation of the large, hard nodules called tophi (Fig. 44-13). They are found most commonly in the synovium, olecranon bursa, Achilles tendon, subchondral bone, and extensor surface of the forearm and may be mistaken for rheumatoid nodules. Tophi usually do not appear until 10 years or more after the first gout attack. This stage of gout, called chronic tophaceous gout, is characterized by more frequent and prolonged attacks, which often are polyarticular.67
Clinical Manifestations. The typical acute attack of gout is monoarticular and usually affects the first metatarsophalangeal joint. The tarsal joints, insteps, ankles, heels, knees, wrists, fingers, and elbows also may be initial sites of involvement. Acute gout often begins at night and may be precipitated by excessive exercise, certain medications or foods, alcohol, or dieting. The onset of pain typically is abrupt, and redness and swelling are observed. The attack may last for days or weeks. Pain may be severe enough to be aggravated even by the weight of a bed sheet covering the affected area.

In the early stages of gout after the initial attack has subsided, the person is asymptomatic, and joint abnormalities are not evident. This is referred to as intercritical gout. After the first attack, it may be months or years before another attack. As attacks recur with increased frequency, joint changes occur and become permanent.

Diagnosis and Treatment. Although hyperuricemia is the biochemical hallmark of gout, the presence of hyperuricemia cannot be equated with gout because many persons with this condition never develop gout. A definitive diagnosis of gout can be made only when monosodium urate crystals are present in the synovial fluid or in tissue sections of tophaceous deposits. Synovial fluid analysis is useful in excluding other conditions, such as septic arthritis, pseudogout, and RA. Diagnostic methods also include measures to determine if the disorder is related to overproduction or to underexcretion of uric acid. This is done through measurement of serum uric acid levels and collection of a 24-hour urine sample for determination of urate excretion in the urine.

The objectives for treatment of gout include the termination and prevention of the acute attacks of gouty arthritis and the correction of hyperuricemia, with consequent inhibition of further precipitation of sodium urate and absorption of urate crystal deposits already in the tissues.

Pharmacologic management of acute gout is directed toward reducing joint inflammation. Hyperuricemia and related problems of tophi, joint destruction, and renal problems are treated after the acute inflammatory process has subsided. Nonsteroidal anti-inflammatory drugs, particularly indomethacin and ibuprofen, are used for treating acute gouty arthritis. Alternative therapies include colchicine and intra-articular deposition of corticosteroids. Colchicine produces its anti-inflammatory effects by inhibition of leukocyte migration and phagocytosis. Although the drug usually is given orally, a more rapid response is obtained when colchicine is given intravenously. The acute symptoms of gout usually subside within 48 hours after treatment with oral colchicine has been instituted and within 12 hours after intravenous administration of the drug. The corticosteroid drugs have not been systemically studied, but can be useful in the treatment of acute gout limited to a single joint or bursa.

Between acute attacks nonpharmacologic and pharmacologic measures are used to normalize uric acid levels as a means of reducing or preventing the frequency and severity of recurrence. Nonpharmacologic methods include maintenance of ideal weight, moderation in alcohol consumption, and avoidance of purine-rich foods (e.g., liver, kidney, sardines, anchovies, and sweet-breads). Avoidance of medications that inhibit renal excretion of uric acid (e.g., loop and thiazide diuretics, low-dose aspirin, and niacin) is also needed.

Three classes of drugs may be used to lower the serum uric acid—xanthine oxidase inhibitors, uricosuric agents, and uricase agents. Xanthine oxidase inhibitors block the synthesis of uric acid. In this classification, the most commonly prescribed drug to lower urate levels is allopurinol. Another xanthine oxidase inhibitor, febuxostat, is used for treatment in persons with a hypersensitivity to allopurinol. The uricosuric agents (e.g., probenecid, sulfinpyrazone, and benzobromarone) prevent the tubular reabsorption of urate and increase its excretion in the urine. The serum urate concentrations are monitored to determine efficacy and dosage. Uricase agents convert insoluble uric acid to a soluble product that
can be excreted easily. Pegloticase is an infusible uricase agent that works rapidly to reduce serum uric acid and tophaceous deposits of urate. Prophylactic colchicine may be used between gout attacks.

### Rheumatic Diseases in Children and the Elderly

Rheumatic diseases differ among children, adults, and the elderly in terms of diagnosis, impact of activities, and availability of treatment modalities. These conditions, which affect not only the child but also the family, can seriously impact a child’s growth and development, limit their participation in childhood activities, and require an extensive plan of drug treatment and rehabilitation.

Weakness and gait disturbance that often accompany the rheumatic diseases in the elderly can contribute to the likelihood of falls and fracture, causing suffering, increased health care costs, further loss of independence, and the potential for a decreased life span.

### Rheumatic Diseases in Children

Children can be affected by many of the same types of rheumatic diseases that occur in adults. About 1 child in every 1000 develops some type of juvenile arthritis. It can affect a single joint or multiple joints, and cause systemic manifestations such as fevers, rash, and eye disorders. Rheumatic disorders of children include juvenile idiopathic arthritis, juvenile spondyloarthropathies, and juvenile dermatomyositis.

#### Juvenile Idiopathic Arthritis

Juvenile idiopathic arthritis (JIA), formerly known as *juvenile rheumatoid arthritis*, is the most common form of childhood arthritis, and one of the most common forms of chronic disease in children. The disorder...
can be regarded not as a single disease but as a category of disorders, all involving chronic (long-term) joint inflammation, that begins before a child reaches the age of 16 and lasts for 6 weeks to 3 months. It may be present as an oligoarticular disorder (involving less than 5 joints) or as a polyarticular disorder (involving 5 or more joints), and may include other systemic manifestations such as fever, rash, and/or eye inflammation.

The initial symptoms of JIA may be subtle or acute, and often include morning stiffness and gelling; easy fatigability, particularly after school; and joint swelling. The involved joints are often warm, resist full range of motion, and are painful on motion, but not erythematous. Oligoarthritis, which is the most common type of JIA, predominantly affects joints of the lower extremities, usually the knees or ankles. Involvement of upper extremity large joints and the hip is rarely a presenting sign. Often a single joint is affected at onset. The severity of joint symptoms is usually mild, and it is not uncommon for children to present with normal or near-normal overall function. Children with this form of JIA are usually younger (1 to 5 years at onset), more likely to be girls (girls outnumber boys by 4 to 1), often rheumatoid factor (RF) positive (discussed under rheumatoid arthritis), and at greater risk for developing chronic eye inflammation. The inflammation primarily involves the anterior chamber of the eye and is associated with minimal, if any, symptoms in about 80% of cases. Because severe eye changes can occur, these children should be screened at regular intervals and treated by an experienced eye specialist.

The polyarticular form of the disorder is generally characterized by involvement of both large and small joints. This form of JIA may develop at any age up to 16 years of age, with girls outnumbering boys by 3 to 1. This form of arthritis more closely resembles the adult form of the disease than the other two subgroups. The RF sometimes is present and may indicate a more active disease process. Clinical manifestations are highly variable and include fatigue, low-grade fever, weight loss, malaise, anemia, stunted growth, slight organomegaly (e.g., hepatosplenomegaly), and lymphadenopathy.

Systemic-onset disease, which affects approximately 2% to 17% of children with JIA, is characterized by arthritis and prominent visceral involvement that include hepatosplenomegaly, lymphadenopathy, and inflammation of serous membranes, such as in pericardial effusion. The symptoms of systemic JIA include a daily intermittent high fever, which usually is accompanied by a characteristic faint, erythematous, macular rash. The salmon-colored lesions of the rash may be linear or circular, from 2 to 5 mm in size, and appear in groups with a linear distribution on the trunk and proximal extremities. The rash is not pruritic (it does not cause itching). The most prominent diagnostic feature is its transient nature, with a group of lesions lasting less than an hour. Systemic symptoms usually subside in 6 to 12 months.

The prognosis for most children with JIA is good. NSAIDs are the first-line drugs used in treating JIA. Most children with polyarticular or systemic JIA, however, need additional anti-inflammatory therapy. Corticosteroids are recommended only for overwhelming inflammation of systemic disease. Disease-modifying antirheumatic drugs (DMARDs), such as methotrexate, may also be used. Careful attention to growth and development and nutritional issues are additional aspects of treatment of children with JIA. Children are encouraged to lead as normal a life as possible.

**Juvenile Spondyloarthropathies**

Ankylosing spondylitis, reactive arthritis, psoriatic arthritis, and spondyloarthropathies associated with ulcerative colitis and regional enteritis can affect children as well as adults. The arthropathies of inflammation-bowel disease and reactive arthritis are much less common in childhood.

In children, spondyloarthropathy manifests in peripheral joints first, mimicking pauciarticular JIA, with no evidence of sacroiliac or spine involvement for months to years after onset. The spondyloarthropathies are more common in boys and commonly occur in children who have a positive family history. HLA-B27 typing is helpful in diagnosing children because of the unusual presentation of the disease. Juvenile ankylosing spondylarthritis frequently begins with oligoarthritis and enthesitis or inflammation at the site where muscles insert into bone. The arthritis occurs predominantly in the lower extremities and frequently involves the hips. Enthesitis is particularly common, manifesting as local and often severe tenderness over involved tendons and ligaments, especially those around the plantar surface of the foot, ankle, and knee. The disease course is variable and can include periods of low and high disease activity.

Juvenile psoriatic arthritis is composed of two subgroups, differentiated by age of onset. Older children have features of spondyloarthritis, including a relative male preponderance, increased risk of axial involvement, and enthesitis. The mechanisms appear to involve autoimmune dysregulation centered at the synovial-entheseal complex. In contrast, children with early-onset disease bear similarities to children with early onset oligoarticular and polyarticular JIA disorders, including a female preponderance and positive RF factor, suggesting a possible role for autoimmune mechanisms. Inflammation of the fingers is seen in both groups, however.

Management of the disease involves physical therapy, education, and attention to growth and developmental issues. Medication includes the use of salicylates or other NSAIDs. In children who are not responsive to these medications, sulfasalazine or methotrexate may be considered. Exercises to maintain range of motion of the back, thorax, and affected joints should be instituted early in the disease. Custom-fitted shoes are particularly useful in managing painful entheses of the feet.

**Juvenile Dermatomyositis**

Juvenile dermatomyositis (JDM) is a rare, presumably autoimmune disorder that causes proximal muscle weakness and a characteristic rash. The disorder can affect children of all ages, with an average age at onset...
of 7 years.\textsuperscript{80,81} There is an increased incidence among girls. The cause is unknown, but there is a history of infection in the 3 months before disease onset in most affected children. Symmetric proximal muscle weakness, elevated muscle enzymes, evidence of vasculitis, and electromyographic changes confirming an inflammatory myopathy are diagnostic for JDM. The rash may precede or follow the onset of proximal muscle weakness. Periorbital edema with swelling and purple red discoloration of the upper eyelid is common. An erythematous (red) papulosquamous (containing both papules and scales) rash may also be present on the dorsal surfaces of the finger joints and on the extensor surfaces of the elbows and knees. Ulcerative skin disease is a serious and potentially life-threatening manifestation of JDM.

Calciﬁcations can occur in 30\% to 50\% of children with JDM and are by far the most debilitating symptom. The calciﬁcations appear at pressure points or sites of previous trauma. Juvenile dermatomyositis is treated primarily with corticosteroids to reduce inﬂammation. DMARDs, such as methotrexate, may be used as a steroid-sparing agent in cases of refractory disease. All children with JDM should avoid exposure to the sun, use a sunscreen with a sun protection factor (SPF) greater than 36, eat a calcium-sufficient diet, and take vitamin D therapy.\textsuperscript{81}

Rheumatic Diseases in the Elderly

Rheumatic disorders are common causes for complaint among elderly persons.\textsuperscript{82,83} Pain and severe limitations in function often threaten independence and quality of life. The weakness and gait disturbance that often accompany the rheumatic diseases can increase the risk of falls and fracture, causing suffering, increased health care costs, and further loss of independence.

Arthritic complaints in the elderly are most frequently associated with degenerative forms of arthritis, such as osteoarthritis, but forms of inﬂammatory arthritis such as rheumatoid and gouty arthritis are also seen. One form of rheumatic disease that has a predilection for the elderly is polymyalgia rheumatica.

Osteoarthritis

Osteoarthritis is by far the most common form of arthritis among the elderly.\textsuperscript{82} It may affect any joint but is most common in the spine and small joints of the hand, particularly the distal interphalangeal joints, and knees, hip, ankle, and shoulder. When the upper extremity joints are affected, activities of daily living, such as holding on to an object, putting on a coat, buttoning a shirt, or turning a key may be a problem. When the lower extremities are involved, climbing and descending stairs and getting out of a chair are difﬁcult.

Management of OA in older persons includes both conservative management and surgical correction or joint replacement.\textsuperscript{85} Conservative management focuses on rehabilitative and pharmacologic measures. Rehabilitative measures are directed at reducing the load on the affected joint and maintaining joint mobility. Weight reduction signiﬁcantly reduces the load in persons in whom weight-bearing joints are involved. Although resting painful arthritis joints is helpful in the short term, prolonged inactivity will lead to the more serious problem of immobility. Exercise programs are important to maintain joint motion and strength. Both passive and active exercises should be encouraged. The use of a cane will signiﬁcantly reduce the loading force in all lower extremities and should be recommended to allow for continuation of a walking program. Attention to environmental hazards to prevent falls is essential. For persons with knee involvement, bracing and orthotics provide a shift in the medial knee compartment and, in so doing, may provide considerable relief of pain and improvement in function. The use of appropriate footwear may also reduce joint forces for persons with arthritic involvement of the lower extremities.

Pharmacologic treatment is accomplished mainly through the use of NSAIDs and analgesics.\textsuperscript{82} As the disease progresses, these medications become less effective and other methods such intra-articular hyaluronic sone injection may be used. Injection of hyaluronic acid preparations into the knee may be used as an alternative to steroids. Surgical treatment, including joint replacement, may be indicated for severely arthritic joints that are unresponsive to conservative treatment.

Rheumatoid Arthritis

The prevalence of RA increases with advancing age.\textsuperscript{83,84} There are two distinct clinical presentations of RA in older persons: RA diagnosed before age 60, and elderly onset RA (EORA), in which the disease is ﬁrst diagnosed after age 60. There is a slightly less female predominance and acute onset with marked elevations in inﬂammatory markers than in persons diagnosed at an earlier age. There is also signiﬁcant morning stiffness, with prominent involvement of the upper extremities, particularly the shoulders. This is in contrast to older persons who have had disease activity for several decades and demonstrate advanced sequelae of the disease and its treatment.

Whether either form of RA has a better prognosis than the other is uncertain. Both forms require special considerations in terms of pharmacologic therapy, and both can have a negative impact on the functional status of the elderly.

Crystal-Induced Arthropathies

The two best-recognized forms of crystal-induced joint disease are caused by the deposition of monosodium urate (gout) and calcium pyrophosphate (pseudogout).\textsuperscript{85} Gout typically has its onset in middle-aged adults, whereas pseudogout has an increasing prevalence in older adults and is often associated with unique and atypical features.

Gout. The incidence of clinical gout increases with advancing age, in part because of the increased involvement of joints after years of continued hyperuricemia.
High serum urate levels rarely occur in women before menopause; initial attacks of clinical gout occur around the age of 70 years, or 20 years after menopause. The treatment of gout is often more difficult in the elderly. Although colchicine may be effective in controlling the symptoms of chronic gout, it may cause diarrhea in some patients, limiting its effectiveness in maintenance therapy.

**Pseudogout.** As part of the tissue aging process, OA develops with associated cartilage degeneration and the shedding of calcium pyrophosphate crystals into the joint cavity. These crystals may produce a low-grade chronic inflammation—the chronic pseudogout syndrome. The accumulation of calcium pyrophosphate and related crystalline deposits in articular cartilage is common in the elderly. There are no medications that can remove the crystals from the joints. Although it may be asymptomatic, presence of the crystals may contribute to more rapid cartilage deterioration. This condition may coexist with severe OA. Calcium pyrophosphate deposition disease may also present with proximal muscle pain mimicking polymyalgia rheumatica.

**Polymyalgia Rheumatica**

Polymyalgia rheumatica is an inflammatory condition of unknown origin characterized by aching and morning stiffness in the cervical regions and shoulder and pelvic girdle areas. Of the forms of arthritis affecting the elderly, it is one of the more difficult to diagnose and one of the most important to identify. Elderly women are especially at risk. Polymyalgia rheumatica is a common syndrome of older persons, rarely occurring before 50 years of age (and usually after age 60). The onset can be abrupt, with the patient going to bed feeling well and awakening with pain and stiffness in the neck, shoulders, and hips.

**Diagnosis and Treatment.** Diagnosis is based on the pain and stiffness persisting for at least 1 month and an elevated ESR. The diagnosis is confirmed when the symptoms respond dramatically to a small dose of prednisone, a corticosteroid. Biopsies have shown that the muscles are normal, despite the name, but that a nonspecific inflammation affecting the synovial tissue is present. It is possible that a number of patients are erroneously diagnosed as having RA or OA. For patients with an elevated ESR, the diagnosis usually is based on a 3-day trial of prednisone treatment. Patients with polymyalgia rheumatica typically exhibit striking clinical improvement on the second day. Patients with RA also show improvement, although usually days later.

Treatment with NSAIDs provides relief for some patients, but most require continuing therapy with prednisone, with gradual reduction of the dose over the course of 1.5 to 2 years, using the person’s symptoms as the primary guide. Patients need close monitoring during the maintenance phase with prednisone therapy. Because their symptoms are relieved, they often quit taking the prednisone and their symptoms recur, or doses are missed and the decreased dosage leads to an increase in symptoms. Unless careful assessment reveals the frequency of missed doses, the physician may be misled into increasing the dosage when it is not needed. Because of the side effects of the corticosteroids, the goal is to use the lowest dose of the drug necessary to control the symptoms. Weaning patients off low-dose prednisone therapy after this length of time can be a difficult and extended process.

**Complications.** A certain percentage of patients with polymyalgia rheumatica also develop giant cell arteritis (i.e., temporal arteritis) with involvement of the ophthalmic arteries. The two conditions are considered to represent different manifestations of the same disease. Giant cell arteritis, a form of systemic vasculitis, is a systemic inflammatory disease of large and medium-sized arteries. The inflammatory response seems to be a T-cell response to an antigen.

Clinical manifestations of giant cell arteritis usually begin insidiously and may exist for some time before being recognized. It is potentially dangerous if missed or mistreated, especially if the temporal artery or other vessels supplying the eye are involved, in which case blindness can ensue quickly without treatment. The condition is responsive to appropriate therapy. For those patients at risk, adherence to the medication program is critical, with preservation of sight being the goal. Because this complication can occur so quickly and is relatively asymptomatic, it is vital that the patient understand the importance of taking the correct dose regularly as prescribed. Initial treatment consists of large doses of prednisone. This dosage is continued for 4 to 6 weeks and then decreased gradually.

**Management of Rheumatic Diseases in the Elderly**

In addition to diagnosis-specific treatment, the elderly require special considerations. Management techniques that rely on modalities other than drugs are particularly important. These include splints, walking aids, muscle-building exercise, and local heat. Muscle-strengthening and stretching exercises are particularly effective in the elderly person with age-related losses in muscle function and should be instituted early. Rest, the cornerstone of conservative therapy, is hazardous in the elderly, who can rapidly lose muscle strength.

In terms of medications, the NSAIDs may be less well tolerated by the elderly, and their side effects are more likely to be serious. In addition to bleeding from the gastrointestinal tract and renal insufficiency, there may be cognitive dysfunction manifested by forgetfulness, inability to concentrate, sleeplessness, paranoid ideation, and depression.

Joint arthroplasty can also be used for pain relief and increased function. Chronicologic age is not a contraindication to surgical treatment of arthritis. In appropriately selected elderly candidates, survival and functional outcome after surgery are equivalent to those in younger age groups. The more sedentary activity level of the elderly makes them even better candidates for joint replacement because they put less stress and demand on the new joint.
Rheumatic diseases that affect children include juvenile idiopathic arthritis, juvenile dermatomyositis, and juvenile-onset spondyloarthopathies. Although the childhood form of the arthritis may be similar to that seen in the adult, there are manifestations and treatment issues that are unique to the younger population.

Arthritis is the most common complaint of the elderly population. There is a difference in the manifestations, diagnosis, and treatment of some of the rheumatic diseases in the elderly compared with those in the younger population. Osteoarthritis is the most common form of arthritis among the elderly. The prevalence of rheumatoid arthritis and gout increases with advancing age. One form of rheumatic disease that has a predilection for the elderly is polymyalgia rheumatica. A certain percentage of persons with polymyalgia rheumatica also develop giant cell arteritis (i.e., temporal arteritis) with involvement of the ophthalmic arteries, a condition that can cause blindness if not recognized and treated.

**REVIEW EXERCISES**

1. A 60-year-old postmenopausal woman presents with a compression fracture of the vertebrae. She has also noticed increased backache and loss of height over the last few years.
   - A. Explain how aging and the lack of estrogen contribute to the development of osteoporosis.
   - B. What other factors should be considered when assessing the risk for developing osteoporosis?
   - C. What is the best way to measure bone density?
   - D. Name the two most important factors in preventing osteoporosis.
   - E. What medications might be used to treat this woman's condition?

2. A 30-year-old woman recently diagnosed with rheumatoid arthritis (RA) complains of general fatigue and weight loss along with symmetric joint swelling, stiffness, and pain. The stiffness is more prominent in the morning and subsides during rest. Laboratory measures reveal an elevated RF. Physical examination reveals an enlarged joint with a varus deformity; coarse crepitus is felt over the joint on passive movement.
   - A. Describe the immunopathogenesis of the joint changes that occur with RA.
   - B. How do these changes relate to this woman's symptoms?
   - C. What is the significance of her RF test results?
   - D. How do her complaints of general fatigue and weight loss relate to the RA disease process?

3. A 65-year-old obese woman with a diagnosis of osteoarthritis (OA) has been having increased pain in her right knee that is made worse with movement and weight bearing and is relieved by rest. Physical examination reveals an enlarged joint with a varus deformity; coarse crepitus is felt over the joint on passive movement.
   - A. Compare the pathogenesis and articular structures involved in OA with those of RA.
   - B. What is the origin of the enlargement of the affected joint, the varus deformity, and the crepitus that is felt on movement of the affected knee?
   - C. Explain the predilection for involvement of the knee in persons such as this woman.
   - D. What types of treatment are available for this woman?

4. A 75-year-old woman is seen by a health care provider because of complaints of fever, malaise, and weight loss. She is having trouble combing her hair, putting on a coat, and getting out of a chair because of the stiffness and pain in her shoulders, hip, and lower back. Because of her age and symptoms, the health care provider suspects the woman has polymyalgia rheumatica.
   - A. What laboratory test can be used to substantiate the diagnosis?
   - B. What other diagnostic strategies are used to confirm the diagnosis?
   - C. How is the disease treated?

**REFERENCES**

The integumentary system, including the skin and its appendages (sweat and sebaceous glands, hair follicles, and nails), constitutes a complex organ with many cell types. The diversity of these cells and their ability to work together provide many functions needed to cope with the constantly changing external environment.

**Structure and Function of the Skin**

The skin is one of the largest and most versatile organs in the body. It has a surface area of 1.5 to 2 square meters, weighs approximately 4 kg (9 pounds), and forms the major interface between the internal organs and the external environment. Besides providing a covering for the entire body surface, the skin performs many other functions, including protection against physical injury, sunlight, and microorganisms; prevention of loss of fluids from the internal environment; regulation of body temperature; continual reception of sensations from the environment, such as touch, temperature, and pain; and synthesis of vitamin D through the action of sunlight on the skin.

The properties of the skin, such as the thickness of skin layers, their cell types, the distribution of sweat and sebaceous glands, and the number and size of hair follicles, vary in different parts of the body. Nevertheless, certain properties are common to the skin on all areas of the body. Structurally, the skin consists of two main...
layers: a superficial and thinner epithelial tissue layer, called the *epidermis*, and a deeper and thicker connective tissue layer, called the *dermis* (Fig. 45-1). The basement membrane zone is an interface between the dermis and epidermis. A layer of subcutaneous tissue, sometimes called the *hypodermis*, serves as a storage site for fat and contains large blood vessels that supply the skin.

**Epidermis**

The functions of the skin depend largely on the properties of its epidermis, which is composed of stratified keratinized epithelium containing four types of cells: keratinocytes, melanocytes, Langerhans cells, and Merkel cells.

**Keratinocytes**

The keratinocytes are the predominant cell type of the epidermis. They produce a fibrous protein called *keratin*, which is essential to the protective function of skin and may be involved in the immune system and wound healing. As they divide and mature, the keratinocytes form five distinct layers, or *strata*: the stratum germinativum, the stratum spinosum, the stratum granulosum, the stratum lucidum, and the stratum corneum.

The deepest layer, the *stratum germinativum* or *stratum basale*, consists of a single layer of basal cells that are attached to the basal lamina in the basement membrane zone (to be discussed). The basal cells are the only epidermal cells that are mitotically active. All cells of the epidermis arise from this layer. As new cells form in the basal layer, the older cells change shape and are pushed upward toward the skin surface (Fig. 45-2). As these cells approach the skin surface, their cytoplasm becomes converted to keratin and they form flattened plates of dead cells on the skin surface. It normally takes 3 to 4 weeks for the epidermis to replicate itself. The rate of cell division in the stratum germinativum is greatly accelerated when the outer layers of the epidermis are stripped away as occurs in abrasions and burns.

The remaining layers of epidermis are formed as cells from the basal cell layer move upward toward the skin surface. The second layer, the *stratum spinosum*, is two to four layers thick. The cells of this layer are commonly

---

**FIGURE 45-1.** Three-dimensional view of the skin.
referred to as prickle cells because they develop a spiny appearance as their cell borders interact.

The third layer, the stratum granulosum, consists of three to five layers of flattened keratinocytes. The nuclei and organelles of these cells begin to degenerate and keratin filaments become more apparent. A distinctive feature of cells in this layer is the appearance of dark staining granules of a protein called keratohyalin, which serve as a support for the keratin filaments. The stratum lucidum, the fourth layer, which lies just superficial to the stratum granulosum, is a thin, transparent layer mostly confined to the palms of the hands and soles of the feet. It consists of transitional cells that retain some of the functions of living skin cells from the layers below but otherwise resemble the cells of the stratum corneum.

The top or surface layer of the epidermis is the stratum corneum. The cells in the stratum corneum are made up of numerous layers of dead keratinized cells. The interiors of the cells contain mostly keratin and keratohyalin. These cells are continuously shed and replaced by cells from the deeper strata. The stratum corneum is the layer that varies most in cell layers and thickness. It ranges from 15 layers of cells in areas such as the face to 25 or more layers on the arm. Specialized areas, such as the palms of the hand and soles of the feet, have 100 layers or more.

Melanocytes

Melanocytes are dendritic cells found scattered among the basal cells in the stratum germinativum. They function to produce pigment granules called melanin, the substance that is responsible for skin color, tanning, and protection against ultraviolet radiation.

During embryonic life, melanocyte precursor cells migrate from the neural crest and enter the developing epidermis. A specific functional association is then established in which one melanocyte maintains an association with a given number of keratinocytes. This association is called the dermal melanin unit. The ratio of melanocytes to keratinocytes varies in different parts of the body and is constant in all races.

As dendritic cells, melanocytes are round to columnar cells with long undulating processes that extend between the keratinocytes of the stratum spinosum (Fig. 45-3). Melanocytes synthesize melanin from the amino acid tyrosine in the presence of an enzyme called tyrosinase that is activated by ultraviolet light. Synthesis of melanin occurs in membrane-bound structures called premelanosomes, which are derived from the Golgi complex. As melanin accumulates in the premelanosomes, they are transformed into mature melanin granules, called melanosomes. Premelanosomes are concentrated near the Golgi apparatus, and nearly mature and mature melanocytes among the basal cells of stratum germinativum. Melanosomes and their melanin content are transferred to neighboring keratinocytes by pigment donation. This process involves the phagocytosis of the tips of the melanocyte process by keratinocytes. After pigment donation, the melanocyte process elongates and receives more melanosomes, and the process is repeated. Thus, a single melanocyte is able to provide melanin to all of the associated keratinocytes in its epidermal melanin unit.

Skin color is determined by the type, number, and size of the melanosomes transferred into the surrounding keratinocytes. Dark-skinned and light-skinned people have approximately the same number of melanocytes, but the production and packaging of pigment are different. In dark-skinned people, larger melanin-containing melanosomes are produced and transferred individually to the keratinocyte, whereas in light-skinned people, smaller melanosomes are produced and then packaged together in a membrane before being transferred to the keratinocyte.

There are two major forms of melanin: eumelanin and pheomelanin. Exposure to the sun's ultraviolet rays
increases the production of eumelanin, a brownish-black pigment, which causes tanning to occur. The primary function of such melanin is to protect the skin by absorbing and scattering harmful ultraviolet rays, which are implicated in skin cancers. Localized concentrations of eumelanin are also responsible for the formation of freckles and moles. Pheomelanin, a reddish-yellow pigment, is particularly concentrated in the lips, nipples, glans penis, and vagina. Both types of melanin are found in hair, particularly red hair. It has been suggested that the reason fair-haired individuals are more susceptible to skin cancers may be due to the enhanced photoreactivity of pheomelanin, as compared to eumelanin.

**Langerhans Cells**

Langerhans cells are dendritic cells that reside principally in the stratum spinosum of the epidermis and play a major role in the functioning of the skin’s immune system (Fig. 45-4). They are antigen-presenting cells that originate in the bone marrow and are part of the mononuclear phagocytic system. Like macrophages, Langerhans cells express both major histocompatibility class (MHC) I and II molecules as well as receptors for immunoglobulins (see Chapter 15). Their major function is to phagocytose and process foreign antigens. They then migrate into regional lymph nodes in the dermis, where they present the processed antigens to T lymphocytes (see Fig. 45-4). As antigen-presenting cells, the Langerhans cells are involved in delayed-type hypersensitivity reactions such as contact dermatitis and other cell-mediated immune responses in the skin.

**Merkel Cells**

Merkel cells are epidermal cells that function in cutaneous sensation. They are interspersed among the keratinocytes of the stratum germinativum of the epidermis, usually as single cells, and are particularly abundant in areas of the skin where sensory perception is acute, such as the fingertips. Myelinated sensory neurons traverse the basement membrane to approach the Merkel cell, forming a Merkel cell–neuron complex. These complexes may function as tactile mechanoreceptors. Merkel cells display distinctive, dense granules in their organelles and cytoplasm, suggesting that they possess neurosecretory function. These functions may include metabolic support of their associated neurons, neuron development, and regeneration after injury. These cells are also involved in a form of skin cancer called Merkel cell carcinoma.

**Dermis**

The dermis is the connective tissue layer that separates the epidermis from the subcutaneous fat layer (see Fig. 45-1). It supports the epidermis and serves as its primary source of nutrition. The main component of the dermis is collagen, a group of fibrous proteins. Collagen represents 70% of dry skin weight and serves as the major stress-resistant material of the skin. The hair follicles and glandular structures are embedded in the dermis and continue through the epidermis.

Based on its tissue structure, the dermis can be divided into a superficial papillary dermis and a deeper reticular dermis. Both layers contain fibroblasts that synthesize the tissue's ground substance and collagen, as well as immune cells, blood vessels, and nerves.

**Papillary Dermis**

The papillary layer of the dermis is a thin superficial layer that interdigitates directly with the epidermis, but is separated from it by the basement membrane zone. It consists of loosely arranged collagen fibers and ground substance. This layer is densely covered with conical projections called dermal papillae (see Fig. 45-1). The basal cells of the epidermis project into the papillary dermis, forming rete ridges. It is believed that the dense structure of the dermal papillae serves to maximize the adhesion of the dermis and the epidermis. This layer of
the dermis is richly vascularized. It contains capillaries, end arterioles, and venules that nourish the epidermal layers of the skin. Lymph vessels and nerve tissue also are found in this layer.

**Reticular Dermis**

The reticular layer of the dermis is the thicker area of the dermis and forms the bulk of the dermal layer. This is the tough layer in animal hides from which leather is made. The reticular dermis is characterized by a complex meshwork of dense collagen bundles interconnected with large elastic fibers and ground substance, a viscid gel that is rich in mucopolysaccharides. The collagen fibers are oriented parallel to the body’s surface in any given area. Collagen bundles may be organized lengthwise, as on the abdomen, or in round clusters, as on the heel. The direction of surgical incisions is often determined by this organizational pattern.

**Immune Cells**

Once thought to be composed primarily of fibroblasts, it is now believed that the dermis is mainly composed of dendritic cells called dermal dendrocytes. Believed to be one of the main cell types of the dermis, dermal dendrocytes are spindle-shaped cells that have both phagocytic and antigen-presenting functions and play an important part in the immunobiology of the dermis. In addition, it is possible that dermal dendrocytes may be able to initiate or respond to immunologic events in the epidermis. Dermal dendrocytes also are thought to be involved in processes such as wound healing, blood clotting, and inflammation.

The dermis also contains macrophages, T cells and mast cells. Dermal macrophages and venular epithelial cells may present antigen to T cells in the dermis, most of which are previously activated or memory T cells. T-cell responses to macrophage- or endothelium-associated antigens in the dermis are probably more important in generating an immune response to antigen challenge in previously exposed persons than in initiating a response to a new antigen. The major type of T-cell–mediated immune response in the skin is delayed-type hypersensitivity (see Chapter 16).

Mast cells, which have a prominent role in immunoglobulin E–mediated immediate hypersensitivity, also are present in the dermis. These cells are strategically located at body interfaces such as the skin and mucous membranes and are thought to interact with antigens that come in contact with the skin.

**Blood Vessels**

The arteries that nourish the skin form two plexuses (i.e., collections of blood vessels), one located between the dermis and the subcutaneous tissue and the other between the papillary and reticular layers of the dermis. The pink color of light skin results primarily from blood in the vessels of this latter plexus. Capillary flow that arises from vessels in this plexus also extends up and nourishes the overlying epidermis by diffusion. Blood leaves the skin through small veins that accompany the subcutaneous arteries. The lymphatic system of the skin, which aids in combating certain skin infections, also is limited to the dermis.

The skin is richly supplied with arteriovenous anastomoses in which blood flows directly between an artery and a vein, bypassing the capillary circulation. These anastomoses are important for temperature regulation. They can open up, letting blood flow through the skin vessels when there is a need to dissipate body heat, and close off, conserving body heat if the environmental temperature is cold.

**Innervation**

The innervation of the skin is complex. The dermis is well supplied with sensory receptors for temperature, pain, and touch (see Chapter 35), as well as nerves that supply the blood vessels, sweat glands, and arrector pili muscles.

The papillary layer of the dermis is supplied with free nerve endings that serve as nociceptors (i.e., pain receptors) and thermoreceptors. The dermis also contains encapsulated pressure-sensitive receptors that detect pressure and touch. The largest of these are the *pacinian corpuscles*, which are widely distributed in the dermis and subcutaneous tissue in the digits of the hands and breasts. These mechanoreceptors are specialized to perceive pressure, touch, and vibration. *Meissner corpuscles* are encapsulated mechanoreceptors specialized for tactile discrimination. They are concentrated on the fingertips and palms of the hands, where they account for about half of the tactile receptors. They are also located on the eyelids, lips, tongue, nipples, and skin of the foot and forearm. The deep dermis is supplied with small, oval mechanoreceptors called *Ruffini corpuscles*. They are slowly adapting receptors, responding to heavy pressure and joint movement. They are also believed to detect cold. The skin is also supplied by *Krause end bulbs*, nerve endings contained in a cylindrical or oval capsule. They are found most frequently in the oral cavity, conjunctiva, and genitalia. Although their function is uncertain, they are thought to act as mechanoreceptors and heat detectors.

Most of the skin’s blood vessels are innervated by the sympathetic nervous system. The sweat glands are innervated by cholinergic fibers but controlled by the sympathetic nervous system. Likewise, the sympathetic nervous system controls the arrector pili (pilo-motor) muscles that cause elevation of hairs on the skin (*pilo-* means hair). Contraction of these muscles tends to cause the skin to dimple, producing “goose bumps.”

**Basement Membrane Zone**

The basement membrane zone is a layer of intercellular and extracellular matrices that serves as an interface between the dermis and the epidermis. It separates the epithelium from the underlying connective tissue, anchors the epithelium to the loose connective tissue underneath, and serves as a selective filter for molecules.
moving between the two layers. It is also a major site of immunoglobulin and complement deposition in skin disease.

Most of the structures of the basal membrane zone are produced by cells of the epidermis. The basal lamina is the zone’s primary organizational structure. Its layers include the lamina lucida, lamina densa, and hemidesmosome (Fig. 45-5). The lamina lucida consists of fine anchoring filaments and a cell adhesion glycoprotein, called laminin, which plays a role in the organization of the macromolecules in the basement membrane zone and promotes attachment of cells to the extracellular matrix. The lamina densa contains an adhesive called type IV collagen as well as laminin. It is important in dermal–epidermal attachment. The hemidesmosome is similar in structure to half a desmosome, and serves as an attachment site for the dermis and epidermis. Bundles of tonofilbrils, epidermal fibers similar to keratin filaments, converge and terminate in the hemidesmosomes. Because they form a continuous link between the intracellular tonofilbrils of the epidermis and the extracellular basement membrane, the hemidesmosomes are also thought to be involved in relaying signals between the epidermis and dermis.

The basement membrane zone is often involved in skin disorders that cause bullae or blister formation. One of these disorders, bullous pemphigoid, is a blistering disease caused by antibodies against basement membrane proteins. The blisters of bullous pemphigoid are large and tense and may appear on skin that otherwise looks normal. The thighs and flexor tendons are most commonly affected. The disease is self-limited but chronic, and the person’s general health is unaffected.

### Appendages of the Skin

Skin appendages are derived from outgrowths of epidermal epithelium during development. They include the eccrine and apocrine sweat glands, sebaceous glands, hair follicles, and nails.

### Sweat and Sebaceous Glands

Two types of exocrine glands originate in the dermis and release their products onto the skin surface. These are sweat (or sudoriferous) glands and sebaceous glands (commonly referred to as oil glands).

There are two types of sweat glands: eccrine and apocrine. Eccrine sweat glands are simple tubular structures that originate in the dermis and open directly to the skin surface. They are numerous (several million), vary in density, and are located over the entire body surface. Their purpose is to transport sweat to the outer skin surface to regulate body temperature. Apocrine sweat glands are less numerous than eccrine sweat glands. They are larger and located deep in the dermal layer. They open through a hair follicle, even though a hair may not be present, and are found primarily in the axillae and groin. The major difference between the two types of sweat glands is that
the secretion of apocrine glands is oily. In many animals, apocrine secretions give rise to distinctive odors that enable animals to mark their territory and attract a mate. In humans, apocrine secretions are sterile and odorless until mixed with the bacteria on the skin surface; they then produce what is commonly known as “body odor.”

The sebaceous glands are located over the entire skin surface except for the palms, soles, and sides of the feet. They are part of what is called the pilosebaceous unit, with their ducts opening into the upper third of the hair follicle. They secrete sebum, a waxlike mixture of triglycerides, cholesterol, and cellular debris. Sebum lubricates the hair and skin, prevents undue evaporation of moisture from the stratum corneum during cold weather, and helps to conserve body heat.

Sebum production is an example of holocrine secretion. The cytoplasm of the glandular epithelial cell produces and becomes filled with the fatty product. Eventually, the cell’s plasma membrane ruptures, and the cell dies. Both the secretory product and the cell fragments, which together constitute sebum, are then discharged from the gland into the hair follicle. New cells are produced by mitosis of the basal cells in the gland.

Sebum production is under the control of genetic and hormonal influences. Sebaceous glands are relatively small and inactive until individuals approach adolescence. The glands then enlarge, stimulated by the rise in sex hormones. Gland size directly influences the amount of sebum produced, and the level of androgens influences gland size. The sebaceous glands are the structures that become inflamed in acne (see Chapter 46).

**Hair and Hair Follicles**

Hair is a filamentous, keratinized structure that consists of the hair follicle, sebaceous gland, hair muscle (arrector pili), and, in some instances, an apocrine gland (Fig. 45-6). Most hair follicles are associated with sebaceous glands, and these structures combine to form the pilosebaceous unit. The arrector pili muscle, located under the sebaceous gland, provides a thermoregulatory function by contracting to cause goose bumps, thereby reducing the skin surface area that is available for the dissipation of body heat.

Hair color is attributable to the melanin pigments that the hair contains. Variations mainly reflect the quantity and ratio of the black to dark brown pigment eumelanin and the reddish-brown pigment pheomelanin.

The hair follicle is divided into three parts: the infundibulum, which extends from the surface opening to the level of the opening for the sebaceous gland; the isthmus, which extends from the infundibulum to the level of the arrector pili muscle; and the expanded inferior hair bulb, which is indented to conform to the shape of the dermal papilla occupying it. The dermal papilla contains a rich supply of nutrients and oxygen for the cells in the hair follicle.

Growth of the hair is centered in the bulb (i.e., base) of the hair follicle, and the hair undergoes changes as it is pushed outward. Hair growth goes through three cyclic phases: the anagen (growth), catagen (atrophy), and telogen (resting) phases. Anagen hair has long inner roots and outer root sheaths, is deeply rooted in the dermis, is difficult to detach, and does not come out with regular brushing. Anagen follicles are actively replicating and therefore especially susceptible to nutritional deficiencies and metabolic insults. The catagen phase represents degeneration of the root structure and migration of dermal papillae and the follicular unit toward the more superficial layers of the dermis. Catagen hair usually represents approximately 1% of all scalp hairs. Telogen hair has short, white, club-shaped roots. With formation of new anagen hair below the root, the developing follicle will eventually replace the telogen hair, leading to the shedding of approximately 50 to 100 hairs a day.

**Nails**

Nails are hardened keratinized plates that protect the fingers and toes and enhance dexterity. The nails grow out from a curved transverse groove called the nail groove. The floor of this groove, called the nail matrix, is the germinai region of the nail plate (Fig. 45-7). The underlying epidermis, attached to the nail plate, is called the nail bed.
Like hair, nails are the end product of dead cells that are pushed outward from the nail matrix. Unlike hair, nails grow continuously rather than cyclically, unless permanently damaged or diseased. The epithelium of the fold of skin that surrounds the nail consists of the usual layers of skin. The stratum corneum forms the eponychium or cuticle. The nearly transparent nail plate provides a useful window for viewing the amount of oxygen in the blood, and providing a view of the color of the blood in the dermal vessels. Changes or abnormalities of the nail can also serve to help diagnose skin or systemic diseases.

**SUMMARY CONCEPTS**

- Skin appendages, including the sweat glands, sebaceous glands, hair follicles, and nails, are derived from outgrowths of the epidermal epithelium during development.
- The skin glands are exocrine glands. Eccrine sweat glands secrete sweat directly onto the skin surface, whereas the apocrine sweat glands and sebaceous glands release an oily secretion into hair follicles.
- A hair is a keratin filament arising from a hair follicle, whereas a nail is a hardened keratinized plate emerging from a germinal region called the nail matrix.

**Manifestations of Skin Disorders**

No two skin disorders look exactly alike. Their appearance varies according to the causative agent, location, skin color, and many other factors, and may be further influenced by excessive scratching, secondary infection, or the effects of self-treatment. Nevertheless, most skin disorders have some common characteristics that can be used to describe them. This section of the chapter covers lesions and rashes, pigmentary skin disorders, pruritus, dry skin, and variations in dark skin.

**Lesions and Rashes**

The term lesion refers to a traumatic or pathologic loss of normal tissue continuity, structure, or function. Skin lesions may occur as primary lesions arising in previously normal skin, or they may develop as secondary lesions resulting from other disease conditions. Figure 45-8 illustrates various types of skin lesions.

Rashes are temporary eruptions of the skin, such as those associated with childhood diseases, heat, diaper irritation, or drug-induced reactions. The components of a rash often are referred to as lesions.

Lesions and rashes may range in size from a fraction of a millimeter (e.g., the pinpoint spots of petechiae) to many centimeters (e.g., pressure ulcer). They may be blanched (white), erythematous (reddened), hemorrhagic or purpuric (containing blood), or pigmented (colored). A macule is a small (<1.0 cm in diameter) flat spot, such as a freckle; a papule is an elevated (≥1.0 cm) superficial lesion. Plaques are elevated lesions (≥1 cm), often formed by the coalescence of papules. Nodules are solid marblelike lesions (>0.5 cm) that are deeper and firmer than a papule. A wheal is a somewhat irregular, relatively transient area of localized skin edema, such as a mosquito bite. Lichenification is a thickened and leathery roughening of the skin with increased visibility of the normal skin furrows and excoriations caused by scratching.

Blisters are circumscribed elevations of the skin caused by fluid under or within the epidermis. Pustules are circumscribed pus-filled elevations of the skin. Vesicles are small (<1.0 cm in diameter) and bullae are large (1.0 cm or larger in diameter) fluid-filled blisters (see Fig. 45-8). Friction blisters most commonly occur on the palmar and plantar surfaces of the hands and feet where the skin is constantly exposed to mechanical trauma, such as from shoes and household tools and appliances.

An erosion is a loss of the superficial epidermis, the surface of which is moist but does not bleed. An ulcer is a skin defect in which there has been loss of the epidermis and papillary layer of dermis. It may extend into the subcutaneous tissue, and often occurs in pathologically damaged tissue.

A callus is a hyperkeratotic plaque of skin that develops because of chronic pressure or friction. It represents hyperplasia of the dead keratinocytes that make up the stratum corneum. Increased cohesion between cells results in hyperkeratosis and decreased skin shedding. A callus may be filed down but is likely to recur if pressure continues in the localized area.

Corns (helomas) are small, well-circumscribed, conical, keratinous thickenings of the skin. They usually appear on the toes from rubbing or ill-fitting shoes. The corn may be either hard (heloma durum) with a central hard, horny core, or soft (heloma molle), as commonly seen between the toes. They may appear on the hands as an occupational hazard. The hard tissue at the center of the corn looks like a funnel with a broad top and a pointed bottom, hence the name “corn.” Corns on the feet often are painful, whereas corns on the hands may be asymptomatic. Corns may be abraded or surgically removed, but they recur if the causative agent is not removed.

**Pigmentary Skin Disorders**

Pigmentary skin disorders involve the melanocytes. In some cases, there is an absence of melanin production, as in vitiligo or albinism. In other cases, there is an increase in melanin or some other pigment, as in melasma. In either case, the emotional impact can be devastating.
Albinism, a genetic disorder in which there is complete or partial congenital absence of pigment in the skin, hair, and eyes, is found in all races. Although there are over 10 different types of albinism, the most common type is recessively inherited oculocutaneous albinism, in which there is a normal number of melanocytes but they lack tyrosinase, the enzyme needed for synthesis of melanin. It affects the skin, hair, and eyes. Individuals have pale or pink skin, white or yellow hair, and light-colored or sometimes pink eyes. Persons with albinism have ocular problems, such as extreme sensitivity to light and refractive problems. Treatment efforts for people with albinism are aimed at reducing their risk for skin cancer through protection from solar radiation and screening for malignant changes. Efforts to manage the vision impairment, such as glasses, preferential seating in classrooms, and large-print books, are important.

Vitiligo is a pigmentary problem of concern to darkly pigmented persons of all races. It may be an autoimmune disease, a genetic defect, an excessive reactive oxygen species, a calcium imbalance, or any combination of these; all are being studied. Vitiligo also affects fair-skinned persons, but not as often, and the effects usually are not as socially problematic. The classic sign of vitiligo is the sudden appearance of white patches on the skin. The lesion is a depigmented macule with definite smooth borders on the face, axillae, neck, or extremities (Fig. 45-9). The patches vary in size from small macules to ones involving large skin surfaces. The large macular type is more common. Depigmented areas appear white, pale colored, or sometimes grayish-blue. Histologically, the depigmented areas may contain no melanocytes, greatly altered or decreased numbers of...
Pruritus

Pruritus is an unpleasant sensation of itch leading to the desire to scratch. Symptoms of pruritus range from mild to so severe that it interrupts sleep and the general quality of life. While pruritus most commonly occurs in skin disorders, it may also occur with systemic disorders, such as chronic kidney disease, diabetes, and biliary disease. Pruritus is multidimensional and has been classified into four types: (a) pruritoceptive (generated in the skin: bug bites), (b) neurogenic (generated in the central nervous system: cholestasis), (c) neuropathic (due to lesions in the central nervous system blocking normal responses), and (d) psychogenic (emotional or stress related).

Pruritus originates within the skin’s free nerve endings, is carried by small myelinated type C nerve fibers to the dorsal horn of the spinal cord, and is then transmitted to the somatosensory cortex through the spinohalamic tract (see Chapter 35). Many chemicals have been found to produce the itch sensation, including histamine, serotonin, and cytokines. Substances such as bradykinin and bile salts act locally to stimulate the itch sensation. Prostaglandins are modulators of the itch response, lowering the threshold for other mediators. Opioids produce pruritus in a number of patients who receive them while narcotic antagonists have been used successfully to relieve pruritus. Regardless of cause, pruritus is often exacerbated by skin inflammation, dry or hot ambient temperatures, skin vasodilation, and psychological stressors.

Scratching, the well-known response to itch, is a spinal reflex response that to varying degrees can be controlled by the individual. While providing momentary relief, scratching increases inflammation and stimulates nerve endings, leading to more itching and scratching. Repeated scratching also causes undesirable changes in the skin such as lichenification. Successful treatment of pruritus requires interruption of this cycle.

The focus of treatment measures for pruritus can be grouped into two categories: specific and nonspecific. Specific treatment involves finding and correcting the underlying disorder, thereby eliminating the itch sensation. Nonspecific measures involve the use of measures to relieve the itch sensation and prevent complications that arise from intense and persistent scratching.

Measures such as using the entire hand to rub over large areas and keeping the fingernails trimmed often can relieve itch and prevent skin damage. Self-limited or seasonal cases of pruritus may respond to treatment measures such as moisturizing lotions, bath oils, and the use of humidifiers. Because vasodilation tends to increase itching, cold applications may provide relief. Cool showers before bed, light sleepwear, and cool home temperatures also may be helpful. Also helpful can be cooling over-the-counter anti-itch agents containing menthol, camphor, or phenol. These substances stimulate nerve fibers that transmit the sensation of cold, thereby masking the itch sensation. Mild cutaneous disorders, such as bug bites, are mediated by histamine; therefore, topical antihistamines tend to be the treatment of choice. Topical corticosteroids are effective as antipruritics, particularly when used for urticaria (hives) or insect bites.

However, because most cases of pruritus are not histamine related, their management should be directed at the underlying cause. For example, systemic antihistamines and corticosteroids may be indicated for persons with severe pruritus or atopic dermatitis. Topical capsaicin cream and topical aspirin have been used for localized chronic pruritic disorders. Other modalities that have been used for pruritus with varying degrees of success are phototherapy, acupuncture, antidepressant medications, behavior modification, and alternative therapies (herbal, nutritional, and reflex therapies). In persons with pruritus due to a systemic cause, itching gradually recedes as the primary condition improves.

Dry Skin

Dry skin, also called xerosis, may be a natural occurrence, as in the drying of skin associated with aging, or it may be symptomatic of an underlying systemic disease or skin disorder such as contact dermatitis. Most cases of dry skin are caused by dehydration of the stratum corneum. The effects of aging on skin dryness include a change in the composition of sebaceous gland secretions and a decrease in the secretion of moisture from the sweat glands. Aging is also accompanied by a decrease in skin capillaries as well as a flattening of the dermal rete ridges, resulting in less surface area for exchange of fluids between the dermis, epidermis, and skin surface.

Dry skin appears rough and scaly; there may be increased wrinkles or lines. Persons with dry skin often experience severe pruritus, most commonly of the extremities, back, abdomen, or waist. They may resort to scratching, resulting in cracking, fissuring, and a number of other skin maladies.

Moisturizing agents are the cornerstone of treatment for dry skin. These agents exert their effects by repairing the skin barrier, increasing the water content of the
skin, reducing transepidermal water loss, and restoring the lipid barrier's ability to attract, hold, and redistribute water. Moisturizing agents can be classified as emollients, humectants, and occlusives. *Emollients* are fatty acid–containing lotions that replenish the oils on the skin surface, but usually do not leave a residue on the skin. They have a short duration of action and need to be applied frequently. *Humectants* are the additives in lotions, such as α-hydroxy acids and urea, that draw out water from the deeper skin layers and hold it on the skin surface. However, the water that is drawn to the skin is transepidermal water, not atmospheric water; thus, continued evaporation from the skin can actually exacerbate dryness. α-Hydroxy acids are derived from fruits, hence the abundance of fruit additives in over-the-counter shampoos and lotions. Urea is a nitrogenous substance that has been quite effective in reducing xerosis when combined with lotions. It is a humectant at lower concentrations (10%), but in higher concentrations (20% to 30%) it is mildly keratolytic. Clinical trials of urea have indicated its utility compared with ammonium lactate (lactic acid) lotion and glycerin. *Occlusives* are thick creams that contain petroleum or some other moisture-proof material. They prevent water loss from the skin. They are the most effective agents for relieving skin dryness, but because of their greasiness and lack of cosmetic appeal, some people do not wish to use them.

Lotion or cream additives include corticosteroids or mild anesthetics, such as camphor, menthol, lidocaine, or benzocaine. These agents work by suppressing itching while moisturizing the skin. Using room humidifiers and keeping room temperatures as low as possible to prevent water loss from the skin also may be helpful. Soaps with moisturizers may be helpful. Glycerine soaps, although popular and visually appealing, are drying and can exacerbate the symptoms.

**Variations in Dark-Skinned People**

Some skin disorders common to people of African, Hispanic, or East Indian descent are not commonly found in those of European descent. Other skin disorders, such as skin cancers, affect light-skinned persons more commonly than dark-skinned persons. Because of these differences, serious skin disorders may be overlooked, and normal variations in darker skin may be mistaken for anomalies.

As noted earlier, skin color is determined by the melanin produced by the melanocytes. Although the number of melanosomes in dark and white skin is the same, black skin produces more melanin, and more quickly, than white skin. Because of their skin color, dark-skinned persons are better protected against skin cancer, premature wrinkling, and aging of the skin that occurs with sun exposure.

A condition common in people with dark skin is too much or too little color. Areas of the skin may darken after injury, such as a cut or scrape, or after disease conditions such as acne. These darkened areas may take many months or years to fade. Dry or “ashy” skin is also a common problem for people with dark skin. It often is uncomfortable, and it also is easily noticed because it gives the skin an ashen or grayish appearance. Although using a moisturizer may help relieve the discomfort, it may cause a worsening of acne in predisposed persons.

Normal variations in skin structure and skin tones often make evaluation of dark skin difficult. The darker pigmentation can make skin pallor, cyanosis, and erythema more difficult to observe. Therefore, verbal histories must be relied on to assess skin changes. The verbal history should include the client’s description of her or his normal skin tones. Changes in skin color, in particular hypopigmentation and hyperpigmentation, often accompany disorders of dark skin and are very important signs to observe when diagnosing skin conditions. Common variations in dark skin and nails are described in Table 45-1.

**SUMMARY CONCEPTS**

- Skin lesions are a loss of skin integrity and rashes are temporary skin eruptions. They are the most common manifestations of both skin and many systemic diseases. They vary in size and color; they can be flat (macule or patch), palpable (papule, plaque, or nodule), or fluid-filled elevations (vesicle or bullae).
- Erosions involve a loss of the superficial epidermis, and an ulcer a loss of the epidermis and papillary layer of dermis.

(continued)
SUMMARY CONCEPTS (continued)

- Pigmentary skin disorders involve the melanocytes. In some cases, there is an absence of melanin production, as in vitiligo or albinism. In other cases, there is an increase in melanin or some other pigment, as in melasma.
- Pruritus, an unpleasant sensation of itch leading to the desire to scratch, may occur with both skin and systemic disorders.
- Dry skin, also called xerosis, may be a natural occurrence, as in the drying of skin associated with aging, or occur as a result of a skin or systemic disorder.
- Normal variations in skin structure and skin tones often make evaluation of dark skin difficult.

REVIEW EXERCISES

1. Bullous pemphigoid is an autoimmune blistering disease caused by autoantibodies to constituents of the dermal–epidermal junction.
   A. Explain how antibodies, which attack glycoproteins in the lamina lucida and their attachment to the hemidesmosomes, can cause blisters to form (hint: see Fig. 45-5).

2. “Allergy tests” involve the application of an antigen to the skin, either through a small scratch or intradermal injection.
   A. Explain how the body’s immune system is able to detect and react to these antigens.

- Study Guide for Essentials of Pathophysiology
The skin serves as the interface between the body’s internal organs and the external environment. Therefore, skin disorders reflect a combination of environmental and internal factors. Sunlight, infectious organisms, chemicals, and physical agents all play a role in the pathogenesis of skin diseases. Although most of the disorders in this chapter are intrinsic to the skin and its integuments, the hair and nails, these structures also provide observable signs of many systemic disorders.

### Primary Disorders of the Skin

A dermatosis is any skin condition involving acute or chronic lesions or eruptions. Primary dermatoses are those originating in the skin. They include infectious processes, acne, rosacea, papulosquamous dermatoses, allergic disorders, and drug reactions. Although most of these disorders are not life-threatening, they can affect the quality of life.

### Infectious Processes

Normally, the skin flora, sebum, immune responses, and other protective mechanisms defend against serious systemic infections. However, the skin frequently succumbs to attack by microorganisms, including fungi, bacteria, and viruses.

#### Superficial Fungal Infections

Fungi are free-living, saprophytic, plantlike organisms, certain strains of which are considered part of the normal skin flora (see Chapter 14). There are two types of fungi: yeasts and molds. Yeasts, such as *Candida albicans*, grow as single cells and reproduce asexually. Molds grow in long filaments called hyphae. Fungal infections of the skin or mycoses are commonly classified as deep or superficial.\(^1\) Deep fungal infections of the skin primarily involve the dermis and subcutaneous tissue, and may extend into deeper tissues. In contrast, superficial fungal infections, commonly known as tinea
or ringworm, are confined to the epidermis and its integuments, the hair and nails.

Most of the superficial mycoses are dermatophytoises—dermatoses caused by the dermatophytes, a group of closely related fungi classified into three genera: Microsporum, Epidermophyton, and Trichophyton. Some dermatophytes are anthropophilic; that is, they are parasitic in humans and are spread by other infected humans. These tend to cause chronic infections that are difficult to treat. Zoophilic species cause parasitic infections in animals, some of which can be spread to humans. Geophilic species originate in the soil, but may infect animals, which in turn serves as a source of infection for humans. These species tend to cause inflammatory lesions that respond well to therapy or may even resolve spontaneously.

The fungi that cause superficial mycoses emit an enzyme that enables them to digest keratin, which results in superficial skin scaling, nail disintegration, or hair breakage, depending on the location of the infection. Deeper reactions involving vesicles, erythema, and infiltration are caused by the inflammation that results from exotoxins liberated by the fungus.

Diagnosis of superficial fungal infections is primarily done by microscopic examination of skin scrapings for fungal spores, the reproducing bodies of fungi. Potassium hydroxide (KOH) preparations are used to prepare slides of skin scrapings. Potassium hydroxide disintegrates human tissue and leaves behind the threadlike filaments, or hyphae, that grow from the fungal spores. Cultures also may be done using a dermatophyte test medium or a microculture slide that allows for direct microscopic identification. The Wood light is an ultraviolet (UV) light that can assist with the diagnosis of tinea, as some types of fungi fluoresce yellow-green when the light is directed onto the affected area.

Topical agents are commonly used in the treatment of tinea infections; however, success often is limited because of the lengthy duration of treatment, poor compliance, and high rates of relapse at specific body sites. The principal agents are the azoles (ketoconazole, miconazole, clotrimazole, etc.) and the allylamines (naltifine and terbinafine). Both act by inhibiting the synthesis of ergosterol, which is an essential part of fungal cell membranes. Topical corticosteroids may be used in conjunction with topical antifungal agents to relieve itching and erythema secondary to inflammation.

The systemic (i.e., oral) antifungal agents include griseofulvin, the azoles, and the allylamines. Griseofulvin is an antifungal agent derived from a species of penicillium, whose only use is in the systemic treatment of dermatophytosis. It acts by binding to the keratin of newly formed skin, protecting the skin from new infection. It must be administered for 2 to 6 weeks to allow for skin and hair replacement, and nail infections often require months of treatment. Systemic azoles and allylamines are also used. In contrast to griseofulvin, the synthetic agents are fungicidal (i.e., kill the fungus) and therefore are more effective over shorter treatment periods. Some of the oral agents can produce serious side effects, such as hepatic toxicity, or interact adversely with other medications.

**Tinea of the Body or Face.** Tinea corporis (ringworm of the body) can be caused by any of the dermatophyte species. Although it affects all ages, children seem most prone to infection. Transmission is most commonly from kittens, puppies, and other children who have infections. The most common types of lesions are oval or circular patches on exposed skin surfaces and the trunk, back, or buttocks (Fig. 46-1). Less common are foot and groin infections. The lesion begins as a red papule and enlarges, often with a central clearing. Patches have raised red borders consisting of vesicles, papules, or pustules. The borders are sharply defined, but lesions may coalesce. Pruritus, a mild burning sensation, and erythema frequently accompany the skin lesion.

**Tinea faciale,** or ringworm of the face, is typically caused by one of the Trichophyton species. Tinea faciale may mimic the annular, erythematous, scaling, pruritic lesions characteristic of tinea corporis. It also may appear as flat erythematous patches.

Topical antifungal agents usually are effective in treating tinea corporis and tinea faciale. Oral antifungal agents may be used in resistant cases.

**Tinea of the Scalp.** Tinea capitis, the most common type of fungal infection in children, is an infection of the scalp and hair shaft. Children between the ages of 3 and 14 years are primarily affected. The primary lesions vary from grayish, round, hairless patches to balding spots. The lesions vary in size and are most commonly seen on the back of the head (Fig. 46-2). Mild erythema, crust, or scale may be present. The individual usually is asymptomatic, although pruritus may exist. Treatment is with oral griseofulvin or synthetic antifungal agents that penetrate the hair shafts. Topical ointments or shampoos are sometimes indicated.

The inflammatory type of tinea capitis is caused by virulent strains of T. mentagrophytes, T. verrucosum, and M. gypseum. The onset is rapid, and inflamed lesions usually are localized to one area of the head. The inflammation is believed to be a delayed hypersensitivity reaction to the invading fungus. The initial lesion consists

![FIGURE 46-1. Tinea of the arm due to the dermatophytic fungus trichophyton rubrum. (From the Centers for Disease Control and Prevention Public Health Image Library. No. 4811.)](image-url)
of a pustular, scaly, round patch with broken hairs. A secondary bacterial infection is common and may lead to a painful, circumscribed, boggy, and indurated lesion called a kerion. The highest incidence is among children and farmers who work with infected animals.

Both the noninflammatory and inflammatory forms of tinea capitis are treated with oral griseofulvin or synthetic antifungal agents that penetrate the hair shafts. Topical ointments or shampoos are sometimes indicated in addition to oral medications, both to decrease the spore population and to protect household members. Because of the lower fatty acid content in the sebum of young children, several of the topical antifungal agents are prepared with fatty acid bases. Wet packs, medicated shampoos, steroids, and antibiotics may be prescribed for secondary infections that occur.

**Tinea of the Foot and Hand.** Tinea pedis (athlete's foot) is the most common fungal dermatosis, primarily affecting the spaces between the toes, the soles, or the sides of the feet (Fig. 46-3). The lesions vary from a mildly scaling lesion to a painful, exudative, erosive, inflamed lesion with fissuring. Lesions often are accompanied by pruritus, pain, and foul odor. Mild forms are more common during dry environmental conditions. Exacerbations occur as a result of hot weather, sweating, and exercise or when the feet are exposed to moisture, occlusive shoes, and communal swimming.

Tinea of the hand (Tinea manus) is usually a secondary infection with tinea pedis as the primary infection. In contrast to other skin disorders, it usually occurs only on one hand. The characteristic lesion is a blister on the palm or finger surrounded by erythema. Chronic lesions are scaly and dry. Cracking and fissuring may occur. The lesions may spread to the plantar surfaces of the hand. If chronic, tinea manus may lead to tinea of the fingernails.

Simple forms of tinea pedis and tinea manus are treated with topical applications of antifungals. Complex cases are treated with oral antifungals. Other treatment and preventive measures include careful cleaning and drying of affected areas.

**Tinea of the Nails.** Tinea unguium is a dermatophyte infection of the nails. It is a subset of a condition called onychomycosis, which includes dermatophyte, nondermatophyte, and candidal infections of the nails.

The infection often begins at the tip of the nail, where the fungus digests the nail keratin (Fig. 46-4). In some cases, it may be caused by a crushing injury to a toenail or the spread of tinea pedis. Initially, the nail appears opaque, white, or silver. The nail then turns yellow or brown. The condition often remains unchanged for years. During this time it may involve only one or two nails and may produce little or no discomfort. As the infection spreads, the nail thickens and cracks and the nail plate separates from the nail bed.

The standard for the diagnosis of fungal nail disease is a positive result on microscopic examination and culture of nail clippings with subungual debris. Persons with minimal toenail involvement and no associated symptoms may not require treatment.

**FIGURE 46-2.** Ringworm or tinea of the scalp (tinea capitis) caused by the Microsporum species. (From the Centers for Disease Control and Prevention Public Health Image Library. No. 2940. Courtesy of Dr. Lucille K. Georg.)

**FIGURE 46-3.** Chronic tinea of the sole caused by Trichophyton rubrum. (From the Centers for Disease Control and Prevention Public Health Image Library. No. 15441.)

**FIGURE 46-4.** Onychomycosis due to Trichophyton rubrum, right and left great toes. (From the Centers for Disease Control and Prevention Public Health Image Library. No. 579. Courtesy of Edwin P. Ewing, Jr.)
conditions such as diabetes mellitus, antibiotic therapy, pregnancy, oral contraceptive use, poor nutrition, and immunosuppressive diseases. Oral candidiasis may be the first sign of infection with human immunodeficiency virus (HIV).

*Candida albicans* thrives on warm, moist, intertriginous areas (i.e., between folds or adjacent surfaces) of the body. The rash is red with well-defined borders. Patches erode the epidermis, and there is scaling. Mild to severe itching and burning often accompany the infection. Severe forms of infection may involve pustules or vesiculopustules as well as maculopapular satellite lesions found outside the clearly demarcated borders of the candidial infection. Satellite lesions often are diagnostic of diaper rash complicated by *Candida*. The appearance of candidal infections varies according to the site (see Chapter 41 for a discussion of vaginal candidiasis).

Diagnosis usually is based on microscopic examination of skin or mucous membrane scrapings placed in a KOH solution. Treatment measures vary according to the location. Preventive measures such as wearing rubber gloves are encouraged for persons with infections of the hands. Intertriginous areas often are separated with clean cotton cloth and allowed to air dry as a means of decreasing the macerating effects of heat and moisture. Topical and oral antifungal agents, such as clotrimazole, econazole, ketoconazole, and miconazole, are used in treatment depending on the site and extent of involvement.

**Bacterial Infections**

Bacteria are considered normal flora of the skin. Most bacteria are not pathogenic, but when pathogenic bacteria invade the skin, superficial or systemic infections may develop. Bacterial skin infections are commonly classified as primary or secondary. Primary infections are superficial skin infections such as impetigo. Secondary infections consist of deeper cutaneous infections, such as infected ulcers. Diagnosis usually is based on cultures taken from the infected site. Treatment methods include antibiotic therapy and measures to promote comfort and prevent the spread of infection.

**Impetigo.** Impetigo is a common, superficial bacterial infection caused by staphylococci, group A β-hemolytic streptococci, or both. It is common among infants and young children, although older children and adults occasionally contract the disease. Impetigo initially appears as a small vesicle or pustule or as a large bulla on the face or elsewhere on the body. As the primary lesion ruptures, it leaves a denuded area that discharges a honey-colored serous liquid that dries as a honey-colored crust with a “stuck-on” appearance (Fig. 46-6). New vesicles erupt within hours. Pruritus often accompanies the lesions, and skin excoriations that result from scratching multiply the infection sites. Although a very low risk, a possible complication of untreated streptococcal impetigo is poststreptococcal glomerulonephritis (see Chapter 25). Topical mupirocin...
(Bactroban), which has few side effects, may be effective for limited infections. If the area is large or if there is concern about complications, systemic antibiotics are used.

Another form of impetigo exists, bullous impetigo, which is usually caused by Staphylococcus aureus. Bullous impetigo is more common among children and occurs intermittently, with some cases transmitted among family members, but most often found among the institutionalized. Thin bullae erupt that appear clear to cloudy and coalesce. The bullae open, leaving the original bullous rim with central thin, flat, honey-colored crusts, or in some cases denuded areas. The face is often affected, but bullous impetigo may occur anywhere on the body. The treatment measures are the same as for nonbullous impetigo.

Cellulitis. Cellulitis is a deeper infection affecting the dermis and subcutaneous tissues. It is usually caused by group A β-hemolytic streptococci or S. aureus, but can be caused by bacteria specific to certain activities, such as fish handling, swimming in fresh or salt water, or from animal bites or scratches. Preexisting wounds (e.g., ulcers, erosions) and tinea pedis are often portals of entry. Legs are the most common sites, followed by the hands and pinnae of the ears, but cellulitis may occur on many body sites. The lesion consists of an expanding red, swollen, tender plaque with an indefinite border, covering a variety of widths (Fig. 46-7). Cellulitis is frequently accompanied by fever, erythema, heat, edema, and pain. Cellulitis often involves the lymph system and, once compromised, repeat infections may impair lymphatic drainage, leading to chronically swollen legs, and eventually dermal fibrosis and lymphedema. Incorrectly treated, it may result in sepsis, nephritis, or death. Treatment measures (oral and intravenous antibiotics) are aimed at the invasive organisms and the extent of the infection.

Viral Infections

Viruses are intracellular pathogens that rely on live cells of the host for reproduction. They have no organized cell structure but consist of a deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) core surrounded by a protein coat. The viruses seen in dermatoses tend to contain DNA. They invade the keratinocyte, begin to reproduce, and cause cellular proliferation or cellular death. The incidence of viral dermatoses is increasing. This has been attributed to the use of corticosteroid drugs, which have immunosuppressive properties, and the use of antibiotics, which alter the bacterial flora of the skin. As the number of bacterial infections has decreased, there has been a proportional rise in viral skin diseases.

Verrucae. Verrucae, or warts, are common benign papillomas caused by the DNA-containing human papillomavirus (HPV). As benign papillomas, warts represent an exaggeration of the normal skin structures. There is an irregular thickening of the stratum spinosum and greatly increased thickening of the stratum corneum. The classification of warts is based largely on morphology and location.

Although warts vary in appearance depending on their location, it is now recognized that the clinically distinct types of warts result not simply because of the anatomic sites in which they arise, but also because of the distinct type of HPV. There are more than 80 types of HPV found on the skin and mucous membranes of humans that cause several different kinds of warts, including skin warts and genital warts. Many of the HPV types that cause genital warts are sexually transmitted, some of which (types 6, 11, 16, and 18) may increase the risk of cervical cancer (discussed in Chapter 41).

Nongenital warts often occur on the hands and feet. They are commonly caused by HPV types 1, 2, 3, 4, 27, and 57, and are not considered precancerous lesions. They are classified as common warts, flat warts, and plantar or palmar warts. Common warts, or verrucae vulgaris, are the most common type. The lesions can occur anywhere, but most frequently occur on dorsal surfaces of the hands, especially the periungual area,
where they appear as small, grayish-white to tan, flat to convex papules with a rough, pebblelike surface (Fig. 46-8). Verrucae plana, or flat warts, are common on the face or dorsal surfaces of the hands. These warts are slightly elevated, flat, smooth, tan papules that are slightly larger than verrucae vulgaris. Verrucae plantaris and verrucae palmaris (i.e., plantar and palmar warts, respectively) occur on the soles of the feet and palms of the hands, respectively. They appear as rough, scaly lesions that may reach 1 to 2 cm in diameter, coalesce, and be confused with ordinary calluses.

Transmission of HPV infection is largely by direct contact between individuals or by autoinoculation, usually through breaks in skin integrity. For example, plantar warts, which occur on the soles of the feet, frequently are transmitted to the abraded, softened heels of children in swimming areas. Common hand warts can be transmitted by biting the cuticles surrounding the nail.

Treatment is usually directed at inducing a “wart-free” period without producing scarring. Warts resolve spontaneously when immunity to the virus develops. The immune response, however, may be delayed for years. Because of their appearance or discomfort, people usually desire their removal, rather than waiting for immunity to develop. Removal is usually done by applying a keratolytic agent, such as salicylic acid, which works by dissolving intercellular cement and producing desquamation of the horny layer of skin without affecting normal epidermal cells. Duct tape or “Ducto-Therapy” has been found effective for treatment of common warts. Intralesional bleomycin injections have been effective for recalcitrant warts. Various types of laser surgery, electrosurgery, cryotherapy, immunotherapy (e.g., oral zinc sulfate), and antiviral therapy (e.g., cidovir) also have been successful in wart eradication.

Herpes Simplex. Herpes simplex virus (HSV) infections of the skin and mucous membrane (i.e., cold sores or fever blisters) are common. Two types of HSV infect humans: type 1 and type 2. HSV-1 is usually associated with oropharynx infections (labial herpes), and the organism is spread by respiratory droplets or by direct contact with infected saliva. Genital herpes usually is caused by HSV-2 (see Chapter 41). HSV-1 genital infections and HSV-2 oral infections are becoming more common, perhaps because of oral–genital sex.

Infection with HSV-1 may present as a primary or recurrent infection. Primary HSV-1 symptoms include fever, sore throat, painful vesicles, and ulcers of the lips, tongue, palate, and buccal mucosa. Primary infection results in the production of antibodies to the virus so that recurrent infections are more localized and less severe. After an initial infection, the herpesvirus persists in the trigeminal and other dorsal root ganglia in the latent state, periodically reactivating as recurrent infections. The symptoms of a primary HSV-1 infection most often occur in young children (1 to 5 years of age).

The recurrent lesions of HSV-1 are often found in the vicinity of the primary infection and usually begin with a burning or tingling sensation. Umbilicated vesicles and erythema follow and progress to pustules, ulcers, and crusts before healing (Fig. 46-9). Lesions are most common on the lips, face, mouth, nasal septum, and nose. When a lesion is active, HSV-1 is shed and there is risk of transmitting the virus to others. Pain is common, and healing takes place within 10 to 14 days. Precipitating factors include stress, menses, or injury. In particular, ultraviolet B exposure seems to be a trigger for recurrence. Individuals who are immunocompromised may have severe attacks.

There is no cure for oropharyngeal herpes; most treatment measures are palliative. Over-the-counter topical preparations containing antihistamines, antipruritics, and anesthetic agents along with aspirin or acetaminophen may be used to relieve pain. Topical medications are best applied gently with a cotton-tipped applicator to prevent increased viral shedding and viral inoculation to another anatomic site. Oral acyclovir, valacyclovir, and...
and famciclovir may be used for prophylaxis. Sunscreen applied to the lips can prevent sun-induced herpes simplex. Efforts to develop vaccines to prevent HSV infections are in process.\(^\text{13}\)

**Herpes Zoster.** Herpes zoster (shingles) is an acute, localized vesicular eruption distributed over a dermatomal segment of the skin.\(^\text{14}\) It is caused by the same herpesvirus, varicella-zoster, that causes chickenpox. It is believed to be the result of reactivation of a latent varicella-zoster virus infection that was dormant in the sensory dorsal root ganglia since a primary childhood infection. During an episode of herpes zoster, the reactivated virus travels from the ganglia to the skin of the corresponding dermatome (Fig. 46-10A). Although herpes zoster is not as contagious as chickenpox, the reactivated virus can be transmitted to nonimmune contacts.

The incidence of herpes zoster increases with age; it occurs most frequently in persons older than 60 years of age. The normal age-related decrease in cell-mediated immunity is thought to account for the increased viral activation in this age group. Other persons at increased risk because of impaired cell-mediated immunity are persons with conditions such as HIV infection and certain malignancies, and those receiving long-term corticosteroid treatment, cancer chemotherapy, and radiation therapy.

The lesions of herpes zoster typically are preceded by a prodrome consisting of a burning pain, a tingling sensation, extreme sensitivity of the skin to touch, and pruritus along the affected dermatome (see Chapter 35). Among the dermatomes, the most frequently involved are the thoracic, the cervical, the trigeminal, and the lumbar sacral.\(^\text{14}\) Prodromal symptoms may be present for 1 to 3 days or longer before the appearance of the rash. During this time, the pain may be mistaken for a number of other conditions, such as heart disease, pleurisy, musculoskeletal disorders, or gastrointestinal disorders.

The lesions appear as an eruption of vesicles with erythematous bases that are restricted to skin areas supplied by sensory neurons of a single or associated group of dorsal root ganglia (Fig. 46-10B). In immunosuppressed persons, the lesions may extend beyond the dermatome. Eruptions usually are unilateral in the thoracic region, trunk, or face. New crops of vesicles erupt for 3 to 5 days along the nerve pathway. The vesicles dry, form crusts, and eventually fall off. The lesions usually clear in 2 to 3 weeks, although they can persist up to 6 weeks in some elderly persons.

Serious complications can accompany eruptions. Eye involvement can result in permanent blindness and occurs in a large percentage of cases involving the ophthalmic division of the trigeminal nerve (see Chapter 38). Postherpetic neuralgia, which is sharp, burning pain that persists longer than 1 to 3 months after the resolution of the rash, is seen most commonly in persons older than 60 years of age (see Chapter 35).

The treatment of choice for herpes zoster is the administration of an antiviral agent (e.g., acyclovir, valacyclovir, famciclovir).\(^\text{14}\) Treatment is most effective when started within 72 hours of rash development. When given in the acute vesicular stage, the antiviral drugs have been shown to decrease the amount of lesion development and pain. Narcotic analgesics, tricyclic antidepressants, gabapentin, anticonvulsant drugs, and nerve blocks have been used for management of postherpetic neuralgia. Local application of capsaicin cream or lidocaine patches may be used in selected cases. Palliative treatments, such as heat and gentle pressure, may also be helpful.

A live herpes zoster vaccine is available to prevent both herpes zoster and postherpetic neuralgia. The vaccine is recommended for use in people 60 years of age and older, although the efficacy of the vaccine continues to be studied.\(^\text{15,16}\)

**Pustular Disorders**

Although acne vulgaris, acne conglobata, and rosacea may present with a variety of skin lesions, they are characterized by the presence of pustules, which are circumscribed skin lesions filled with pus.

**Acne Vulgaris**

Acne vulgaris is a disorder of the pilosebaceous unit (see Chapter 45, Fig. 45-7) that results in formation of discrete papular or pustular lesions and may lead to scarring.\(^\text{17–20}\) Acne can be cosmetically disfiguring and often psychologically disabling. It typically begins around puberty, as a result of increased androgen production. It may begin earlier and persist longer in females; however,
Pustules, nodules, and, in severe cases, cysts. Inflammatory lesions consist of papules, whiteheads and blackheads consist of the sebaceous glands from adjoining epidermal cells. Blackheads are pale, slightly elevated papules with no visible orifice. Inflammatory lesions consist of papules, pustules, nodules, and, in severe cases, cysts. Papules are raised areas less than 5 mm in diameter. Pustules have a central core of purulent material. Nodules are larger than 5 mm in diameter and may become suppurrative or hemorrhagic. Suppurative nodules often are referred to as cysts because of their resemblance to inflamed epidermal cysts. The inflammatory lesions are believed to develop from the escape of sebum into the dermis and the irritating effects of the fatty acids contained in the sebum.

The cause of acne vulgaris is largely unknown. There is a hereditary factor, multiple generations of family members being affected. Several factors are believed to contribute to acne, including (1) the influence of androgens on sebaceous gland activity; (2) increased proliferation of the keratinizing epidermal cells that form the sebaceous cells; (3) increased sebum production in relation to the severity of the disease; and (4) the presence of Propionibacterium acnes, the microorganism responsible for the inflammatory stage of the disorder. These factors are probably interrelated. Increased androgen production results in increased sebaceous cell activity, with resultant plugging of the pilosebaceous ducts. The excessive sebum provides a medium for P. acnes growth, and the organism contains lipases that break down the free fatty acids that produce the acne inflammation. P. acnes is also thought to form a biofilm (an extracellular polysaccharide lining in which the bacteria are encased) that acts as a protective barrier to antibiotic treatment (see Chapter 14), explaining why prolonged antibiotic treatments are necessary. The sebaceous glands also may serve as sites for immune reactions. Acne may be triggered or worsened by external factors such as obstructions (e.g., head bands, collars), manipulation of the lesions, cosmetics, and occupational exposures.

The diagnosis of acne is based on history and physical examination. The severity of the acne is generally assessed by the number, type, and distribution of lesions. Mild acne is usually characterized by the presence of a small number (generally <10) of open and closed comedones, with a few inflammatory papules; moderate acne by the presence of a moderate number (10 to 40) of erythematous papules and pustules (Fig. 46-11), usually limited to the face; and moderately severe acne by the presence of numerous papules and pustules (40 to 100) and occasionally larger, deeper, nodular inflamed lesions involving the face, chest, and back. Treatment of acne focuses on clearing up existing lesions, preventing new lesions, and limiting scar formation.

Treatment measures include the use of topical antimicrobials, oral antibiotics, topical retinoids, and isotretinoin. Soaps are usually not effective in treating acne, and unless the skin is exceptionally oily, a mild soap should be used to avoid additional irritation that will limit the effectiveness of other topical treatments. Mild acne is usually treated with a topical preparation containing a combination of erythromycin or clindamycin and benzoyl peroxide. Topical antibiotics do not affect existing lesions but decrease the P. acnes on the skin, thereby reducing subsequent inflammation resulting from free fatty acid release and breakdown. Benzoyl peroxide, which is a bactericide, does not induce resistance, and when used with topical and oral antibiotics it protects against the development of lesions. Azelaic acid, products containing sodium sulfacetamide and sulfur, and salicylic acid preparations are also available. These agents are usually not considered as first-line therapies, but may be used in persons who cannot tolerate other topical agents.

Moderate to severe cases of acne may be managed with systemic antibiotics (e.g., tetracycline), topical vitamin A derivatives (retinoids), or oral retinoids (isotretinoin). Systemic antibiotics decrease P. acnes colonization and have intrinsic anti-inflammatory effects. The action of topical vitamin A (e.g., tretinoin) has been attributed to decreased cohesiveness of epidermal cells and increased epidermal cell turnover. This is thought to result in increased extrusion of open comedones and transformation of closed comedones into open ones. Isotretinoin is approved for treatment of recalcitrant cases of acne and cystic acne. Although the exact mode of action is unknown, isotretinoin decreases sebaceous gland activity, prevents new comedones from forming, reduces the P. acnes count through sebum reduction, and has an anti-inflammatory effect. Because of its many side effects, it is used only in persons with severe acne. The oral retinoids are known teratogens and must not
be used in women who are pregnant or may become pregnant.

A frequently seen adverse effect of acne in darker
skinned persons is postinflammatory hyperpigmentation. Hence, treatment measures for persons of color
may vary.23

**Acne Conglobata**

Acne conglobata occurs later in life as a severe, chronic
form of acne. Comedones, papules, pustules, nodules,
abscesses, cysts, and scars occur on the back, buttocks,
and chest. Lesions occur to a lesser extent on the abdom-
men, shoulders, neck, face, upper arms, and thighs. The
comedones or cysts have multiple openings, large
abscesses, and interconnecting sinuses. Inflammatory
nodules are not uncommon. Their discharge is odorif-
erous, serous or mucoid, and purulent. Healing often
leaves deep keloidal lesions. Affected persons have anemia
with elevated white blood cell counts, erythrocyte
sedimentation rates, and neutrophil counts. The treat-
ment is difficult and stringent. It often includes debride-
ment, systemic corticosteroid therapy, oral retinoids,
and systemic antibiotics.

**Rosacea**

Rosacea is a chronic skin disorder of middle-aged and
older persons. The disease has a variety of clinical mani-
festations (blushing, presence of telangiectatic vessels,
eruption of inflammatory papules and pustules) that pri-
marily affect the central areas of the face. In the early
stage of rosacea development, there are repeated episodes
of blushing.24,25 The blush eventually becomes a perma-
nent, dark-red erythema on the nose and cheeks that
sometimes extends to the forehead and chin (Fig. 46-12).
This stage often occurs before 20 years of age. Ocular
problems occur in at least 50% of persons with rosacea.
Prominent symptoms include eyes that are itchy, burning,
or dry; a gritty or foreign body sensation; and erythema
and swelling of the eyelid. As the person ages, the ery-
theta persists, and telangiectasia with or without acne
components (e.g., comedones, papules, pustules, nodules,
erythema, and edema) develops. After years of afflic-
tion, rosacea may develop into an irregular bullous hyperpla-
sia (thickening of the skin) of the nose, known as rhino-
phyma. Although rosacea is more common in women,
rhinophyma is more common in men.

The cause of rosacea is unknown; however, it is
believed to be a chronic inflammatory process involving
the area surrounding the pilosebaceous units, accompa-
nied by vascular instability with leakage of fluid and
inflammatory mediators into the dermis. The lesions are
accompanied by nonspecific perifollicular infiltrate of
lymphocytes surrounded by dermal edema and dilated
capillaries and terminal arterioles (telangiectases).24,25
In the pustular phase, neutrophils may colonize the
follicles, and follicular rupture may produce a granu-
ломatous response. Rhinophyma is associated with
hypertrophy of the sebaceous glands.

Rosacea is distinguished from acne vulgaris by the
presence of the neurovascular component and absence
of comedones. Treatment measures are similar to those
used for acne vulgaris. Persons with rosacea are heat
sensitive. They are instructed to avoid vascular stimulat-
ating agents such as heat, sunlight, hot liquids, foods, and
alcohol. Topical metronidazole and azelaic acid creams
have proved effective as treatment. Topical antibiotics
(e.g., clindamycin, erythromycin), as well as systemic
antibiotics (e.g., tetracycline and its derivatives) are also
used in treatment of the disorder.26 Pulsed dye laser ther-
apy may be used for ablation of vessels in persons with
prominent telangiectases. Rhinophyma can be treated by
a number of surgical methods, including electrosurgery,
laser ablation, dermabrasion, cryosurgery, and excision.

**Allergic and Hypersensitivity Dermatoses**

Allergic and hypersensitivity dermatoses involve the
inflammatory response to multiple exogenous and
endogenous agents. The disorders, which are usually
characterized by epidermal edema with separation of
epidermal cells, include atopic dermatitis, urticaria,
drug-induced skin eruptions, and allergic contact der-
matitis (discussed in Chapter 16).

**Atopic Dermatitis**

Atopic dermatitis (atopic eczema) is a highly pruritic
chronic inflammatory skin disease. It usually begins
early in life and often occurs in children with a personal
or family history of other atopic disorders, such as aller-
gic rhinitis and asthma.27,28 The condition often remits
during childhood, although it may reappear in adoles-
cence and persist throughout adulthood.28 The hall-
marks of atopic dermatitis are a chronic, relapsing form
of skin inflammation; a disturbance in the epidermal
barrier function that leads to increased transepidermal

---

**FIGURE 46-12.** Papulopustular and ocular rosacea of moderate severity. The pustules are seen over the central portion of the face with sparing of the periorcular area. Erythema and edema of the upper eyelids are also present. (From Powell FC. Rosacea. N Engl J Med. 2005;352:793–803. Copyright © 2005. Massachusetts Medical Society.)
water loss and dry skin; and immunoglobulin E (IgE)-
mediated sensitization to food and environmental anti-
gen.

Whether the primary defect is dermatoic or
immunologic is uncertain. It has been suggested that the
epidermal barrier disturbance allows increased antigen
absorption and contributes to the hyperreactivity charac-
teristic of atopic dermatitis.

The lesions of atopic dermatitis are usually character-
ized by erythematous papules and vesicles, erosions, and
serous exudates. Scratching causes crusted erosions. The
clinical manifestations of the disorder often vary with
age. In infancy the eczematous lesion usually appear
on the cheeks and scalp (Fig. 46-13). The skin of the
cheeks may be paler, with extra creases under the eyes,
called Dennie-Morgan folds. During childhood, lesions
involve flexures in the nape of the neck, and the dorsal
aspects of the limbs.

Adolescents and adults usually have dry, red patches
affecting the face, neck, and upper trunk. The bends
of the elbows and knees are usually involved. In chronic
cases, the skin is dry, leathery, and lichenified. Persons
with dark skin may have a papular eruption and poorly
demarcated hypopigmentation patches on the cheeks
and extremities. In persons with black skin, pigmen-
tation may be lost from lichenified skin. Acute flares
may present with red patches that are weepy, shiny, or
lichenified, and with plaques and papules. Itching may
be severe and prolonged with both childhood and adult
forms of atopic dermatitis. Secondary infections are
common.

Treatment is designed to target the underlying
abnormalities: dryness, pruritus, infection, and inflam-
mation. Basic therapy begins with optimal skin care,
addressing the skin barrier defect with continuous use
of emollients and skin hydration, along with avoiding
exposure to irritants such as wool clothing, soaps, and
hot water.

Topical corticosteroids remain an important treat-
ment for acute flare-ups but can cause local and sys-
temic side effects. Potency of topical corticosteroids is
classified by the potential for vasoconstriction. In gen-
eral, only preparations that have weak or moderate
potency are used on the face and genital areas, whereas
those that have moderate or high potency are used on
other areas of the body. Lower-potency corticosteroids
may be sufficient on all areas of the body in younger
children. One of the main concerns of topical corticoste-
roid use is skin thinning. Another concern is secondary
adrenal suppression and the suppression of growth in
children resulting from systemic absorption. Wet-wrap
therapy, in which a wet dressing is applied over emol-
lients in combination with topical antiseptics or topical
corticosteroids, has been shown to be beneficial in some
cases of severe atopic dermatitis. Elimination of aller-
gens in the living environment is a hallmark of therapy.

Systemic or adjuvant therapy is usually reserved
for severe acute exacerbations. Short-term corticoste-
roids are also used during acute flare-ups in adults.
Antihistamines may be used to relieve itching. Secondary
infection with S. aureus is common and may be treated
with systemic antimicrobial therapy. Phototherapy can
be an important adjunct for severely affected adults and
adolescents older than 12 years of age.

**Urticaria**

Urticaria, or hives, is a common skin disorder character-
ized by the development of edematous wheals accompa-
nied by intense itching. The lesions typically appear
as raised pink or red areas surrounded by a paler halo
(Fig. 46-14). They blanch with pressure and vary in size
from a few millimeters to centimeters. Angiöedema,
which can occur alone or with urticaria, is character-
ized by nonpitting, nonpruritic, well-defined edematous
swelling that involves subcutaneous tissues of the face,
hands, feet, or genitals. It is more likely than urticaria
to produce life-threatening swelling of the tongue and
upper airways.

Urticaria can be acute or chronic and due to known or
unknown causes. Numerous factors, both immunologic

and nonimmunologic, can be involved in its pathogenesis. The urticarial wheal results from liberation of histamine from mast cells and basophils. Histamine causes hyperpermeability of the microvessels of the skin and surrounding tissue, allowing fluid to leak into the tissues, causing edema and wheal formation.

Acute immunologic urticaria is commonly the result of an IgE-mediated immune reaction that usually occurs within 1 hour of exposure to an antigen. The most common causes of acute urticaria are foods or drinks, medications (most notably penicillin and cephalosporin), insect stings, and exposure to pollens or chemicals. Although nonsteroidal anti-inflammatory drugs, including aspirin, do not normally cause urticaria, they may exacerbate the preexisting disease. In rare cases, urticaria is a manifestation of underlying disease, such as certain cancers, collagen diseases, and hepatitis. A hereditary deficiency of a C1 (complement 1) inhibitor also can cause a condition called hereditary angioneurotic edema.

The physical urticarias are a specific form of chronic urticaria, in which specific physical stimuli reproducibly elicit wheals. Physical urticarias are intermittent, usually last less than 2 hours, are produced by appropriate stimuli, have distinctive appearances and locations, and are seen most frequently in young adults. Dermo-graphism, or skin writing, is one form of physical urticaria in which wheals appear in response to simple rubbing of the skin. The wheals follow the pattern of the scratch or rubbing, appearing within 10 minutes and dissolving completely within 20 minutes. Other types of physical urticaria are induced by exercise, sunlight, water, vibration, cold, and heat. Appropriate challenge tests (e.g., application of an ice cube to the skin to initiate development of cold urticaria) are used to differentiate physical urticaria from chronic urticaria due to other causes.

Most types of urticaria are treated with nonsedating antihistamines that alleviate pruritus and decrease the incidence of hives without producing drowsiness. Leukotriene antagonists (zafirlukast and montelukast) may also be used. Oral corticosteroids may be used in the treatment of refractory urticaria. Tricyclic antidepressant drugs, particularly those with antihistamine actions, may also be used. Persons who have experienced angioedema of the larynx and pharynx should be counseled to carry a prescription of epinephrine in an autoinjectable syringe.

**Drug-Induced Skin Eruptions**

Most drugs can cause a localized or generalized skin eruption. Topical drugs are usually responsible for localized contact dermatitis types of rashes, whereas systemic drugs cause generalized skin lesions. Although many drug-induced skin eruptions are exanthematous or morbilliform (i.e., measleslike), they may mimic most of the skin disorders described in this chapter. Because the lesions vary greatly, the diagnosis depends almost entirely on an accurate patient report, including a full drug history. Early recognition and discontinuation of the drug are essential. Management of mild cases is aimed at eliminating the offending drug while treating the symptoms. Severe cases require prompt medical attention.

Some drug reactions result in epidermal cell detachment and bullae (fluid-filled blisters) formation. The skin detachment seen with bullous skin lesions is different from the desquamation (i.e., peeling) that occurs with other skin disorders. In the bullous disorders, there is full-thickness detachment of the entire epidermis from the dermis. This leaves the person vulnerable to multiple problems, including loss of body fluids and electrolytes, impaired body temperature control, and a greatly increased risk of infection. Three types of drug reactions that result in bullous skin lesions are erythema multiforme minor, which is usually self-limiting, with a small amount of skin detachment at the lesion sites; Stevens-Johnson syndrome, which involves less than 10% of the body surface area; and toxic epidermal necrolysis, which involves detachment of more than 30% of the epidermis. Detachment of 10% to 30% of the epidermis is considered an overlap of Stevens-Johnson syndrome and toxic epidermal necrolysis.

**Etiology and Pathogenesis.** Although the cause of erythema multiforme minor may be drug induced or unknown, it frequently occurs after infections, especially HSV infection. Stevens-Johnson syndrome and toxic epidermal necrolysis are caused by a hypersensitivity reaction to drugs, the most common being sulfonamides, anticonvulsants, nonsteroidal anti-inflammatory drugs, antimalarial agents, and allopurinol. The incidences of Stevens-Johnson syndrome and toxic epidermal necrolysis are rare, but mortality rates are high. Recovery is based on the severity and quick, aggressive treatment.

**Manifestations.** The lesions of erythema multiforme minor and Stevens-Johnson syndrome are similar. The primary lesion of both is a round, erythematous papule resembling an insect bite. Within hours to days, these lesions change into several different patterns. The individual lesions may enlarge and coalesce, producing small plaques, or they may change to concentric zones of color appearing as “target” or “iris” lesions (Fig. 46-15). The outermost rings of the target lesions usually are erythematous; the central portion usually is opaque white, yellow, or gray (dusky). In the center, small blisters may form on the dusky purpuric macules, giving them their characteristic targetlike appearance. Although there is wide distribution of lesions over the body surface area, there is a propensity for them to occur on the face and trunk.

Toxic epidermal necrolysis is the most serious type of drug reaction, with mortality rates of 40%. The person experiences a prodromal period of malaise, low-grade fever, and sore throat. Within a few days, widespread erythema and large, flaccid bullae appear, followed by the loss of the epidermis, leaving a denuded and painful dermis. The skin surrounding the large denuded areas may have the typical target-like lesions seen with...
Psoriasis

Psoriasis is a common, chronic, inflammatory skin disease characterized by raised erythematous plaques with silvery scales. It affects approximately 2% of the population and occurs worldwide, although the incidence is lower in warmer, sunnier climates. The average age of onset is in the third decade; its prevalence increases with age. Approximately one third of persons have a genetic history, indicating a hereditary factor. Childhood onset of the disease is more strongly associated with a family history than psoriasis occurring in adults older than 30 years of age. In rare cases, psoriasis is associated with arthritis (see Chapter 44).

Etiology and Pathogenesis. Although the primary cause of psoriasis is uncertain, it is thought to be an immunologic disorder in persons with a genetic predisposition. It is not known if the inciting antigen is of self or environment origin. A genetic component is supported by population studies indicating a greater incidence of psoriasis among relatives of persons with the disease than among the general population. There is a strong association between psoriasis and the human leukocyte antigen-C (HLA-C), particularly the HLA-Cw6 allele. Immunologically, T lymphocytes may be the key to the pathogenesis of psoriasis. Eruption of psoriatic lesions coincides with T-cell infiltration into the epidermis, and resolution of the lesions follows disappearance or reduction in epidermal T cells, suggesting a T-cell–mediated release of cytokines and growth factors that stimulate abnormal growth of keratinocytes and dermal blood vessels. Accompanying inflammatory changes are caused by infiltration of neutrophils and monocytes. Environmental stimuli may trigger the release of cytokines and growth factors from keratinocytes and other cells, with ensuing immune and inflammatory responses that lead to the full development of psoriatic lesions. For example, psoriatic lesions can be induced in susceptible individuals by trauma, a process known as the Köbner phenomenon.

Clinical Features. Histologically, psoriasis is characterized by increased epidermal cell turnover with marked epidermal thickening, a process called hyperkeratosis. The granular layer (stratum granulosum) of the epidermis is thinned or absent, and neutrophils are found in the stratum corneum. There also is an accompanying thinning of the epidermal cell layer that overlies the tips of the dermal papillae, and the blood vessels in the dermal papillae become tortuous and dilated. These capillary beds show permanent damage even when the disease is in remission or resolved. The close proximity of the vessels in the dermal papillae to the hyperkeratotic scale accounts for multiple, minute bleeding points that are seen when the scale is lifted.

Psoriasis most frequently affects the elbows, knees, scalp, lumbosacral area, and intragluteal cleft. The primary lesions are sharply demarcated, thick, red plaques covered by a silvery scale that varies in size and shape (Fig. 46-16). In darker-skinned persons, the plaques may appear purple. There may be excoration, thickening, or oozing from the lesions. A differential diagnostic finding is that the plaques bleed from minute points when removed, which is known as the Auspitz sign.

Papulosquamous Dermatoses

Papulosquamous dermatoses are a group of skin disorders characterized by scaling papules and plaques. Among the major papulosquamous diseases are psoriasis, pityriasis rosea, and lichen planus.

Stevens-Johnson syndrome. Lateral pressure causes the surrounding skin to separate easily from the dermis (Nikolsky sign). The tracheobronchial mucosa and conjunctiva may be involved in severe cases with resultant scarring. Ophthalmologic consultation is required when ocular involvement is present.

Treatment. Treatment of erythema multiforme minor and less-severe cases of Stevens-Johnson syndrome includes relief of symptoms using compresses, antipruritic drugs, and topical anesthetics. Corticosteroid therapy may be indicated in moderate cases, although its use is controversial. For severe cases of Stevens-Johnson syndrome and toxic epidermal necrolysis, hospitalization is required for fluid replacement, respiratory care, administration of antibiotics and analgesics, and application of moist dressings. When large areas of skin are detached, the care is similar to that of a thermal burn. Intravenous immunoglobulin may hasten the healing response of the skin. Generally, healing is a slow process, taking 6 weeks or more to regenerate skin. The mucous membranes heal slowly and follow-up treatment is often needed for ophthalmologic and mucous membrane sequelae. Discontinuation of the responsible drug and chemically related compounds is imperative, as are measures to prevent future exposures to the drug.

Histologically, psoriasis is characterized by raised erythematous plaques with silvery scales. The plaques may appear purple. There may be excoration, thickening, or oozing from the lesions. A differential diagnostic finding is that the plaques bleed from minute points when removed, which is known as the Auspitz sign.
Tazarotene, a synthetic retinoid, also has been shown to inhibit epidermal cell proliferation and enhance cell differentiation. Tazarotene, a synthetic retinoid, also has been effective, but it is teratogenic and should be avoided in women of childbearing age.

Topical corticosteroids are widely used and relatively effective. They are generally more acceptable because they do not stain and are easy to use. Low-potency preparations usually are used on the face and on areas of the body, such as the groin and axilla, where the skin tends to be thinner. High-potency preparations are reserved for treatment of thick chronic plaques that do not respond to less-potent preparations. Although the corticosteroids are rapidly effective in the treatment of psoriasis, they are associated with flare-ups after discontinuation and they have many potential side effects. Their effectiveness is increased when used under occlusive dressings, but there is an increase in side effects.

Systemic treatments include phototherapy, photochemotherapy, methotrexate, corticosteroids, and cyclosporine. The positive effects of sunlight have long been established. Phototherapy with UVB radiation is a widely used treatment. Newly developed narrow-band UVB radiation is reportedly more effective than broad-band UVB. Photochemotherapy involves using a light-activated form of the drug methoxsalen. Methoxsalen, a psoralen or phototoxic drug, exerts its actions when exposed to UVA radiation in 320- to 400-nm wavelengths. The combination treatment regimen of psoralen and UVA is known by the acronym PUVA. Methoxsalen is given orally before UVA exposure. Activated by the UVA energy, methoxsalen inhibits DNA synthesis, thereby preventing cell mitosis and decreasing the hyperkeratosis that occurs with psoriasis. Although viewed as one of the safest therapies since its introduction in the 1970s, PUVA increases the risk for squamous cell carcinoma, and it may increase the risk for development of melanoma.

Methotrexate, which is used for cancer treatment, is an antimitabolite that inhibits DNA synthesis and prevents cell mitosis. Oral methotrexate has been effective in treating psoriasis when other approaches have failed. The drug has many side effects, including nausea, malaise, leukopenia, thrombocytopenia, and liver function abnormalities. Cyclosporine is a potent immunosuppressive drug used to prevent rejection of organ transplants. It suppresses inflammation and the proliferation of T cells in persons with psoriasis. Its use is limited to severe psoriasis because of serious side effects, including nephrotoxicity, hypertension, and increased risk of cancers. Intraleisonal cyclosporine also has been effective. Biologic agents (drugs that are taken from or made of living tissues or cells instead of chemicals) that target the activity of T lymphocytes and cytokines responsible for the inflammatory nature of psoriasis have proven effective.

Pityriasis Rosea

Pityriasis rosea is a rash that primarily affects children and young adults. The origin of the rash is unknown, but it is thought to be caused by an infective agent, possibly a herpesvirus. Its incidence is highest in winter. Cases occur in clusters and among persons who are in close contact; however, there are no data to support communicability, suggesting it may be an immune response to any number of agents.

The characteristic lesion is an oval macule or papule with surrounding erythema (Fig. 46-17). The lesion spreads with central clearing, much like tinea corporis. This initial lesion is called the herald patch and is usually on the trunk or neck. As the lesion enlarges and begins to fade (2 to 10 days), successive crops of lesions appear on the trunk and neck. The lesions on the back have a characteristic...
“Christmas tree” pattern. The extremities, face, and scalp may be involved. Mild to severe pruritus may occur. The disease is self-limited and usually disappears within 6 to 8 weeks. Treatment measures are palliative and include topical steroids, antihistamines, and colloid baths. Systemic corticosteroids may be indicated in severe cases.

**Lichen Planus**

The term *lichen* (Greek, “tree moss”) refers to skin disorders characterized by small (2 to 10 mm), flat-topped papules with irregular, angulated borders. *Lichen planus* is a relatively common chronic pruritic disease. It involves inflammation and papular eruption of the skin and mucous membranes. There are variations in the pattern of lesions (e.g., annular, linear) and differences in the sites (e.g., mucous membranes, genitalia, nails, scalp). The characteristic lesion is a purple, polygonal papule covered with a shiny, white, lace-like pattern (Fig. 46-18). The lesions appear on the wrist, ankles, and trunk of the body. Most persons who have skin lesions also have oral lesions, appearing as milky white lacework on the buccal mucosa or tongue. Other mucosal surfaces, such as the genital, nasal, laryngeal, otic, gastric, and anal areas, may also be affected. As with psoriasis, lichen planus lesions can develop on scratches or skin injuries (Köbner phenomenon).

The etiology of lichen planus is unknown, but it is believed to be an abnormal immune response in which epithelial cells are recognized as foreign. The disorder involves the epidermal–dermal junction with damage to the basal cell layer. Some cases of lichen planus have been linked to hepatitis C virus infections or medication use. The most common medications include gold, antimalarial agents, thiazide diuretics, beta blockers, nonsteroidal anti-inflammatory agents, quinidine, and angiotensin-converting enzyme inhibitors.

Diagnosis is based on the clinical appearance of the lesions and the histopathologic findings from a punch biopsy. For most persons, lichen planus is a self-limited disease. Treatment measures include discontinuation of all medications, followed by treatment with topical corticosteroids and occlusive dressings. Antipruritic agents are helpful in reducing itch. Systemic corticosteroids may be indicated in severe cases. Photochemotherapy (i.e., PUVA) may also be used. Acitretin, an orally administered retinoid agent, also may be effective. Because retinoids are teratogenic, they should be avoided in women of childbearing age.

**Lichen Simplex**

Lichen simplex chronicus is a localized lichenoid pruritic dermatitis resulting from repeated rubbing and scratching. It is characterized by the occurrence of itchy, reddened, thickened, and scaly patches of dry skin. Persons with the condition may have a single lesion or, less frequently, multiple lesions. The lesions are seen most commonly at the nape of the neck, wrists, ankles, or anal area. The condition usually begins as a small pruritic patch, which after a repetitive cycle of itching and scratching develops into a chronic dermatitis. Because of the chronic itching and scratching, excoriations and lichenification with thickening of the skin develops, often giving the appearance of tree bark.

**SUMMARY CONCEPTS**

- Primary dermatoses are conditions that have their origin in the skin.
- Infectious skin disorders are caused by fungi, bacteria, and viruses that invade the skin, incite inflammatory responses, and otherwise cause rashes and lesions that disrupt the skin surface.
- Superficial fungal infections or dermatophytoses are commonly known as tinea or ringworm. Tinea can affect the whole body (tinea corporis), scalp (tinea capitis), feet or hands (tinea pedis or manus), or nails (tinea unguium).
Candidal skin infections due to C. albicans occur most often in persons with diabetes mellitus, those who are immunosuppressed, or those who have been treated with broad-spectrum antibiotics.

Impetigo, which is caused by staphylococci or β-hemolytic streptococci, is the most common superficial bacterial infection.

Viruses are responsible for verrucae (warts), herpes simplex type 1 lesions (cold sores or fever blisters), and herpes zoster (shingles).

Disorders of the pilosebaceous unit include acne vulgaris, which is a common skin disorder of adolescents and young adults that involves increased sebum production and the presence of P. acnes; and rosacea, which is a chronic acneform disorder of middle-aged and older persons.

Allergic skin responses involve the body’s immune system and are caused by hypersensitivity reactions to allergens such as environmental agents, drugs, and other substances. They include atopic dermatitis, urticaria, and drug-induced skin eruptions (erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis).

Papulosquamous dermatoses are characterized by scaling papules and plaques that result from uncontrolled keratinocyte proliferation. Psoriasis is a chronic proliferative skin disease characterized by epidermal hyperplasia. Lichen planus is a hypersensitivity reaction with lymphocytic infiltration at the dermal–epithelial junction.

Skin Disorders Due to Ultraviolet Radiation, Heat, and Pressure Injury

The skin is highly vulnerable to injury from excessive ultraviolet (UV) radiation, heat, and unrelieved pressure.

Ultraviolet Radiation

Sunlight is composed of a continuous spectrum of electromagnetic radiation that is divided into three main parts or wavelengths: ultraviolet (UV), visible, and infrared. The UV light region occurs between 100 and 400 nm (nm: one billionth of a meter). Long-wave UVA radiation is 320 to 400 nm; medium-wave UVB is 280 to 320 nm; and short-wave UVC is 100 to 280 nm. The ozone layer effectively absorbs UV radiation up to 310 nm, absorbing all of UVC and much of UVB radiation. However, damage to the protective ozone layer is allowing an increased amount of UVB to reach the earth. The ozone layer does not absorb UVA.

Ultraviolet Radiation Skin Damage

UVA makes up more than 95% of the solar radiation that reaches us. Compared to UVB, this long-wave radiation penetrates deep into the dermis of the skin and is more effective in producing an immediate tan. UVB radiation is a minor but more active constituent of sunlight. It is more genotoxic and about 1000 times more capable of causing sunburn than UVA light. UVB acts mainly on the cells in the basal layer of the epidermis. It produces direct damage to the DNA and other nuclear proteins. It also provokes free radical production and induces a significant reduction in skin antioxidants, impairing the ability of the skin to protect itself against damage by the free radicals that are generated.

Etiology and Pathogenesis. Exposure to UVA and UVB produces acute effects that are short lived and reversible. They include erythema, pigmentation, and injury to Langerhans cells and keratinocytes in the epidermis. These reactions differ depending on whether the inciting agent is UVA or UVB. For example, UVA-induced erythema occurs immediately, fades within hours, and is believed to be due to the “heat load.” UVB-induced erythema has a delayed response, peaking within 6 to 24 hours after exposure to sunlight and fading over 1 or 2 days. Pigmentation or tanning induced by UVA and UVB is due to increased synthesis of melanin by melanocytes, along with increased transfer of the melanin to keratinocytes (see Chapter 45). Small doses of UVA produce transient, immediate darkening of the skin that fades within 2 hours, whereas higher doses of UVA can produce pigmentary changes lasting for several hours to days. Tanning induced by UVB is protective against subsequent exposures, whereas tanning induced by UVA provides limited protection.

Skin damage induced by UVB is believed to be caused by the generation of reactive oxygen species and by damage to melanocytes. Cellular proteins and DNA are primarily damaged because of their abundance and ability to absorb UVB radiation. Both UVA and UVB also deplete Langerhans cells and immune cells. It is believed that these effects prevent immune cells from detecting and removing sun-damaged cells with malignant potential. Both UVA and UVB are now considered causes of skin cancer. UVA may actually be more carcinogenic than UVB. Although it causes less sunburn, UVA is present during all daylight hours, year-round. Artificial sources of UVA, such as tanning beds and therapeutic solar interventions (PUVA) for certain skin conditions, also produce the same effects as solar UVA in terms of skin cancer. This is of particular concern because of the increased use of indoor tanning, particularly among adolescents and young adults who are at greatest risk of melanoma. Educating the population about avoiding tanning booths has not increased compliance; the number of people who use tanning...
booths continues to rise, while adherence of tanning booths to national guidelines is often violated.\textsuperscript{46}

**Clinical Features.** Sunburn is caused by excessive exposure of the epidermal and dermal layers of the skin to UV radiation, resulting in an erythematous inflammatory reaction.\textsuperscript{47} Sunburn ranges from mild to severe. Mild sunburn consists of various degrees of skin redness. The burn continues to develop for 24 to 72 hours, occasionally followed by peeling skin in 3 to 8 days. Some peeling and itching may continue for several weeks. Inflammation, blistering, weakness, chills, fever, malaise, and pain often accompany severe forms of sunburn. Scaling and peeling follow any overexposure to sunlight. Dark skin also burns and may appear grayish or gray-black. Severe sunburns are those that cover large portions of the body or are accompanied by a high fever or intense pain.

The UV rays of sunlight or other sources can be completely or partially blocked from the skin surface by sunscreens. There are two primary types of sunscreens available on the market—chemical (soluble) agents and physical (insoluble) agents.\textsuperscript{43} Chemical agents (e.g., para-aminobenzoic acid [PABA] derivatives) protect the skin from absorbing sunlight, and physical agents (e.g., micronized titanium dioxide and microfine zinc) work by reflecting sunlight. The *sun protection factor* (SPF) rating of the various sunscreen products is based on their ability to obstruct UV radiation (UVR) absorption. The ratings usually are on a scale of 1 to 30+, with the higher ratings indicating greater blocking of UVR.\textsuperscript{45} Products with a higher SPF screen out more UVB rays, which are primarily responsible for acute sun damage. Shielding the skin with protective clothing and hats or head coverings helps decrease UVR exposure.

Mild to moderate sunburns are treated with anti-inflammatory medications, such as aspirin or ibuprofen, until redness and pain subside. Cold compresses, cool baths, and applying a moisturizing cream, such as aloe, to affected skin help treat the symptoms. Steroid and nonsteroidal agents are used depending on the severity of the burn. Blisters should not be broken to preserve the protective layer of the skin, hasten the healing process, and decrease the risk of infection. Extensive second- and third-degree sunburns may require hospitalization and specialized burn care techniques, as described in the section on thermal injury.

**Drug-Induced Photosensitivity**

Some drugs are classified as photosensitive drugs because they produce an exaggerated response to UVR when the drug is taken in combination with sun exposure. Examples include some of the anti-infective agents (sulfonamides, tetracyclines, nalidixic acid), antihistamines (cyclophosphamide, diphenhydramine), antipsychotic agents (phenothiazines, haloperidol), diuretics (thiazides, acetazolamide, amiloride), hypoglycemic agents (sulfonylureas), and nonsteroidal anti-inflammatory drugs (phenylbutazone, ketoprofen, naproxen).

**Thermal Injury**

About 450,000 people in the United States require medical care for burns each year, with 40,000 requiring hospitalization.\textsuperscript{48} Flame burns occur because of exposure to direct fire. Scald burns result from hot liquids spilled or poured on the skin surface.

The effects and complications of burns fully illustrate the essential function that the skin performs in protecting the body from the many damaging elements in the environment while serving to maintain the constancy of the body’s internal environment. The massive loss of skin tissue not only predisposes to attack by microorganisms that are present in the environment, but also allows for the massive loss of body fluids, interferes with temperature regulation, challenges the immune system, and imposes excessive demands on the metabolic and reparative processes that are needed to restore the body’s interface with the environment.

**Classification of Burns**

Burns are typically classified according to the depth of involvement as first-degree, second-degree, and third-degree burns.\textsuperscript{49,50} The depth of a burn is largely influenced by the duration of exposure to the heat source and the temperature of the heating agent. First-degree burns (superficial partial-thickness burns) involve only the outer layers of the epidermis. They are red or pink, dry, and painful. There usually is no blister formation, as with a mild sunburn. The skin maintains its ability to function as a water vapor and bacterial barrier and heals in 3 to 10 days. First-degree burns usually require only palliative treatment, such as pain-relief measures and adequate fluid intake. Extensive first-degree burns on infants, the elderly, and persons who receive radiation therapy for cancer may require more care.

Second-degree burns involve both the epidermis and dermis. Second-degree partial-thickness burns involve the epidermis and various degrees of the dermis. They are painful, moist, red, and blistered. Underneath the blisters is weeping, bright pink or red skin that is sensitive to temperature changes, air exposure, and touch. The blisters prevent the loss of body water and superficial dermal cells. Excluding excision of large burn areas, it is important to maintain intact blisters after injury because they serve as a good bandage and may promote wound healing. These burns heal in approximately 1 to 2 weeks.

Second-degree full-thickness burns involve the entire epidermis and dermis. Structures that originate in the subcutaneous layer, such as hair follicles and sweat glands, remain intact. These burns can be very painful because the pain sensors remain intact. Tactile sensation may be absent or greatly diminished in the areas of deepest destruction. These burns appear as mottled pink, red, or waxy white areas with blisters and edema. The blisters resemble flat, dry tissue paper, rather than the bullous blisters seen with superficial partial-thickness injury. After healing in approximately 1 month, these burns maintain their softness and elasticity, but there may be the loss of some sensation. Scar formation is common.
These burns heal with supportive medical care aimed at preventing further tissue damage, providing adequate hydration, and ensuring that the granular bed is adequate to support re-epithelialization.

Third-degree full-thickness burns extend into the subcutaneous tissue and may involve muscle and bone. Thrombosed vessels can be seen under the burned skin, indicating that the underlying vasculature is involved. Third-degree burns vary in color from waxy white or yellow to tan, brown, deep red, or black. These burns are hard, dry, and leathery. Edema is extensive in the burn area and surrounding tissues. There is no pain because the nerve sensors have been destroyed. However, there is no such thing as a “pure” third-degree burn. Third-degree burns are almost always surrounded by second-degree burns, which are surrounded by an area of first-degree burns. The injury sometimes has an almost targetlike appearance because of the various degrees of burn. Full-thickness burns wider than 1.5 inches usually require skin grafts because all the regenerative (i.e., dermal) elements have been destroyed. Smaller injuries usually heal from the margins inward toward the center, the dermal elements regenerating from the healthier margins. However, regeneration may take many weeks and leave a permanent scar, even in smaller burns.

In addition to the depth of the wound, the extent of the burn also is important. Extent is measured by estimating the amount of total body surface area (TBSA) involved. Several tools exist for estimating the TBSA. For example, the rule of nines counts anatomic body parts as multiples of 9% (the head and neck is 9%, each arm 9%, each leg 18%, anterior trunk 18%, posterior trunk 18%), with the perineum 1%. The Lund and Browder chart includes a body diagram table that estimates the TBSA by age and anatomic part. Children are more accurately assessed using this method because it takes into account the difference in relative size of body parts. The estimates of TBSA are then converted to the American Burn Association Classification of Extent of Injury (Table 46-1).

Other factors, such as age, location, other injuries, and preexisting conditions, are taken into consideration for a full assessment of burn injury. These factors can increase the assessed severity of the burn and the length of treatment. For example, a first-degree burn is reclassified as a more severe burn if other factors are present, such as burns to the hands, face, and feet; inhalation injury; other trauma; or existence of psychosocial problems. Genital burns almost always require hospitalization because edema may cause difficulty urinating and the location complicates maintenance of a bacteria-free environment.

### Systemic Complications

Burn victims often are confronted with hemodynamic instability, impaired respiratory function, a hypermetabolic response, and sepsis. The magnitude of the response is proportional to the extent of injury, usually reaching a plateau when approximately 60% of the body is burned. In addition to loss of skin, burn victims often have associated injuries or illnesses. The treatment challenge is to provide immediate resuscitation efforts and long-term maintenance of physiologic function. Pain and emotional problems are additional challenges faced by persons with burns.

#### Hemodynamic Instability

Hemodynamic instability begins almost immediately with injury to capillaries in the burned area and surrounding tissue. Fluid is lost from the vascular, interstitial, and cellular compartments. Because of a loss of vascular volume, major burn victims often present in the emergency department in a form of hypovolemic shock (Chapter 20) known as burn shock. Because proteins from the blood are lost into the interstitial compartment, generalized edema, including pulmonary edema, can be severe.

Respiratory System Dysfunction. Another injury commonly associated with burns is postburn lung injury from smoke inhalation. Victims often are trapped in a burning structure and inhale significant amounts of smoke, carbon monoxide, and other toxic fumes. Water-soluble gases found in smoke from burning plastics and rubber, such as ammonia, sulfur dioxide, and chlorine, react with mucous membranes to form strong acids and alkalis that induce ulceration of the mucous membrane, bronchospasm, and edema. Lipid-soluble gases, such as nitrous oxide and hydrogen chloride, are transported to the lower airways, where they damage lung tissue. There also may be thermal injury to the respiratory passages. Manifestations of inhalation injury include hoarseness, drooling and inability to handle secretions, hacking cough, and labored, shallow breathing. Serial blood gases show a fall in the partial pressure of arterial oxygen (PO₂). Signs of mucosal injury and airway obstruction often are delayed for 24 to 48 hours after a burn. Other pulmonary conditions, such as pneumonia, pulmonary embolism, or pneumothorax, may occur secondarily to the burn.

Hypermetabolic Response. The stress of burn injury increases metabolic and nutritional requirements. Secretion of stress-related hormones such as catecholamines and cortisol is increased in an effort to maintain homeostasis. Heat production is increased in an effort to balance heat losses from the burned area. Hypermetabolism, characterized by increased oxygen consumption, increased glucose use, and protein and fat wasting, is a characteristic response to burn trauma and infection. The hypermetabolic state peaks at approximately 7 to 17 days after the burn, and tissue breakdown diminishes as the wounds heal. Nutritional support is essential to recovery from burn injury. Enteral and parenteral hyperalimentation may be used during this time to deliver sufficient nutrients to prevent tissue breakdown and postburn weight loss.

Sepsis. Immunologically, the skin is the body’s first line of defense. When the skin is no longer intact, the body is open to bacterial infection. Destruction of the skin also prevents the delivery of cellular components of the immune system to the site of injury. There also is loss of normal protective skin flora and a shift to colonization by more pathogenic flora. Thus, a significant complication of the acute phase of burn injury is sepsis. It may arise from the burn wound, pneumonia, urinary tract infection, infection elsewhere in the body, or the use of invasive procedures or monitoring devices. The burn site is an ideal growth area for microorganisms; the serum and debris provide nutrients, and the burn injury compromises blood flow.

Emergency and Long-Term Treatment

Regardless of the type of burn, the first step in any burn situation is to stop the burning process, cool the burn, provide pain relief, and cover the burn. Active cooling removes the heat and prevents progression of the burn. Immersion or irrigation with lukewarm water for at least 20 minutes can be extremely helpful. Immediate submersion is more important than removal of clothing, which may delay cooling the involved areas. The application of ice or cold water is not recommended because it can further limit blood flow to an area, turning a partial-thickness into a full-thickness burn.

Depending on the depth and extent of the burn, medical treatment may be necessary. Emergency care consists of resuscitation and stabilization with intravenous fluids while maintaining cardiac and respiratory function. Once hospitalized, the immediate treatment regimen focuses on continued maintenance of cardiorespiratory function, pain alleviation, wound care, and emotional support. After hemodynamic and pulmonary stability have been established, treatment is directed toward initial care of the wound. Treatment of the burn wound focuses on protection from desiccation and further injury of those burn areas that re-epithelialize in 7 to 10 days (superficial second-degree burns). “Nature’s own blister” is the best protection for these burns. Topical antimicrobial preparations (e.g., silver sulfadiazine) and dressings are used to cover the wound when the blister has been broken. Wounds that will not heal spontaneously in 7 to 10 days (deep second-degree and third-degree burns) are usually treated by excision and skin grafts. The sloughed tissue, or eschar, produced by the burn is excised as soon as possible. This decreases the chance of infection and allows the skin to regenerate faster.

Burns that encircle the entire surface of the body or a body part (e.g., arms, legs, torso) can act as a tourniquet, causing major tissue damage to the muscles, tendons, and vascular under the area of the leathery burn eschar. These burns are called circumferential burns. The eschar is incised longitudinally (escharotomy), and sometimes a fasciotomy (surgical incision through the fascia of the muscle) is performed. Systemic infection remains a leading cause of morbidity among persons with extensive burns. Continuous microbiologic surveillance is necessary; protective isolation measures are often instituted. There is an increasing trend toward use of prophylactic antibiotic treatment in persons with major burns.

Skin grafts are surgically implanted as soon as possible, often at the same time the burn tissue is excised, to promote new skin growth, limit fluid loss, and act as a dressing. Skin grafts can be permanent or temporary, and split thickness or full thickness. Permanent skin grafts are used over newly excised tissue. Temporary skin grafts are used to cover a burned area until the tissue underneath it has healed. Various sources of skin grafts exist: autograft (skin obtained from the person’s own body), homograft (skin obtained from another human being, alive or recently dead), and heterograft (skin obtained from another species, such as pigs). The best choice is autografting when there is enough uninterrupted skin on the person’s body. The thickness of these grafts depends on the donor site and the needs of the burn patient. A split-thickness skin graft is one that includes the epidermis and part of the dermis.
A split-thickness skin graft can be sent through a skin mesher that cuts tiny slits into the skin, allowing it to expand up to nine times its original size. These grafts are used frequently because they can cover large surface areas and there is less autorejection. **Full-thickness skin grafts** include the entire thickness of the dermal layer. They are used primarily for reconstructive surgery or for small deep areas. The donor site of a full-thickness skin graft requires a split-thickness skin graft to help it heal.

Two-layered synthetic skin grafts, such as Apligraf or Integra, are composed of a layer of silicone, mimicking the properties of the epidermis, and a layer or matrix of fibers. Skin cells attach to the fibers, enabling dermal skin growth. Once the dermal skin has regenerated, the silicone layer is removed and a thin epidermal skin graft is applied, thus requiring less skin grafting overall.

Other treatment measures include positioning, splinting, and physical therapy to prevent contractures and maintain muscle tone. Because the normal body response to disuse is flexion, the contractures that occur with a burn are disfiguring and cause loss of limb or appendage use. Once the wounds have healed sufficiently, elastic pressure garments, sometimes for the full body, often are used to prevent hypertrophic scarring.

**Pressure Ulcers**

Pressure ulcers are ischemic lesions of the skin and underlying structures caused by unrelieved pressure that impairs the flow of blood and lymph. Pressure ulcers often are referred to as decubitus ulcers or bedsores. The word decubitus comes from the Latin term meaning “lying down.” However, a pressure ulcer may result from pressure exerted when seated or lying down. Pressure ulcers are most likely to develop over a bony prominence, but they may occur on any part of the body that is subjected to external pressure, friction, or shearing forces.

Approximately 2.2 million people in the United States develop pressure ulcers annually. Several subpopulations are at particular risk, including persons with quadriplegia, elderly persons with restricted activity and hip fractures, and persons in the critical care setting.

**Mechanisms of Development**

Many factors contribute to the development of pressure ulcers, such as length of stay in the hospital, vasopressure infusion, spinal cord injury, age, and body mass index. Pressure, shearing forces, friction, and moisture contribute to the incidence of pressure ulcers. External pressures that exceed capillary pressure interrupt blood flow in the capillary beds. When the pressure between a bony prominence and a support surface exceeds the normal capillary filling pressure, capillary flow essentially is obstructed. If this pressure is applied constantly for 2 hours, oxygen deprivation coupled with an accumulation of metabolic end products leads to irreversible tissue damage. While pressure magnitude and duration are important in the creation of a pressure ulcer, no specific amount of pressure necessary to compress capillaries and interrupt blood flow has been determined. Tolerance to pressure loads differs according to tissue, location, and metabolism. Persons with impaired circulation require less pressure to interrupt circulation. The same amount of pressure causes more damage when it is distributed over a small area than over a larger area. Whether a person is sitting or lying down, the weight of the body is borne by tissues covering the bony prominences. Most pressure ulcers are located on the lower part of the body, such as the sacrum, the coccygeal area, the ischial tuberosities, and the greater trochanters. Pressure over a bony area is transmitted from the surface to the underlying dense bone, compressing all of the intervening tissue. As a result, the greatest pressure occurs at the surface of the bone and dissipates outward in a cone-like manner toward the surface of the skin (Fig. 46-19). Thus, extensive underlying tissue damage can be present when a small superficial skin lesion is first noticed.

Altering the distribution of pressure from one skin area to another prevents tissue injury. Pressure ulcers most commonly occur in persons with conditions such as spinal cord injury in which normal sensation and the ability to move to redistribute body weight are impaired. Normally, persons unconsciously shift their weight to redistribute pressure on the skin and underlying tissues. For example, during the night, people turn in their sleep, preventing ischemic injury of tissues that overlie the bony prominences that support the weight of the body; the same is true for sitting for any length of time.

![Figure 46-19](image.png)
The movements needed to shift the body weight are made unconsciously, and only when movement is restricted do people become aware of discomfort.

Shearing forces are caused by the sliding of one tissue layer over another with stretching and angulation of blood vessels, causing injury and thrombosis. Shear occurs when the skeleton moves, but the skin remains fixed to an external surface, such as occurs with transfer from a stretcher to a bed or pulling a person up in bed. The same thing happens when the head of the bed is elevated, causing the torso to move toward the foot of the bed while friction and moisture cause the skin to remain fixed to the bed linens. Friction contributes to pressure ulceration by damaging the skin at the epidermal–dermal interface. It occurs as persons who are bedridden use their elbows and heels to aid in movement. Moisture contributes to pressure ulcer formation by weakening the cell wall of individual skin cells and by changing the protective pH of the skin. This makes the skin more susceptible to pressure, shear, and friction injury.

**Prevention and Treatment**

The prevention of pressure ulcers is preferable to their treatment. Preventive measures include identifying at-risk persons and the specific factors placing them at risk, maintaining and improving tissue tolerance to prevent injury, and protecting the skin and underlying tissue against the adverse effects of external mechanical forces (i.e., pressure, friction, shear). Risk factors contributing to the development of pressure ulcers are those related to sensory perception and the ability to respond meaningfully to pressure-related discomfort, level of skin moisture, urine and fecal continence, nutrition and hydration status, mobility, and circulatory status.

**Prevention Methods.** Methods for preventing pressure ulcers include frequent position changes, meticulous skin care, and frequent and careful observation to detect early signs of skin breakdown. Moisture macerates and injures skin. Sources of moisture include sweat, wound drainage, urine, and feces. Both urinary and fecal incontinence increase the risk of pressure ulcers. Food crumbs, intravenous tubing, and other debris in the bed can greatly increase local skin pressure points. Adequate hydration of the stratum corneum appears to protect the skin against mechanical insult. The prevention of dehydration improves the circulation. It also decreases the concentration of urine, thereby minimizing skin irritation in persons who are incontinent, and it reduces urinary problems that contribute to incontinence. Maintenance of adequate nutrition is important. Anemia and malnutrition contribute to tissue breakdown and delay healing after tissue injury has occurred.

**Staging and Treatment.** Pressure ulcers can be staged using four categories. Stage I ulcers are characterized by a defined area of persistent redness in lightly pigmented skin or an area of persistent redness with blue or purple hues in darker skin. Stage II ulcers represent a partial-thickness loss of skin involving the epidermis or dermis, or both. The ulcer is superficial and presents clinically as an abrasion, a blister, or a shallow crater. Stage III ulcers represent a full-thickness skin loss involving damage and necrosis of subcutaneous tissue that may extend down to but not through underlying fascia. The ulcer manifests as a deep crater with or without undermining of adjacent tissue. Stage IV ulcers involve full-thickness skin loss and necrosis with extensive destruction or damage to the underlying subcutaneous tissues that may extend to involve muscle, bone, and supporting structures (e.g., tendon or joint capsule).

After skin breakdown has occurred, special treatment measures are needed to prevent further ischemic damage, reduce bacterial contamination and infection, and promote healing. Treatment methods are selected based on the stage of the ulcer. Stage I ulcers usually are treated with frequent turning and measures to remove pressure. Stage II or III ulcers with little exudate are treated with semipermeable or occlusive dressings. Occlusive dressings are credited with preventing the loss of wound fluid and maintaining a moist environment that is necessary for epithelial cell migration. Wound fluid is thought to contain a variety of growth factors that enhance wound healing. Occlusive dressings may also relieve wound pain and prevent bacterial contamination. Several types of occlusive dressings are available, and each has advantages and disadvantages. Finally, vasopressor infusions may be important in the healing of pressure ulcers.

Necrotic debris increases the possibility of bacterial infection and delays wound healing. Stage III ulcers with exudate and necrotic debris and stage IV ulcers usually require debridement (i.e., removal of necrotic tissue and eschar). This can be done surgically, with wet-to-dry dressings, or through the use of proteolytic enzymes. Stage IV wounds often require packing to obliterate dead space and are covered with nonadherent dressings. Stage IV ulcers may require surgical interventions, such as skin grafts or myocutaneous flaps.

**SUMMARY CONCEPTS**

- Because the skin covers the body, it is exposed to a number of potentially damaging agents in the external environment.
- Repeated exposure to the ultraviolet (UV) rays of the sun predisposes to sunburn, premature aging of the skin (wrinkling, degenerative changes, and irregularities in pigmentation), and skin cancer. Solar and artificial sources of UV radiation, such as from a tanning bed, contribute to the amount of radiation to which human beings are exposed. Sunburn, which is caused by excessive exposure to UV radiation, is an erythematous inflammatory reaction, ranging from mild to severe. Photosensitive drugs can also produce an exaggerated response to UV radiation when
Nevi and Skin Cancers

Nevi, or moles, are common congenital or acquired tumors of the skin that are benign. However, some nevi can become malignant.

**Nevi**

Almost all adults have nevi, some in greater numbers than others. Nevii can be pigmented or nonpigmented, flat or elevated, and hairy or nonhairy.

Melanocytic nevi are pigmented skin lesions resulting from proliferation of melanocytes in the epidermis or dermis. Melanocytic nevi are tan to deep brown, uniformly pigmented, small papules with well-defined, rounded borders (Fig. 46-20A). They are formed initially by melanocytes with their long dendritic extensions that are normally interspersed among the basal keratinocytes (see Chapter 45, Fig. 45-3). The melanocytes are transformed into round or oval melanin-containing cells that grow in nests or clusters along the dermal–epidermal junction. Because of their location, these lesions are called junctional nevi (see Fig. 46-20B).

Most junctional nevi eventually grow into the surrounding dermis as nests or cords of cells. Compound nevi contain epidermal and dermal components. In older lesions, the epidermal nests may disappear entirely, leaving dermal nevi. Compound and dermal nevi usually are more elevated than junctional nevi.

Another form of nevus, the dysplastic nevus, is important because of its capacity to transform into malignant melanoma. Dysplastic nevi are usually larger than other nevi (often >5 mm in diameter). Their appearance is a flat, slightly raised plaque with a pebbly surface, or a targetlike lesion with a darker, raised center and irregular border (Fig. 46-21). They vary in shade from brown and red to flesh tones. A person may have hundreds of these lesions. Although dysplastic nevi can give rise to melanoma, the vast majority are stable and never progress, suggesting that they are best viewed as markers for melanoma risk. Dysplastic nevi have been documented in multiple members of families prone to development of malignant melanoma.

Because of the possibility of malignant transformation, any mole that undergoes a change warrants immediate medical attention. Observe and report changes in size, thickness, or color; itching; and bleeding.

---

**FIGURE 46-20.** (A) Normal mole, with no different shades of brown, black, or tan. (From National Cancer Institute Visuals. No. AV-8809-4032. Courtesy of Skin Cancer Foundation.) (B) Junctional melanocytic nevi. These small, flat lesions are uniform in color. (From Goodheart HP. Goodheart’s Photoguide to Common Skin Disorders. Philadelphia, PA: Wolters Kluwer Health | Lippincott Williams & Wilkins; 2009:364.)
Skin Cancer

Skin cancer represents the most common malignancy in white-skinned people in the Western world. The majority of skin cancers are nonmelanomas, either basal cell or squamous cell carcinoma, which are not associated with a high risk of morbidity or mortality. Although malignant melanoma represents a small subset of skin cancers, it is the most deadly. In 2009, 61,646 people in the United States were diagnosed with malignant melanoma—35,436 men and 26,210 women. In the United States, 9199 people also died from melanomas of the skin (5992 men and 3207 women). The rising incidence of melanoma and other skin cancers has been attributed to increased sun exposure associated with social and lifestyle changes.

The factors linking sun exposure to skin cancer are not completely understood, but both total cumulative exposure and altered patterns of exposure are strongly implicated. Basal cell and squamous cell carcinomas are often associated with total cumulative exposure to UV radiation. Thus, basal cell and squamous cell carcinomas occur more commonly on maximally sun-exposed parts of the body, such as the face and back of the hands and forearms. Melanomas occur most commonly on areas of the body that are exposed to the sun intermittently, such as the back in men and the lower legs in women. They are more common in persons with indoor occupations whose exposure to sun is limited to weekends and vacations. Excessive childhood sun exposure is an important risk factor for melanoma, particularly blistering sunburns.

Malignant Melanoma

Malignant melanoma is a cancerous tumor of the melanocytes. It is a rapidly progressing, metastatic form of cancer. The dramatic increase in the incidence of malignant melanoma over the past several decades has been credited to increased UV light exposure, including tanning salons. Other risk factors include a family history of malignant melanoma, fair hair and skin, tendency to freckle, and a history of blistering sunburns as a child. Still other significant risk factors for melanoma are atypical moles/dysplastic nevus syndrome, immunosuppression, and prior PUVA therapy.

Roughly 90% of malignant melanomas in whites occur on sun-exposed skin. However, in darker-skinned people melanomas often occur on non-sun-exposed areas, such as the mucous membranes and subungual, palmar, and plantar surfaces. Malignant melanomas differ in size and shape. Usually, they are slightly raised and black or brown. Borders are irregular and surfaces are uneven. Most appear to arise from preexisting nevi or new molelike growths (Fig. 46-22). There may be surrounding erythema, inflammation, and tenderness. Periodically, melanomas ulcerate and bleed. Dark melanomas are often mottled with shades of red, blue, and white. These three colors represent three concurrent processes: melanoma growth (blue), inflammation and the body's attempt to localize and destroy the tumor (red), and scar tissue formation (white).
Pathogenesis. Four types of melanomas have been identified based on their radial and vertical growth progression: lentigo maligna, superficial spreading, acral lentiginous, and nodular. Radial growth describes the horizontal spread of the melanoma within the epidermis and superficial dermis. During this initial stage, the tumor seems to lack the ability to metastasize. Lentigo maligna melanomas, superficial spreading melanomas, and acral lentiginous melanomas are tumors that are in the radial growth phase. Lentigo maligna melanomas are flat, slow-growing nevi that may remain in the radial growth phase for several decades. They are seen primarily on sun-exposed skin of elderly persons. Superficial spreading melanoma, the most common type of melanoma, is seen most commonly in persons who sunburn easily and have intermittent sun exposure. It is characterized by a raised-edged nevus with lateral growth and a disorderly appearance in color and outline. It typically ulcerates and bleeds with growth. Acr al lentiginous melanoma has an appearance similar to that of lentigo maligna, and is seen primarily on the palms, soles, nail beds, and mucous membranes. Its occurrence is unrelated to sun exposure.

After a variable and unpredictable period of time, melanomas shift from a radial to vertical growth phase, during which the tumor cells invade downward into the deeper dermis layers. This growth phase is heralded by the nodular phase and correlates with the emergence of a clone of cells with metastatic potential. Nodular melanomas are raised, dome-shaped lesions that can occur anywhere on the body. They are commonly a uniform blue-black color and tend to look like blood blisters. Nodular melanomas tend to rapidly invade the dermis from the start, with no apparent horizontal growth phase.

Diagnosis and Treatment. Early detection is critical with malignant melanoma. Regular self-examination of the total skin surface in front of a well-lighted mirror provides a method for early detection. It requires that a person undress completely and examine all areas of the body using a full mirror, handheld mirror, and handheld hair dryer (to examine the scalp). An ABCD rule has been developed to aid in early diagnosis and timely treatment of malignant melanoma. The ABCD acronym stands for asymmetry, border irregularity, color variation, and diameter greater than 6 mm (1/4 inch or pencil eraser size). People should be taught to watch for these changes in existing nevi or the development of new nevi, as well as other alterations such as bleeding or itching. Because of the existence of small-diameter melanomas (i.e., <6 mm in diameter), it has been suggested that people routinely screen their skin for all possible manifestations of skin cancer. Since their description over 20 years ago, evidence has accumulated to add an E for “evolving” to the ABCD rule. The E for evolving is intended to encourage the recognition of melanomas at an earlier stage by emphasizing the dynamic nature of their growth.

Diagnosis of melanoma is based on biopsy findings from a lesion. Because most melanomas initially metastasize to regional lymph nodes, additional information may be obtained through lymph node biopsy. Consistent with other cancerous tumors, melanoma is commonly staged using the TNM (tumor, lymph node, and metastasis) staging system (see Chapter 7) or the American Joint Committee on Cancer Staging System for Cutaneous Melanoma, in which the tumor is rated 0 to 4 depending on numerous factors, including extent of tumor invasion, ulceration, and metastasis. Ulceration and invasion of the tumor into the deeper skin tissue result in a poorer prognosis. The degree and number of lymph nodes involved correlate well with overall survival.

Treatment of melanoma is usually surgical excision, the extent of which is determined by the thickness of the lesion, invasion into the deeper skin layers, and spread to the regional lymph nodes. Deep, wide excisions with elective removal of lymph tissue and the use of skin grafts were once the hallmarks of treatment. When diagnosed in a premetastatic phase, melanoma is now treated in ambulatory settings, lessening the cost and inconvenience of care. Current capability allows for mapping lymph flow to a regional lymph node that receives lymphatic drainage from tumor sites on the skin. This lymph node, which is called the sentinel lymph node, is then sampled for biopsy. If tumor cells have spread from the primary tumor to the regional lymph nodes, the sentinel node will be the first node in which tumor cells appear. Therefore, sentinel node biopsy can be used to test for the presence of melanoma cells and determine if radical lymph node dissection is necessary. When nodes are positive, consideration is also given to systemic adjuvant therapy. Although no effective chemotherapy is available for melanoma, interferon alfa-2b is a biologic therapy available for adjuvant treatment of melanoma. At this time, however, the use of interferon is controversial. Clinical trials with other therapies, including combination chemotherapy, vaccines, and hyperthermic isolation limb perfusion, are ongoing.

Basal Cell Carcinoma

Basal cell carcinoma is a neoplasm of the nonkeratinizing cells of the basal layer of the epidermis. It is the most common invasive cancer in humans; approximately 75% of all skin cancers are basal cell carcinomas. Basal cell carcinomas have a tendency to occur in fair-skinned persons with a history of significant long-term sun exposure. They are most frequently seen on the head and neck, most often occurring on skin that has hair.

Basal cell carcinomas are slow-growing tumors that extend wide and deep if left untreated, but rarely metastasize. Advanced lesions are often invasive and ulcerative. Risk factors for extensive spread include a tumor diameter greater than 2 cm, location on the central part of the face or ears, long-standing duration, incomplete excision, and perineural or perivascular involvement.

Histologically, the tumor cells resemble those in the normal basal layer from the epidermis or follicular epithelium and do not occur on mucosal surfaces.
There are two types of basal cell carcinoma, determined by their pattern of growth: superficial basal cell carcinomas originating from the epidermis and extending upward, and nodular basal cell carcinomas in which the tumor grows downward into the dermis. *Nodular basal cell carcinoma*, the classic type, presents as a small, flesh-colored or pink, smooth, translucent nodule that enlarges over time (Fig. 46-23). Telangiectatic vessels frequently are seen beneath the surface. Over the years, there is a central depression that forms and develops into an ulcer surrounded by the original shiny, waxy border.

*Squamous cell carcinoma* presents as a scaly erythematous patch or plaque. Both nodular and superficial forms may contain melanin, imparting a brown, blue, or black color to the lesions.

Since basal cell carcinoma is highly curable if detected and treated early, all suspected lesions should undergo biopsy for diagnosis. The treatment depends on the site and extent of the lesion. The most important treatment goal is complete elimination of the lesion. Also important is the maintenance of function and optimal cosmetic effect. Curettage with electrodesiccation, surgical excision, irradiation, laser, cryosurgery, and chemosurgery are effective in removing all cancerous cells. Immune therapy, gene therapy, and photodynamic therapy are emerging treatments. Persons should be checked at regular intervals for recurrences.

**Squamous Cell Carcinoma**

Squamous cell carcinomas are the second most common malignant tumors arising on sun-exposed sites in older people, exceeded only by basal cell carcinoma. In addition to sun exposure, occupational exposure to arsenic (i.e., Bowen disease), industrial tars, coal, and paraffin increase the risk for squamous cell carcinoma. Men are twice as likely as women to have squamous cell carcinoma. Black persons are rarely affected.

Squamous cell cancers are composed of tumor cells that resemble the epidermal cells of the stratum spinosum to varying degrees and extend into the adjacent dermis. There are two types of squamous cell carcinomas: intraepidermal (termed in situ carcinoma) and invasive carcinoma. *Intraepidermal squamous cell carcinoma* remains confined to the epidermis for a long time. However, at some unpredictable time, it penetrates the basement membrane to the dermis and metastasizes to the regional lymph nodes. It then converts to *invasive squamous cell carcinoma*. The invasive type of squamous cell carcinoma can develop from intraepidermal carcinoma or from a premalignant lesion (e.g., actinic keratoses). It may be slow growing or fast growing with metastasis.

Squamous cell carcinoma is a red, scaling, keratotic, slightly elevated lesion with an irregular border, usually with a shallow chronic ulcer (Fig. 46-24). The lesions usually lack the pearly rolled border and superficial

**FIGURE 46-23.** Nodular basal cell carcinoma, which presents as a reddish-brown papule, often with telangiectatic blood vessels, and a central depression with rolled borders. (From National Cancer Institute Visuals. No. AV-8500-3608.)

**FIGURE 46-24.** Squamous cell carcinoma as manifested by a raised lesion of the skin of the face. (From National Cancer Institute Visuals. No. AV-CDR728323. Courtesy of Kelly Nelson, photographer.)
telangiectases found on basal cell carcinomas. Later, lesions grow outward, show large ulcerations, and have persistent crusts and raised erythematous borders. The lesions occur on sun-exposed areas of the skin, particularly the nose, forehead, helix of the ear, lower lip, and back of the hand. Invasive squamous cell carcinoma has the potential to recur and metastasize. Chief among the risk factors for tumor recurrence and metastasis are the size and location of the tumor. Large lesions (>2 cm in diameter), tumors of the lip and ear, tumors arising in injured or chronically diseased skin, and rapidly growing lesions are at particular risk.

Treatment measures are aimed at the removal of all cancerous tissue using methods such as electrosurgery, excision surgery, chemosurgery, or radiation therapy. After treatment, the person is observed for the remainder of his or her life for signs of recurrence.

### Age-Related Skin Conditions

Some skin problems occur in specific age groups. These include not only birthmarks, but also disorders characteristic of childhood, as well as skin changes common in the elderly.

### Skin Manifestations of Infancy and Childhood

Infancy connotes the image of perfect, unblemished skin. For the most part, this is true. However, several acquired skin conditions, including diaper dermatitis, pricky heat, and cradle cap, are relatively common in infants. Moreover, congenital skin lesions, such as Mongolian spots, hemangiomas, and nevi, are associated with the neonatal period, and many childhood infections are commonly accompanied by skin changes.

### Skin Disorders of Infancy

Throughout infancy, the skin is especially sensitive to irritation from harsh chemicals, humidity, and heat.

**Diaper Dermatitis.** Irritant diaper dermatitis, or diaper rash, is a form of contact dermatitis caused by the interaction of several factors, including prolonged contact of the skin with a mixture of urine and feces. The appearance of diaper rash ranges from simple (i.e., widely distributed macules on the buttocks and anogenital areas) to severe (i.e., beefy, red, excoriated skin surfaces in the diaper area). Secondary infections with bacteria and yeasts are common; discomfort may be marked because of intense inflammation. Such conditions as contact dermatitis, seborrheic dermatitis, candidiasis, and atopic dermatitis should be considered when the eruption is persistent and recalcitrant to simple therapeutic measures.

Diaper dermatitis often responds to simple measures, including frequent diaper changes with careful cleansing of the irritated area to remove all waste products. Feces in particular should be removed from the skin as soon as possible after the diaper has been soiled. Because soap and lipid solvents remove protective lipids from the stratum corneum, using water or an alcohol-free baby wipe is recommended. Exposing the irritated area to air is helpful. It has been shown that application of a barrier ointment after each diaper change is a valuable component of therapy. Topical corticosteroid therapy is usually effective, but should be used cautiously because infants absorb proportionately greater quantities through their skin than adults. Antifungal therapy should not be used routinely, but can be helpful when *Candida* infection is established or suspected. Antibacterial agents should not be used because bacterial infections are rarely involved in diaper dermatitis, and the normal microflora should be preserved.

Intractable and severe cases of diaper dermatitis should be seen by a health care provider for treatment.
of any secondary infections. Secondary candidal or other skin manifestations discussed in this chapter may occur in the diaper area. It is important to differentiate between normal diaper dermatitis and more serious skin problems.

**Prickly Heat.** Prickly heat (heat rash) results from constant maceration of the skin because of prolonged exposure to a warm, humid environment. Maceration leads to midepidermal obstruction and rupture of the sweat glands. Although commonly seen during infancy, prickly heat may occur at any age. The treatment includes removing excessive clothing, cooling the skin with warm water baths, drying the skin with powders, and avoiding hot, humid environments.

**Cradle Cap.** Cradle cap is a greasy crust or scale formation on the scalp. It is usually attributed to infrequent and inadequate washing of the scalp. Cradle cap is treated using mild shampoo and gentle combing to remove the scales. Sometimes oil can be left on the head for minutes to several hours, softening the scales before scrubbing. Other emulsifying ointments or creams may be helpful in difficult cases. The scalp may need to be rubbed firmly to remove the buildup of keratinized cells. Recalcitrant cases need to be seen by a health care provider; serious or chronic forms of seborrheic dermatitis may exist.

**Pigmented and Vascular Birthmarks**

Pigmented birthmarks represent abnormal migration or proliferation of melanocytes. For example, **Mongolian spots** are caused by selective pigmentation. They usually occur on the buttocks or sacral area and are seen commonly in Asian and black persons. **Nevi or moles** are small, tan to brown, uniformly pigmented solid macules. **Melanocytic nevi** are formed initially from aggregates of melanocytes and keratinocytes along the dermal–epidermal border. **Congenital melanocytic nevi** are collections of melanocytes that are present at birth or develop within the first year of life. They present as macular, papular, or plaquelike pigmented lesions of various shades of brown, with a black or blue focus. The texture of the lesions varies and they may be with or without hair. They usually are found on the hands, shoulders, buttocks, entire arm, or trunk of the body. Some involve large areas of the body in garmentlike fashion. They usually grow proportionately with the child. Congenital melanocytic nevi are clinically significant because of their association with malignant melanoma.

Vascular birthmarks are cutaneous anomalies of angiogenesis and vascular development. Two types of vascular birthmarks commonly are seen in infants and small children: bright red, raised hemangiomas of infancy and flat, reddish-purple port-wine stains.

**Hemangiomas of infancy** (formerly called strawberry hemangiomas) are small, red lesions that are noticed shortly after birth. Hemangiomas of infancy are generally benign vascular tumors produced by prolifera-

**Port-wine stains** are pink or red patches that can occur anywhere on the body and are very noticeable (Fig. 46-25). They represent slow-growing capillary malformations that grow proportionately with the child and persist throughout life. There is progressive dilation of the dermal capillaries, which initially is confined to the immediate epidermis, with gradual involvement of deeper dermal blood vessels, although the greater number is always in the upper dermis. Distribution of lesions on the face roughly corresponds to the sensory branches of the trigeminal nerve. Port-wine stains usually are confined to the skin, but may be associated with vascular malformations of the eye, resulting primarily in glaucoma, or leptomeningeal involvement, leading to cognitive disorders, seizures, and other neurologic deficits (Sturge-Weber syndrome). Cover-up cosmetics are useful in concealing the stains. Laser surgery has revolutionized the treatment of port-wine stains.

Skin Manifestations of Common Infectious Diseases

Infectious childhood diseases that produce rashes include roseola infantum, rubella, rubeola, and varicella. Because these diseases are seen less frequently than in the past because of successful immunization programs and the use of antibiotics, they may be misdiagnosed or their diagnosis may be delayed.

Roseola Infantum. Roseola infantum (exanthem subitum or sixth disease) is a contagious disease caused by human herpes virus type 6 (HHV-6).70 Because HHV-6 is the etiologic agent, the condition is often referred to as sixth disease. Primary HHV-6 infection occurs early in life. More than 95% of roseola cases occur in children younger than 3 years of age, with a peak at 6 to 15 months of age.70 Transplacental antibodies likely protect most infants until 6 months of age. Roseola produces a characteristic maculopapular rash covering the trunk and spreading to the appendages. The rash is preceded by an abrupt onset of high fever (≤105°F), inflamed tympanic membranes, and coldlike symptoms usually lasting 3 to 4 days. These symptoms improve at approximately the same time the rash appears. Because infants with roseola exhibit a unique constellation of symptoms over a short time, the infection may be confused with other childhood illnesses. Blood antibody titers may be taken to determine the actual diagnosis. In most cases, there are no long-term effects from this disease. Infants who spike high temperatures should be seen by their health care providers.

Rubella. Rubella (i.e., 3-day measles or German measles) is a childhood disease caused by the rubella virus. It is characterized by a diffuse, punctate, macular rash that begins on the trunk and spreads to the arms and legs (Fig. 46-26). Mild febrile states occur (usually <100°F). Postauricular, suboccipital, and cervical lymph node adenopathy is common. Coldlike symptoms usually accompany the disease in the form of cough, congestion, and coryza (i.e., nasal discharge).

Rubella usually has no long-lasting sequelae; however, the transmission of the disease to pregnant women early in their gestation periods may result in congenital rubella syndrome. Among the clinical signs of congenital rubella syndrome are cataracts, microcephaly, mental retardation, deafness, patent ductus arteriosus, glaucoma, purpura, and bone defects. Most states have laws requiring immunization to prevent transmission of rubella. Immunization is accomplished by live-virus injection. Rubella vaccination has close to a 100% immunity response in treated children. Many states require a second preschool or later dose of rubella vaccine to increase immunity. Cases and outbreaks of rubella occur in the United States, especially among foreign-born unvaccinated adults.

Rubeola. Rubeola (measles, 7-day measles) is an acute, highly communicable viral disease caused by a morbillivirus.71 The characteristic rash is macular and blotchy; sometimes the macules become confluent (Fig. 46-27). The rubeola rash usually begins on the face and spreads to the appendages. There are several accompanying symptoms: a fever of 100°F or greater, Koplik spots (i.e., small, irregular red spots with a bluish-white speck...
in the center) on the buccal mucosa, and mild to severe photosensitivity. The person commonly has coldlike symptoms, general malaise, and myalgia. In severe cases, the macules may hemorrhage into the skin tissue or onto the outer body surface. This form is called hemorrhagic measles. The course of measles is more severe in infants, adults, and malnourished children. The World Health Organization recommends vitamin A treatment for measles in developing countries to reduce morbidity and mortality. There may be severe complications, including otitis media, pneumonia, and encephalitis. Antibody titers are determined for a conclusive diagnosis of rubella. Measles is a disease preventable by vaccine, and immunization is required by law in the United States.

Varicella. Varicella (chickenpox) is a common communicable childhood disease. It is caused by the varicella-zoster virus, which also is the agent in herpes zoster (shingles). The characteristic skin lesion occurs in three stages: macule, vesicle, and granular scab. The macular stage is characterized by development within hours of macules over the trunk, spreading to the limbs, buccal mucosa, scalp, axillae, upper respiratory tract, and conjunctiva (Fig. 46-28). During the second stage, the macules form vesicles with depressed centers. The vesicles break open and a scab forms during the third stage. Crops of lesions occur successively, so that all three forms of the lesion usually are visible by the 3rd day of the illness.

Mild to extreme pruritus accompanies the lesions, which can lead to scratching and subsequent development of secondary bacterial infections. Chickenpox also is accompanied by coldlike symptoms, including cough, coryza, and sometimes photosensitivity. Mild febrile states usually occur, typically beginning 24 hours before lesion outbreak. Side effects, such as pneumonia, septic complications, and encephalitis, are rare.

Varicella in adults may be more severe, with a prolonged recovery rate and greater chances for development of varicella pneumonitis or encephalitis. Immunocompromised persons may experience a chronic, painful form of the infection.

Despite breakthrough cases and lower efficacy rates overall than in other vaccines, live attenuated varicella vaccine has been demonstrated to have dramatically decreased varicella morbidity and mortality since 1995, when the vaccine was introduced in the United States. The vaccine is most effective in children under 10 years of age. One dose of the vaccine is required by law in the United States; however, a second dose is now recommended to address what is called primary vaccine failure. It is believed that a single dose of varicella vaccine may only prime the host response, without inducing protective immunity. Outbreaks of mild cases of varicella, called breakthrough varicella, have occurred in vaccinated populations. The breakthrough infection is difficult to diagnose because the maculopapular rash does not have the classic sign of vesicles.

Skin Manifestations and Disorders in the Elderly

Elderly persons experience a variety of age-related skin disorders and exacerbations of earlier skin problems. Aging skin is believed to involve a complex process of actinic (solar) damage, normal aging, and hormonal influences. Actinic changes primarily involve increased occurrence of lesions on sun-exposed surfaces of the body.

Normal Age-Related Changes

Normal skin changes associated with aging are seen on areas of the body that have not been exposed to the sun. They include thinning of the dermis and the epidermis, diminution in subcutaneous tissue, a decrease and thickening of blood vessels, and a decrease in the number of melanocytes, Langerhans cells, and Merkel cells. The keratinocytes shrink, but the number of dead keratinized cells at the surface increases. This results in less padding and thinner skin, with color and elasticity changes. The skin also loses its resistance to environmental and mechanical trauma. Tissue repair takes longer.

With aging, there is also less hair and nail growth, and there is permanent hair pigment loss. Hormonally, there is less sebaceous gland activity, although the glands in the facial skin may increase in size. Hair growth reduction also may be hormonally influenced. Although the reason is poorly understood, the skin in most elderly persons older than 70 years of age becomes dry, rough, scaly, and itchy. When there is no underlying pathologic process, it is called senile pruritus. Itching and dryness become worse during the winter, when the need for home heating lowers the humidity.

The aging of skin, however, is not just a manifestation of age itself. Most skin changes associated with the elderly are the result of cumulative actinic or environmental damage. For example, the wrinkled, leathery look of aged skin, as well as odd scars and ecchymotic spots, are due to solar elastotic degenerative change.
**Skin Lesions Common Among the Elderly**

Among the most common benign skin lesions in the elderly are skin tags, seborrheic keratoses, solar lentigines, and vascular lesions. Most are actinic manifestations; they occur as a result of exposure to sun and weather over the years.

**Skin Tags.** Skin tags are soft, brown, or flesh-colored papules. They occur on any skin surface, but most frequently the neck, axilla, and intertriginous areas. They range in size from a pinhead to the size of a pea. Skin tags have the normal texture of the skin. They are benign and can be removed with scissors or electrodessication for cosmetic purposes.

**Seborrheic Keratosis.** A keratosis is a circumscribed overgrowth of the horny layer of keratinocytes. Seborrheic keratoses are common benign tumors that arise spontaneously and are particularly numerous on the trunk, although they can also occur on the extremities, head, and neck. In people of color, multiple small lesions on the face are termed dermatoses papulosa nigra. The lesions characteristically appear as round, flat, coin-shaped waxy plaques that vary in diameter from a few millimeters to several centimeters in diameter.73 Seborrheic keratoses are benign, but they must be watched for changes in color, texture, or size, which may indicate malignant transformation.

**Actinic Keratoses.** Actinic keratoses are the most common premalignant skin lesions that develop on sun-exposed areas. The lesions usually are less than 1 cm in diameter and appear as dry, brown, scaly areas, often with a reddish tinge (Fig. 46-29). Actinic keratoses often are multiple and more easily felt than seen. They often are indistinguishable from squamous cell carcinoma without biopsy. Actinic keratoses may accumulate dense scale on the surface of the skin and become hyperkeratotic (i.e., developing cutaneous growths of fingernail-type tissue that grow into hornlike appendages). This form is more prominent and palpable. Often, there is a weathered appearance to the surrounding skin. Slight changes, such as enlargement or ulceration, may indicate malignant transformation. Roughly 20% of actinic keratoses convert to squamous cell carcinomas. There is controversy regarding the classification of actinic keratoses. Most experts agree that they are capable of converting to cancerous growths; however, some believe that actinic keratoses do not convert or progress to cancerous cells, but that they are actual early malignancies.73

Actinic keratoses are removed with cryosurgery, electrodessication, or lasers. When surgery is not indicated, they are treated with topical chemotherapeutic agents, such as 5-fluorouracil or imiquimod creams, which erode the lesions.

**Solar Lentigines.** Also referred to as liver spots, solar lentigines are small (5- to 10-mm), benign, oval or round, tan-brown macules or patches resulting from localized hyperplasia of melanocytes. Solar lentigines gradually appear on sun-exposed areas, particularly the dorsum of the hand. They do not fade with cessation of sun exposure. Like all pigmented lesions, they should be evaluated. If the pigmentation is homogenous and they are symmetric and flat, they are most likely benign. Solar lentigines can be treated with a topical bleaching agent such as hydroquinone (e.g., Eldoquin, Solaquin), laser therapy, or cryotherapy.

**Lentigo maligna** (i.e., Hutchinson freckle) is a slowly progressive preneoplastic disorder of melanocytes, also referred to as lentigo maligna melanoma in situ. It occurs on sun-exposed areas, particularly the face. The lesion is a pigmented macule with an irregular border and grows to 5 cm or sometimes larger. As it grows over the years, it may become slightly raised and wartlike. If untreated, a true malignant melanoma often develops. Surgery, curettage, and cryotherapy have been effective at removing the lentigines. Careful monitoring for conversion to melanoma is important.

**Vascular Lesions.** Vascular lesions include angiomas, telangiectases, and venous lakes. **Cherry angiomas** are smooth, cherry-red or purple, dome-shaped papules that occur in nearly all people older than 30 years of age. They usually are found on the trunk and are generally benign unless there is a sudden appearance of many cherry angiomas. **Telangiectases** are single, dilated blood vessels, capillaries, or terminal arteries that appear on areas exposed to sun or harsh weather, such as the cheeks and the nose. They occur individually or in clusters, measure 1 cm or less, are nonpalpable, and easily blanch. They can become large and disfiguring. Pulsed dye lasers have been effective in removing them. **Venous lakes** are small, dark blue, slightly raised papules. They occur on exposed body parts, particularly the backs of the hands, ears, and lips. They are smooth and compressible. Venous lakes can be removed by electrosurgery, laser therapy, or surgical excision if desired.
SUMMARY CONCEPTS

- Some skin problems occur in specific age groups. Common in infants are diaper rash, prickle heat, and cradle cap. Nevi, hemangiomas, and port-wine stains may be present at birth. Infectious childhood diseases that are characterized by rashes include roseola infantum, rubella, rubola, and varicella. Vaccines are available to protect against rubella, rubeola, and varicella.
- With aging, there is thinning of the dermis and the epidermis, diminution in subcutaneous tissue, loss and thickening of blood vessels, and slowing of hair and nail growth. Dry skin is common among the elderly, becoming worse during the winter months. Among the skin lesions seen in the elderly are skin tags, keratoses, lentigines, and vascular lesions.

REVIEW EXERCISES

1. The mother of a 7-year-old boy notices that he is scratching his head frequently. On close examination she notices a grayish, round, and roughened area where the hair has broken off. Examination by the child’s pediatrician produces a diagnosis of tinea capitis.
   - A. Explain the cause of the infection and propose possible mechanisms for spread of this infection in school-age children, particularly during winter months.
   - B. Referring to Chapter 14, explain the preference of the superficial mycoses (dermatophytes) for the skin-covered areas of the body.
   - C. What methods are commonly used in the diagnosis of superficial fungal infections?

2. A 75-year-old woman presents with severe burning pain and a vesicular rash covering a strip over the rib cage on one side of the chest. She is diagnosed with herpes zoster or shingles.
   - A. What is the source of this woman’s rash and pain?
   - B. Explain the dermatomal distribution of the lesions.

3. Psoriasis is a chronically recurring papulosquamous skin disorder, characterized by circumscribed red, thickened plaques with an overlying silvery-white scale.
   - A. Explain the development of the plaques in terms of epidermal cell turnover.
   - B. Persons with psoriasis are instructed to refrain from rubbing or scratching the lesions. Explain the rationale for these instructions.
   - C. Among the methods used in the treatment of psoriasis are the use of topical keratolytic agents and corticosteroid skin preparations. Explain how these two different types of agents exert their effect on the plaque lesions.

4. During the past several decades there has been an alarming increase in the incidence of skin cancers, including malignant melanoma, that has been attributed to increased sun exposure.
   - A. Explain the possible mechanisms whereby ultraviolet radiation promotes the development of malignant skin lesions.
   - B. Cite two important clinical signs that aid in distinguishing a dysplastic nevus from a malignant melanoma.

**Ampulla** A saclike dilatation of a duct, canal, or any other tubular structure.

**Amphoteric** Capable of reacting chemically as an acid or a base.

**Amine** An organic compound containing nitrogen.

**Amorphous** Without a definite form; shapeless.

**Amblyopia** A condition of vision impairment without a detectable organic lesion of the eye.

**Abrasion** The wearing or scraping away of a substance or structure, such as the skin, through an unusual or abnormal mechanical process.

**Abscess** A collection of pus that is restricted to a specific area in tissues, organs, or confined spaces.

**Accommodation** The adjustment of the lens (eye) to variations in distance.

**Acromion** The lateral extension of the spine of the scapula, forming the highest point of the shoulder. (Adjective: acromial)

**Acuity** The clearness or sharpness of perception, especially of vision.

**Adrenergic** Activated by or characteristic of the sympathetic nervous system or its neurotransmitters (i.e., epinephrine and norepinephrine).

**Aerobic** Growing, living, or occurring only in the presence of air or oxygen.

**Afferent** Bearing or conducting inward or toward a center, as an afferent neuron.

**Agglutination** The clumping together of particles, microorganisms, or blood cells in response to an antigen–antibody reaction.

**Antagonist** A muscle whose action is opposed by another muscle (agonist) with which it is paired or a drug or other chemical substance that has affinity for or stimulates a predictable physiologic function.

**Aplasia** The absence of an organ or tissue due to a developmental failure.

**Anabolism** A constructive metabolic process characterized by the conversion of simple substances into larger, complex molecules.

**Anaerobic** Growing, living, or occurring only in the absence of air or oxygen.

**Analog** A part, organ, or chemical having the same function or appearance but differing in respect to a certain component, such as origin or development.

**Anaplasia** A change in the structure of cells and in their orientation to each other that is characterized by a loss of cell differentiation, as in cancerous cell growth.

**Anastomosis** The connection or joining between two vessels; or an opening created by surgical, traumatic, or pathologic means.

**Androgen** Any substance, such as a male sex hormone, that increases male characteristics.

**Anergy** A state of absent or diminished reaction to an antigen or group of antigens.

**Aneuploidy** A variation in the number of chromosomes within a cell involving one or more missing chromosomes rather than entire sets.

**Anaphylaxis** An outpouching or dilation in the wall of a blood vessel or the heart.

**Anesthesia** The absence of pain or the state of being insensible to pain.

**Anergetoemia** Loss of the ability to carry out familiar, purposeful acts or to manipulate objects in the absence of paralysis or other motor or sensory impairment.

**Anergy** A state of absent or diminished reaction to an antigen or group of antigens.

**Aneuploidy** A variation in the number of chromosomes within a cell involving one or more missing chromosomes rather than entire sets.

**Aneurysm** An outpouching or dilation in the wall of a blood vessel or the heart.

**Anesia** The absence of pain or the state of being insensible to pain.

**Anesthesia** The absence of pain or the state of being insensible to pain.

**Anergy** A state of absent or diminished reaction to an antigen or group of antigens.

**Aneuploidy** A variation in the number of chromosomes within a cell involving one or more missing chromosomes rather than entire sets.

**Anaphylaxis** An outpouching or dilation in the wall of a blood vessel or the heart.

**Anesthesia** The absence of pain or the state of being insensible to pain.

**Anergy** A state of absent or diminished reaction to an antigen or group of antigens.

**Aneuploidy** A variation in the number of chromosomes within a cell involving one or more missing chromosomes rather than entire sets.

**Anaphylaxis** An outpouching or dilation in the wall of a blood vessel or the heart.

**Anesthesia** The absence of pain or the state of being insensible to pain.

**Anergy** A state of absent or diminished reaction to an antigen or group of antigens.

**Aneuploidy** A variation in the number of chromosomes within a cell involving one or more missing chromosomes rather than entire sets.

**Anaphylaxis** An outpouching or dilation in the wall of a blood vessel or the heart.

**Anesthesia** The absence of pain or the state of being insensible to pain.

**Anergy** A state of absent or diminished reaction to an antigen or group of antigens.

**Aneuploidy** A variation in the number of chromosomes within a cell involving one or more missing chromosomes rather than entire sets.

**Anaphylaxis** An outpouching or dilation in the wall of a blood vessel or the heart.
Articulation  The place of connection or junction between two or more bones of a skeletal joint.

Ascites  An abnormal accumulation of serous fluid in the peritoneal cavity.

Asepsis  The condition of being free or freed from pathogenic microorganisms.

Astereognosis  A neurologic disorder characterized by an inability to identify objects by touch.

Asterixis  A motor disturbance characterized by a hand-flapping tremor, which results when the prolonged contraction of groups of muscles lapses intermittently.

Ataxia  An abnormal condition characterized by an inability to coordinate voluntary muscular movement.

Athetosis  A neuromuscular condition characterized by the continuous occurrence of slow, sinuous, writhing movements that are performed involuntarily.  (Adjective: athetoid)

Atopy  Genetic predisposition toward the development of hypersensitivity or an allergic reaction to common environmental allergens.

Atresia  The absence or closure of a normal body orifice or tubular organ, such as the esophagus.

Atrophy  A wasting or diminution of size, often accompanied by a decrease in function, of a cell, tissue, or organ.

Aura  A distinct subjective feeling, sensation, or motor phenomenon that precedes and marks the onset of an episode of a neurological condition, such as a migraine or epileptic seizure.

Autocrine  A mode of hormone action in which a chemical messenger acts on the same cell that secretes it.

Autophagy  Segregation of part of the cell’s own damaged cytoplasmic material within a vacuole and its disposal.

Autosome  Any chromosome other than a sex chromosome.

Axillary  Of or pertaining to the axilla, or armpit.

Bacteremia  The presence of bacteria in the blood.

Bactericide  An agent that destroys bacteria.  (Adjective: bactericidal)

Bacteriostat  An agent that inhibits bacterial growth.  (Adjective: bacteriostatic)

Ballismus  An abnormal condition characterized by violent flailing motions of the arms and, occasionally, the head, resulting from injury to or destruction of the subthalamic nucleus or its fiber connections.

Baroreceptor  A type of sensory nerve ending, such as those found in the aorta and the carotid sinus, that is stimulated by changes in pressure.

Basal  Pertaining to, situated at, or forming the base; or the fundamental or basic.

Benign  Not malignant; or of the character that does not threaten health or life.

Bipolar neuron  A nerve cell that has an afferent process at one end and an efferent process at the other end.

Bolus  A rounded mass of food ready to swallow or such a mass passing through the gastrointestinal tract; or a concentrated mass of medicinal material or other pharmaceutical preparation injected all at once intravenously for diagnostic purposes.

Borborygmus  The rumbling, gurgling, or tinkling noise produced by the propulsion of gas through the intestine.

Bruit  A sound or murmur heard while auscultating an organ or blood vessel, especially an abnormal one.

Buccal  Pertaining to or directed toward the inside of the cheek.

Buffer  A substance or group of substances that prevents change in the concentration of another chemical substance.

Bulla  A thin-walled blister of the skin or mucous membranes greater than 5 mm in diameter containing serous or seropurulent fluid.

Bursa  A fluid-filled sac or saclike cavity situated in places in the tissues at which friction would otherwise develop, such as between certain tendons and the bones beneath them.

Cachexia  A condition of general ill health and malnutrition, marked by weakness and emaciation.

Calcarius  A stony mass formed within body tissues, usually composed of mineral salts.

Capsid  The protein shell that envelopes and protects the nucleic acid of a virus.

Carcinogen  Any substance or agent that causes the development or increases the incidence of cancer.

Carpal  Of or pertaining to the carpus, or wrist.

Caseation  A form of tissue necrosis in which the tissue is changed into a dry, amorphous mass resembling crumbly cheese.

Catabolism  A metabolic process through which living organisms break down complex substances to simple compounds, liberating energy for use in work, energy storage, or heat production.

Catalyst  A substance that increases the velocity of a chemical reaction without being consumed by the process.

Catecholamines  Any one of a group of biogenic amines having a sympathomimetic action and composed of a catechol molecule and the aliphatic portion of an amine.

Caudal  Signifying an inferior position, toward the distal end of the spine.

Cellulitis  An acute, diffuse, spreading, edematous inflammation of the deep subcutaneous tissues and sometimes muscle, characterized most commonly by an area of heat, redness, pain, and swelling, and occasionally by fever, malaise, chills, and headache.

Cephalic  Of pertaining to the head, or to the head end of the body.

Cerumen  The waxlike secretion produced by vestigial apocrine sweat glands in the external ear canal.

Cheirosis  A noninflammatory disorder of the lips and mouth characterized by chapping and fissuring.

Chelate  A chemical compound composed of a central metal ion and an organic molecule with multiple bonds, arranged in ring formation, used especially in treatment of metal poisoning.

Chemoreceptor  A sensory nerve cell activated by chemical stimuli; for example, a chemoreceptor in the carotid artery is sensitive to changes in the oxygen content in the blood and reflexly increases or decreases respiration and blood pressure.
**Chemosis** Excessive edema of the mucous membrane of the eyeball and eyelid lining (conjunctiva).

**Chemotaxis** A response involving cell orientation or cell movement that is either toward (positive chemotaxis) or away from (negative chemotaxis) a chemical stimulus.

**Chimeric** Relating to, derived from, or being an individual possessing one’s own immunologic characteristics and that of another individual; a phenomenon that can occur as the result of procedures such as a bone marrow graft.

**Chondrocyte** Any one of the mature polymorphic cells that form the cartilage of the body.

**Chromatid** One of the paired threadlike chromosome filaments, joined at the centromere, that make up a metaphase chromosome.

**Chromosome** Any one of the structures in the nucleus of a cell containing a linear thread of DNA, which functions in the transmission of genetic information.

**Chyme** The creamy, viscous, semifluid material produced during digestion of a meal that is expelled by the stomach into the duodenum.

**Cilia** A minute, hairlike process projecting from a cell, composed of nine microtubules arrayed around a single pair. Cilia beat rhythmically to move the cell around in its environment, or they move mucus or fluids over the surface.

**Circadian** Being, having, pertaining to, or occurring in a period or cycle of approximately 24 hours.

**Circumduction** The active or passive circular movement of a limb or of the eye.

**Cisterna** An enclosed space, such as a cavity, that serves as a reservoir for lymph or other body fluids.

**Clathrin** The major structural coat protein of the coated vesicles involved in the intracellular transport between membranous organelles.

**Clone** One or a group of genetically identical cells or organisms derived from a single parent.

**Coagulation** The process of transforming a liquid into a semisolid mass, especially of blood clot formation.

**Coarctation** A condition of stricture or contraction of the walls of a vessel.

**Cofactor** A substance that must unite with another substance in order to function.

**Colic** Sharp, intermittent abdominal pain localized in a hollow or tubular organ, resulting from torsion, obstruction, or smooth muscle spasm. (Adjective: colicky)

**Collagen** The protein substance of the white, glistening, inelastic fibers of the skin, tendons, bone, cartilage, and all other connective tissue.

**Collateral** Secondary or accessory rather than direct or immediate; or a small branch, as of a blood vessel or nerve.

**Complement** Any one of the complex, enzymatic serum proteins that are involved in physiologic reactions, including antigen–antibody reaction and anaphylaxis.

**Confluent** Flowing or coming together; not discrete.

**Congenital** Present at, and usually before, birth.

**Conjugate** To pair and fuse in conjugation; or a form of sexual reproduction seen in unicellular organisms in which genetic material is exchanged during the temporary fusion of two cells.

**Contiguous** In contact (or nearly so) in an unbroken sequence along a boundary or at a point.

**Contralateral** Affecting, pertaining to, or originating in the opposite side of a point or reference.

**Contusion** An injury of a part without a break in the skin, characterized by swelling, discoloration, and pain.

**Convolution** An elevation or tortuous winding, such as one of the irregular ridges on the surface of the brain, formed by a structure being folded in upon itself.

**Corpuscle** Any small mass, cell, or body, such as a red or white blood cell.

**Costal** Pertaining to a rib or ribs.

**Crepitus** A sound or sensation that resembles a crackling or grating noise.

**Cutaneous** Pertaining to the skin.

**Cyanosis** A bluish discoloration, especially of the skin and mucous membranes, caused by an excess of deoxygenated hemoglobin in the blood.

**Cytokine** Any of a class of polypeptide immunoregulatory substances that are secreted by cells, usually of the immune system, that affect other cells.

**Cytology** The study of cells, including their origin, structure, function, and pathology.

**Cytosol** Cytoplasm exclusive of membranous components (e.g., mitochondria, endoplasmic reticulum) and nonmembranous insoluble components.

**Decibel** A unit for expressing the relative power sound intensity that is equal to one tenth of a bel.

**Defecation** The evacuation of feces from the digestive tract through the rectum.

**Defecation** The process of adapting in form or shape; also, the product of such alteration.

**Degeneration** The deterioration of a normal cell, tissue, or organ to a less functionally active form. (Adjective: degenerative)

**Deglutition** The act or process of swallowing.

**Degradation** The reduction of a chemical compound to a compound-less complex, usually by splitting off one or more groups.

**Dehydration** The condition that results from excessive loss of water from the body tissues.

**Delirium** An acute, reversible organic mental syndrome characterized by confusion, disorientation, restlessness, incoherence, fear, and often illusions.

**Dendrite** One of the branching processes that extends and transmits impulses toward a cell body of a neuron. (Adjective: dendritic)

**De novo** Anew; often applied to the biochemical pathway where a complex biomolecule is synthesized in a new or different form from simple molecules.

**Depolarization** The reduction of a cell membrane potential to a less-negative value than that of the potential outside the cell.
**Dermatome** The area of the skin supplied with afferent nerve fibers of a single dorsal root of a spinal nerve.

**Desmosome** A small, circular, dense area within the intercellular bridge that forms the site of adhesion between intermediate filaments and cell membranes.

**Desquamation** A normal process in which the cornified layer of the epidermis is shed in fine scales or sheets.

**Dialysis** The process of separating colloids and crystalline substances in solution, which involves the two distinct physical processes of diffusion and ultrafiltration; or a medical procedure for the removal of urea and other elements from the blood or lymph.

**Diapedesis** The outward passage of red or white blood corpuscles through the intact walls of the vessels.

**Diaphoresis** Perspiration, especially the profuse perspiration associated with elevated body temperature, physical exertion, exposure to heat, and mental or emotional stress.

**Diarthrosis** A specialized articulation that permits, to some extent, free joint movement. (Adjective: diarthrodial)

**Diastole** The dilatation of the heart; or the period of dilatation, which is the interval between the second and the first heart sound and is the time during which blood enters the relaxed chambers of the heart from the systemic circulation and the lungs.

**Differentiation** The act or process in development in which unspecialized cells or tissues acquire more specialized characteristics, including those of physical form, physiologic function, and chemical properties.

**Diffusion** The process of becoming widely spread, as in the spontaneous movement of molecules or other particles in solution from an area of higher concentration to an area of lower concentration, resulting in an even distribution of the particles in the fluid.

**Dimer** A compound or unit formed by the combination of two identical molecules or radicals of a simpler compound. (Adjective: dimeric)

**Diopter** A unit of measurement of the refractive power of lenses equal to the reciprocal of the focal length in meters.

**Diploid** Pertaining to an individual, organism, strain, or cell that has two full sets of homologous chromosomes.

**Disseminate** To scatter or distribute over a considerable area.

**Distal** Away from or being the farthest from a point of reference.

**Diurnal** Of, relating to, or occurring in the daytime.

**Diverticulum** A pouch or sac of variable size occurring naturally or through herniation of the muscular wall of a tubular organ.

**Dorsum** The back or posterior. (Adjective: dorsal)

**Dysgenesis** Defective or abnormal development of an organ or part, typically occurring during embryonic development. (Also called dysgenesis.)

**Dyslexia** A disturbance in the ability to read, spell, and write words.

**Dyspepsia** The impairment of the power or function of digestion, especially epigastric discomfort following eating.

**Dysphagia** A difficulty in swallowing.

**Dysphonia** Any impairment of the voice that is experienced as difficulty in speaking.

**Dysplasia** The alteration in size, shape, and organization of adult cell types.

**Eburnation** The conversion of bone or cartilage, through thinning or loss, into a hard and dense mass with a worn, polished, ivorylike surface.

**Ecchymosis** A small hemorrhagic spot, larger than a petechia, in the skin or mucous membrane caused by the extravasation of blood into the subcutaneous tissues.

**Ectoderm** The outermost of the three primary germ layers of the embryo, and from which the epidermis and epidermal tissues, such as nails, hair, and glands of the skin, develop.

**Ectopic** Relating to or characterized by an object or organ being situated in an unusual place, away from its normal location.

**Edema** The presence of an abnormal accumulation of fluid in interstitial spaces of tissues. (Adjective: edematous)

**Efferent** Conveyed or directed away from a center.

**Effusion** The escape of fluid from blood vessels into a part or tissue, as an exudation or a transudation.

**Embolus** A mass of clotted blood or other formed elements, such as bubbles of air, calcium fragments, or a bit of tissue or tumor, that circulates in the bloodstream until it becomes lodged in a vessel, obstructing the circulation. (Plural: emboli)

**Empyema** An accumulation of pus in a cavity of the body, especially the pleural space.

**Emulsify** To disperse one liquid throughout the body of another liquid, making a colloidal suspension, or emulsion.

**Endocytosis** The uptake or incorporation of substances into a cell by invagination of its plasma membrane, as in the processes of phagocytosis and pinocytosis.

**Endoderm** The innermost of the three primary germ layers of the embryo, and from which epithelium arises.

**Endogenous** Growing within the body; or developing or originating from within the body or produced from internal causes.

**Endoscopy** The visualization of any cavity of the body with an endoscope.

**Enteral** Within or pertaining to the intestine.

**Enteropathic** Relating to any disease of the intestinal tract.

**Enzyme** A protein molecule produced by living cells that catalyzes chemical reactions of other organic substances without itself being destroyed or altered.

**Epiphysis** The expanded articular end of a long bone (head) that is separated from the shaft of the bone by the epiphyseal plate until the bone stops growing, the plate is obliterated, and the shaft and the head become united.

**Epithelium** The covering of the internal and external surfaces of the body, including the lining of vessels and other small cavities.

**Epitope** The simplest form of an antigenic determinant that combines with an antibody or a T-cell receptor to cause a specific reaction by an immunoglobulin.
Epizootic A diffuse, rapidly spreading outbreak of a disease affecting many animals in any region at the same time, often with the implication that it may extend to humans, such as bird flu.

Erectile Capable of being erected or raised to an erect position.

Erythema The redness or inflammation of the skin or mucous membranes produced by the congestion of superficial capillaries. (Adjective: erythematous)

Etiology The study or theory of all factors that may be involved in the development of a disease, including susceptibility of an individual, the nature of the disease agent, and the way in which an individual’s body is invaded by the agent; or the cause of a disease.

Eukaryotic Pertaining to an organism with cells having a true nucleus; that is, a highly complex, organized nucleus surrounded by a nuclear membrane containing organelles and exhibiting mitosis.

Euploid Pertaining to an individual, organism, strain, or cell with a balanced set or sets of chromosomes, in any number, that is an exact multiple of the normal, basic haploid number characteristic of the species; or such an individual, organism, strain, or cell.

Evisceration The removal of the viscera from the abdominal cavity, or disembowelment; or the extrusion of an internal organ through a wound or surgical incision.

Exacerbation An increase in the severity of a disease as marked by greater intensity in any of its signs and symptoms.

Exfoliation Peeling and sloughing off of tissue cells in scales or layers. (Adjective: exfoliative)

Exocytosis The discharge of cell particles, which are packaged in membrane-bound vesicles, by fusion of the vesicular membrane with the plasma membrane and subsequent release of the particles to the exterior of the cell.

Exogenous Developed or originating outside the body, as a disease caused by a bacterial or viral agent foreign to the body.

Exophthalmos A marked or abnormal protrusion of the eyeball.

Extension A movement that allows the two elements of any jointed part to be drawn apart, increasing the angle between them, as extending the leg increases the angle between the femur and the tibia.

Extrapyramidal Pertaining to motor systems supplied by fibers outside the corticospinal or pyramidal tracts.

Extravasation A discharge or escape, usually of blood, serum, or lymph, from a vessel into the tissues.

Extubation The process of withdrawing a previously inserted tube from an orifice or cavity of the body.

Exudate Fluid, cells, or other substances that have been slowly exuded or have escaped from blood vessels and have been deposited in tissues or on tissue surfaces. (Adjective: exudation)

Fascia A sheet or band of fibrous connective tissue that may be separated from other specifically organized structures, such as the tendons, aponeuroses, and ligaments.

Febrile Pertaining to or characterized by an elevated body temperature, or fever.

Fibrillation A small, local, involuntary contraction of muscle resulting from spontaneous activation of a single muscle fiber or of an isolated bundle of nerve fibers.

Fibrin A stringy, insoluble protein formed by the action of thrombin on fibrinogen during the clotting process.

Fibrosis The formation of fibrous connective tissue, as in the repair or replacement of parenchymatous elements.

Filtration The process of passing a liquid through or as if through a filter, which is accomplished by gravity, pressure, or vacuum.

Fimbria Any structure that forms a fringe, border, or edge or the processes that resemble such a structure.

Fissure A cleft or a groove, normal or otherwise, on the surface of an organ or a bony structure.

Fistula An abnormal passage or communication from an internal organ to the body surface or between two internal organs.

Flaccid Weak, soft, and lax; lacking normal muscle tone.

Flatus Air or gas in the intestinal tract that is expelled through the anus. (Adjective: flatulent)

Flexion A movement that allows the two elements of any jointed part to be brought together, decreasing the angle between them, as bending the elbow.

Flora The microorganisms, such as bacteria and fungi, both normally occurring and pathologic, inhabiting the external or internal surfaces of the body.

Focal Relating to, having, or occupying a focus.

Follicle A sac or pouchlike depression or cavity.

Fontanel A membrane-covered opening in or between bones, such as the soft spot covered by tough membranes between the bones of an infant’s incompletely ossified skull.

Foramen A natural opening or aperture in a membranous structure or bone.

Fossa A hollow or depressed area, especially on the surface of the end of a bone.

Fovea A small pit or depression in the surface of a structure or organ.

Fundus The base or bottom of an organ or the portion farthest from the mouth of an organ.

Ganglion One of the nerve cell bodies, chiefly collected in groups outside the central nervous system. (Plural: ganglia)

Genotype The entire genetic constitution of an individual, as determined by the particular combination and location of the genes on the chromosomes; or the alleles present at one or more sites on homologous chromosomes.

Glia The neuroglia, or supporting structure of nervous tissue.

Globulin One of a broad group of proteins classified by solubility, electrophoretic mobility, and size.

Gluconeogenesis The formation of glucose from any of the substances of glycolysis other than carbohydrates.
A series of enzymatically catalyzed reactions, occurring within cells, by which glucose is converted to adenosine triphosphate (ATP) and pyruvic acid during aerobic metabolism.

A gamete-producing gland, as an ovary or a testis.

The rate of increase or decrease of a measurable phenomenon expressed as a function of a second; or the visual representation of such a change.

A small mass of nodular granulation tissue resulting from chronic inflammation, injury, or infection. (Adjective: granulomatous)

A small, nonproteinaceous substance that is not antigenic by itself but that can act as an antigen when combined with a larger molecule.

A structure resembling a recess or saculation. (Plural: haustra)

A localized collection of extravasated blood trapped in an organ, space, or tissue, resulting from a break in the wall of a blood vessel.

The normal formation and development of blood cells.

Defective vision or blindness in half of the visual field of one or both eyes.

Consisting of or composed of dissimilar elements or parts; or not having a uniform quality throughout. (Noun: heterogeneity)

The taking into the cell of an exogenous substance by phagocytosis or pinocytosis and the subsequent digestion of the newly formed vacuole by a lysosome.

Having two different alleles at corresponding loci on homologous chromosomes.

The branch of anatomy that deals with the minute (microscopic) structure, composition, and function of cells and tissue. (Adjective: histologic)

Any organ or part corresponding in function, position, origin, and structure to another organ or part, as the flippers of a seal correspond to human hands. (Adjective: homologous)

Having two identical alleles at corresponding loci on homologous chromosomes.

Relating to elements dissolved in the blood or body fluids.

A tumor of hybrid cells produced by fusion of normal lymphocytes and tumor cells.

The chemical alteration or decomposition of a compound into fragments by the addition of water.

Excess amounts of carbon dioxide in the blood.

An excess or engorgement of blood in a part of the body.

An unusual or pathologic increase in sensitivity of a part, especially the skin, or of a particular sense.

An abnormal multiplication or increase in the number of normal cells of a body part.

A solution having a greater concentration of solute than another solution with which it is compared, hence exerting more osmotic pressure than that solution.

The enlargement or overgrowth of an organ that is due to an increase in the size of its cells rather than the number of its cells.

An abnormal decrease of sensation in response to stimulation of the sensory nerves. (Also called hypoesthesia.)

A deficiency of carbon dioxide in the blood.

A solution having a lesser concentration of solute than another solution with which it is compared, hence exerting less osmotic pressure than that solution.

An inadequate supply of oxygen to tissue that is below physiologic levels despite adequate perfusion of the tissue by blood.

Induced inadvertently through the activity of a physician or by medical treatment or diagnostic procedures.

A physical or behavioral characteristic or manner that is unique to an individual or group. (Adjective: idiosyncratic)

The property that provides a substance with the capacity to produce an immune response. (Adjective: immunogenic)

The rate at which a certain event occurs (e.g., the number of new cases of a specific disease during a particular period of time in a population at risk).

The act of enclosing or the condition of being enclosed; or anything that is enclosed.

Native, or natural, to a particular country or region.

Necrosis or death of tissues due to local ischemia resulting from obstruction of blood flow.

Influencing the force or energy of muscular contractions.

In the natural or normal place; or something, such as cancer, that is confined to its place of origin and has not invaded neighboring tissues.

Any one of a group of small glycoproteins (cytokines) produced in response to viral infection and which inhibit viral replication.

Any of several multifunctional cytokines produced by a variety of lymphoid and nonlymphoid cells, including immune cells, that stimulate or otherwise affect the function of lymphopoietic and other cells and systems in the body.

Relating to or situated between parts or in the interspaces of a tissue.

Situated or occurring within the wall of an organ.

A biologic reaction occurring in an artificial environment, such as a test tube.

A biologic reaction occurring within the living body.

The act or instance of enfolding, entangling, or turning inward.
Ionize  To separate or change into ions.
Ipsilateral  Situated on, pertaining to, or affecting the same side of the body.
Ischemia  Decreased blood supply to a body organ or part, usually due to functional constriction or actual obstruction of a blood vessel.
Juxta-articular  Situated near a joint or in the region of a joint.
Juxtaglomerular  Near to or adjoining a glomerulus of the kidney.
Karyotype  The total chromosomal characteristics of a cell; or the micrograph of chromosomes arranged in pairs in descending order of size.
Keratin  A fibrous, sulfur-containing protein that is the primary component of the epidermis, hair, and horny tissues. (Adjective: keratinous)
Keratosis  Any skin condition in which there is overgrowth and thickening of the cornified epithelium.
Ketosis  A condition characterized by the abnormal accumulation of ketones (organic compounds with a carboxyl group attached to two carbon atoms) in the body tissues and fluid.
Kinesesthesia  The sense of movement, weight, tension, and position of body parts mediated by input from joint and muscle receptors and hair cells. (Adjective: kinesthetic)
Lethargy  The lowered level of consciousness characterized by listlessness, drowsiness, and apathy; or a state of indifference.
Lipid  Any of the group of fats and fatlike substances derived from a single zygote.
Lysis  Destruction or dissolution of a cell or molecule through the action of a specific agent.
Maceration  Softening of tissue by soaking, especially in acidic solutions.
Macroscopic  Large enough to be visible with the unaided eye without a microscope.
Macula  A small, flat blemish, thickening, or discoloration that is flush with the skin surface; or a structure having the form of a spot differentiated from surrounding tissues (e.g., macula lutea). (Adjective: macular)
Malaise  A vague feeling of bodily fatigue and discomfort.
Manometry  The measurement of tension or pressure of a liquid or gas using a device called a manometer.
Marasmus  A condition of extreme protein-calorie malnutrition that is characterized by growth retardation and progressive wasting of subcutaneous tissue and muscle and occurs chiefly during the first year of life.
Matrix  The intracellular substance of a tissue or the basic substance from which a specific organ or kind of tissue develops.
Meatus  An opening or passage through any body part.
Medial  Pertaining to the middle; or situated or oriented toward the midline of the body.
Mediastinum  The mass of tissues and organs in the middle of the thorax, separating the pleural sacs containing the two lungs.
Meiosis  The division of a sex cell as it matures, so that each daughter nucleus receives one half of the number of chromosomes characteristic of the somatic cells of the species.
Mesoderm  The middle layer of the three primary germ layers of the developing embryo, lying between the ectoderm and the endoderm.
Metabolism  The sum of all the physical and chemical processes by which living organisms are produced and maintained, and also the transformation by which energy is provided for vital processes and activities.
Metaplasia  Change in type of adult cells in a tissue to a form that is not normal for that tissue.
Metastasis  The transfer of disease (e.g., cancer) from one organ or part to another not directly connected with it. (Adjective: metastatic)
Miosis  Contraction of the pupil of the eye.
Mitosis  A type of indirect cell division that occurs in somatic cells and results in the formation of two daughter nuclei containing the identical complements of the number of chromosomes characteristic of the somatic cells of the species.
Molecule  The smallest mass of matter that exhibits the properties of an element or compound.
Morbidity  A diseased condition or state; the relative incidence of a disease or of all diseases in a population.
Morphology  The study of the physical form and structure of an organism; or the form and structure of a particular organism. (Adjective: morphologic)
Mosaicism  In genetics, the presence in an individual or in an organism of cell cultures having two or more cell lines that differ in genetic constitution but are derived from a single zygote.
Osmolality The concentration of osmotically active particles in solution expressed in osmols or milliosmols per liter of solution.

Osmolarity The concentration of osmotically active particles in solution expressed in osmols or milliosmols per kilogram of solvent.

Osmosis The movement or passage of a pure solvent, such as water, through a semipermeable membrane from a solution that has a lower solute concentration to one that has a higher solute concentration.

Osteophyte A bony project or outgrowth.

Palpable Perceptible by touch.

Pandemic A sudden outbreak, or epidemic, of a disease occurring over a widespread geographic area and affecting a high proportion of the population.

Papilla A small, nipple-shaped projection, elevation, or structure, such as the conoid papillae of the tongue.

Papule A small, circumscribed, solid elevation of the skin less than one centimeter in diameter. (Adjective: papular)

Paracrine A mode of hormone action in which a chemical messenger that is synthesized and released from a cell acts on nearby cells of a different type and affects their function.

Paralysis An abnormal condition characterized by the impairment or loss of motor function due to a lesion of the neural or muscular mechanism.

Paraneoplastic Relating to alterations produced in tissue remote from a tumor or its metastases.

Parenchymal The basic tissue or elements of an organ as distinguished from supporting or connective tissue or elements. (Adjective: parenchymal)

Paresis Slight or partial paralysis.

Paresthesia Any abnormal touch sensation, which can be experienced as numbness, tingling, or a “pins and needles” feeling, often in the absence of external stimuli.

Parietal Pertaining to the outer wall of a cavity or organ; or pertaining to the parietal bone of the skull or the parietal lobe of the brain.

Parous Having borne one or more viable offspring.

Pathogen Any microorganism capable of producing disease.

Pedigree A systematic presentation, such as in a table, chart, or list, of an individual’s ancestors that is used in human genetics in the analysis of inheritance.

Peptide Any of a class of molecular chain compounds composed of two or more amino acids joined by peptide bonds.

Perfusion The process or act of pouring over or through, especially the passage of a fluid through a specific organ or an area of the body.

Peripheral Pertaining to the outside, surface, or surrounding area of an organ or other structure; or located away from a center or central structure.

Permeable A condition of being pervious, or permitting passage, so that fluids and certain other substances can pass through, as in a permeable membrane.

Pervasive Pertaining to something that becomes diffused throughout every part.

Petechia A tiny, perfectly round, purplish-red spot that appears on the skin as a result of minute intradermal or submucous hemorrhage. (Plural: petechiae)
Proprioception  The process by which certain cells engulf and consume foreign material and cell debris.

Phalanx  Any one of the bones composing the fingers of each hand and the toes of each foot.

Phenotype  The complete physical, biochemical, and physiologic makeup of an individual, as determined by the interaction of both genetic makeup and environmental factors.

Pheresis  A procedure in which blood is withdrawn from a donor, a portion (plasma, leukocytes, etc.) is separated and retained, and the remainder is reinfused into the donor. It includes plasmapheresis and leukopheresis.

Pili  Hair; or in microbiology, the minute filamentous appendages of certain bacteria. (Singular: pilus)

Plethora  A body condition characterized by an excess of any of the body fluids, especially blood, marked by distention and a beefy red coloration. (Adjective: plethoric)

Plexus  A network of intersecting nerves, blood vessels, or lymphatic vessels.

Polygene  Any of a group of nonallelic genes that interact to influence the same character in the same way so that the effect is cumulative, usually of a quantitative nature, as size, weight, or skin pigmentation. (Adjective: polygenic)

Polymorph  One of several, or many, forms of an organism or cell. (Adjective: polymorphic)

Polyv  A small, tumor-like growth that protrudes from a mucous membrane surface.

Polypeptide  A molecular chain of more than two amino acids joined by peptide bonds.

Presbyopia  A visual condition (farsightedness) that commonly develops with advancing years or old age in which the lens loses elasticity, causing defective accommodation and inability to focus sharply for near vision.

Prevalence  The number of new and old cases of a disease that are present in a population at a given time, or occurrences of an event during a particular period of time.

Prodrome  An early symptom indicating the onset of a condition or disease. (Adjective: prodromal)

Prokaryotic  Pertaining to an organism, such as bacteria, with cells lacking a true nucleus and nuclear membrane that reproduces through simple fission.

Prolapse  The falling down, sinking, or sliding of an organ from its normal position or location in the body.

Proliferation  The reproduction or multiplication of similar forms, especially cells.

Pronation  Assumption of a position in which the ventral, or front, surface of the body or part of the body faces downward. (Adjective: prone)

Propagation  The act or action of reproduction.

Proprioreception  The reception of stimuli originating from within the body regarding body position and muscular activity by proprioceptors (sensory nerve endings found in muscles, tendons, joints).

Prosthesis  An artificial replacement for a missing body part; or a device designed and applied to improve function, such as a hearing aid.

Proteoglycans  Any one of a group of polysaccharide-protein conjugates occurring primarily in the matrix of connective tissue and cartilage.

Proto-oncogene  A normal cellular gene that with alteration, such as by mutation, becomes an active oncogene.

Proximal  Closer to a point of reference, usually the trunk of the body, than other parts of the body.

Pruritus  The symptom of itching, an uncomfortable sensation leading to the urge to rub or scratch the skin to obtain relief. (Adjective: pruritic)

Purpura  A small hemorrhage, up to about 1 cm in diameter, in the skin, mucous membrane, or serosal surface; or any of several bleeding disorders characterized by the presence of purpuric lesions.

Purulent  Producing or containing pus.

Quiescent  Quiet, causing no disturbance, activity, or symptoms.

Reflex  An abnormal backward or return flow of a fluid, such as stomach contents, blood, or urine.

Regurgitation  A flow of material that is in the opposite direction from normal, as in the return of swallowed food into the mouth or the backward flow of blood through a defective heart valve.

Remission  The partial or complete disappearance of the symptoms of a chronic or malignant disease; or the period of time during which the abatement of symptoms occurs.

Resorption  The loss of substance or bone by physiologic or pathologic means; for example, the loss of dentin and cementum of a tooth.

Retrograde  Moving backward or against the usual direction of flow; reverting to an earlier state or worse condition (degenerating); catabolic.

Retroversion  A condition in which an entire organ is tipped backward or in a posterior direction, usually without flexion or other distortion.

Rhabdomyolysis  Destruction or degeneration of muscle, associated with myoglobinuria (excretion of myoglobin in the urine).

Rostral  Situated near a beak (oral or nasal region).

Sacrolilits  Inflammation in the sacroiliac joint.

Saprophyte  An organism that obtains nourishment from the products of organic breakdown and decay. (Adjective: saprophytic)

Sclerosis  A condition characterized by induration or hardening of tissue resulting from any of several causes, including inflammation, diseases of the interstitial substance, and increased formation of connective tissues.

Scotopic vision  Describes vision, especially night vision, when the eye is dark adapted.

Semipermeable  Partially but not wholly permeable, especially a membrane that permits the passage of some (usually small) molecules but not the passage of other (usually larger) particles.

Senescence  The process or condition of aging or growing old.

Sepsis  The presence in the blood or other tissues of pathogenic microorganisms or their toxins; or the condition resulting from the spread of microorganisms or their products. (Adjective: septic)
Serous  Relating to or resembling serum; or containing or producing serum, such as a serous gland.

Shunt  To divert or bypass bodily fluid from one channel, path, or part to another; a passage or anastomosis between two natural channels, especially between blood vessels, established by surgery or occurring as an abnormality.

Soma  The body of an organism as distinguished from the mind; all of an organism, excluding germ cells; the body of a cell.

Spasticity  The condition characterized by spasms or other uncontrolled contractions of the skeletal muscles. (Adjective: spastic)

Spatial  Relating to, having the character of, or occupying space.

Sphincter  A ringlike band of muscle fibers that constricts a passage or closes a natural orifice of the body.

Stenosis  An abnormal condition characterized by the narrowing or stricture of a duct or canal.

Stochastic  Involving a random process.

Stria  A streak or a linear scarlike lesion that often results from rapidly developing tension in the skin; or a narrow bandlike structure, especially the longitudinal collections of nerve fibers in the brain.

Stricture  An abnormal temporary or permanent narrowing of the lumen of a duct, canal, or other passage, as the esophagus, because of inflammation, external pressure, or scarring.

Stroma  The supporting tissue or the matrix of an organ as distinguished from its functional element, or parenchyma.

Stupor  A lowered level of consciousness characterized by lethargy and unresponsiveness in which a person seems unaware of his or her surroundings.

Subchondral  Beneath a cartilage.

Subcutaneous  Beneath the skin.

Subluxation  An incomplete or partial dislocation in which the relationship between joint surfaces is altered, but contact remains.

Sulcus  A shallow groove, depression, or furrow on the surface of an organ, such as a sulcus on the surface of the brain, separating the gyri.

Supination  Assuming the position of lying horizontally on the back, or with the face upward. (Adjective: supine)

Suppuration  The formation of pus, or purulent matter.

Symbiosis  Mode of living characterized by close association between organisms of different species, usually in a mutually beneficial relationship.

Sympathomimetic  An agent or substance that produces stimulating effects on organs and structures similar to those produced by the sympathetic nervous system.

Syncope  A brief lapse of consciousness due to generalized cerebral ischemia.

Syncytium  A multinucleate mass of protoplasm produced by the merging of a group of cells.

Syndrome  A complex of signs and symptoms that occur together to present a clinical picture of a disease or inherited abnormality.

Synergist  An organ, agent, or substance that aids or cooperates with another organ, agent, or substance.

Synthesis  An integration or combination of various parts or elements to create a unified whole.

Systemic  Pertaining to the whole body rather than to a localized area or region of the body.

Systole  The contraction, or period of contraction, of the heart that drives the blood onward into the aorta and pulmonary arteries.

Tamponade  Stoppage of the flow of blood to an organ or a part of the body by pathologic compression, such as the compression of the heart by an accumulation of pericardial fluid.

Teratogen  Any agent or factor that induces or increases the incidence of developmental abnormalities in the fetus.

Thermistor  A device that is used to measure extremely small changes in temperature.

Thrombus  A stationary mass of clotted blood or other formed elements that remains attached to its place of origin along the wall of a blood vessel, frequently obstructing the circulation. (Plural: thrombi)

Tinnitus  A tinkling, buzzing, or ringing noise heard in one or both ears.

Tophus  A chalky deposit containing sodium urate that most often develops in periarticular fibrous tissue, typically in individuals with gout. (Plural: tophi)

Torsion  The act or process of twisting in either a positive (clockwise) or negative (counterclockwise) direction.

Trabecula  A supporting or anchoring stand of connective tissue, such as the delicate fibrous threads connecting the inner surface of the arachnoid to the pia mater.

Transmural  Situated or occurring through the wall of an organ.

Transudate  A fluid substance passed through a membrane or extruded from the blood.

Tremor  Involuntary quivering or trembling movements caused by the alternating contraction and relaxation of opposing groups of skeletal muscles.

Trigone  A triangular-shaped area.

Ubiquitous  The condition or state of existing or being everywhere at the same time.

Ulcera  A circumscribed excavation of the surface of an organ or tissue, which results from necrosis that accompanies some inflammatory, infectious, or malignant processes. (Adjective: ulcerative)

Urticaria  A pruritic skin eruption of the upper dermis, usually transient, characterized by wheals (hives) of various shapes and sizes.

Uveitis  An inflammation of all or part of the uveal tract of the eye.

Vector  An invertebrate animal (e.g., tick, mite, mosquito) that serves as a carrier, transferring an infective agent from one vertebrate host to another.

Ventral  Pertaining to a position toward the belly of the body; or situated or oriented toward the front or anterior of the body.
Vertigo  An illusory sensation that the environment or one’s own body is revolving.

Vesicle  A small bladder or sac, as a small, thin-walled, raised skin lesion, containing liquid.

Visceral  Pertaining to the viscera, or internal organs of the body.

Viscosity  Pertaining to the physical property of fluids, caused by the adhesion of adjacent molecules, that determines the internal resistance to shear forces.

Zoonosis  A disease of animals that may be transmitted to humans from its primary animal host under natural conditions. (Adjective: zoonotic)

Index

site of, 309–310
of skin, 1153–1159
fungal, 1153–1156, 1154f–1156f
skin manifestations of, 1179–1180, 1179f–1180f
source of, 307
terminology for, 297–298
treatment for, 314–315
vulnence factors, 307–309, 308f
viruses, 299–300, 299f–300f
in wounds, 84
Infectious agents, as teratogenic agent, 123
Infectious mononucleosis, 248–249, 248f
Infective endocarditis (IE), 131
Infectious agents, as teratogenic
Inflammation, 49
acute, 50, 53–60, 57f–59f
adipose tissue and, 231
of breast, 1042–1043
CAMs in, 52
chronic, 50, 61–62, 62f
impaired response to, in wound healing, 84
of penis, 1000
systemic manifestations of acute-phase response, 62–63
fever, 63–68, 63f, 64f, 64f,
66f
in wound healing, 80, 82f
Inflammatory bowel disease (IBD), 706–707, 706f, 707f
etiology and pathogenesis of, 707f
Inflammatoty diarrhea, 713–714
Inflammatory response, 325
Influenza, 542–544, 543f
Infratendinal herniation, of brain, 921f, 922
Ingestion, of infectious agents, 306–307
Inhalation, of infectious agents, 307
Inheritance, patterns of, 98–99
Inhibin A, for prenatal screening and diagnosis, 125
Injury, cellular
causes of, 36–39, 37f
mechanisms of, 39–41, 40f reversible, 42, 42f
Innate immunity, 318–320, 319f
cells of, 325–326
epithelial barriers, 325
pathogen recognition, 326–327, 327f
soluble mediators of, 327–331, 328f–329f
in stimulating adaptive immunity, 331
Innervation
of dermis, 1145
of lungs, 520
Inotropic influence, in cardiac contractility, 393
Inotropy, 487–488, 488f
Input association (IA) neuron, 832, 833f
Insensible perspiration, 65
Insensible water losses, 168
In situ hybridization, 101
Inspiratory capacity (IC), 526
Inspiratory retractions, 556f, 557
Insulin, 795–798, 795f, 296f–797f, 809–810
Insulin-like growth factors (IGFs), 771
deficiency, in children, 772–773, 772f
Insulin resistance syndrome. See Metabolic syndrome
Insulin secretagogues, 807–808, 809f
Integrin proteins, 2, 3
Intestinal smooth muscle, 683, 683f
Intestinal obstruction, 715–716, 716f
Intestinal flora, 692–693
Intestinal obstruction, 715–716, 716f–717f
Intestinal secretions, 686f, 687–688
Intestinal smooth muscle, 683, 683f
Intravenous. See Colon; Large intestine; Small intestine
Intoxication, 1098–1099, 1098f–1099f
Intracellular accumulations, 34–35, 35f
Intracellular fluid (ICF) compartment, 159–160, 160f, 161f
body fluid distribution, 162–163
Intracerebral hematomas, 925–926, 926f
Intracranial hemorrhage, 937–939
Intracranial pressure (ICP), 920–921, 920f–921f
increased, 919
Intrathecal papillomas, 1043
Intraepidermal squamous cell carcinoma, 1176
Intracranial pressure, 967–969, 968f
Intrapleural pressure, 521, 521f
Intrapulmonary pressure. See Alveolar pressure
Intrarenal renal failure, 640c, 640f, 641–642
Intrathoracic pressure, 521, 521f
Inteus prolapsus, 1018, 1018f
Intensos, 91, 94f
Intrusions, 1018
Intussusception, 715, 716f–717f
Interventional nephrology, 308f, 309
Invasive squamous cell carcinoma, 1176
Involuntary muscle. See Smooth muscle
Ionizing radiation. See Radiation IPC, for pulmonary compression
IPF. See Idiopathic pulmonary fibrosis
Iron-deficiency anemia, 287–288
Irritable bowel syndrome (IBS), 705–706
Irritant receptors, 536
Ishemic brain injury, 917–918, 917f
Ishemic cell injury from, 40f, 41
Ishemic stroke, 932–934, 932f
Islet amyloid polypeptide. See Amylin
Islet cell autoantibodies, 801
Islets of Langerhans, 794, 795f
Isonic acidosis, 617–618
Isonic fluid volume deficit of, 171–173, 173f
excess of, 173–174, 173f
Isoosmotic contraction period, 390
Isoosmotic expansion period, 391
IUP. See Immune thrombocytopenic purpura
Jaundice, 34–35, 280, 729–730, 730f, 730f
JEMS. See Juvenile dermatomyositis
JIA. See Juvenile idiopathic arthritis
Joint. See Arthritis
Joint injuries to, 1079–1084, 1080f–1083f
synovial, 1074–1076, 1074f–1075f
vasculature and innervation, 1075
Juvenile nonviral arthritis, 1173
Juvenile dermatomyositis (JDM), 1134–1135
Juvenile diabetes. See Type 1A immune-mediated diabetes mellitus
Juvenile idiopathic arthritis (JIA), 1133–1134
Juvenile osteochondroses, 1104–1105, 1105f
Juvenile spondyloarthropathies, 1134
Juxtacapillary receptors, 536
Juxtaglomerular complex, 610, 610f
Juxtamedullary nephrons, 601f, 602
Kaposi sarcoma (KS), with AIDS, 368–369, 369f
Kathytype, 95f, 96
Kawasaki disease, 480–481
Keloïd, 81f, 81f
Keratin, 21, 1142
Keratinocytes, 1142–1143, 1143f
Keratitis, 959–960
Keratohyalin, 1143, 1143f
Kerion, 1155
Kernicterus, 292–293
Ketocids, formation of, 193f, 197
Kidneys. See also Renal entries
in acid-base balance, 194–195, 197, 199–200, 200f
alterations in position and form, 618, 618f
blood flow in, regulation of, 609–611
blood supply, 600–601, 601f
congenital disorders of, 617–618
cystic diseases, 618–621
cystic diseases of, 619f
disease, chronic. See Chronic kidney disease
function of, elimination, 611–613
echodrine, 613
tests of, 614–615, 614f, 614f–615f
horseshoe, 618, 618f
hypertension, 427
location of, 599–600, 600f–601f
malignant tumors of, 636–637
nephron in, 601–603,
601f–602f
obstructive disorders of. See Urinary tract obstruction
in potassium regulation, 177
stones, 633–635, 633f, 634f
structure of, 600, 600f–601f
transplantation of, for CKD, 651
urine formation in, 603–611,
604f–609f
Kilocalorie, 223
Kimmelstiel-Wilson syndrome, 627
Kinins, 345
Kininase, 119–120
Knee, injuries to, 1081–1083, 1082f
Knee-jerk reflex, 885, 885f
Knock-knees. See Knee, injuries to
Knöchle phenomenon, 1164
Koplik spots, 1179–1180
Krause end bulbs, 1145
KS. See Kaposi sarcoma
Kupfer cells, 726, 726f
Kwashiorkor, 234–235, 235f
Labia, 1017, 1018f
Labile tissues, 73
Superficial basal cell carcinoma, 1176
Superficial myocyes, 305
Superficial spreading melanoma, 1175
Superior vena cava syndrome, 554
Supernormal excitatory period, 389
Superoxide dismutase (SOD), 40–41
Supplementary motor cortex, 842, 843f
Suppression tests, for endocrine function, 764
Suppurative exudates, 60
Supratentorial herniations, of brain, 920, 921f–922f, 922
Surface tension, in lung compliance, 523–524, 523f
Surfactant, 681, 684f
Surgery for cancer, 149
for infections, 315
for pain, 868
Sustained fever, 65–66, 66f
SVA neurons. See Special visceral afferent neurons
Swallowing, 681, 684f
disorders of, 697
Swallowing center, 681, 684f
Swan neck deformity, 1120
Swallowing, 681, 684f
SVA neurons. See Special visceral afferent neurons
Synovial joints, 1074–1076,
Syndrome of inappropriate antidiuretic hormone (SIADH), 171
Syndrome X. See Metabolic syndrome
Syngeneic graft, 353
Synovial fluid, 1074
Synovial joints, 1074–1076,
Synphils, 303, 1059–1061, 1059f–1060f
Systemic autoimmune rheumatic disease, 1119–1125, 1119f,
1121f, 1122e, 1124f
Systemic circulation, 375–376, 376f, 394–400
Systemic immune complex disorders, 349–350
Systemic inflammation
acute-phase response, 62–63
fever, 63–68, 63f, 64f, 64f, 66f
Systemic inflammatory response syndrome, 63
Systemic lupus erythematosus (SLE), 1123–1125, 1124f
glomerulonephritis with, 627
Systemic sclerosis, 1125
Syxote, 390, 391f
Systolic pressure, 420, 420f, 422, 422f
Tactile sensation, 860
Takotsubo cardiomyopathy, 471
Tall stature, 773
Tamm-Horsfall mucoprotein, 615
Target organ damage, with hypertension, 428c, 428–429, 431c
Tay-Sachs disease, 6, 16, 111
Tazaronate, for psoriasis, 4115
TB. See Tuberculosis
TBW. See Total body water
TCB. See Total body water
T-cell receptor (TCR), 333, 334f, 336f, 338f–339f
T cells, 52
TCR. See T-cell receptor
Talipes equinovarus, 1181
Telengiectases, 1181
Telogen follicles, 1147
Telomerase, 45
Telomeres, 45
Temperature
body regulation of, 63–65, 63f, 64f
Tonic seizures, 946–947
Tonic-clonic seizures, 946
Tone, 1147–1148, 1147f
Threshold potential, 825–826, 826f
Thrombosis, 471
Thrombocytopenia, 271–272
Thoracic aneurysm, 418
Thoracic duct, 25
Thoracic duct injury, 479
Thoracic duct lymphatics, 479
Thoracic duct rupture, 479
Thoracolumbar junction, 750
Thrombotic stroke, 933–934
Thrombotic thrombocytopenic purpura (TTP), 271
Thrombotic thrombocytopenic purpura, 271
Thrombotic thrombocytopenic purpura, 271
Thymectomy, 416f
Thymus, 849
Thyroid gland
hyperplasia, 775–778, 776
Thyroid hormone, 775–778, 776
Thyroglobulin, 776
Thyroid storms, 783
Thyroid stimulating hormone, 783
Thyroid storm, 783
Thyroid stimulating hormone, 783
Thyroidectomy, 416f
Thyroidectomy, 416f
Thyroid gland disorders of, 778–783, 778f
hyperthyroidism, 778f,
781–783, 782f
hypothyroidism, 778f,
779–781, 779f, 781f
function tests for, 778
hormones of, 776–778
structure and function of, 775–778, 776f–777f
Thyroid storm, 783
TIA. See Transient ischemic attacks
Tibial nerve, 416f
Tibia vara, 1100–1101, 1101f
Tic douloureux. See Trigeminal neuralgia
Tidal volume (TV), 525–526, 526f
TII. See Trivalent inactivated influenza vaccine
Tinea capitis, 1154, 1155f
Tinea corporis, 1154, 1154f
Tinea faciale, 1154
Tinea manus, 1155
Tinea pedis, 1155, 1155f
Tinea unguium, 1155–1156, 1155f
Tinea versicolor, 1155f
Tinel sign, 893
Tinnitus, 980–981
Tissue, 1, 17, 20–29
connective. See Connective tissue
extracellular components of, 27–29
muscle. See Muscle tissue
Tissue oxygen dissociation curve
533–534, 533f
proliferative capacity of, 73
repair of, 71
Turbidity, 81–82
Turkic. See Tracheobronchial airways
Tumor necrosis factor
TNF-α. See Tumor necrosis factor-α
Toucans, 1147–1148, 1147f
Tolerance, in immune system, 340
Toll-like receptors (TLRs), 327, 327f
Tonic-clonic seizures, 946
Toxicity, 162, 162f
Tonic movements, of gastrointestinal system, 680
Toxic shock syndrome, 946–947
Tophi, 1131, 1132
Total peripheral vascular resistance, 378
Total body water (TBW), 167–168, 168f
Total lung capacity (TLC), 526, 526f, 526f
in emphysema, 578
Total peripheral vascular resistance, 378
Tortoicollis deformity, 73
Toxic epidermal necrolysis, 1163
Toxins, 307–308, 308f
neuromuscular junction disorder, 890–891
Toxoplasmosis, 333–334
Toxoplasma gondii, 334f
Toxoplasma gondii, 334f
Traction retinal detachment, 965
Transcerebral compartment, 163
Transcription, RNA in, 91–92, 92f–94f
Transcription factors, 94
Transferrin, 279, 279f
Transfusion RNA (tRNA), 3
structure and function of, 91
Transient ischemic attacks (TIAs), 933
Transient middle cerebral artery ischemia
1220
Index

Viral conjunctivitis, 958
Ventilatory assist devices (VAD), for heart failure, 498
Ventricular septal defects, 476f, 477–478
Ventricular system, 844–845, 845f
Ventricular volume overload, in heart failure, 491
Verrucae, 1157–1158, 1158f
Vertebral column, injury to, 904–905, 905f
Vertical transmission, of infectious agents, 306
Vertigo, 986
benign paroxysmal positional, 985f, 987
Very–low-density lipoprotein (VLDL), 404–405, 405f
Vesicoureteral reflux, 668
Vesicular transport, 5f, 15
Vessel spasm, in hemostasis, 263–264, 264f
Vestibular folds, 515, 515f
Vestibular system, 984–986, 985f–986f
disorders of, 986–988
stabilization of, 988–989
tests of, 988
Vestibule, 1018, 1018f
Villus, 687–688, 688f, 690, 690f
Vimentin, 8
Viral conjunctivitis, 958
Viral croup, 559–560, 559f, 560f
Viral hepatitis, 732–735
chronic, 735
Viral infections
in intestines, 710
of skin, 1157–1159, 1158f–1159f
Viral meningitis, 941
Virulence of infections, 307–309, 308f
Viruses, 298r, 299–300, 299f–300f
cancer and, 143–144
Visceral calcifications, 647
Vesicovascular ureteral reflux, 668
Vessel transport, 5f, 15
Vessel spasm, in hemostasis, 263–264, 264f
Vestibular folds, 515, 515f
Vestibular system, 984–986, 985f–986f
disorders of, 986–988
stabilization of, 988–989
tests of, 988
Vestibule, 1018, 1018f
Villus, 687–688, 688f, 690, 690f
Vimentin, 8
Viral conjunctivitis, 958
Viral croup, 559–560, 559f, 560f
Viral hepatitis, 732–735
chronic, 735
Viral infections
in intestines, 710
of skin, 1157–1159, 1158f–1159f
Viral meningitis, 941
Vomitus, 693
von Gierke disease, 34
Von Recklinghausen disease. See Neurofibromatosis
Von Willebrand disease, 272
Von Willebrand factor (vWF), 263
Vulva, 1026
Vulvodynia, 1026
vWF. See von Willebrand factor
Washout phenomenon, 667
Wasting syndrome, 369
Water
absorption of, 717, 718f
movement across cell membrane, 14–15
Water balance
disorders of, 171–176, 172f
with CKD, 645, 645f
regulation of, 167–168, 168f, 168f
mechanism of, 168–171
Water intoxication, 174–175
Weakness, with heart failure, 494–495
Wear-and-tear arthritis. See Osteoarthritis
Wear-and-tear pigment. See Lipofuscin
Wegener granulomatosis, 414, 414f
Wegener granulomatosis, 414, 414f
Weight
loss of, 232–233
measurement of, 228–229, 229f
Weil syndrome, 302
Werner syndrome, 46
Wernicke-Korsakoff syndrome, 951
Western blot assay, for HIV, 370
West Nile virus (WNV), 316
Wheat, 1148, 1149f
White blood cells. See Leukocytes
White fat, 224
Whiteheads, 1160
White matter, 823
longitudinal tracts of, 835–836, 835f–836f, 835f
Wild-type allele, 107
Wilms tumor, 636, 636f
Windpipe. See Trachea
Wiskott-Aldrich syndrome, 362
WNV. See West Nile virus
Women, urinary tract infections in, 669
Wound healing, 78, 78f
cutaneous, 79–81, 80f–83f
in elderly, 84
factors affecting, 81, 83–84
phases of, 78–79, 79f
Wound separation, 84
Woven bone, 1066
Xanthine oxidase inhibitors, 1132
Xanthomas, 407, 407f
X chromosome, 95, 95f
Xeroderma pigmentosum, 38
Xerosis, 1150–1151
X-linked agammaglobulinemia, 359
X-linked disorders, 107f, 111, 111f
Y chromosome, 95, 95f
Yeasts, 304–305, 304f
Z line, 24f, 25
Zollinger-Ellison syndrome, 704
Zygote, 88
