The TOR protein regulates the p7056k protein, which is present in mammalian cells, and, as a protein kinase, phosphorylates various intracellular substrates that are involved in protein synthesis and cell cycle control. T-cell activation by antigen induces within the first 30 minutes a number of transcription factors (e.g., FOS, NFAT, and NFKB; immediate response). These factors in turn activate the transcription of cytokine genes, such as IL2, IFN-γ, IL4, and IL5 (early response). IL2 stimulates T-cell clonal expansion and dictates proliferation of antigen-selected T cells. Antigenic stimulation induces IL2R’s expression and secretion of IL2 and other cytokines. Cross-linking of surface Ig leads to IL2R expression on B cells and responsiveness to IL2. IL2 stimulates proliferation of B cells and Ig secretion and mediates the switch from the membrane form to the secretory form of the μ chain, allowing formation of pentameric IgM molecules. Therefore, IL2 is critical for primary immune responses that are characterized by the production of IgM antibodies. IL2 stimulates secretion of other cytokines, such as IL4, IL5, and IFN-γ, preparing the stage for isotype switch and the maturation of the antibody response. Antigen activation of T cells initiates a series of waves of gene activation that is coordinated by TCR signaling and IL2 secretion, with the expansion of the role of T-cell cytokines in B-cell proliferation, antibody secretion, affinity maturation, and class switch (late response).

X-linked Severe Combined Immunodeficiency

The γc chain gene of the IL2R is located in chromosome Xq13, which is also the locus for X-linked SCID. X-linked SCID patients are phenotypically identical: T, B, and NK. Of a large group of patients with SCID, γc deficiency accounted for 42%, and Jak-3 deficiency accounted for approximately 6% of the cases. This form of SCID is associated with severe defects in T-cell development and lack of peripheral T and NK cells. Patients have severe persistent infections of the upper respiratory and gastrointestinal tracts by CMV, fungal, and bacterial pathogens and require bone marrow transplantation to survive. B-cell levels are normal or elevated in the T, B, and NK-SCID cases. With the exception of two large deletions, the γc mutations are missense mutations involving one or a few nucleotides. Five mutational hotspots have been identified in exons that encode part of the extracellular domain. In patients with autosomal SCID, a single amino acid substitution, Y100C, in the JH7 domain of JAK3 prevents the interaction of JAK3 with the receptor. Interleukin-4 and Interleukin-4 Receptor
The IL4 is one of the small four-helix bundle cytokines with four α helices, A, C, B, and D, two end-to-end long loops, and a short β sheet that is packed against the B and D helices. It has biologic activity that is species-specific, in spite of the fact that the main binding residues are conserved.

IL4 is a pleiotropic cytokine that is produced by CD4+ T\textsubscript{H}2 cells, NKT cells, γδ T cells, basophils, and mast cells, and it is essential for T\textsubscript{H}2 differentiation (see Chapter 13). IL4 binds with high affinity to the IL4RA, and this complex recruits the γc chain (Fig. 14.17). IL4 binding induces a conformational change in the receptor, forming a structural mosaic in the binding interface. The interacting residues are grouped into three clusters, with the first two clusters consisting of a nucleus of polar groups that are surrounded by hydrophobic side chains. They have been compared to the avocado fruit, in which a nucleus is enveloped by an oily shell. The first cluster is around Glu9, and the second cluster is around Arg88 of IL4 and Asp72 of the IL4RA.

The third cluster steers and accelerates the binding of the IL4 with the receptor. The first and second clusters show cooperativity and additive properties, which reinforce the binding to higher affinity. IL4R consists of a complex of two proteins, IL4RA and the γc chain. The IL4RA has two FnIII domains. The N terminal (D1) has the conserved disulfide bonds of an Ig fold, whereas the second domain (D2) has no disulfide bonds; both have unique structural features. A membrane-proximal WSXWS domain maintains the favorable conformation for cytokine binding. The cytoplasmic region has the box 1 motif (prolinerich) and an acidic region that is adjacent to box 1 that interacts with SRC TYR kinases. Ligand binding causes heterodimerization of the α and γc chains and activation of JAK1, JAK2, and JAK3 kinases, the first two associating with IL4RA and the last associating with γc.

Activation of Tyr kinases that are associated with the IL-4R leads to phosphorylation of the five tyrosines of the cytoplasmic region of IL4RA, which function as docking sites for SRC kinases. The functions of IL4RA are mediated by distinct domains in the cytoplasmic region. The first, most membrane-proximal domain contains the Y497 (Y1), which interacts with the IL phosphorytrosine substrate (4PS), a 180-kDa protein related to insulin receptor substrate 1 (IRS1) that is phosphorylated and generates proliferative signals. It is interesting that 4PS was found to be homologous to a cytoplasmic protein, which is used as a substrate for the insulin receptor. Insulin binding to the insulin receptor results in rapid autophosphorylation of the receptor, which is a receptor protein kinase. The receptor subsequently phosphorylates cytoplasmic substrates that link to downstream signaling pathways. One such major substrate of the insulin receptor is the IRS1. 4PS, which is homologous to IRS1, has been called IRS2. IRS1 and -2 bind to the sequence (PL-[X] 4 NPXYXSXSD) around Y497 of the IL4R, which is highly homologous to a sequence in the cytoplasmic regions of the insulin receptor, and of the insulin growth factor-1 receptor, both of which activate IRS1 and -2. This sequence is critical for transducing signals through the insulin receptor and IL4RA and was termed the insulin IL4 receptor or I4R motif (Fig. 14.17). The IRS2 has a phosphotyrosine-binding domain, which binds to the I4R motif of the IL4RA and insulin receptor. IRS1 and -2 become phosphorylated when they bind to phosphorylated IL4RA and act as a docking site for several SH2-domain-containing signaling molecules. Among such signaling molecules are the PI3K that generates phosphoinositides, which in turn activate Akt and protein kinase C (PKC), which are important in cell growth and survival.
Interleukin (IL)-4 signaling. IL-4 binds to a receptor, which consists of two chains, α and γc. The α receptor has two extracellular fibronectin III domains (Fn; D1 and D2), with features of a cytokine receptor homology domain, which is seen in type I cytokine receptors. D2 is characterized by the WSXWS motif (amino acid letter code: W is tryptophan, S is serine, and X is any amino acid) that is implicated in folding and transport of the receptor. The binding of IL-4 to the α chain is mediated by three discrete clusters. Two of them are known as avocado clusters because they consist of a central core of polar groups that is surrounded by a hydrophobic (oily) shell. The third cluster is dominated by electrostatic interactions and stabilizes the complex. The α chain associates with Jak-1 and the γc chain with Jak-3. Distinct domains of the cytoplasmic tail of the α chain mediate the multiplicity of IL-4 function. A unique feature in the IL-4R α chain is its association with a protein known as IL-4 phosphotyrosine substrate (4PS), which links to phosphoinositide 3-kinase (PI3K) and downstream signaling for cell growth and survival. 4PS also connects to the Ras pathway for mitogen-activated protein kinase (MAPK) activation. 4PS binds to a unique sequence of IL-4Rα that is shared by the insulin receptor. In the insulin receptor, this motif binds a protein-linking signaling pathway, which is known as insulin receptor signalling.
substrate 1 (IRS-1). 4PS of the IL-4Ra is homologous to IRS-1 and has been called IRS-2. Jak-3 phosphorylates tyrosines of the α chain that are used by the signal transducer and activator of transcription 6 (STAT-6) for binding. This phosphorylation is regulated by SHIP phosphatases, which are associated with the C-terminal part of the α chain. STAT-6 induces the suppressor proteins, suppressors of cytokine signaling (SOCSs), which inhibit Jak-3 activation. GTP, guanosine triphosphate; PTB, phosphotyrosine-binding domain.

The adaptor protein Shc binds to the phosphorylated IL4RA chain and links through GRB2 to RAS pathway activation. STAT6 is the primary STAT that is activated by IL4 stimulation, leading to expression of IL4-responsive genes. STAT6 plays an important role in IL4-induced responses, and, for IL4 signaling to be maintained, STA-6 undergoes continuous cycling. When STAT6 is deactivated in the nucleus, it is exported back to the cytoplasm, where it becomes available for another cycle of phosphorylation and reactivation. STAT6 (together with STAT4) is the most important STAT in the immune response to sepsis, mainly because of its role in TH1 differentiation. STAT6 is essential for TH2 differentiation on activation by IL4.

The phosphorylated C-terminal immunoreceptor tyrosine-based inhibitory motif of the IL4RA acts as docking site for SHP-1 and SHP-2 phosphotyrosine phosphatases. The former is expressed primarily in hematopoietic tissues, whereas the latter is expressed in several other tissues. Another phosphatase, SHIP, regulates the PI3K signaling pathways.

The JAK-STAT pathway is also subject to regulation by a family of newly discovered suppressor proteins termed suppressors of cytokine signaling (SOCSs). There are four members in the SOCS family: SOCS1, SOCS2, SOCS3, and CIS (cytokine-inducible SH2-containing protein). The SOCS proteins have an SH2 domain in the center, an N-terminal-variable region, and a region of homology at the C terminus, which is termed the SOCS box, with a unique sequence and an unknown function. Five families (20 members) have been identified with a sequence that is homologous to the SOCS box, but the rest of their structure is different. SOCS proteins are not constitutively present in the cells but are induced only after cytokine stimulation. The mechanism of their action is different among the members of the family. SOCS1 binds to the catalytic domain of JAK2 kinase, whereas CIS competes with signaling molecules, such as STATs, for binding to STAT binding sites. SOCS1 and SOCS3 inhibit IL4-dependent STAT6 activation by binding to JAK1.

IL4 activates the RAS-MAPK pathway through interaction of IRS2 with the GRB2 protein. The RAS pathway, and other small guanosine triphosphatases (GTPases) that are related to RAS, are regulated by the RAS GTPase activating protein, which activates the GTPase activity of RAS. Down-regulation of RAS is controlled by a molecule termed IL-four receptor interacting protein, which binds to the IL4R motif of IL4RA and, through RAS GTPase activating protein, inactivates the RAS GTP active form.

Functions of Interleukin-4 in T-cell-B-cell Interactions

IL4 plays a central role in differentiation of naive T cells to TH2 cells capable of producing IL4, IL5, IL10, and IL13 (see Chapter 13). Thus, IL4, through TH2 differentiation, controls humoral immunity. IL4 increases MHC class II expression in B cells, DCs, and macrophages, thus enhancing their class II antigen presentation, and up-regulates the CD23 expression of B cells. IL4 promotes activation and viability of B cells. A major role of IL4 in B-cell function is in the class switch, as it induces the switch to IgG1, IgG3, IgG4, and, most important, IgE. In this respect, it plays a major role in allergic reactions and protection against helminthic infestations.

The mechanism of promotion of CSR by IL4 is through up-regulation of AID. AID is required for CSR and hypermutation (see section “Immunoglobulin Class Switch”). CD45 has recently been defined as a Janus phosphatase, which negatively regulates IgE CSR in human B cells through inhibition of IL4-induced (plus anti-CD40) IgE germline transcription.

Interleukin-5 and Interleukin-5 Receptor

IL5 was originally described as a T-cell-replacing factor or B-cell growth factor 2. It affects the terminal differentiation of B cells and is a single polypeptide of a total of 134 amino acids with a molecular weight of 30 to 40 kDa. Its tertiary structure reveals two domains with a cytokine fold (four α helices and two β sheets), as is seen in GM-CSF, IL2, and IL4. The IL5 gene is found on chromosome 5.

The IL5 receptor is expressed on B cells, eosinophils, and certain cell lines. It consists of an α chain and a β chain. The βc chain is shared by GM-CSF and IL3 receptors and is functionally analogous to other common chains that are shared by several cytokines, such as the gp130 of the IL6 family and the common γ chain of the IL2 receptor family. The βc chain
consists of 880 amino acids with four extracellular domains that are related to the FnIII domains, a single region, and the intracellular region.\textsuperscript{530} The four extracellular domains consist of seven $\beta$ strands (A through G), which form two cytokine receptor modules. The membrane proximal module contains the recognition contact sites for the $\alpha$ chain.\textsuperscript{531} The membrane proximal cytoplasmic region shows similarities to the sequences of box 1 and box 2 of other receptors and serves in recruitment of members of the family of JAKs. The cytoplasmic region also contains several TYR residues that are phosphorylated after cytokine binding. Binding of the cytokine induces dimerization of the receptor through free Cys that is present in the $\alpha$ subunit and in the first domain of the $\beta_c$ chain. The disulfide bonds that are formed involve the $\alpha$ chain of one receptor with the $\beta_c$ chain of the second receptor and vice versa. Dimerization is essential for the Tyr phosphorylation of the receptors. Because the $\beta_c$ chain is shared by different cytokines, there are sites that are specific for shared interactions.

Detailed studies of the function of IL5 on mouse B cells have concluded that IL5 stimulates production of IgM, IgG1, and IgA, and induces IgA production; therefore, it acts on B cells that are committed to IgA secretion. IL5 synergizes with IL4 in augmenting IgM secretion of human B cells and with IL2 for IgG1, IgG3, and IgA secretion. The effects of IL5 are detected on activated B lymphocytes.

IL5 plays a unique role in the production, activation, and localization of eosinophils,\textsuperscript{532} which are seen in patients with asthma and helminthic infestations. IL5 is detected in some patients with severe exacerbations of asthma,\textsuperscript{533} and it is conceivable that exacerbations are associated with activation of T cells that secrete IL-5. Local expression of IL5 was detected by in situ hybridization in mucosal bronchial biopsies, which was correlated with the number of infiltrating eosinophils.\textsuperscript{534}

**Interleukin-6 and Interleukin-6 Receptor**

IL6 is a cytokine with pleiotropic activities that is produced by a great variety of cells (Table 14.3) and plays a central role in immunity and inflammation. IL6 induces (a) terminal differentiation and Ig secretion of B cells; (b) growth promotion of B cells, plasma cells, and myeloma cells; (c) support of colony formation by stem cells; (d) induction of acute-phase response (APR) proteins; (e) differentiation and activation of T cells and macrophages; and (f) neural differentiation. It is also involved in the pathology of several diseases, such as rheumatoid arthritis, proliferative glomerulonephritis, and multiple myeloma. At least 11 different activities are known, with an equal number of acronyms; these turned out to be mediated by the same molecule, which was called IL6. IL6 is a member of a family of structurally and functionally related cytokines that includes IL11, LIF, oncostatin M (OSM), ciliary neurotrophic factor (CNTF), and cardiotoxin-1. Redundancy of function is a result of the sharing of the signal-transducing component of gp130.

IL6 is a glycoprotein that belongs to the long chain, four-$\alpha$-helical bundle of cytokines\textsuperscript{535,536} and binds to the IL6R-gp130 complex (see the following discussion) but, in addition, has the intriguing property of a lectin that interacts with a trisaccharide (HNK-1 or CD57)\textsuperscript{537} (see Appendix, CD57). CD57 is a sulfated trisaccharide that is carried by N-glycans, that is, complex polysaccharides. It has been identified in the nervous system as a major target of peripheral neuropathies in patients with lymphomas.

has the sequence WSXWS. IL6 binds to the IL6R-gp130 complex by three contact sites. Site one is located in the loop that connects helices A and B of the IL6 and interacts with the D2 domain of IL6R. Site two is located at the C terminus of helix D of IL6, and interacts with the D2 domain of gp130. A third site interacts with the N-terminal Ig-like domain (D1) of gp130. gp130 is the signal transduction component of the IL6-gp130 complex, because the cytoplasmic region of IL6R is short.

The gp130 protein has an extracellular region that consists of six domains. D2 and D3 have the features that are characteristic of the CBD of class I cytokine receptors. D1 is an Ig-like domain, whereas D4 to D6 are FNIII domains. IL6 induces the formation of a hexamer that consists of two molecules each of IL6, IL6R, and gp130. The crystal structure of gp130 shows that the uncomplexed receptor assumes an L-shaped quaternary structure with limited flexibility. gp130 associates with other cytokines, such as OSM, LIF, and CNTF. The crystal structure shows that there is little domain reorientation of the ligand-binding domains, indicating that the overall structure is adaptable to bind multiple cytokines. The gp130 protein also has an N-glycan that carries the HNK-1 epitope, which interacts with IL6. The lectin activity of the IL6 is necessary for the initial signal transduction.

Binding of IL6 to the IL6R-gp130 complex triggers signal transduction, which follows two pathways: the SRC protein tyrosine kinases and the JAKs (Fig. 14.18). Activated JAKs phosphorylate several TYR (Y) residues of the gp130 cytoplasmic region, which then become docking sites for signaling molecules that possess SH2 domains. The second membrane-proximal Y recruits the SHP-2 phosphatase, leading to the activation of MAPK. Activation of the SRC kinase, HCK, phosphorylates adaptor molecules that link to the GRB2, SOS, RAS pathway to MAPK activation. This pathway mediates proliferative signaling and, at the same time, through activation of SHP-2 phosphatase, dephosphorylates PYK2 and blocks dexamethasone-induced apoptosis of myeloma cells.

Any of the four most distal TYR residues mediates STAT3 activation. The STAT3 structure is similar to that of other STATs: an N-terminal tetramerization domain, a central DNA-binding domain, a conserved SH2 domain (which binds to the cytokine receptor or another STAT molecule for dimerization), followed by a conserved Y and a C-terminal transactivation domain. STAT3 is the major STAT in IL6 signaling. IL6 signaling is down-regulated by SOCS1 (see the previous discussion), which is induced via activation of STAT3. Another mechanism of IL6R down-regulation involves endocytosis of gp130, after IL6 binding. It is mediated by a dileucine motif after phosphorylation of a SER residue in the cytoplasmic tail of the gp130 protein (Fig. 14.18).
FIGURE 14.18. Interleukin (IL)-6 and IL-6 receptor (IL-6R) signaling. The IL-6 binds first to IL-6Rα (site I). This binary complex forms a composite site that is termed site II, which interacts with the cytokine-binding domain (CBD) of gp130 (which includes domains D2 and D3), forming a trimolecular complex. Recruitment of site III on the immunoglobulin-like activation domain (IGD; i.e., D1 of the gp130) results in the formation of higher-order activation complexes (i.e., a hexamer), which is
fully active (gene transcription). High-affinity binding to the N-terminal domains of gp130 (D1 to D3) is not sufficient for receptor activation. The membrane-proximal (D4 to D6) domains of gp130 are necessary for activation, as they facilitate appropriate spacing (especially D5) of the cytoplasmic components of gp130. gp130 is the signaling component of the complex and recruits Jak-1 and Jak-2 kinases, with Jak-1 having an essential role. Jaks bind to box 1 and box 2 of the membrane-proximal cytoplasmic regions. The N-terminal domain of Jaks comprises a 4.1-ezrin-radixin-moesin domain, which is crucial to link Jak with the receptor. Proteins 4.1 is a large family of proteins that link the membrane of the cell with the cytoskeleton. Jaks phosphorylate tyrosines (Y), which then act as docking sites for signal transducer and activator of transcription (STAT) 3 factors. On dimerization, STAT-3 is translocated to the nucleus, binding to DNA through its DNA-binding domain. STAT-3 is phosphorylated on serines by PKC-δ kinase. Phosphoinositide 3-kinase (PI3-K) is recruited on phosphorylated tyrosine 657. The other important signaling pathway involves activation of SHP-2 phosphatase, which interacts with Grb2-SOS adaptor proteins and leads to Ras activation and the ERK1/2-mitogenactivated protein kinase (MAPK) cascade. STAT-binding sites are in close proximity with binding sites of other transcription factors. MEK, mitogen-activated extracellular signal-regulated kinase; PIP, phosphatidylinositol phosphate.

Interleukin-6 in T- and B-cell Interaction and Myeloma

On T cells, IL6 acts as an activation, growth, and differentiation factor. It can replace co-stimulatory signals from APCs to stimulate IL2 secretion and T-cell proliferation (Table 14.4). IL6 is the most important growth factor for B cells (normal and malignant). It is a potent stimulator of terminal B-cell differentiation and antibody formation. The role of IL6 in multiple myeloma has been extensively studied. It is involved in proliferation of plasmablasts and differentiation into mature plasma cells, acting by an autocrine or paracrine mechanism. In addition to its proliferative activity, it blocks the apoptotic pathway (see the previous discussion). The gp130 protein is activated sometimes in the absence of direct ligand binding, i.e., independent of IL6R and IL6. IFN-α induces tyrosine phosphorylation of gp130 in myeloma cell lines that are responsive to IL6. The question is raised whether receptor cross-talk may be a common theme in the biology of multiple myeloma. The human herpes virus (HHV)-8 is associated with all forms of Kaposi sarcoma (KS) as well as primary effusion lymphoma. It is found in the lymph nodes of a high proportion of patients with multicentric Castleman disease, a polyclonal plasmacytosis that is characterized by hyperplastic lymphadenopathy. IL6 is present at elevated levels in KS and multicentric Castleman disease lesions, and IL6 promotes the growth of KS cells in culture. HHV-8 encodes a homolog of human IL-6 that is known as viral interleukin-6 (vIL6), which acts as a mitogenic factor and induces intracellular signaling that is generally the same as IL6. vIL6 induces receptor dimerization and forms complexes with IL6R and gp130. Signaling by vIL6 may be dependent or independent of the IL6RA.

Survival of cholinergic neurons

Ig, immunoglobulin.

One of the most striking responses to injury and inflammation is the APR. APR consists of alterations in several serum proteins that are known as acute-phase proteins (APPs), which are synthesized mainly by the liver. The response involves more than 1,000-fold increases in C-reactive protein and serum amyloid A and moderate increases in fibrinogen, α-1 antitrypsin, complement factor B, and others. The biosynthesis of these proteins takes place in the liver and is regulated by a factor that was known as hepatocytes stimulating factor, which later was shown to be IL6. Several other cytokines, such as IL1, TNF-α, IL11, and TGF-β, are also capable of inducing APP from the liver. In addition to induction of APP, other systemic responses are associated with APR, such as fever and release of ACTH. These responses are also mediated through IL6.

IL6 has multiple other effects, such as bone remodeling, proliferation of keratinocytes, increase of endothelial cell permeability, and proliferation of astrocytes.

P. 348

Interleukin-10 and Interleukin-10 Receptor

The search for a product of T<sub>n</sub>2 cells that would inhibit proliferation, effector function, and even development of T<sub>n</sub>1 cells resulted in the discovery of a factor that inhibited cytokine synthesis. This cytokine synthesis inhibitory factor was called IL10. It is produced by T<sub>n</sub>2 clones and inhibits the synthesis of IFN-γ from the T<sub>n</sub>1 clones. 559

The primary structure of IL10 was determined from a complementary DNA that was isolated from T<sub>n</sub>2 cells. It has four α helices and is expressed as a noncovalent dimer. 560 The IL10 gene is located on chromosome 1. It expresses strong homology to an open reading frame in the Epstein-Barr virus genome.

In addition to T cells, IL10 is produced by macrophages in response to LPS, by B cells, especially after Epstein-Barr virus transformation, 561 and by keratinocytes, especially after exposure to ultraviolet light.

IL10 strongly stimulates proliferation of B cells, especially after cross-linking of CD40 by anti-CD40 antibody, 562 and this effect is synergistically enhanced by IL4. IL10 induces B-cell differentiation that is activated by anti-CD40 antibodies, with the production of large amounts of IgM, IgG, and IgA antibodies. This activity is antagonized by IL4 but is enhanced by TGF-β, especially for IgA secretion. 563 In general, the effects of IL4 and IL10 on proliferation and differentiation of B cells account for much of the noncontact help that is provided during T-cell-B-cell interactions in antibody responses. As a suppressor cytokine of cell proliferation and cytokine response, IL10 plays an important role in tolerating exogenous antigens, especially in immunotherapy of allergy. 564 It selectively inhibits the CD28-mediated co-stimulatory pathway and, as a result, inhibits T-cell responses that are initiated by engagement of a small number of TCRs, a situation that is critically dependent on CD28 co-stimulation. Blocking of CD28 co-stimulation depends on inhibition of CD28 tyrosine phosphorylation, which is the initial step in co-stimulation by CD28. IL10 regulates cyclo-oxygenase-2 expression and reduces production of prostaglandins that act directly on cyclo-oxygenase-2 expression or through regulation of inflammatory cytokines. 565

IMMUNOGLOBULIN STRUCTURE

Antibodies are Igs that are produced by B cells in response to foreign antigens; therefore, they have the property of binding specifically to the antigen that triggered their production. Igs constitute the fraction of plasma proteins, originally defined as γ-globulins, because they were located behind the α- and β-globulins, as a result of their slow electrophoretic mobility. When it was shown that these γ-globulins are products of cells of the immune system, they were given the name immunoglobulins.

Antibodies have two fundamental properties for defense against pathogens: they bind specifically to the antigen that is responsible for their induction by one part of their molecule and then dispose the captured antigen with the cooperation of other molecules (complement) or cells (phagocytes) of the immune system.

Primary Structure: One Polypeptide from Two Genes

One of the most revolutionary hypotheses in the recent history of molecular biology was proposed for the structure of the antibody molecule: the Ig molecule is encoded by two different sets of genes. 566 The C-terminal region is encoded by one gene that is selected from a small group of genes, whereas the N-terminal region is encoded by two or three genes that
are selected from a large number (hundreds) of genes. The Ig molecule consists of two short or light (L) chains and two long or heavy (H) chains, which are held together by disulfide bonds.

The two L chains are of equal length, each consisting of 214 amino acids. The H chains vary in length; the shortest is the \( \gamma 1 \) chain, which is made of 446 amino acids, and the longest is the \( \mu \) chain, which is made of 567 amino acids. A striking feature of the primary structure of H and L chains is the considerable variation at the N-terminal end of the chains, compared to a significant degree of homology at the C-terminal end. The former region is known as the variable or V region and the latter as the constant or C region. In L chains, the V region of the light chain (\( \text{V}_L \)) constitutes one half of the chain (amino acids 1 to 107), and the remaining part of the chain is the constant (C\(_L\)) region of the light chain. The L chains are encoded by a \( V \) and a \( J \) allele (N-terminal half) and a \( C \) allele (C-terminal half). For L chains, the \( V \) allele contributes amino acids 1 to 95, and the \( J \) allele contributes the remaining 13 amino acids. The V region of the H chains is encoded by three alleles, \( \text{V}_H \), \( \text{J}_H \), and \( D \) (see Chapter 12). For the \( \text{V}_H \) region, the \( V \) allele encodes amino acids 1 to 94, and the remaining amino acids are encoded by the \( D \) and \( J_H \) genes. The rest of the chain is divided into three constant regions, \( C_{1H} \), \( C_{2H} \), and \( C_{3H} \), for IgG, IgA, and IgD, and four constant regions for IgM and IgE.

Within the V regions are three short stretches of amino acid sequences that show extreme variability and are therefore known as hypervariable regions. Hypervariable regions contain amino acids that are in contact with the antigen, and, in the primary structure of the molecule, these regions are separated by long stretches of less variable amino acid sequences. However, these hypervariable regions are in close proximity to each other when the molecule assumes its functional tertiary structure. Amino acid sequences that are not part of the hypervariable regions form the framework regions and constitute 80% of the V region.

Secondary Structure: Immunoglobulin Fold

Results from crystallographic studies confirm that the Ig polypeptide chain is folded back and forth on itself in opposite directions (antiparallel), forming a sheet, which is known as the \( \beta \)-pleated sheet, and is arranged as a sandwich (or \( \beta \) barrel), with a hydrophobic center. This is known as the Ig fold (Fig. 14.19). Each strand bends in a hairpin fashion when it changes direction. Almost all bends contain a Gly that is highly conserved.

Tertiary Structure: Immunoglobulin Domain

The intrachain disulfide bonds divide each chain into globular structures of approximately 100 to 110 amino acids that are known as domains. The IgG molecule has four V-region domains, one \( C_1 \) per L chain and three \( C_{1H} \) per H chain. Considerable homology exists among the V domains and among all the C domains. The degree of homology suggests that domains originated from one primordial gene and evolved independently rather than as a group comprising a single H chain. Each Fab fragment (see the following discussion) has four domains: the \( V_L \) and \( V_H \) interact to form the V module, and the \( C_{1L} \) and \( C_{1H} \) interact to form the C module. Each domain is made of two \( \beta \)-pleated sheets (x and y), one consisting of three, the other of four, antiparallel strands that are labeled A through G. In each of the two V domains, there are two additional strands that are called \( C' \) and \( C'' \). The sheets are held together by one \( \epsilon \) disulfide bond and by interactions between the strands A-B-E and D for the C modules and C-C-F and G for the V module. The hypervariable regions correspond to the hairpin loops that link the strands as they turn around to run in the opposite direction, which are called complementarity-determining regions (CDRs) (Fig. 14.19). Each V domain has three CDRs, for a total of six in the V module. They are known, in sequence order along the polypeptide chain, as L1, L2, and L3 for the \( V_L \) domain, and H1, H2, and H3 for the \( V_H \) domain. The length of each CDR varies considerably, both as a function of usage of the V allele, mainly affecting CDR1 and -2, and as a consequence of junctional diversity, i.e., additions of amino acids during V(D)J recombination that affect the CDR3 (see Chapter 12). All six CDRs contribute to the formation of each combining site. Because of their positioning in the free end of the

V module, they are endowed with some mobility, which may be important for binding with the antigen. In the Fab fragment, they form a cavity that is 15 Å long, 6 Å wide, and 6 Å deep. The strands correspond to conserved sequences that are known as framework (FR) sequences. Each V domain has four conserved FR sequences, FR1 through FR4. The Ig fold is not unique to the Ig molecule but is also found in other molecules, such as the \( \alpha \beta \) and \( \gamma \delta \) TCRs; the class I and class II MHC molecules; the CD2, CD3, CD4, and CD8; and the \( \beta_2 \)m, which represents a free domain. Several other proteins have Ig-like domains that form the Ig superfamily.
FIGURE 14.19. Tertiary structure of a light chain that depicts the variable (V) and constant (C) domains. Each domain is composed of two sheets that are formed by strands of polypeptide chains that possess the basic β-pleated structure. In each sheet, the strands run in alternating directions (antiparallel). The strands are shown as broad arrows, pointing in an N-terminal-to-C-terminal direction. The strands that belong to the same sheet are blank or hatched. Stretches of polypeptide chains that connect the strands form loops. Three of these loops in the V domain include the complementarity-determining regions (CDR), which are involved in antigen binding. The strands are identified by letters, A to G, starting from the N-terminal end. The V domain contains two additional strands C′ and C′ (which are not shown in the diagram as broad arrows). Interactions between the VL and VH sheets contribute to the formation of a cylindric V module that contains the antigen combining site. The black bars represent the disulfide bonds.

Quaternary Structure: Immunoglobulin Monomer

The Ig molecule consists of four polypeptide chains, which are held together by disulfide bonds and noncovalent interactions\(^567\) (Fig. 14.20). Two of the chains have a molecular weight of 53 kDa (IgG) or 75 kDa (IgM) and are known as H chains. The other two chains have a molecular weight of 22.5 kDa and are known as L chains. The former determine the major Ig class of the molecule: IgG, IgM, IgA, IgD, and IgE. The respective H chains are designated by Greek letters: \(\gamma\) (IgG), \(\mu\) (IgM), \(\alpha\) (IgA), \(\delta\) (IgD), and \(\varepsilon\) (IgE). Within each class are subclasses: four for IgG (1, 2, 3, and 4), two for IgM, and two for IgA. The H chains are distinguished by isotypes to identify antigenic determinants that are shared by all individuals of a given species. Humans have 10 loci for constant region genes and, therefore, 10 isotypes that correspond to the total number of what otherwise are known as subclasses: \(\mu_1, \mu_2, \delta, \gamma_1, \gamma_2, \gamma_3, \gamma_4, \alpha_1, \alpha_2, \) and \(\varepsilon\). There are only two types of L chains, kappa (\(\kappa\)) and lambda (\(\lambda\)). The L chains of the \(\lambda\) type exist in four isotypes (\(\lambda_1, \lambda_2, \lambda_3,\) and \(\lambda_4\)). Any given Ig molecule has two \(\kappa\) chains or two \(\lambda\) chains but never one of each type. The \(\kappa\)-to-\(\lambda\) ratio varies between species: in humans it is 70:30, whereas in the mouse it is 95:5.

The hinge region is located between C\(_{H2}\) and C\(_{H3}\) and is rich in proline residues. Cysteines form the inter-heavy chain disulfide bonds. Because of its unique amino acid sequence, this region does not fold well and thus becomes susceptible to enzymatic attack. The hinge region also affects the flexibility of the molecule and other properties, such as complement binding. IgM and IgE have no hinge region but instead have an extra C domain.

Disulfide bonds are important because they maintain the association of the four chains and divide the Ig molecule into functional domains. The H and L chains are held together by interchain disulfide bonds. Each L chain is attached to the H chain by one disulfide bond, with the exception of human IgA2, which contains no disulfide bond between H and L chains. The disulfide bond is formed between C-terminal cysteine of the \(\kappa\) chain or the penultimate cysteine in the \(\lambda\) chain and the cysteine that is closest to the middle of the H chain.

The two half-molecules are held together by interchain disulfide bonds between the two H chains. The number of these bonds varies among classes: the IgG1 molecule has two, whereas IgG3 possesses 15. Disulfide bonds exist within each chain (intrachain). All L chains have two bonds, and all \(\gamma\) and \(\alpha\) chains have four bonds; \(\mu, \delta,\) and \(\varepsilon\) chains have five bonds. Because the cysteines that form the intrachain bonds are separated by 40, or even 70, amino acids, the bond can be formed only if the two cysteines are brought into apposition by looping the intervening sequence. The regularity of the distribution of the intrachain disulfide bonds formed the basis of the domain hypothesis, in which the Ig molecule is separated into distinct functional regions.\(^568\)

Carbohydrate Moiety
Carbohydrate chains are of variable length and shape. The number of these chains varies among isotypes: 2 in IgG molecules, 10 in IgM molecules, 16 in IgA molecules, and 12 in IgE molecules. The carbohydrate chains are attached to the C\textsubscript{H}2 domain, forming a bond between the first carbon of asparagines and the sugar N-acetylglucosamine (GlcNAc). Procedures that interfere with the glycosylation of the \( \alpha \) and \( \epsilon \) chains prevent the secretion of IgA and IgE molecules.

**Enzymatic Fragments**

Treatment of the Ig molecule with papain generates three fragments. Two of these fragments are identical; each contains one antigen-binding site and thus they are known as Fab (fragment antigen binding).\(^{569}\) The third piece, which is known as Fc (fragment crystallizable), mediates fixation of Ig molecules to skin and other cells (macrophages and lymphocytes), fixes complement, and mediates transport of the Ig molecule across the placenta. Digestion of the Ig molecule with pepsin yields one large piece, with a molecular weight of 100 kDa. This divalent fragment, which is known as F(ab)\(_2\), consists of two Fab fragments, each capable of binding antigen. The Fc fragment is digested by pepsin into small peptides (Fig. 14.21).

---

**FIGURE 14.20.** Basic arrangement of the polypeptide chains, the enzymatic fragments, and their domain structure of the immunoglobulin G molecule. Locations for structures that are defined as idiotypes, allotypes, and isotypes are shown, as
well as the position of the carbohydrate (CHO). Various domains are shown on the left side.

Combining Site

The antigen-combining site is located near the tip of the two arms on the Y-shaped Ig molecule. The size of the combining site was determined initially by Kabat, using antidextran antibodies that reacted with oligosaccharides of different lengths. Maximal inhibition of the binding was obtained with an oligosaccharide that consisted of six isomaltohexose molecules. The structure of the combining site has also been studied by means of affinity labeling. With this technique, the hapten is linked to a chemical group that interacts with the amino acids that are closest to those that form the combining site. This method helped demonstrate that H and L chains participate in the formation of the combining site. The antigen-binding V module may be viewed as a stable, packed FR structure with six superimposed flexible CDRs. Molecular biologists have now constructed hybrid genes that combine FR and CDR from different Ig. Upon transfection to lymphoid cell lines, these genes produced antibodies with the specificity of the CDR donor.

Idiotypes and Allotypes

Antibodies and myeloma proteins possess determinants that are characteristic for each antibody or myeloma protein and are known as individually specific antigenic determinants or idiotypes. Idiotypes can be detected by means of antisera. Some anti-idiotypic antibodies detect determinants that are restricted to a single Ig (individual, or private, IdI), and other antibodies detect determinants that are present in antibodies or myeloma proteins other than those that are used for immunization (public, or cross-reactive, IdX). Idiotypic determinants, which are known as idiotopes, have also been classified according to their location in relation to the combining site: α-idiotopes are located outside of the combining site; β-idiotopes are close to the site, so that the binding of the anti-idiotypic antibody interferes with the binding of the antigen; and γ-idiotopes are formed by the site itself.

In addition to CDR, the idiotope-determining region (IDR) can be defined, not on the basis of amino acid sequence variability, but as a surface-variable structure that is complementary to a structure on the V region of another Ig molecule. Although all CDRs are also IDRs, the partial overlap between these two kinds of regions suggests that IDRs outnumber CDRs. IDRs, therefore, are functionally involved in antigen recognition, as well as in recognizing and being recognized by other Ig molecules. This functional attribute of IDR is central to the network theory of immune regulation of Jerne.

Allotypes are allelic variants of Ig polypeptide chains that segregate in Mendelian fashion in outbred populations. Allotypes that vary by one or a few amino acids are simple allotypes, whereas those that are characterized by greater differences are complex allotypes. In humans, Ig allotypes have been well characterized for all subclasses of the IgG (γ) H chains (Gm allotypes), for IgA (α) H chains (Am allotypes), and for the κ chains (Km allotypes). The H chain allotypes of different H chain isotypes are inherited together as a group, which is sometimes referred to as a haplotype.

**IMMUNOGLOBULIN FUNCTION**

**Immunoglobulin G**

IgG is the major Ig in humans and constitutes approximately three fourths of the total Ig (Table 14.5). The serum concentration varies from 8 to 16 g/L in adults, but the intravascular pool accounts for less than one half the total body IgG; approximately 55% is found widely distributed within the extravascular space. The total body content is in excess of 1 g/kg of body weight. IgG molecules have a half-life of 21 days and therefore have the longest lifespan.

P.351
FIGURE 14.21. Proteolytic fragmentation of the immunoglobulin G molecule by papain and pepsin. Papain hydrolyzes the molecule to the N-terminal side of the interchain disulfide bonds and releases three fragments of approximately equal size.
size, two Fab and one Fc. Pepsin acts on the C-terminal side of the disulfide bonds and forms one large divalent fragment (F\(\text{ab}'\)2); the Fc is fragmented to small peptides and one larger fragment known as pFc'.

The four isotypic subclasses of IgG molecules are distributed as follows: IgG1, 66%; IgG2, 23%; IgG3, 7%; and IgG4, 4%. These antigenic differences are the result of variations in amino acid sequences of the carboxy-terminal parts of the \(\gamma\) chains. All four types of molecules are found in any given normal serum, but individual molecules contain only a single type of \(\gamma\) chain. The IgG subclasses carry numbers of disulfide bonds that are arranged in different ways. The hinge region is also strikingly different among the subclasses; the longest is in IgG3 and supports certain functions of the Fc fragment.

**Biologic Properties**

Most of the antibodies that are found in secondary antibody responses to antigen are IgGs. IgG is selectively transferred across the placenta, thereby giving a measure of protection to the newborn\(^{577}\) (Table 14.5).

Some biologic properties of IgG proteins, and particularly those that are mediated by the Fc fragment, are distinctly subclass-specific. IgG1 and IgG3 react most readily with C1q, the first component of complement, and therefore activate complement most efficiently. IgG2 is less reactive, and intact IgG4 proteins are completely unreactive. The binding of Fc to macrophage and granulocyte Fc receptors is most efficient with IgG1 and IgG3, and this reaction is important in the process of opsonization. Anti-Ig antibodies (rheumatoid factors) react most readily with IgG1, IgG2, and IgG4 proteins and not at all with IgG3 proteins. IgG3, on the other hand, has a tendency to aggregate,\(^ {578}\) a property that probably is also responsible for the affinity of the molecule for C1q. Aggregation of IgG3 may lead to clinically significant hyperviscosity states, especially in patients with IgG3 myeloma. In addition, IgG3 is selectively retained in the sera of some patients who have generalized hypogammaglobulinemia.

Ig, immunoglobulin; +, weak; ++++, strong; -, negative; ±, borderline.

Some antibody activities are subclass-specific. Thus, anti-Rh antibodies are usually IgG1 or IgG3; antifactor VIII antibodies are often restricted to IgG4, and other antibodies, such as antidextran and antilevan, have been found to be IgG2.

Immunoglobulin A
The IgA class of antibodies can be divided into two separate systems of Ig. One system, IgA1, provides IgA antibodies for the circulation and the internal secretions, such as the aqueous humor of the eye, the cerebrospinal fluid, and the synovial, amniotic, pleural, and peritoneal fluids. These IgA antibodies probably are synthesized by nonmucosal lymphoid tissues. The other system, IgA2, is found in external secretions, such as saliva, tears, bile, and colostrum, as well as secretions of the respiratory tract, the gastrointestinal tract, the seminal vesicles, the cervix, and the urinary tract. The IgA of external secretions is, for the most part, not derived from the blood but is produced locally by plasma cells that are situated in proximity to the epithelial mucosa. It is the predominant Ig in external secretions, although smaller amounts of IgM and IgG also may be found.

In the serum, 85% of IgA molecules are monomers, with a molecular weight of 170 kDa and a sedimentation coefficient of 7S; 9S, 11S, and 13S polymers make up the remainder. Approximately 1% is secretory IgA (sIgA); this percentage increases in association with a variety of mucosal inflammatory diseases. The serum concentration of IgA is in the range of 2 to 3 g/L, with a half-life of 6 days. Monomeric IgA is composed of two H (α) and two L chains. The α chains of IgA1 and IgA2 subclasses are strikingly different in the hinge region. Certain bacterial proteases cleave IgA1, but not IgA2, into Fab and Fc fragments. These IgA1 proteases are exquisitely specific. In the IgA2 subclass, the H and L chains are not held together by a disulfide bond.

slgA is a large molecule with a molecular weight of 390 to 400 kDa. It consists of two IgA molecules that form a dimer and two additional non-Ig components, which are known as the J chain and the secretory component (SC). The J chain joins two IgA molecules through a disulfide bond to form a dimer, whereas the SC is the extracellular part of the polymeric Ig receptor (pIgR), which remains attached to IgA after trans-epithelial crossing (Fig. 14.22). The epithelial cells in the glands and basolateral crypts of the gastrointestinal and upper respiratory tracts produce the full-length (100-kDa) pIgR located in the nonserosal surface of the epithelial cells. It consists of five V-type Ig-like domains in the extracellular region, a transmembrane, and a 103-amino acid intracellular region. Binding of polymeric IgA (pIgA) to the first extracellular domain of the pIgR is followed by endocytosis and transcytosis across the epithelial cell. The initial step is through clathrin-coated pits and requires two cytoplasmic tyrosines of pIgR and phosphorylation of serine 726. The endocytosed complex is delivered first to RAB1 basolateral early endosomes and then on to RAB17 common recycling endosome. In this compartment, the complex is sorted and directed to the apical plasma membrane.

The IgA dimer is released on the lumenal side of the epithelial cell, with the extracellular portion of the pIgR (i.e., the SC) still attached, forming the slgA. During transcytosis, disulfide bonds form between pIgR and pIgA. The J chain is essential for the transport of IgA, and expression of the J chain by plasma cells is particularly critical for the overall function of slgA in mucosal surfaces. A disulfide bond between the J chain and the IgA monomer is sufficient for IgA dimerization. IgA polymers are also formed that retain high affinity for free SC. The SC protects the IgA from intracellular digestion by proteolytic enzymes. The SC is more efficient than IgR in providing protection because, as a result of its carbohydrates, it is able to anchor the slgA to mucus within infected areas, in contrast to the random distribution of pIgR. Furthermore, pIgR can be used by some bacteria (e.g., Streptococcus pneumoniae) to gain access to the transcytosis pathway. The IgA transport system is unique in that, in contrast to other pathways, it does not lead to degradation of its ligand, the IgA molecule. The IgA and the asialo glycoprotein transport of hepatocytes occupy the same compartment inside the cell, yet each follows distinct pathways subsequently.
FIGURE 14.22. A: Dimer of immunoglobulin A (IgA). The J chain is linked through disulfide bonds with the Ca3 domains of the monomers. The secretory piece attaches through disulfide bonds to the Fc fragments of the monomers. B: IgA dimers. (Courtesy of Dr. K. H. Roux.)

Biologic Properties

Although IgA is incapable of fixing complement or acting as an opsonin, the slgA molecule, together with complement and lysozyme, is capable of killing Escherichia coli. IgA does not activate complement, except in its aggregated form and even then it activates complement only through the alternate pathway. Like other Igs, slgA is capable of blocking bacterial adherence to mucosal surfaces, thereby preventing colonization. It may also act as a blocking antibody to reaginic reactions on mucosal surfaces and may prevent the absorption of antigenic molecules from the lumen of the gut.

Surprisingly, most IgA-deficient individuals appear to be fairly healthy and not overly susceptible to upper respiratory tract infections. IgA antibodies against intrinsic factor have been reported in the gastric secretions of patients with pernicious anemia. It has been proposed that IgA may serve as a carrier of antigens from the blood to the mucosal sites, providing an
explanation of how antigens find their way into external secretions through the SC transport system. Perhaps the mucosal synthesis of IgA makes it particularly suitable for removal of dietary and microbial antigens that are absorbed from the gut. More recently, receptors for the Fc portion of IgA were identified on peripheral and alveolar macrophages, lymphocytes, and neutrophils. Through such receptors, IgA participates in antibody-dependent, cell-mediated cytotoxicity reactions.

**Immunoglobulin M**

IgM antibodies are proteins with a molecular weight of 850 kDa that sediment predominantly at 18S to 19S but also at 22S, 26S, and 35S (Table 14.5). Because of their size, IgM molecules are referred to as macroglobulins. Their rate of synthesis is only 1/20 of that of IgG, whereas their fractional catabolic rate is two to three times that of IgG, which accounts for the relatively short survival (half-life of 5 days) and low serum levels (0.8 to 3.0 g/L) of IgM.

IgM macromolecules are composed of five identical subunits called IgM monomers, each of which consists of two \( \mu \) (H) chains and two L chains (Fig. 14.23A). The L chains may be \( \kappa \) or \( \lambda \) and are identical to those of other Ig. The H chains, on the other hand, have some unique structural features. Whereas human \( \gamma \) chains vary in length from 446 to 450 amino acid residues, \( \mu \) chains contain in excess of 500 residues and have a correspondingly higher molecular weight of approximately 70 kDa. In addition, \( \mu \) chains appear to consist of a variable region and four constant regions, in contrast to the three constant regions of \( \gamma \) chains. Similar to \( \gamma \) chains, however, each region (constant and variable) contains a loop of approximately 60 amino acids with an internal disulfide bridge that is flanked on either side by approximately 20 amino acids. Carbohydrates account for 10.7% of the molecule by weight and are distributed over five sites within the constant region: one within the Fd region, one in the hinge region, two within Fc, and one near the COOH terminus. They affect the conformation and other properties of the molecule but do not contribute directly to antibody specificity. Two subclasses of IgM (IgM1 and IgM2) have been identified on the basis of antigenic differences within the \( \mu \) chain.

In the intact IgM molecule, five monomers are assembled in a star-shaped configuration, with the carboxy terminal (Fc pieces) being joined at the center through disulfide bonds, whereas the antigen-binding sites (Fab pieces) extend toward the periphery.

The molecule appears to have a great deal of rotational freedom, and, although it is bound to particulate antigen, it may take on the appearance of a staple or a spider (Fig. 14.23B), with its legs (Fab pieces) extending toward the plane of the antigen (a cell surface) and its body consisting of closely linked Fc fragments that protrude from the center, thus making it ideally suited for complement fixation (Fig. 14.24).
molecule appears star-shaped (a). When it is bound to antigen, such as the flagellum of Salmonella, it assumes the crab or staple form (b: 1-4), a model of which is shown in c. (From Feinstein A, Munn EA. Conformation of the free and antigen-bound IgM antibody molecules. Nature 1969;224:1307-1309, with permission.)

Because the IgM molecule consists of five subunits, each with two antigen-combining sites, there are 10 combining sites per IgM pentamer. A single J chain has been found attached to the IgM pentamer by disulfide bridges. IgM monomers do not have J chains.

FIGURE 14.24. Immunoglobulin M (IgM)-C1 esterase interaction. On the surface of pathogens, IgM assumes the staple (as seen sideways) or crab conformation. Whereas the Fabs touch the surface of a pathogen, or immune complexes deposited on tissues, the Fc fragments form a plateau on which C1q finds space to touch down with the heads of the arms. The C1r-C1s tetramer weaves between the arms as a necklace. Recognition of patterns by C1q creates a conformational shakeup, which is transmitted to the catalytic domains of C1r, which is activated. In turn, C1r activates the C1s, which performs the esterase functions of the whole complex, C1 esterase.

Biologic Properties

Macroglobulins are restricted mostly to the intravascular pool. Little if any IgM crosses the placental barrier, and the amount that is present at birth is almost entirely of fetal origin. Detectable levels of IgM may be synthesized by the human fetus by as early as the 20th week of gestation, but high levels of IgM at birth usually are indicative of intrauterine sepsis.

On cell surfaces, a single molecule of IgM readily fixes complement, whereas antibody doublets are required for fixation of complement by IgG. IgG is efficient at 4°C and 37°C, however, whereas IgM is inefficient at the lower temperature. Binding of C1q to IgM has been assigned to both Cµ3 and Cµ4 domains. Mutations that involve a single amino acid in the Cµ3 domain abolishes complement fixation.

Specific macrophage receptor sites for the Fc region of IgM have been described in animal systems. Such receptors may play a critical role in the process of phagocytosis of immune complexes.
IgM antibodies are the first to be produced in a primary immune response, to be replaced subsequently by IgG antibodies. However, certain types of antibody responses remain mostly IgM, including those against LPS and the heterophil (Forsmann) antigens. Wassermann antibodies, isoagglutinins, cold agglutinins, and antibodies to the O antigens of Gram-negative bacteria are usually IgM.

**Immunoglobulin M Monomer**

IgM monomer (7S IgM) is the predominant Ig on the B-cell surface. Naturally occurring 7S to 8S IgM monomers also have been identified in normal sera, and higher concentrations of monomers occur in association with various diseases, including SLE, Waldenström macroglobulinemia and other hypergammaglobulinemic states, congenital rubella, and immune deficiency disorders, such as ataxia telangiectasia and dysgammaglobulinemia. In some instances, IgM monomers possess antibody activity against blood-group substances or cell nuclei (antinuclear factors). IgM monomers may be related to more primitive Ig and appear to be synthesized as such, rather than to represent an in vivo or in vitro breakdown product of IgM.

**Immunoglobulin D**

IgD is found in low concentration (3 to 400 mg/L) in normal serum. It consists of two H (δ) chains and two L (κ or λ) chains, has a molecular weight of 180 kDa, and sediments at 7S. It appears to be catabolized rapidly (half-life 2.8 days), is confined largely to the intravascular space, and does not cross the placental barrier. The IgD has three constant region domains and an unusual hinge region, which is strikingly different from the hinge regions of other Ig. It is longer than the γ1, γ2, and α2 hinges and has a highly charged C-terminal half. Its unusual structure makes it extremely susceptible to proteolytic cleavage. IgD is a major surface Ig of peripheral blood lymphocytes.

IgD plays an important role as antigen receptor in B-cell activation. It is expressed during certain periods of B-cell differentiation. IgD may function as an antigen receptor that is capable of triggering antibody production, whereas binding of antigen to IgM leads to tolerance. Both receptors, however, are capable of inducing proliferation and differentiation of B lymphocytes.

**Immunoglobulin E**

Reaginic antibodies, which mediate acute and sometimes lifethreatening allergic reactions in atopic patients, belong to this distinct class of Igs. IgE molecules also have two H (ε) chains and two L (κ or λ) chains. They have a molecular weight of 200 kDa and a sedimentation coefficient of 8.2S, and they contain 12% carbohydrate. The ε chains are approximately the same size as the μ chains, with four constant region domains totaling approximately 550 amino acids. Each molecule has 15 half-cysteines, eight of which form intrachain disulfide bonds within the four constant domains. The formation of two interchain H-H bonds between two noncomplementary regions, that is, between Ce1 and Ce2 and between Ce2 and Ce3, is unique to ε chains. Carbohydrates are found throughout the chains. All six oligosaccharide units are N linked to Asn. The survival of IgE molecules in the serum is shorter than that of any other Ig (half-life 2.4 days), and their serum concentration is in the range of 0.1 to 0.7 mg/L, with a mean of 0.3 mg/L. Higher concentrations may be found in the sera of patients who have asthma, hay fever, eczema, Wiskott-Aldrich syndrome, and helminthic infestations. IgE-forming plasma cells are found most commonly in the respiratory, gastric, and intestinal mucosa and in the regional lymph nodes, but a few are noted in the spleen and in other lymph nodes. Thus, IgE, like IgA, is classified as an sIg.

**Biologic Properties**

IgE antibodies are capable of sensitizing basophils and mast cells. The Fc portion of the IgE molecule fits into specific receptor sites on the cell surface. When bivalent or multivalent antigens bind at least two adjacent IgE molecules, the mast cell or basophil is triggered to degranulate, thereby releasing vasoactive substances, especially histamine and slow-reacting anaphylaxis substances, which are responsible for such clinical manifestations as whealand-flare reactions, bronchospasm, small-vessel dilation, and shock. Reduction of the disulfide bonds destroys the ability of the molecule to bind to the Fc receptor, and heating of the IgE at 56°C inactivates its cytotoxic activity. This inactivation is associated with loss of antigenic determinants in the Ce3 and Ce4 domains, suggesting that these regions are important for binding to the receptor.

**J Chain**

The J (joining) chain has been detected in association with polymeric forms of serum and sIgA, as well as with the IgM pentamer. This chain has a molecular weight of 15 kDa. It is attached to IgA or IgM polymers by disulfide linkages. It is...
not detectable by antisera while the polymers are in their native state, but it becomes readily accessible if the polymers are dissociated. In contrast to the secretory piece, J chains are produced by plasma cells and appear to play a key role in the process of polymerization of Ig, serving as a clasp or zipper to fasten the last two monomeric components of a plg together.

The complete amino acid sequence has been inferred from cloned genomic DNA. The chain is larger than previously determined, containing 137 amino acids. Many cysteine residues are scattered throughout the molecule. Of the 137 amino acids in mouse and human J chains, 106 are identical (77%). This characteristic, plus the fact that the C-terminal regions of the µ and α chains are also conserved, suggests that the polymerization of Ig molecules has been conserved in evolution, probably because they confer advantages in defense mechanisms in that they aggregate complex pathogens more effectively.

COMPLEMENT
The name complement was introduced by Paul Ehrlich and J. Morgenroth, because it was thought to complete the activity of the antibodies from which it could be distinguished by its particular properties. It is now recognized that complement represents a multimolecular system and is activated by three different pathways, the classical, the alternate, and the lectin, with the final lytic or effector function being carried out by a common pathway. This final common pathway leads to the formation of the membrane attack complex (MAC).

Classical Pathway
The classical pathway is initiated by two functional units: the recognition unit, which consists of three proteins, C1q, C1r, and C1s; and the activation unit, which consists of C2, C3, and C4 (Fig. 14.25). The MAC is activated by the classical pathway by the generation of three complex enzymes with proteolytic activity, the formation of which requires the association of two or more proteins. Not all Ig classes are capable of binding to C1q; IgG1 and IgG 3 bind readily, whereas IgG4 does not bind at all. Complement binding to the IgG subclasses is determined by the flexibility of the hinge that prevents steric interference between Fab and C1q binding. IgG3, with the longest hinge region, is the most efficient of all IgG subclasses. Exposure of the C1q-binding site of IgM molecules is optimal when the molecule assumes the staple configuration as it binds to the antigen (Fig. 14.24). This site is hidden in the native form of IgM by the closeness of the subunits. IgM has the strongest binding ability because one C1q molecule that is bound to one IgM antibody is capable of lysing an erythrocyte, whereas two IgG molecules in close proximity are required to achieve the same effect. Ig antibodies that are bound to independent epitopes can activate the complement cascade in this way. Depending on the epitope density, activation occurs when at least 800 IgG molecules bind to the cell. For this reason, IgM antibodies are considerably more efficient lysins.

Step 1: C1 Esterase (C1)
C1 esterase is a complex that is assembled from three proteins: C1q (recognition subunit), C1r, and C1s (catalytic complex). C1q: Recognition Unit of C1s
All activators of the complement cascade recognize the C1q, which consists of a total of 18 polypeptide chains, six of each of the three different types, A, B, and C. All polypeptide chains are equal in length, and each is comprised of a short N-terminal region that is involved in the formation of A-B and C-C interchain disulfide bonds. It is followed by collagenlike sequences, which consist of repeating triplets X-Y-Gly, a collagenlike motif (X is often a proline; Y is usually hydroxyproline or hydrolysine). These sequences are not found in human serum proteins but are present in collagen fibrils. At the beginning, three heterotrimers (each consisting of A, B, and C polypeptide chains) associate, forming a stalk. Because of the interruption of the collagen sequence, the triplets dissociate into six radiating arms (Fig. 14.26A). At the C-terminal end, each arm ends in a globular head, which consists of heterotrimeric protein domains known as C1q modules. When viewed by electron microscopy, the C1q resembles a bouquet of flowers (Fig. 14.26B).
FIGURE 14.25. The complement (C) pathways. The hemolytic function of the C is activated by three pathways, which converge to the same final common pathway (see the text for details). The classical pathway uses C1q as the recognition molecule, which generates sequentially three enzymatic functions: C1 esterase, C3 convertase, and C5 convertase. The alternative pathway initiates activation by a “tick-over” mechanism in the absence of antibody and again generates similar enzymatic functions as the classical pathway. The lectin pathway is triggered by a receptor, mannose-binding lectin (MBL), which, through carbohydrate binding, activates the MBL-associated serine protease (MASP) esterases. A MASP cleaves C4 and C2, generating the same C3 convertase as the classical pathway, which it joins at this point. All pathways converge to the same membrane attack complex (MAC) pathway, which they initiate by cleaving C5.
FIGURE 14.26. A: C1q molecule. Each of the six subunits is made of three polypeptide chains that form a triple helical strand. The N-terminal ends have a collagenlike structure and are packed together, forming a central stalk (a); halfway, they bend and separate from each other (b) to end at the C-terminal end in a globular domain (c) that binds to the immunoglobulin. B: Electron micrographs of the C1q molecule (upper) and bird's eye view (lower). (From Knobel H, Villiger W, Isliker H. Chemical analysis and electron microscopy studies of human C1q prepared by different methods. Eur J Immunol 1975;5:78-82.)

Modules of the C1

gC1q Module. Most of the C1 activators, such as immune complexes, β-amyloid fibrils, and HIV, are recognized by the globular heads of C1q. Each head is composed of trimers of the gC1q domain, which is detected not only in C1q but also in type VIII and type X collagens and several other proteins. The gC1q modules bear structural features that are seen in members of the TNF family.

CUB Module: C1r-C1s Uegf Bone Morphogenic Protein-1 Module. The acronym CUB was given from the detection of this module for the first time in the sea urchin protein, Uegf, and the human bone morphogenetic protein-1. The CUB modules of C1r and C1s surround the single epidermal growth factor (EGF) module and a pair of complement control protein (CCP) modules. CUB modules are detected in proteins that are involved in developmental processes. They contain four cysteine residues, forming two disulfide bonds, except the N-terminal CUB module of C1r and C1s, which has only two cysteines.
Epidermal Growth Factor Module: Epidermal Growth Factor-like. EGF-like modules are detected in diverse proteins that are involved in processes such as blood coagulation and cell adhesion. They have six cysteines that form three disulfide bonds. In C1r and C1s, the EGF module has characteristic consensus sequences with residues Asp and Asn that are hydroxylated and are involved in Ca\(^{2+}\) binding.

Complement Control Protein Module. The CCP module is detected in complement receptors and other CCPs. Their consensus sequence consists of aromatic and hydrophobic residues and four cysteines. The crystal structure has been solved and shows six β strands around a hydrophobic core.\(^{595}\) The modules are ellipsoidal with the β strands aligned along their long axis, with N and C termini at opposite ends.

Serum Protease Domain

The target bonds in the substrates for cleavage by the C1 esterase have one Arg residue. Indicative of its trypsin-like enzymatic specificity is the Asp residue that is found close to the substrate-binding site. Arginyl bonds, such as Arg-isoleucine (Ile), are the targets in the autoactivation of C1r and in the activation of C1s by C1r. Arg-containing bonds are also cleaved in C4 and C2 by the active C1s. C1s esterase activity is expressed only by the multimolecular complex, which is a tetramer that is formed by two C1r and two C1s. Therefore, the enzymatic activity depends on protein-protein interactions among the four components of the esterase, which are facilitated by Ca\(^{2+}\).\(^{596}\) Ca\(^{2+}\) brings together one CUB and one EGF module to form a compact structure.\(^{597}\) During the formation of the tetramer, interactions are flexible to allow a single C1r to cleave the neighboring and the distant C1s.\(^{598}\)

C1r and C1s

The C1r and C1s are single polypeptide chains of approximately 85 kDa, with a SER protease activity. In the proenzyme form, they are single glycoproteins, which are activated by cleavage of a single Arg-Ile bond, forming a two-chain active enzyme. They are composed of two CUB modules,\(^{599}\) an EGF-like module, two CCP modules, and a C-terminal chymotrypsin-like SER protease domain (Fig. 14.27).

Assembly of C1 Esterase

The first enzymatic activity of the C cascade is assembled from five components, one C1q, two C1r, and two C1s (Fig. 14.27). The C1r-C1s tetramer, in isolation, is a linear structure, with the C-terminal domains responsible for the catalytic function and the N-terminal domain involved in the Ca\(^{2+}\)-dependent protein interactions. In the linear form, the two C1r catalytic domains are in the center, whereas those of the C1s are at the two ends. In the assembly of the C1 esterase, which is the first enzymatic activity of the classical complement cascade, the linear tetramer assumes a compact figure-eight conformation. In this configuration, all four catalytic domains of C1r and C1s are brought into juxtaposition under the cone that is formed by the arms of the C1q. The protein interaction domains are located outside the arms of C1q.\(^{600,601}\)

Activation of C1 esterase occurs upon recognition by the globular heads of C1q of pattern target sites (e.g., antibody bound to pathogen surfaces and immune complexes). This binding generates transient conformational changes, which activate C1r by disrupting the C1r homodimer. Activated C1r in turn breaks an Arg-Ile bond, activating C1s.\(^{596}\) These transient “earthquakes” do not bring about the collapse of the elaborate C1 esterase edifice, because C1r and C1s are associated tightly with the C1q collagen arms by the CUB-EGF modules that were discussed previously.

C1s is a highly specific enzyme, but, within the mechanical constraints that are imposed by the superstructure of the whole assembly, it requires some degree of freedom of mobility for its interaction with the substrate. These requirements are provided by the CCP modules, especially CCP-2, which is linked by a flexible hinge to the CCP-1 module. This allows CCP-2 to act as a handle and a spacer, to amplify the shift that is required for the serine protease domain.\(^{595,601}\)

C1q-binding Proteins

In addition to its function in C activation, C1q binds to other proteins that are sometimes called receptors, mediating other C1q functions.\(^{602,603}\) There are two types of surface proteins that bind to C1q. One binds to the collagenous portion of C1q (cC1q receptor), and the other binds to the globular heads (gC1q receptor). Some of these proteins are transmembrane, whereas others are intracellular, such as calreticulin (CALR) and the gC1q-binding protein (gC1qR, now known as C1QBP). The C1q structure bears similarity to the proteins of the collectin family, which includes the mannos-binding lectin (MBL), the pulmonary surfactant protein A, and conglutinin. However, the collectins are C-type lectins and bind carbohydrates, whereas the heads of C1q recognize protein patterns on immune complexes.
The C1 esterase is a complex that consists of one C1q molecule (recognition component) and a tetramer of two C1r and two C1s. The tetramer in isolation assumes a linear form: C1s-C1r-C1r-C1s. It weaves among the arms of the C1q in a necklacelike way and assumes a figure eight. This arrangement allows access of the catalytic domain of the C1 in the zymogen form to be in contact with the active catalytic domain of C1r for C1s to be activated. Both C1rs have access to both C1s. The flexibility of the tetramer allows changes in their relative position, so that the active C1s sites have access to C4 and C2 for their cleavage and formation of the C4a-C2b C3 convertase. The CUB and EGF modules of C1r are connected by a flexible loop and form a high-affinity Ca\(^{2+}\)-binding site that is involved in the interaction with C1s. The CUB-EGF pair interacts with the C1q arm. When the heads of C1q interact with a pattern of sites on the surface of a target, a conformational stress that is transmitted through the arms of C1q triggers the C1r catalytic domain and results in its activation. CCP, complement control protein.
The term C1qR has been used loosely, sometimes without hard evidence that the receptor triggers cell signaling that leads to some cellular functions. The gC1qR is expressed on myeloid cells and microglial cells, in which it mediates chemotaxis and phagocytosis, and in platelets, modulating their function in injured vascular sites. Calreticulin is a Ca\(^{2+}\)-binding protein that is located primarily in the ER of most nucleated cells. It has been found that calreticulin binds C1q and therefore qualifies as cC1qR, but the significance of this interaction remains elusive.

Step 2: C4 and C2 Complex: C3 Convertase

C3 convertase is formed by the interaction of two fragments from the C4 and C2 components of complement. Complement component 4 circulates in the blood as a disulfide-linked heterotrimer that consists of α (93 kDa), β (75 kDa), and γ chains (33 kDa). C3 and C5 components share a similar structure that is considered to be evolutionarily derived from one ancestral gene. The C3 and C4 components share an internal thioester bond, which is formed between a cysteine and a glutamine, which are two residues apart.

C4 is synthesized as a single polypeptide chain but is later hydrolyzed, giving rise to the three constituent chains. C1s activates C4 by splitting the α chain, releasing the C4a fragment from the N-terminal end of the chain. The thioester bond, which is normally hidden in the C4b fragment, is exposed, reacts with an NH\(_2\) or OH group of the surrounding molecules (Fig. 17.28), and deposits C4b on the surface of potential targets for C attack.

C2 is a single chain protein of approximately 100 to 110 kDa, with a distinct structure that consists of three globular regions: three N-terminal CCP domains, a single von Willebrand factor (vWF) domain in the center, and a serine protease domain in the C terminus. CCP modules are highly compact structures, folding independently into a β barrel (e.g., two interacting antiparallel β sheets), that form an ellipsoid structure. Loops that connect the β strands protrude from the module and may function as the ligandbinding sites. The vWF type A module consists of five parallel β strands and a short antiparallel strand that form a central twisted core, which is surrounded by seven amphipathic α helices. Cleavage of C2 by C1s occurs in the N-terminal region of the vWF domain, which results in the generation of two fragments, a larger (70-kDa) C2a, consisting of most of vWF and SP domains, and a smaller (30-kDa) C2b fragment (CCP-1, CCP-2, and CCP-3).

Fragmentation of C2 exposes a C4b-binding site that is located on the C2b fragment, which interacts with C4b. C4b-C2a complex formation depends on Mg\(^{2+}\) ions, which are coordinated by residues in the metal ion-binding MIDAS (metal-ion-dependent adhesion site) motif of the vWF modules, which is also present in several integrins (see Appendix A, CD61). By electron microscopy, the C2a fragment appears as a two-lobed structure that links the C4b and C3b fragments in the final C5 convertase (see the following discussion). The C4b-C2a complex is a Ser esterase with an esterolytic activity and with the C3 as the natural substrate.

Step 3: C3b-C4b-C2a Complex: C5 Convertase

C3 Component

The C3 component of complement is the most abundant in the serum (1.2 mg/ml) and occupies the most critical position in all three C cascades. The prevailing hypothesis is that a gene that was common for all three components, C3, C4, and C5, originated from an ancestral α\(_2\)m-macroglobulin gene. Subsequent duplication formed the C4 and C3-C5 genes, and a second duplication formed separate C3 and C5 genes.

C3 comprises an α chain (110 kDa) and a β chain (75 kDa), which are connected covalently by a single disulfide bond. It is synthesized as a single protein and is modified post-translationally by a furinlike enzyme, which removes a sequence of four arginines.

Another disulfide bond within the α chain connects the N and C terminals (Fig. 14.28). C3 convertase cleaves the α chain at a site that is close to the N terminus, generating two fragments: a small C3a (9 kDa) and a large C3b (176 kDa). The C3b consists of the remaining α chain, which is linked by the disulfide bond to the intact β chain. Cleavage of the α chain of C3 by the C3 convertase exposes the thioester bond, which, in the intact molecule, is well protected within a pocket in the α chain, with a half-life of 231 hours. In the metastable C3b fragment, the bond is exposed, with a half-life of 60 microseconds. These differences strikingly express the extraordinary reactivity of the thioester bond for certain groups on the cell surfaces. The thioester bond participates in a chemical transacylation reaction that results in the attachment of C3b on OH or NH\(_2\) groups on cell surfaces, complex carbohydrates, or immune complexes that are within a radius of 600 Å from the point at which it was generated. Attachment of C3b is not discriminatory between self- and nonself-surfaces but is regulated by CCPs (see the following discussion). The selection, however, of the OH groups on the sites of binding is quite restricted. C3b expresses multiple sites for binding to other
complement proteins, which determine its fate. C3b is deposited on and around the C4b-C2a complex, binding through the thioester bond. The deposition produces an enzyme with a change in the specificity from C3 to C5, generating the C5 convertase. C3b is also deposited on other previously deposited C3b molecules, forming C3b-C3b dimers. The C3b-C4b and C3b-C3b form high-affinity binding sites for C5 and probably, the role of these dimers is to hold the substrate in a rigid position for efficient cleavage of C5. It also appears that the C3b-C3b-IgG complexes function as better precursors of convertases than monomeric C3b.
FIGURE 14.28. C3 degradation. The C3 component not only contributes to the classical pathway in the formation of the C5 convertase, it also, as a result of fragmentation, provides parts of its molecule for other important functions. For example,
C3a serves as an anaphylatoxin, C3b serves as a ligand for the CR1 receptor (CD35), C3d serves as a ligand for CR2 receptor (CD21), iC3b serves as a ligand for CR3 receptor (lymphocyte-function-associated antigen-1 integrin, CD11b/CD18) and for CD11c/CD18 integrin. (Courtesy of Dr. J. D. Lambris. From Sahu A, Lambris JD. Structure and biology of complement protein C3, a connecting link between innate and acquired immunity. Immunol Rev 2001;180:35-48, with permission.)

C3 Fragmentation

C3 is fragmented by several enzymes that generate a variety of functionally active fragments (Fig. 14.28). The activation of C3 by the C3 convertase cleaves the peptide bond between residues 726 and 727 (Arg-Ser) and generates a small C3a (9 kDa) and a large C3b (176 kDa) fragment. C3a is the N terminal of the α chain that functions as anaphylatoxin. C3b consists of the remaining α chain (α′) and the entire β chain, which are linked by the disulfide bond. C3b is inactivated by further proteolysis by factor I and one of the co-factors. The first cleavage occurs between residues 1,281 to 1,282 of the α′ chain and generates the inactivated C3b or iC3b2, which is the ligand for CD11b-CD18 integrin (see Appendix A). A second cleavage by factor I separates a small fragment C3f (2 kDa) from the α′ chain and yields another inactivated C3b or iC3b2. Factor I, with CR1 or factor H as co-factor, cleaves the α chain once more, at residues 932 and 933, to yield C3dg and C3c. The C3dg fragment is a ligand for CD21 (CR2), a component of the coreceptor complex CD19-CD21-CD81 on B cells (see Chapter 12). C3dg is cleaved by a protease into C3g and C3d fragments.

Alternate Pathway

The alternate complement pathway represents an important natural defense mechanism that is independent of the immune response (Fig. 14.25). Activation of the alternative pathway involves three components: C3, B factor, and D factor. Polysaccharides (zymosan), bacterial products, aggregated human IgA, cobra venon factor, and many other substances are activators of the alternative C cascade. The mechanisms that initiate this pathway have been the subject of much debate. The enzyme that cleaves C3 contains C3b as one of its components, which is the product of a previous C3 cleavage. The origin of the first C3b becomes a puzzling problem. Normally, the C3 continuously generates a low level of a functionally C3b-like form by a “tick-over” mechanism. The mechanism for the tick-over is not a proteolytic process, but involves the spontaneous hydrolysis of the thioester bond by H2O and the formation of a metastable C3 (H2O). The hydrolysis occurs in vitro at 37°C at a rate of 0.005% per minute.614 The C3 (H2O) is an uncleaved C3 molecule and yet has the conformation and function of a C3b in the presence of Mg2+, which provides a site for binding of the B factor.

Factor B

Factor B (90 kDa) has a similar structure to C2: it consists of three CCP modules, a vWF type A module, and a serine protease domain that are all connected by short amino acid sequences. By electron microscopy, it appears as a three-lobed structure, presumably with each module corresponding to one of the lobes.

Factor D

Factor D is a Ser protease with only one known substrate, factor B. The single Arg233-Lys234 bond of factor B becomes susceptible to the enzymatic activity of factor D only when it forms an Mg2+-dependent complex with C3b. It is the only enzyme in blood that is able to catalyze this reaction and is therefore absolutely required for alternative-pathway activation.

P. 359

The concentration of factor D in the blood is 1.8 ± 0.4 µg/ml, the lowest of any complement protein, which makes factor D the limiting factor in the activation of the alternative pathway. It is a single chain protein (24 kDa) and is structurally similar to pancreatic serine proteases. It circulates in blood in a zymogen or profactor form615 converted to the mature enzyme as a result of conformational changes. However, this first step generates a “resting” enzyme because of an inhibitory sequence loop, which prevents its activation. The active enzyme conformation is induced after binding to the substrate in a second step.

Factor D has a structure that is similar to other members of the serine proteases: the polypeptide chain is folded into two antiparallel β barrels. Each barrel consists of six β strands with the same topology in all members.611 Efficient catalysis requires three amino acids, Asp102, His57, and Ser195, forming the “catalytic triad,” and the positioning of the three residues is crucial for the synergistic action that is required for hydrolysis of the target bond. In the bottom of the substrate specificity pocket is an Asp residue, which places factor D in the category of the trypsin subfamily of serine proteases and cleaves an Arg-Lys bond of its single natural substrate, factor B.
Properdin

Properdin is one of six plasma glycoproteins that collectively comprise the alternative pathway of complement. It was first described by Pillem et al.\(^{617}\) as a novel plasma protein that activated complement in the absence of immune complexes. Properdin consists of a single chain (53 kDa), which by electron microscopy appears as a rodlike structure that forms cyclic dimers, trimers, and tetramers.\(^{518}\) The monomer consists of an N-terminal region of no known homology, followed by six thrombospondin type 1 repeats (TSRs) of approximately 60 amino acids.\(^{619}\) Repeats of this type have been identified in the cell adhesion molecule thrombospondin and in a variety of other proteins, including thrombospondin types 1 and 2 (TSP-1 and TSP-2), C6 through C9, and the circumsporozoite protein of malaria parasites.\(^{620}\)

Removal of TSR5 prevents binding to C3b and sulfatide, whereas, with the removal of TSR4, properdin is unable to stabilize the C3b-Bb complex but is still able to bind C3b and sulfatide,\(^{621,622}\) while it exists only as a monomer or a dimer. Absence of TSR3 does not affect any of the functions of properdin, including the formation of the polymers. TSR5 is important for polymer formation, because, in its absence, no cyclic polymers are detected. Properdin, as does thrombospondin, binds sulfated glycoconjugates and sulfatide with especially high affinity when it is activated. Properdin significantly contributes to linking innate and adaptive immunity. It is synthesized by endothelial cells, especially under turbulent blood flow conditions,\(^{623}\) and mRNA has been detected in neutrophils, monocytes, and T cells. In response to chemoattractants C5a or IL8, neutrophils discharge their properdin content promptly, as well as C3 and factor B, which they store within their granules. Factor D is produced locally by blood, which completes the list of the components that are essential for activation of the alternative pathway. T cells and monocytes participate in the process, because they also secrete properdin, factor B, and C3. Activation-produced fragments C3d and iC3b are essential B-cell activation factors,\(^{624}\) thus linking with the adaptive immune system.

Activation of the Alternate Complement Pathway

In the presence of Mg\(^{2+}\), C3 (H\(_2\)O; also referred to as iC3) binds factor B, which is cleaved by factor D into a large Bb and a small Ba fragment (Fig. 14.25). The Bb forms a complex with the iC3, which is termed the initial C3 convertase. Although the iC3-Bb complex is destroyed on host surfaces by factor H and factor I (see the following discussion), C3b fragments that are deposited on foreign surfaces associate with factor B in the presence of Mg\(^{2+}\). The C3b-B complex activates factor D, which cleaves factor B into Bb and Ba fragments. The distinction between activator and nonactivator surfaces is not clear. An activator surface is one that allows binding of factor B to C3b in preference of factor H (see the following discussion), thus activating the alternative pathway, and the opposite is true for nonactivators. Nonactivators can be converted to activators by removing sialic acid. A widely used activator is cobra venom factor, which binds to factor B and forms a stable C3 convertase. The factor is functionally analogous to C3b but is related structurally to C3c. It is used to deplete serum of C3 in a variety of experimental situations and is resistant to inactivation by factors H and I.

The C3b-Bb is stabilized by the serum protein properdin, which amplifies the cleavage and deposition of more C3b molecules\(^{625,626}\) to form the C5 convertase. The serine protease activity of the C3b-Bb complex, which is located in the Bb component, accelerates deposition of C3b fragments (C3b amplification), a unique feature of the alternative pathway, on and around the C3b-Bb complex. Some will form C3b-C3b dimers, which have a high affinity for C5 self-amplified C5 convertase\(^{626}\) and switch cleavage from C3 to C5, thus initiating the formation of the cytolytic C5b-9 complex. As the activation continues, at the outer ring of this circle, monomeric C3bs form more C3 convertases with factor B, which in turn deposits a new crop of C3bs, forming a new generation of C3b-C3b dimers, that is, C5 convertases. These cycles of successive outward deposition of C3 and C5 convertase activities continue until all surfaces are covered or the supply of individual components is exhausted.

Lectin Complement Pathway

The lectin pathway is an important humoral mechanism of innate immunity. It is activated by pattern-recognition receptors, such as MBL, which interacts with carbohydrates\(^ {627}\) (Fig. 14.25).

MBL is a member of the collectin family, which includes the lung surfactant proteins, SP-A and SP-D, and a protein that is localized in the hepatic cell cytosol, CL-L1. Collectins are composed of a C-terminal lectin domain (carbohydrate recognition domain) and a neck region that connects to the collagenlike region, followed by a short cross-linking region that contains two to three cysteines. The neck region forms an α-helical coiled-coil structure, which initiates the formation of a trimer. In blood, MBL is found as multimers (i.e., dimers to hexamers). MBL is a C-type lectin, as it requires Ca\(^{2+}\) for binding to a carbohydrate ligand.

Associated with MBL are four serine proteases that are known as MBL-associated serine proteases (MASPs): MASP1, MASP2, MASP3,\(^{628,629}\) and sMAP or MAP-19, a truncated form of MASP2. MASP2 and sMAP are encoded by a single gene, but two different mRNAs are generated by alternative splicing.\(^{630}\) All MASP proteases have a modular structure that is
identical to C1r-C1s: a CUB domain, an EGF-like domain, a second CUB domain, two CCP domains, and a serine protease domain. The serine protease domain is homologous to the chymotrypsinogen family. An Asp residue in the substrate specificity pocket indicates trypsinlike substrate specificity. MASP’s association with MBL is mediated by the CUB-EGF domain and is Ca\(^{2+}\) dependent.\(^6\) The MASP proteases are activated when MBL binds to conserved pathogen-associated sugar arrays that form molecular patterns, which are shared by broad classes of pathogens.\(^6\)

When MASP is activated, it cleaves C4 and C2, and the C4b fragment binds covalently to the microbial surface or the lectin itself and becomes the focus for C2 binding and activation. The remaining cascade is identical to that of the classical pathway (Fig. 14.25).

MBL binds mannose-acetyl glucosamine or GlcNAc, which are also ligands for other types of GlcNAc-binding lectins, which are termed ficolins and are present in the serum. Ficolins contain collagenlike and fibrinogenlike domains. They bind to GlcNAc through the fibrinogenlike domain. They are associated with MASPs and sMAP and have the capacity to activate the lectin complement pathway.\(^6\) In the serum, there are two types of ficolins, which are named L-ficolin and H-ficolin (Hakata antigen).\(^6\)

The recognition that is mediated by MBL and ficolins in complement activation is detected as far back in evolution as the ascidians, our closest invertebrate relatives. It indicates that the complement pathway has been important in innate immunity since before the evolution of adaptive immune systems in jawed vertebrates.

Membrane Attack Complex

C5

C5 (191 kDa) consists of two polypeptide chains, α (115 kDa) and β (75 kDa). C5 convertase selectively cleaves an Arg-Leu bond\(^7\) of the α chain, generating C5a, a potent leukocyte chemotactic peptide that consists of 74 amino acids and has considerable structural homology with C3a and C4a, the other two anaphylatoxins. The remaining larger fragment, C5b, in its nascent state constitutes the nucleus for the MAC. It possesses a metastable binding site with specificity for C6. By electron microscopy, C5 has the shape of a heart or of an ellipse, but the heart-shaped form is related to the elliptical type by rotation.\(^6\) The binding sites for C6 and C7 are located in the α chain of C5b. Interaction with C5b involves the C terminus of C6, specifically the C6c fragment that consists of two factor I modules (FiMs).

C6

C6 is a single polypeptide chain (104 kDa), which, by trypsin digestion, can be separated into an N-terminal region (C6a) with some homology to C8 and C9 and a C-terminal region (C6b) with homology to factor H and factor I. Several disulfide bonds separate discrete segments of C6, which is structurally homologous to a variety of other proteins. Overall, the primary sequence is a patchwork, with several modules that are involved in protein-protein interactions (Fig. 14.29).

Starting from the N terminus, there are several domains: two tandem TSP-1s, a class A low-density lipoprotein receptor (LDLR), an extended central segment that is referred to as the membrane attack complex perforin (MACPF) domain with homology to perforin, an EGF, a third TSP-1, two CCPs, and two FIMs, which are related to those in the H chain of the complement control factor I.\(^6\) The FIMs are specific C5-binding modules, and yet they are not absolutely necessary, probably because other hydrophobic interactions also contribute to the C5 and C6 interactions. As devices that facilitate C5 and C6 interactions, FIMs make a greater contribution to the classical pathway in which C5b density is not as high as it is in the alternative pathway, because fewer C5bs are formed in the classical pathway, and C5b half-life is shorter.\(^6\)
FIGURE 14.29. Structural organization of the C6 through C9 complement components. The last five complement components (C6 through C9) are structurally and genetically related proteins and form the membrane attack complex family. They all have a similar modular structure. In the middle of each molecule is a sequence-designated membrane attack complex perforin to emphasize its similarity with perforin. Membrane attack complex perforin is the portion of the molecule that is inserted in the membrane to form the pore. C8γ is the sixth component, which is not modular and differs structurally from the others. It is considered that the perforin gene gave rise first to the C9 gene, which evolved in retrograde, followed by the appearance of the genes for the other proteins. The modules in the C6 and C7, which are not shared by C8 and C9 (i.e., complement control protein [CCP] and factor I module [FIM]) are used to interact with C5. A, low-density lipoprotein receptor class A; B, low-density lipoprotein receptor class B (or epidermal growth factor precursor module); TSP-1, thrombospondin 1.

The secondary structure of C6 is a mixture of α helices and β sheets. The α helices reside in MACPF, which is free of disulfide bonds. By transmission electron microscopy, C6 appears as a sickle.

C7

C7 is a single polypeptide (97 kDa), which, like C6, is a mosaic of several modules that are found in other proteins. Starting from the N terminus, C7 has one TSP1, one LDLR type A (LDLRA), a second TSP1, two CCPs, and two FIMs. Its secondary structure is high in β sheets (38%), and, by electron microscopy, it appears as a flexible elongated molecule (151-59-43 Å). The three components C5-C6-C7 in a fluid phase form rosettes as a consequence of radial aggregation. However, the complexes on a phospholipid area insert themselves, anchoring by the stalk, whereas the Cys-rich segments fasten the complex for the assembly of the MAC. The C5b-7 complex does not traverse the phospholipid membrane and does not cause lysis. The long flexible stalk of C7 provides greater surface area for interaction within the membrane.

P.361

C8

The C8 component consists of three chains: α (64 kDa), β (64 kDa), and γ (22 kDa), all being encoded by separate genes. The C8α and C8γ are linked by a single disulfide bond, and the C8α-C8β heterodimer is associated noncovalently with C8β through a binding site on the C8α chain. The α chain interacts with C9, directs the insertion into the membrane of the first C9 in the formation of MAC, and interacts with lipids, thus becoming accessible to MAC formation. Note that together with the membrane protein CD59, they inhibit MAC formation in homologous cells and protect them from lysis.
The C8β chain has three binding sites for C8α, the C5b-7 complex, and membrane lipids. For binding of C8β to the C8α-γ complex, the N-terminal TSP1, LDLRA, and the MACPF segment are most important, and, furthermore, they mediate the incorporation of C8 into the MAC.640

The C8 α and β chains are structurally related and are members of the MAC family, whereas the C8 γ chain is a member of the lipocalin family, which is unrelated to the MAC family.641 The lipocalins are widely distributed proteins that are involved in the transport of small lipophilic substances, such as retinol and pheromones, but C8 does not bind retinol. They all share the same folding pattern, which is known as the lipocalin fold. Strikingly, C8γ is the only protein from a different family among the 35 proteins of the complement system. Furthermore, C8γ is not absolutely required for the expression of C8 activity by the α and β chains, but it enhances their function.642 The crystal structure of C8γ has been solved and confirms its lipocalin fold and, furthermore, identifies its structural relationship to the neutrophil gelatinase, a protein that is released from the granules of activated neutrophils.643 Overall, it forms a calyx with a distinct large hydrophobic cavity at the base of the calyx for ligand binding.

C9

Complement component C9 is a single polypeptide chain (71 kDa) that has a modular structure that is similar to that of the other members of the MAC family: an N-terminal TSP1; an LDLR-A; the extended central sequence MACPF, which is homologous to perforin644; and an EGF module in the C-terminal end. C9 is endowed with the capacity to polymerize spontaneously in a circular fashion and to create tubules.

Membrane Attack Complex Formation

The C5b-7 complex binds to the cell membrane, and, although it inflicts no harm on the cell, it marks it for subsequent assault by C8 (Fig. 14.25). The C5b-8 complex appears foliaceous by electron microscopy, with branched structures radiating from the central pedicle, but, on smaller phospholipid vesicles, C5b-8 monomers appear as long rodlike structures that are 250 Å wide.645 The C8α chain mediates binding and self-polymerization of C9 to form MAC.646 The N-terminal TSP1 and LDLRA modules are the principal binding sites for C9 with the cooperative function of MACPF domain. MACs are heterogeneous in size, probably as a result of their composition, and the number of the C9 subunits may vary from 1 to 18, whereas all other components contribute only one molecule.647

The final molecular weight of the MAC therefore varies between 66 and 1,850 kDa. The average C9 binding capacity per C8 molecule is 15.4 molecules. C9 polymerizes spontaneously, but the C5b-8-induced rate of C9 polymerization is 10,000-fold greater. Self-associating C9 complexes develop new antigenic determinants that are not present in the monomer. C9 is inserted into the membrane through its C-terminal region, and disulfide bonds stabilize the complex. Electron microscopically, the polymerized C9 appears as a cylinder that extends 120 Å above the cell surface. The extracellular hydrophilic end terminates in an annulus that is 30 Å thick, with an inner diameter of approximately 100 Å645 (Fig. 14.30). The C5b-8 is attached firmly to the C9 cylinder and actually extends 160 to 180 Å above the annulus. The annulus, which is seen with computer-assisted programs, appears to be made of whorls646 (Fig. 14.30).
FIGURE 14.30. A: C9 molecule in its monomeric form, folded (left) or unfolded (right) and in its polymerized form (center) as a tubular structure that is seen on cell membranes. B: Poly C9 as ring structures (top view) or tubules (side view). (Courtesy of Dr. E. R. Podack. From Podack ER, Tschopp J. Polymerization of the ninth component of complement (C9): formation of poly(C9) with a tubular ultrastructure resembling the membrane attack complex of complement. Proc Natl Acad Sci U S A 1982;79:574-578.) C: Lipid vesicle with a typical cylinder that is formed from polymerization of C9 (side view). The cylinder penetrates the wall and protrudes to the outside, above the surface of the vesicle. D: Lesions that are induced by complement on sheep red blood cell membranes clearly show cylindric structures of the membrane attack complex and its penetration into the membrane (arrows). (Courtesy of Dr. S. Bhakdi. From Bhakdi S, Tranum-Jensen J. Molecular nature of the complement lesion. Proc Natl Acad Sci U S A 1978;75:5655-5659.)

Because the height of the monomeric C9 is only 80 Å, and the poly C9 cylinder is 160 Å, the C9 must be unfolding and must transform into a rodlike structure. Thus, the formation of the cylinder by polymerization of C9 molecules involves the transformation of a hydrophilic C9 monomer into an amphiphilic C9 polymer.

The N-terminal part of C9 does not participate directly in polymerization and is located in the upper rim of the cylinder. The MACPF domain traverses across the thickness of the cell membrane, forming the wall of the cylinder. The C terminal part of C9 returns back up near the rim, indicating that polymerization transforms a straight ellipsoid C9 into a U shape.
C9 aligns with other molecules side by side, like staves of a barrel forming a volutelike structure (i.e., a capital of an Ionian-style Greek column). Not all agree with the cylinder model of MAC. Others suggest that MAC proteins cause a distortion of the phospholipid bilayer, thus creating “leaky patches.”

REGULATION OF COMPLEMENT ACTIVATION

A large number of proteins, known as complement control proteins, are involved in the regulation of complement activation (Table 14.6). This complex regulatory system is best understood if we consider the stages of complement activation that are regulated or whether CCPs exist in fluids versus cellular surfaces. CCPs exert regulation mainly by accelerating dissociation of the convertases, a function that is known as decay-accelerating activity (DAA), or by acting as co-factors to the serine protease factor I, a function that is known as co-factor activity (CA). Some regulators are able to serve as both decay accelerators and co-factors, such as factor H, C4-binding protein (C4bp), and complement receptor 1 (CD35).

Membrane attack
Control of the Initiation Step

C1 Inhibitor

C1 inhibitor (C1 INH) is a heavily glycosylated α-globulin with a molecular weight of 105 kDa. It is synthesized in the liver and by blood monocytes. Its gene is located on chromosome 11. C1 INH belongs to the superfamily of serpin proteins (serine protease inhibitors). The inhibitor possesses a site that is structurally similar to the substrate, and, when a protease binds to this site and cleaves a peptide bond, it forms a covalent bond that results in a stable complex between the inhibitor and the enzyme. C1 INH inhibits activation of the classical and alternative pathways. It binds to C1r and C1s, forming stable complexes that prevent them from acting as an esterase. It also binds to the C1r-C1s complex and causes rapid dissociation of the C1 esterase. In the alternative pathway, it prevents factor B from binding to immobilized C3b. Cleavage of factor B by factor D is markedly inhibited when C3b is incubated with C1 INH. A genetically inherited deficiency of C1 INH is manifested by recurrent acute attacks of circumscribed edema. Hereditary angioneurotic edema (HAE) may cause death from laryngeal edema. The mortality rate that is associated with this condition has been reduced with androgen therapy. This disease assumes two forms. In most (85%) cases (type 1 HAE), the inhibitor is present in reduced concentrations, whereas in the second form (type 2 HAE), it is present in normal concentrations, but is biologically inactive.

Control of C3 and C5 Convertases

The C3 convertase cleaves C3 to C3b and C3a, whereas the C5 convertase cleaves C5 and initiates the final stage that ends with the formation of MAC. These amplification steps are regulated by seven proteins: three of them are present in the serum (C4BP, factor H, and factor I), and four are cell membrane proteins [MCP, decay-accelerating factor (DAF or CD55), CR1, and CR2]. The overall function of these proteins is to prevent formation of the two convertases on self cells. Except for factor I, all other proteins belong to a structurally related family of proteins that is known as the complement control proteins. The genes are clustered on the long arm of chromosome 1q32.

A striking structural feature that is common to these proteins is the multiple homologous cysteine-rich domains, a 60 amino acid sequence referred to as CCP repeats. The CCP module or repeat has four li cysteines, an li tryptophan and highly conserved prolines, glycines and hydrophobic residues. The number of CCP domains are 30 in CR1, 20 in factor H and 4 in CD55. The 60 amino acid unit represents an ancestral domain that gave rise to the complement genes through duplication and splicing. The CCP domains are found in other complement proteins, such as C1r, C1s, C2, and factor B, as well as in noncomplement proteins, such as IL-2 receptor, haptoglobin, and coagulation factor XIII. Each CCP domain has a hydrophobic core that is interlaced with β strands connected by protruding loops, possessing a privileged position for interactions with other proteins. The control of the convertases is achieved by two mechanisms: (a) by dissociating the convertase to its individual components (DAA) and (b) by proteolytic degradation of C4b or C3b components as a result of the CA of the RCA proteins that act as co-factors for the serine protease, factor I. Some proteins have DAA and CA activity in the serum (C4BP, factor H) or cell surface (CR1), whereas others possess only one activity for the C4b and C3b components.

Regulators on Cell Surfaces

Membrane Co-factor Protein (CD46)

The extracellular region of membrane co-factor protein (MCP) consists of four CCP domains that contain the binding site for C3b and C4b and a region that is rich in serines, threonines, and prolines. The serine, threonine, and proline region is O-glycosylated and provides protection from proteolysis. A portion of this region may be removed by alternative splicing, which generates two of the four MCP isoforms. Two alternate forms of cytoplasmic regions contribute to the formation of another two MCP isoforms. MCP is present in almost all cells examined, except for red blood cells. Sites for C3b binding are in CCP2, CCP3, and CCP4 domains. The C3b and C4b binding sites have residues that bind to both complement...
components as well as others that are specific for each component. MCP acts as co-factor for the serine protease factor I for inactivation of C4b that is deposited on self-tissues. MCP in the maternal-fetal interface protects the fetal tissue from attack by the maternal complement. It is found on the inner membrane of the spermatozoa and may play a role in protecting the sperm against C3b deposition. MCP is a receptor for several pathogens. The measles virus binds to an extended surface of MCP that encompasses the area from the top of CCP1 to the bottom of CCP2. The measles virus binding to CD46 is more like that of polio virus to its receptor: a wider open area that is flexibly hinged between CCP1 and CCP2 domains. This leaves the virus still exposed to immune attack. It contrasts with the narrow, recessed binding site or canyon in the case of HIV and rhinoviruses. The P.363

M protein of Streptococcus pyogenes, which causes serious suppurative skin infections (e.g., cellulitis, necrotizing fasciitis), binds directly to CCP3 and CCP4 domains at a site that is distinct from the C3b-binding site. MCP mediates adherence of group A streptococci to keratinocytes. HHV-6 also uses CD46 as a receptor and binds to CCP2 and CCP3.

Decay-accelerating Factor (CD55)

DAF contains four CCP domains and is attached to the membrane by a GPI anchor. Its molecular weight is between 70 and 80 kDa, depending on its glycosylation. Soluble forms exist in body fluids that may arise from the action of a phospholipase on the membrane form. It is expressed on all hematopoietic cells, endothelial and epithelial cells, and cells of the gastrointestinal, genitourinary, and central nervous systems. Erythrocytes possess approximately 3,000 DAF molecules, and, among the lymphoid cells, the NK cells appear to be deficient in DAF. Neutrophil activation results in enhanced expression of DAF (from 10,000 to 20,000 molecules per cell). It is present in a soluble form in many body fluids, including plasma, tears, saliva, urine, synovial fluid, and cerebrospinal fluid.

DAF accelerates the decay of C3 convertase for the classical and alternative pathways but prevents its formation (Fig. 14.31). Regulation by DAF involves separate sites for the two convertases as well as common sites for both. For the alternative C3 convertase, DAF acts on the type A domain (vWF type A domain) of the Bb component. Classical C3 convertase is regulated by a site that is located in the CCP2-CCP3 domain junction, which consists of three consecutive lysines and a hydrophobic patch. DAF is used as receptor by many pathogens, such as several types of echoviruses, enteroviruses, and E. coli. It constitutes a functional component of the LPS receptor complex. CD55 is the ligand (counterreceptor?) of CD97, the prototype of a large seven-span transmembrane family (as many as 2,000 members) with variable numbers of EGF domains and sequence homology to the G-protein-coupled peptide hormone receptors. CD97 is associated with inflammation and is detected in malignancies.

Complement Receptor 1

Receptors for complement components or their breakdown products are expressed on many cells and tissues. They mediate various effector functions listed in Table 14.7. Some of the functions of complement receptors that are related to the regulation of complement activation are briefly reviewed. The complement receptor type one (CR1, C3b/C4b receptor, CD35) was the first to be discovered as the receptor for immune adherence, a fundamental event in the initiation of the immune response. It is a polymorphic membrane protein of 190 to 280 kDa composed of 2,039 residues and present on all peripheral blood cells except platelets, NK cells, and most T cells. CR1 is expressed on kidney podocytes and FDCs. Cell membrane expression of CR1 is up-regulated by chemotactic peptides, such as C5a, endotoxin, and cytokines. Blood cells at resting state express only 5% to 10% of the total cellular CR1 at the plasma membrane, whereas the remaining CR1 is found intracellularly. The red blood cells express 100 to 400 receptors per cell, and the leukocytes have 10,000 to 50,000 receptors per cell. However, because the number of red cells is approximately 1,000 times more than white cells, they possess more than 85% of the total CR1 that is available in the blood.
FIGURE 14.31. A, B: Decay activity on cell surfaces. A: Decay-accelerating factor (DAF, CD55) is a GP I-anchored protein, which dissociates formed C3 convertase complex, as well as prevents its formation. B: Factor H is a serum protein that expresses DA activity by attacking C3 convertases on self surfaces. It binds to the C3b-Bb complex and displaces factor B irreversibly. C, D: Co-factor activity. C: Membrane co-factor protein (MCP, CD46) is a cell membrane protein, which contains binding sites for C3b and C4b. It acts as co-factor for factor I to cleave both proteins. It is also the measles virus receptor. D: The C4b-binding protein (C4BP) is a serum protein that acts as a co-factor for factor I for cleaving C4b.

CR1 contains 30 CCP domains with three sites for C4b binding and two sites for C3b binding. The CCP15 domain is critical for C4b binding and, together with the CCP16 domain, is required for C3b binding. The CCP domains are arranged in larger domains that are known as long homologous repeats, with each one containing seven CCPs. It is likely that this arrangement facilitates the binding of CR1 with clusters of its ligands. There are four allotypes of CR1 (A through D). CR1, one of the most versatile RCAs, possesses DAA and CA, which are restricted to reducing the complement activity on cells that have absorbed immune complexes. The DAA of CD35 is mediated by CCP1 to CCP3 domains for the classical and alternative pathways. In the classical pathway, CR1 inhibits the uptake of C2 by C4b as well as displaces C2a from C4b2a C3 convertase and from C4b2a3b C5 convertase. It also promotes the cleavage of C4b to C4c and C4d by factor I and the P.364 cleavage of C3b to iC3b (ligand of CR3) and C3dg (ligand of CR2) by factor I. In the alternative pathway, the CR1 impairs uptake of factor B by C3b and displaces Bb from C3bBb C3 convertase. Complexes that are bound to erythrocytes are eliminated in the spleen. Conversion of C3b to fragments leads to binding of the complexes to macrophages and monocytes that possess CR3 or to lymphoid follicular areas in which all three CR are expressed.

The CR1 has the capacity to inhibit complement activation on cells and tissues other than those in which it is expressed (extrinsic protection), whereas DAF and MCP protect only the cells on which they are expressed (intrinsic protection). CR1 facilitates phagocytosis which in the absence of other ligands does not occur with resting neutrophils or monocytes. However, activation of these cells up-regulates CR1 expression and alters its function, so that phagocytosis of C3b-coated particles may occur. Soluble human CR1 inhibits complement-dependent tissue damage and reduces inflammatory responses.

Regulators in Body Fluids

Factor H

Factor H is a soluble glycoprotein that is present in blood at concentrations of 0.3 to 0.5 mg/L. It is a single polypeptide chain of 150 kDa with a highly elongated shape. It is composed of 1,213 amino acids that are assembled in 20 CCP domains. Factor H synthesis in the liver and in other extrahepatic sites (myeloblasts) is regulated by IL6.

The main functions of factor H are (a) binding to the α chain of C3b, blocking the amplification cycle in the alternative pathway (tick-over), and preventing the generation of C3 convertase, C3bBb; (b) binding to the C3bBb enzyme and irreversibly displacing the Bb component (DA activity); and (c) acting as co-factor for factor I and enhancing its affinity for C3b. By these three activities, factor H prevents formation of the C5 convertase and, thus, the generation of MACs by the alternative pathway. Factor H possesses an impressive number of discriminatory functional sites. Its 20 CCP domains and its long and flexible structure allow factor H to scan a large surface area. The affinity of factor H for C3b is affected by the properties of the cell or tissue surface. Carbohydrate-rich polymers that are found on yeast and bacterial cells prevent binding of factor H to C3b, thus enabling the complement activation to react against these pathogens. Removal of sialic acid from sheep erythrocytes prevents binding of factor H to C3b and allows activation of complement.

Factor H binds to polyanions and blocking of this site enhances its affinity for C3b. The propensity of factor H to bind on polyanions, such as heparin on host tissues, may function as a protective mechanism against the alternative complement pathway. The discriminatory ability of factor H depends on its differential binding to various types of surfaces to which C3b has been initially deposited (Fig. 14.32). The nonactivating surfaces have sialic acid and other negatively charged glycosaminoglycans to which factor H binds through domain CCP20. The same domain is important for binding within approximately 30 Å from the C3d attachment site, indicating that the binding sites of factor H for polyanion and C3d
It is possible that discrimination by factor H occurs by a joint recognition of C3 and polyanions. The CCP11 to CCP20 domains are important for binding to activator surfaces, but the DAA or CA varies among these CCPs, depending on the nature of the surface on which C3b has been deposited. It appears that factor H uses different CCP domains, individually or in combinations, for recognition of C3, host, or foreign tissues. The CCP1 to CCP4 domains are used to bind intact C3b, the CCP6 to CCP10 domains are used for binding C3c within the C3b, and the CCP16 to CCP20 domains are used for the C3d part of the C3b. Recently, single-base mutations or base pair deletions have been demonstrated in sporadic and familial cases of hemolytic uremic syndrome (HUS). HUS is characterized by microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure in affected individuals and is classified as diarrheal (D+ HUS) or nondiarrheal (D- HUS) and as sporadic or familial.

![Diagram](image)

**FIGURE 14.32.** Self-/nonself-discrimination by factor H. A: Factor H prevents alternative complement activation by blocking the amplification cycle of the alternative pathway. It enhances its affinity to C3b as a result of binding to certain polyanions (negatively charged glycosaminoglycans) on self surfaces. Binding to C3b invites factor I to fragment C3b (cofactor activity). B: On pathogen surfaces, factor B expresses a higher affinity to deposited C3b and, with a lack of appropriate carbohydrate ligand for factor H, forms the alternative C3 convertase.

A set of 12 missense mutations in the CCP domains between CCP16 through CCP20 is associated with HUS. Nine of them are in CCP20 and are inferred to lead to a functional defect. The positions of these mutations correspond to basic residues that are involved in binding to heparin. It is suggested that these mutations interfere with the normal function of factor H to bind to sulfated glycosaminoglycans and to prevent the activation of the alternative complement pathway.
These experiments of nature strongly imply that the host-versus-foreign discrimination by factor H resides in CCP20 and is lost by these mutations. Lack of host recognition results in uncontrolled complement activation and, eventually, renal failure.

Mice that are deficient in factor H develop membranoproliferative glomerulonephritis as a result of uncontrolled activation of the alternative complement pathway. Factor H consists of several members; factor-H-like protein 1 (FHL-1) or reconectin, shares the complement regulatory functions with factor H and interacts with heparin. It contains the first seven of 20 CCP domains of factor H and has four unique residues that are attached to the terminal end. Both factor H and FHL-1 are synthesized by the same gene, but their transcripts are differentially regulated. They are produced by the liver, monocytes, and neuronal cells. Other members of the family are factor-H-related (FHR) proteins 3 and 4 (FHR-3 and FHR-4) which bind to C3b and particularly to C3d fragment.

**C4B-binding Protein**

The C4b-binding protein (C4BP) is a regulator of the classical complement pathway C3 convertase. C4BP possesses CA and DAA. It consists of eight subunits that radiate from a central core in a spiderlike formation (Fig. 14.33). The peripheral end of each subunit is capable of binding one C4 molecule. Each of the seven

subunits known as α chains has a molecular weight of 75 kDa, and the eighth subunit, known as a β chain, is 45 kDa. They are flexible, 33 nm in length, and are linked together by disulfide bonds near the carboxy termini. In addition to the most common form of C4BP, α7;β1, there are two other minor forms, α7;β0 and α6;β1. The α chains are composed of 549 amino acids divided into eight CCP domains, with 58 residues left in the C terminus to form the disulfide bond with the other α chains in the core region. The β chains have three CCP domains and are attached by a disulfide bond in a similar way to the α chains. The genes for C4BP are within the gene cluster of the other RCA proteins. The C4b-binding site is localized in the CCP1 and CCP2 domains of the α chain, in a cluster of positively charged amino acids. The same region is also important for binding to heparin, Bordetella pertussis, and the M-protein of S. pyogenes, Neisseria gonorrhoeae, and E. coli.

---

**FIGURE 14.33.** Electron micrographs of the C4b (A) and the C4b-binding protein (B) that form complexes with C4b (C). (Courtesy of Dr. B. Dahlback. From Dahlback B, Smith CA, Muller-Eberhard HJ. Visualization of human C4b-binding protein and its complexes with vitamin K-dependent protein S and complement protein C4b. Proc Natl Acad Sci U S A 1983;80:3461-3465, with permission.)

C4BP is synthesized in the liver under stimulation of IL6 and TNF-α and is present in the blood at a concentration of 0.2 mg/L. The mechanism of control of the classical pathway by C4BP depends on the binding to C4b and the displacement of C2a from the C4b2a convertase (DAA), as well as its function as a co-factor for cleavage of C4b by factor I. Dissociation of
C2a from the classical pathway C3 convertase destroys its activity and prevents rebinding of the C2a to C4b. C4BP acts also as co-factor for cleavage of C3b by factor I. 687

Protein S binds with high affinity to the β chain of C4BP. 688 Protein S of the coagulation pathway is a vitamin-K-dependent anticoagulant protein. It acts as the co-factor for activated protein C that inactivates factor Va and is also the direct inhibitor of factor Xa. The concentration of free protein S is determined by the concentration of C4BP, as 50% or more of protein S is bound to C4BP. Protein S that is bound to C4BP is unable to participate in the anticoagulant protein C system. It is critical that the balance between free and C4BP-bound protein S is maintained stable, because lack of free protein S leads to thrombosis. Protein-S-bound C4BP is probably localized on negatively charged surfaces that are found in platelets and apoptotic cells. Conditions with elevated C4BP (autoimmune diseases) may be associated with increased clotting tendency as a result of increased binding of protein S to C4BP.

Factor I

Factor I is a serine protease that mediates proteolytic degradation of C3b, iC3b, and C4b only if a co-factor binds to the substrate to promote the binding of the enzyme. These co-factors for C3 and C4 degradation on host cells are MCP (Fig. 14.31), and, to a lesser extent, CR1, whereas in plasma the co-factors are C4BP and factor H (Figs. 14.31 and 14.32). Factor I is constitutively active and essential for control of the fluid and cellular complement reactions. Genetic deficiency of factor I leaves the generation of C3 convertases uncontrolled, leading to incapacitation of the complement system as a result of the continuous low-level conversion of C3. Fragmentation by factor I of C3 and C4 determines the specificity of their derivatives for CR1, CR2, and CR3. Factor I is a two-chain disulfide-linked protein that is synthesized from a single-chain precursor. The H chain is 50 kDa, and the L chain is 38 kDa in molecular mass and has the Ser esterase domain. The H chain is composed of three different types of modules that are derived from different gene superfamilies. One module, which is also found in C6 and C7, is from members of the follistatin family of the extracellular matrix, a second type is a scavenger-receptor cysteine-rich module, and the third type are two LDLR-A modules.

The only known substrates for factor I are C3b and C4b. C3b is cleaved at Arg1303-Ser1304 and Arg1320-Ser1321. For this cleavage, the co-factors are factor H, MCP, and CR1. C4BP acts as a co-factor for cleavage of C4b and C3b. C4b is cleaved at Arg1336-Asn1337. In general, for C3b and C4b and all subsequent fragments, factor I acts on the C-terminal side of an Arg.

Control of the Membrane Attack Complex Assembly

Protein S

Protein S is identical to vitronectin (serum spreading factor). It is a 75- to 80-kDa protein that is synthesized from a single polypeptide chain that is subsequently cleaved to give the mature polypeptide as a single or double chain protein. At the NH₂ terminus, there is a somatomedin B domain (containing eight cysteines) followed by a linear sequence, which contains the RGD sequence

P.366

that is responsible for the binding of integrins. Two domains of the S protein have homology to hemopexin. The C terminus is rich in basic residues that mediate the binding of S protein with sulfated polysaccharides.

Protein S binds to the metastable C5b-7 complex and prevents the formation of MAC. Because MAC in the process of its formation can be inserted on any cell membrane, the most important function of S protein is the protection of the cells of the body that may be attacked by MAC as innocent bystanders. Protein S acts through its heparin-binding site, which prevents the polymerization of C9. The protein S is important in cell matrix interactions, and, through its multiple binding sites, it participates in several other functions of adherence, phagocytosis, the coagulation cascade in which it interacts with thrombin.

Clusterin (Cytolysis Inhibitor)

Clusterin is an 80-kDa protein composed of two chains (α and β). The gene is located on chromosome 8p21-p12. It is present in a variety of tissues and in the serum at concentrations of 35 to 105 µg/L. It forms complexes with lipoproteins and binds to C7, C8b, and C9, to inhibit MAC formation. 689

Clusterin is involved in several other poorly understood functions. It has been found to be up-regulated in injured tissues and in Alzheimer’s disease, as well as in tissues undergoing apoptosis.

Control of Deposited MAC: CD59
CD59 is an 18- to 20-kDa protein that inhibits MAC formation. It has been known by a variety of other names, such as homologous restriction factor 20, membrane inhibitor of reactive lysis, and protectin. It is a GPI-anchored protein and is widely distributed in human tissues and most body fluids (see the following discussion). CD59 expression is lacking in patients with paroxysmal nocturnal hemoglobinuria (PNH).

Conclusion

The RCA proteins exert several important functions in the regulation of complement activity: (a) they prevent complement activation in the blood (factor H and C4BP); (b) they interfere with the assembly and function of convertase activity on cell membranes (DAF and MCP), protecting the cells of the body from complement attack; (c) they transport and clear immune complexes (CR1); and (d) they mediate transmembrane and intracellular trafficking (CR1) and transmembrane signaling (CR2).

The CCP units that are characteristic of the members of the proteins of the RCA gene cluster are present also in C1r, C6, C7, factor B, properdin, and noncomplement proteins, such as coagulation factor XIII and IL2 receptor. The 60 amino acid unit represents an ancestral domain that gave rise to the complement genes through duplication and splicing with domains from the serine protease gene family.

ANAPHYLATOXINS

Activation of the complement cascade leads to the release of important inflammatory factors that are known as anaphylatoxins: the C3a, C4a, and C5a molecules. Their amino acid sequence varies from 74 to 78 residues. The cysteines are conserved in all anaphylatoxins and form three disulfide bonds that stabilize the conformation and form the core of the molecule. The C terminus forms the active site, with the C-terminal Arg being essential for function. Under physiologic conditions, the molecule is folded or compact.

The C-terminal end protrudes from the core and is considered to be the active site of the molecule that mediates biologic activities. Removal of the last Arg (C5a desArg) results in a loss of spasmogenic activity, but the chemotactic and other neutrophil activation functions are retained. The N-terminal region of C5a binds to its high-affinity receptor on neutrophils, which spans the membrane seven times with the N terminus on the extracellular side. It belongs to the rhodopsin family of receptors, the members of which are linked to G proteins. Binding of C5a to its receptor on neutrophils induces a variety of responses, depending on its concentration, such as chemotaxis, granule secretion, up-regulation of adhesion molecules, changes of cytoskeleton, and activation of NADPH oxidase.

All anaphylatoxins are cleaved rapidly in the serum by carboxypeptidase-N, an enzyme that removes the C-terminal Arg that is found on all three anaphylatoxins. The main biologic function of anaphylatoxins is related to their ability to increase vascular permeability as a result of mast-cell degranulation. Anaphylatoxins also cause serious lung injury because of their capacity to recruit and sequester leukocytes in the pulmonary circulation. Anaphylatoxins also mediate production of oxygen and nitrogen-derived radicals, leukocyte margination, release of granule-associated proteolytic enzymes and capillary leakage, all components of an inflammatory response.

COMPLEMENT COMPONENT DEFICIENCIES

C1 Esterase Inhibitor: Hereditary Angioneurotic Edema

HAE is an autosomal dominant disease that affects persons of all races with no sex predominance. It manifests as recurrent attacks of intense, massive localized edema without pruritus and in the absence of any identifiable initiating event. Gastrointestinal and respiratory systems are most commonly involved with upper airways symptoms, including risk of asphyxiation. There are two types of HAE: type 1 (80% to 85% of cases) caused by decreased production of C1 INH and type 2 (15% to 20%) caused by a functionally impaired C1 INH (C1 esterase inhibitor).

C1 INH belongs to the same family as α1-antitrypsin; antithrombin IFN-γ and IL6 stimulate its synthesis and release from the liver and monocytes. The main function of C1 INH is prevention of autoactivation of the complement cascade. It also inactivates coagulation factors XIIa, XIIF, and XId and activated kallikrein. The mechanism of action involves formation of irreversible covalent bonds with the substrates.

Under physiologic conditions, small quantities of factor XII are autoactivated to factor XIIa and trigger the contact system, which cleaves prekallikrein to kallikrein; this cleaves kininogen, generating excessive release of kinins especially bradykinin. This pathway normally is blocked by C1 INH, which inhibits factor XIIa. In the absence of the normal control function of C1 INH, not only is factor XIIa not inhibited, but kallikrein also generates plasmin from plasminogen, activating factor XIIa for more kallikrein as well as activation of the C1 esterase.

Deficiency of Other Early Complement Components
Homozygous deficiencies of the early components of the classical pathway are associated with SLE, and the severity of the associated disease is greatest with C1q deficiency. This is caused by failure of C1q synthesis or synthesis of a dysfunctional molecule. C4 deficiency is associated with early onset of severe SLE. C2 deficiency is the most common homozygous complement deficiency in whites; C3 deficiency is associated with recurrent pyogenic infections, and deficiency of factor H has been associated with membranoproliferative glomerulonephritis.

P.367

Paroxysmal Nocturnal Hemoglobinuria: Deficiencies of Decay-accelerating Factor (CD55) or Clustering (CD59), or Both

PNH is an acquired hematopoietic stem cell disorder, which is manifested by intravascular hemolysis, venous thrombosis, aplastic anemia, myelodysplasia, and leukemia. The defect is the result of somatic mutations that consist of deletions, insertions, or point mutations of the PIGA (phosphatidyl inositol glycan complementation class A) gene, which is involved in the synthesis of GPI.

The GPI anchor consists of three components: (a) phosphoethanolamine (PEA), (b) a glycan core formed by three mannose molecules and one GlcNAc, and (c) PI.

Glycosyl Phosphatidyl Inositol Biosynthesis

GPI synthesis involves multiple steps and takes place in the ER (Fig. 14.34). Initially, GlcNAc is attached to PI, by the GPI-N-acetyltransferase, a complex enzyme that is composed of at least six proteins encoded in genes located on the short arm of the X chromosome, and PIGA, PIGH, PIGC, PIGQ, PIGP, and DPM (dolichol phosphate mannose).

In humans, there is only one PEA, which is added to the third mannose. PIGO is responsible for such a reaction, and its function is stabilized by PIGF. PIGN is involved in the addition of PEA to the first mannose. Once the synthesis of GPI is complete, it is transferred to the protein by a transamidase complex. This complex consists of PIGK (GPI8), a small protein that is a protease, and PIGT (GPI16), PIGS (GPI17), and GPAA1-GAA1 proteins. These proteins interact physically with each other, but PIGT is the most important for the stability of the complex. The protein to have the GPI attached is first processed by removing the N-terminal leader peptide. The protein bound on the luminal side by a C-terminal peptide is translocated to the transamidase complex in the presence of the BiP chaperon. The C-terminal peptide of the protein is removed, and the transamidase complex attaches the GPI through the ethanolamine head to the newly exposed C terminal (ω site). This C-atom is linked to the amino group of PEA, which is attached to the third mannose by an amide bond.

Paroxysmal Nocturnal Hemoglobinuria: Immunopathology

The biochemical defect of PNH occurs in the first step of GPI synthesis and results from mutations in the PIGA gene. Because PIGA is on the X chromosome, one mutational event is sufficient to cause the disease. Cell proteins that are anchored by GPI are missing from PNH hematopoietic cells, and some of the clinical manifestations are due to loss of GPI-anchored proteins. Lack of CD55 alone is not responsible for the hemolytic component of the disease, because individuals with the Inab phenotype in which CD55 is absent have only slightly increased sensitivity. CD59, which binds to C3 and prevents binding and subsequent polymerization of C9, accounts for the intravascular hemolysis and, possibly, thrombosis in PNH.

In addition to hemolysis, thrombosis is an important manifestation of PNH. Thrombosis is probably caused by the release of microparticles from platelets with procoagulant activity, such as particles that are rich in factor Va, factor Xa, and the prothrombinase complex. Endothelial cells are stimulated to express tissue factor and may contribute to thrombosis. Furthermore, lack of the urokinase plasminogen activator receptor (uPAR CD87), a GPI-anchored protein, is absent. Normally, it binds urokinase on the surface of granulocytes and monocytes, converting plasminogen to plasmin-initiating fibrinolysis and its lack may promote thrombosis. An important, albeit still unanswered, question is the relationship of PNH to bone marrow aplasia or myelodysplasia and the development of acute myelogenous leukemia. Normal stem cells from patients with PNH show diminished proliferative potential in vitro compared to mutant PNH CD34+ stem cells. The PNH clone with a proliferative advantage expands and dominates the normal cells. It has been suggested that PNH is expressed only when normal hematopoiesis is impaired and when the PNH clone dominates hematopoiesis. This is supported by some evidence that a tiny proportion of PIGA progeny exists in normal individuals.
FIGURE 14.34. Biosynthesis of glycosyl phosphatidyl inositol (GPI). GPI consists of three components: (a) phosphatidyl inositol (PI), (b) glycan (made of one N-glucosamine and three mannose molecules), and (c) one phosphoethanolamine.
(PEA). GPI anchored is synthesized in the endoplasmic reticulum and to proteins, expressing a signal that is encoded in the C-terminal sequence. The signal sequence is cleaved to expose the GPI attachment site (ω site). The first of several steps (1) in GPI biosynthesis attaches N-acetyl glucosamine (GlcNAc) to PI, by the enzyme GlcNAc transferase. The acetyl group is removed in the second step (2) by a deacetylase. Subsequently, three mannose (M) molecules are added by different mannose transferases (3) (attachment bonds differ), and, finally, the PEA molecule is attached by a PEA transferase. The attachment of the completed GPI to the protein is mediated by a transamidase complex. The first enzyme, GlcNAc transferase, is a complex of at least five gene products (see the text for details). Phosphatidyl inositol glycan complementation class A (PIG-A) performs the catalytic function of the enzyme, and mutations in this gene result in paroxysmal nocturnal hemoglobinuria.

Deficiencies of Terminal Complement Components

Deficiencies of the terminal complement components, such as C7, have been detected in several countries, whereas C6 has been detected primarily in blacks in the United States and in South Africa, and the majority of C9 deficiencies have been found in Japan. C6 deficiency has been defined as quantitatively zero C6 (C6Q0) or subtotal C6 (C6SD), when C6 is structurally abnormal but hemolytically active.

Deficiencies are due to single-base deletions or mutations that lead to premature stop codons. In C6 deficiency there is a tendency for mutations in exon 6 with defects in an area that is adjacent to a sequence that contains seven Gs and a string of six Ts. Carboxy terminally truncated C6, which results in a shorter dysmorphic, but functionally active, molecule, has been detected in South African families. Complement component C6 deficiency is associated with Neisseria infections often being recurrent.

Infections with serogroup B are the major problems in these patients; these infections limit the usefulness of the available vaccine, which is not directed against this group. Other infections have also been detected in homozygous C6 deficiency, such as SLE, Still disease, and glomerulosclerosis.

THE COMPLEMENT SYSTEM

The origins of the complement system, i.e., the C3 and a protein similar to B factor, can be traced to sea urchins. The scidians (sea squirts), or tunicates, occupy an intermediary position between invertebrates and vertebrates.

Two lectins that correspond to mammalian MBL, ficolins, two mannan-binding lectin serine proteases (MASP), the C3 and its receptor the B factor, have been identified in ascidians. These findings indicate that a lectinlike pathway precedes the development of the classical pathway, which seems to emerge only at the stage of cartilaginous fishes at the same time as the appearance of the adaptive immunity. Mannose-binding protein-associated serine protease-2 (MASP2), is an enzyme which in humans is encoded by the MASP2 gene involved in the complement system. MASP2 is very similar to the C1s molecule, of the classical complement pathway, and they are thought to have a common evolutionary ancestor. When the carbohydrate-recognizing heads of MBL bind to specifically arranged mannose residues on the surface of a pathogen, MASP2 is activated to cleave complement components C4 and C2 into C4a, C4b, C2a, and C2b.

Section 5 - Hemostasis

Chapter 15 Megakaryocytes

Megakaryocytes

Amy E. Geddis

Megakaryocytes are large polyploid cells within the bone marrow that produce circulating platelets. Platelets are small anucleate cells that play an essential role in hemostasis, both serving to plug holes in blood vessels and initiate coagulation. To function in this role, platelets have unique properties, including the ability to adhere to injured blood vessels and to other platelets, undergo dramatic shape change, release granules containing vasoactive and thrombogenic substances, and modulate the phospholipid content of their external membrane. Platelets also release agents that promote wound healing. Based on the adult blood volume (5 L), the number of platelets per microliter of blood (~2 × 10^11), and their circulatory half-life (10 days), it can be calculated that each day an adult human produces 1 × 10^11 platelets, although in times of increased demand, platelet production can rise tenfold or more. The process of megakaryocyte and platelet formation is complex and only partially understood. This chapter discusses the molecular mechanisms underlying the development of megakaryocytes and platelets, as well as disease states that have illuminated our understanding of megakaryopoiesis.

HISTORICAL PERSPECTIVE

Platelets were described by Addison in 1841 as “extremely minute ... granules” in clotted blood and were termed platelets (blutplättchen) by Bizzozero, who also observed their adhesive qualities as “increased stickiness when a vascular wall is damaged.” The same elements were identified by microscopic examination of blood smears by Osler and Schaefer and by Hayem in the late nineteenth century. Duke, a student of James Homer Wright’s, associated low platelet counts, or thrombocytopenia, with clinical bleeding that could be corrected by transfusion.

Megakaryocytes are rare polyploid cells within the bone marrow, representing approximately 0.05% of nucleated cells. Although Howell coined the term megakaryocyte as early as 1890, it was not until 1906 that James Homer Wright put forth the hypothesis that blood platelets are derived from the cytoplasm of megakaryocytes, and the basic elements of thrombopoiesis were established. Many years later in the early 1990s, c-Mpl, the cellular homolog of the v-Mpl (myeloproliferative leukemia retrovirus) oncogene, was identified and proposed to be a hematopoietic growth factor receptor. Shortly thereafter, thrombopoietin (TPO) was cloned based on its properties of binding to and stimulating growth of c-Mpl-bearing cells; subsequent characterization of the cytokine revealed it to be the major growth factor promoting megakaryopoiesis. The availability of TPO was a major step forward in megakaryocyte and platelet biology as it facilitated expansion of megakaryocytes for further study as well as dissection of the signaling pathways regulating megakaryocyte proliferation and survival.

This chapter focuses primarily on mammalian species. However, it is worth noting that in nonmammalian vertebrates, such as fish and birds, the hemostatic equivalent of platelets is served by nucleated thrombocytes, and polyploid megakaryocytes are not present. The purpose of megakaryocyte polyploidization in the process of platelet development is not understood but it is speculated that this allows for increased expression of the proteins that are needed for the production of large numbers of platelets.

MEGAKARYOPOIESIS AND THE HEMATOPOIETIC STEM CELL

Megakaryocytes, like cells of all blood lineages, are derived from the hematopoietic stem cell (HSC). HSCs are also very rare cells within the bone marrow, estimated to represent approximately 0.01% of total nucleated cells. Identified in 1961 by Till and McCullough, key properties of HSCs include the capacity for prolonged quiescence, self-renewal, and ultimately expansion and differentiation into the total diversity of blood cell types. Although megakaryocytes are terminally differentiated cells, they share a number of characteristics with HSCs. For example, both megakaryocytes and HSCs express the integrins CD41 (integrin αIIb) and CD61 (integrin β3). The integrin αIIbβ3 complex forms a fibrinogen receptor that is one of the defining markers of the megakaryocyte lineage, but is now known to be expressed much earlier in hematopoiesis, including on HSCs. In addition, expression of integrin β3 in association with integrin αv identifies a population of cells with enhanced long-term repopulating activity in transplantation assays. Several
transcription factors share key roles in both HSC and megakaryocyte development, including SCL/TAL1, RUNX1, GATA, and ETS family members (discussed below). Strikingly, even the global transcriptional profiles of HSCs and early megakaryocytic/erythroid progenitors (MEPs) are highly similar.

In addition to similarities in cell surface protein and gene expression patterns, both HSCs and megakaryocytes require TPO for their growth and survival. The importance of TPO and its receptor c-Mpl for the function of HSCs was suspected when knockout mice, lacking either TPO or c-Mpl, were noted to be deficient in progenitors of all hematopoietic lineages. Transplantation experiments in mice confirmed that in the absence of an intact TPO-c-Mpl axis, HSCs are unable to compete with wild-type cells, either due to reduced numbers or expansion potential, although the mice do not develop bone marrow failure. In humans, mutations that eliminate c-Mpl function are the basis of congenital amegakaryocytic thrombocytopenia (CAMT). Children with CAMT are born with isolated thrombocytopenia and a paucity of megakaryocytes, but typically progress to trilineage bone marrow failure within the first decade of life, providing evidence of an essential and nonredundant role of TPO for the HSC.

TPO has been demonstrated to contribute to both HSC quiescence and expansion in various experimental settings. In mice, the absence of TPO or c-Mpl leads to acceleration of HSC cell cycling and eventual HSC exhaustion, suggesting that TPO is required for HSC quiescence and self-renewal. One potential mechanism by which TPO enhances HSC quiescence is by up-regulation of cyclin-dependent kinase inhibitors. In addition, TPO affects the interactions between the HSC and the bone marrow niche. HSCs are maintained in a quiescent state through interactions with TPO-producing osteoblasts. Although both outside-in and inside-out signaling, TPO triggers a conformational change of integrin αvβ3 to its high-affinity state, and binding of αvβ3 to its extracellular ligand within the niche results in phosphorylation of tyrosine 747 (Y747) of the integrin β3 tail, which cooperates with TPO signals to inhibit cell cycling and maintain HSC long-term repopulating activity.

TPO can also promote HSC expansion. In vitro, single cell experiments demonstrated that TPO supports the survival of HSCs, and in addition promotes their proliferation if either stem cell factor (SCF) or interleukin (IL)-3 is also present. TPO also cooperates with vascular endothelial growth factor (VEGF) through an autocrine mechanism; TPO increases VEGF expression in primitive murine hematopoietic cells through induction of hypoxia-inducible factor (HIF)-1α, and TPO in conjunction with VEGF promotes proliferation of hematopoietic progenitors. In human embryonic stem cell models, the combination of TPO and VEGF enhances the generation of CD34+ cells. In addition to HIF-1α, TPO increases the expression and function of HOX family members. TPO-induced p38 MAPK enhances HOXB4 expression, a homeobox factor that promotes HSC expansion. TPO-induced MAPK also leads to phosphorylation of MEIS1 which binds to and facilitates nuclear translocation of HOXA9. As with HOXB4, disruption of HOXA9 in animal models also leads to HSC defects. Finally, Lnk, an adaptor protein that modulates TPO-induced STAT5, AKT, and p38 MAPK signaling, negatively regulates self-renewal of HSCs. Lnk-deficient HSCs are hypersensitive to TPO and have enhanced long-term repopulating activity due to increased self-renewal. Although the mechanisms remain incompletely understood, clinical studies are examining the possible applications for TPO-receptor agonists in expanding HSCs in patients with acquired aplastic anemia with promising preliminary results.

MEGAKARYOCYTE DEVELOPMENT

In current models of hematopoiesis, the HSC can either undergo symmetric divisions, resulting in self-renewal, or asymmetric divisions, in which the daughter cells become progressively committed to a specific hematopoietic lineage. Lineage commitment is marked by characteristic gene expression patterns and modulated by hematopoietic cytokines (Fig. 15.1). Specific multipotent and megakaryocytic progenitors can be defined using semi-solid colony assays. More recent strategies have used fluorescence-activated cell sorting approaches to identify progenitors and committed cells prospectively based on cell surface protein expression patterns (Table 15.1). The earliest multipotent progenitor that has been isolated is the committed myeloid progenitor, which gives rise to the colony-forming-unit-granulocyte-erythroid-macrophage-megakaryocyte (CFU-GEMM). From the CFU-GEMM arises a bipotential progenitor with both megakaryocytic and erythroid potential, the MEP. Identified within the CD34+CD38low cell population of progenitor cells, murine MEPs have been further defined as existing within the CD150+CD9lo endoglinlo fraction of Lin–cKit+IL7Rα+FcγRII/IIIloSca1+ cells. Megakaryocyte-lineage-committed progenitors in contrast were included in the CD150+CD9lo endoglinlo fraction. The most primitive committed megakaryocytic cell is the megakaryocytic burst-forming unit, which resembles a small lymphocyte and forms a colony of 40 to 500 cells in semi-solid assays. The megakaryocytic colony-forming unit (CFU-MK) is a more mature progenitor that will form a colony of 3 to 50 cells in semi-solid assays.
Whereas all megakaryocytic progenitors can be recognized by staining for CD41 and, in murine cells, acetylcholinesterase, only CFU-MK express HLA-DR. Though this represents the classical model of megakaryocytic differentiation, it has been proposed that an alternative pathway exists in which the MEP can arise directly from the HSC.

Precursors that are committed to the megakaryocyte lineage undergo further maturation before they are capable of platelet production. As they differentiate, megakaryocytes express specific cell surface proteins, become polyploid, develop a complex cytoplasm containing granules and a system of demarcation membranes, and ultimately form proplatelet processes (Fig. 15.2). Historically, the developmental stages of megakaryocytes have been described based on morphologic criteria including the quality and quantity of the cytoplasm and the size, lobulation, and chromatin pattern of the nucleus. Thus, cells can be categorized as promegakaryoblasts and stage I megakaryoblasts, stage II promegakaryocytes, stage III mature megakaryocytes, and stage IV megakaryocytes preparing to release platelets from their cytoplasm. Stage I megakaryocytes account for approximately 25% of all megakaryocyte lineage cells in a normal marrow. They are 6 to 24 µm in diameter and contain a relatively large, minimally indented nucleus (2 to 4 N) with loosely organized chromatin and multiple nucleoli and scant basophilic cytoplasm containing a small Golgi complex, a few mitochondria and α-granules, and abundant free ribosomes. Although the cytoplasm is scant, the demarcation membrane system (DMS) that is characteristic of more mature cells has already begun to form. This early, proliferative megakaryocytic cell is also sometimes termed a megakaryoblast and, in rodent hematopoiesis, is characterized by intense staining for acetylcholinesterase. Stage II megakaryocytes also represent approximately 25% of marrow megakaryocytes. They measure 14 to 30 µm in diameter, with a lobulated nucleus of 8 to 64 N and more abundant polychromatic cytoplasm. Ultrastructurally, the cytoplasm contains more abundant α-granules and organelles, and the DMS begins to expand at this stage of development. The remaining 50% of morphologically recognizable megakaryocytes in the marrow are stage III/IV megakaryocytes. These cells are very large (40 to 60 µm in diameter) with abundant mature cytoplasm. The DMS is prominent, and the multilobulated nucleus becomes more compact and is often eccentrically placed. Stage IV megakaryocytes may display proplatelet processes. It has been calculated that it takes approximately 72 hours for stage III and stage IV cells to develop from stage I megakaryocytes.

Starting in early megakaryocytes, expression of characteristic cell surface proteins, including integrin α2β3 and GPIb/IX, becomes functionally important. Integrin α2β3 is an integral transmembrane protein that acts as a receptor for fibrinogen. Of the two subunits, only integrin α2b is megakaryocyte lineage specific. Loss of integrin α2β3 leads to Glanzmann thrombasthenia due to failure of the defective platelets to engage fibrinogen during aggregation. The two subunits of integrin α2β3 are synthesized in the endoplasmic reticulum and form a Ca²⁺-dependent complex immediately on translation, a step necessary for membrane expression. Subsequently, the α-subunit is cleaved into heavy and light chains and modified with carbohydrate before transfer to the cell surface, demarcation, and α-granule membranes. 51,52 Megakaryocytes and platelets contain approximately twice the amount of integrin α2β3 in granules as is present on the cell surface, the granule compartment serving as a mobilizable pool that is exteriorized on platelet activation.

The GPIb/IX complex is developmentally expressed only slightly later than integrin α2β3 and forms a receptor for von Willebrand factor (vWF). 21 Although known for its role in binding vWF, GPIbα also is an important structural component in platelets through its interaction with the cytoskeletal protein filamin A. Filamin A, in turn, promotes clustering and activation of GPIb, thus regulating its function in platelet aggregation. 53,54 Absence of the GPIb/IX complex results in Bernard-Soulier syndrome (BSS), an autosomal recessive macrothrombocytopenia with severe platelet dysfunction; mutations of filamin A are also associated with macrothrombocytopenia but GPIb surface expression is normal. 55 Except for minor expression in endothelial cells, 56 GPIb is a megakaryocyte-specific protein. GPV is also expressed in complex with GPIb and GPIX in a 2:2:1 (Ib:IX:V) stoichiometric ratio 57,58; however, GPV is not required for the function of the GPIb/V/IX complex in binding vWF. Genetic elimination of GPV has little effect on platelet adhesion 59 and no mutations of GPV have been associated with BSS. 60 Rather, GPV appears to function as a target of thrombin, possibly playing a role in platelet activation. 61,62
FIGURE 15.1. Hematopoietic cell development. Transcription factors regulate the differentiation of the HSC to produce committed progenitors and mature blood cells. The MEP is a bipotential precursor that gives rise to both erythroid and megakaryocytic lineages. Whereas GATA1 and FOG1 are required for both erythropoiesis and megakaryopoiesis, EKLF favors red cell development and FLI1 promotes megakaryopoiesis. With permission from Orkin SH, Zon LI. Hematopoiesis: an evolving paradigm for stem cell biology. Cell 2008;132:631-644.

FIGURE 15.2. Mature megakaryocytes (A) Bone marrow megakaryocyte visualized by Wright’s stain. Note the multilobated nucleus. (B) Electron micrograph of a mature megakaryocyte, showing cytoplasmic alpha granules (A), mitochondria (m),
and demarcation membranes (dm). There appear to be separate nuclei with nucleoli (n), but these represent two lobes of a single nucleus visible in this section.

One of the most characteristic and intriguing features of megakaryocyte maturation is the development of polyploidy. As they mature, megakaryocytes switch from mitotic cell cycling to endomitosis, or DNA replication in the absence of nuclear or cytoplasmic division (Fig. 15.3). Endomitosis begins late in stage I megakaryoblasts, after sufficient diploid cell divisions have occurred to expand the number of megakaryocytic precursor cells, and is completed by the end of stage II megakaryocyte development.\(^63,64\) This carefully controlled process (i.e., cells are polyploid, rather than aneuploid) results in cells containing DNA content from 8 to 128 times the normal chromosomal complement in a single, highly lobated nucleus. Endomitosis is not simply the absence of mitosis, but rather an aborted mitosis.\(^65\) The cell-cycle kinetics of endomitotic cells is also unusual, characterized by a short G\(_1\) phase, a normal or modestly prolonged DNA synthesis phase, a short G\(_2\) phase, and a very short endomitosis phase.\(^66\) During the latter, megakaryocytic chromosomes condense, the nuclear membrane breaks down, and centromeres form mitotic spindles on which the replicated chromosomes assemble. However, after initiation of anaphase with chromosomal separation and cleavage furrow formation, the furrow regresses, the spindle dissociates, and the megakaryocyte re-enters the G\(_1\) phase as a polyploid cell.\(^65\) Attempts at biochemical analysis of this process have come from leukemic cell lines and normal cultured megakaryocytes. Hypotheses for the mechanisms triggering polyploidy in megakaryocytes have included deficiencies of cyclin B, altered cytoskeletal dynamics, a defect of the chromosomal passenger proteins, and malfunction of the contractile ring. Early interest focused on the M-phase cyclin-dependent kinase cyclin B-cdk1. Also termed mitosis-promoting factor, the amount of cyclin B and the activity of the cyclin B-cdk1 complex rise through the cell cycle until mitosis, where they fall abruptly due to proteosomal degradation of cyclin B. As the major departure from normal cell-cycle behavior in megakaryocytes occurs during the M phase, it was proposed that endomitosis might result from impaired activation of cyclin B-cdk2 kinase, as suggested in several cell line models.\(^68,69\) However, results from normal murine and human megakaryocytes argue for normal mitotic kinase activity during endomitosis. Using TPO to expand primary megakaryocytes in vitro, two groups have demonstrated the presence of functional cyclin B and cdc2 in endomitotic megakaryocytes\(^65,71\) as well as a normal metaphase checkpoint mechanism.\(^72\) Although the combined deletion of cyclin D1, D2, and D3 in mouse models did not specifically affect megakaryocytes,\(^73\) deletion of cyclin E did impair megakaryopoiesis as well as trophoblast development,\(^74\) suggesting that cyclin E plays a role in endomitosis.

**Endomitosis in Megakaryocytes**

![Diploid cell](image1.png) ![Polyploid cell](image2.png)

FIGURE 15.3. Endomitosis in megakaryocytes. (A) Mitosis in a megakaryocytic precursor: chromatids (blue) are arranged in a single metaphase plate, microtubules (red) form a bipolar spindle. (B) Endomitosis: chromatids are arranged in two
metaphase plates and the spindle is multipolar.

Alterations in regulation of the microtubule cytoskeleton have also been proposed as fundamental in triggering endomitosis. Stathmin is a microtubule-depolymerizing protein that is important for the regulation of the mitotic spindle. As cells enter mitosis, the microtubule-depolymerizing activity of stathmin decreases, allowing microtubules to polymerize and assemble into a mitotic spindle. Reactivation of stathmin in the later stages of mitosis is necessary for the disassembly of the mitotic spindle and the exit from mitosis. Interfering with stathmin expression disrupts the normal mitotic spindle and leads to aberrant mitotic exit. Thus it has been hypothesized that alterations in stathmin expression underlie endomitosis in megakaryocytes. In support of this view, expression of stathmin is decreased in higher ploidy megakaryocytes, and studies in the erythroleukemia cell line K562 show that inhibition of stathmin expression enhances polyploidy, whereas overexpression of stathmin inhibits the transition from a mitotic cycle to an endomitotic cycle and reduces formation of multipolar mitotic spindles. Whether down-regulation of stathmin leads to polyploidization in megakaryocytes or is a result of it is not known. Proper activation and localization of the chromosomal passenger proteins have also been examined as a potential point of departure from the mitotic cell cycle in megakaryocytes. These proteins, including INCENP, survivin, and Aurora Kinase B, form a complex that localizes to the centrosome prior to anaphase and then shifts to the microtubules of the midbody and cleavage furrow. Elimination of individual members of the passenger protein complex in organisms as diverse as Drosophila and mammals leads to the abrogation of proper cell division and the formation of a cellular syncytium containing a large nuclear mass. Work in cell lines initially suggested that megakaryocytes might be deficient in survivin or Aurora kinase B. However, subsequent examination of primary megakaryocytes revealed that Aurora kinase B as well as associated passenger proteins are active and appropriately localized in both diploid and polyploid megakaryocytes. Further observation of endomitosis by live cell microscopy demonstrated that endomitotic megakaryocytes assemble cleavage furrows that begin to contract and then regress; this fact suggests that the “defect” in endomitosis is beyond anaphase and involves the function of the contractile ring in cytokinesis. Confocal microscopy confirmed poor localization of RhoA and the actin/myosin complex to the cleavage furrow in endomitotic megakaryocytes. In support of the role of RhoA in endomitosis, expression of Ect2 and GEF-H1, guanine exchange factors that activate RhoA during cytokinesis, is decreased in polyploidizing cells, and forced overexpression of Ect2 and GEF-H1 blocks endomitosis. Recent work indicates that nonmuscle myosin II heavy chain, whose expression is controlled by Runx1, is also down-regulated during megakaryocyte maturation, and that loss of myosin II expression inhibits the return of 4 N cells to the diploid state. It is likely that there are multiple alterations in the cell cycle of megakaryocytes that are involved in the process of endomitosis.

Another important aspect of megakaryocyte maturation is the development of the DMS. Initially described more than 30 years ago, what begins as invaginations of the plasma membrane ultimately becomes a highly branched interconnected system of channels that course through the cytoplasm. The use of electron dense tracers indicated that the DMS is in open communication with the extracellular space, in comparison with the rough endoplasmic reticulum which is contiguous with the nuclear membrane. Over the 72 hours it takes for stage III and stage IV cells to develop from stage I megakaryocytes, the DMS grows by approximately 25-fold. The mature DMS contains phosphatidyl inositol-4,5-P2 (PI-4,5-P2), a phospholipid that is usually associated with the plasma membrane, and PI-4,5-P2 promotes actin polymerization by activating Rho-like guanosine triphosphatases (GTPases) and Wiskott-Aldrich syndrome (WASP) family proteins. The purpose of the DMS has been disputed for nearly 20 years; initially, it was thought to compartmentalize the cytoplasm of the mature megakaryocyte into platelet territories, which ultimately fragment into mature platelets along the cleavage planes so formed, but recent evidence suggests that the DMS provides the necessary membrane required for the formation of proplatelet processes and may promote actin polymerization.

Two specific types of granules are characteristic of mature megakaryocytes and platelets. The more abundant α-granules first begin to form adjacent to the Golgi apparatus as 300- to 500-nm round or oval organelles in stage I and II cells. α-Granules contain multiple proteins with functions in coagulation and angiogenesis. Three distinct compartments are recognized in α-granules: (a) a central electron-dense nucleoid containing fibrinogen, platelet factor 4 (PF4), β-thromboglobulin, transforming growth factor (TGF)-β1, vitronectin, multimerin, and tissue-type plasminogen activator; (b) a relatively lucent peripheral zone containing tubules and vWF (an arrangement akin to Weibel-Palade bodies found in endothelial cells); and (c) the granule membrane containing many of the critical platelet receptors for cell rolling (P-selectin, also termed CD62p), firm adhesion (glyb/VIIX), and aggregation (αIIβ3 integrin). In platelets, proteins present in α-granules arise from de novo megakaryocyte synthesis (e.g., glyb/VIIX, glyb, αIIβ3 integrin, vWF, P-selectin, β-
thromboglobulin, and platelet-derived growth factor), nonspecific pinocytosis of environmental proteins (e.g., albumin and IgG), or cell surface membrane receptor-mediated uptake from the environment (e.g., fibrinogen, fibronectin, and factor V). 93–96 Dense granules are less numerous and contain the vasoconstrictive 5-hydroxytryptamine, the nonmetabolic pool of adenosine triphosphate and adenosine diphosphate (ADP), calcium, and magnesium, and they have a fundamental role in hemostasis. Although α-granules contain multiple proteins with opposing functions, proteins with specific functions may be released selectively in response to certain agonists. For example, ADP and PAR1 stimulate the release of angiogenic factors such as VEGF, whereas thromboxane A2 and PAR4 stimulate the release of antiangiogenic factors such as endostatin. 95,96 Therefore, current models propose differential secretion of granule contents in response to different agonists, although the mechanisms by which this selectivity is achieved are still unclear.

Throughout megakaryocyte development, the cytoplasm acquires a rich network of microfilaments and microtubules. Toward stages III and IV, these proteins accumulate in the cell periphery, creating an organelle-poor peripheral zone. Biochemically, the megakaryocyte cytoskeleton is composed of actin, α-actinin, filamin, nonmuscle myosin, β1 tubulin, talin, and spectrin. Spectrin plays an important role in stabilizing the DMS and proplatelet processes. 97 β1 tubulin is expressed exclusively in megakaryocytes and platelets and is critical for proplatelet formation; over 90% of microtubules in the mature megakaryocyte are composed of the β1 isoform. 98,99 At the onset of proplatelet formation, blunt pseudopodia are formed, and β1-tubulin-containing microtubules assemble into thick bundles below the plasma membrane 100 (Fig. 15.4). The pseudopodia elongate, bend, and branch to form proplatelets, and the microtubules form bidirectional linear arrays with terminal loops composed of 8 to 12 microtubule coils at the proplatelet tips. 101 Dynein powers microtubule sliding and proplatelet elongation, whereas actin and myosin are involved in proplatelet bending and branching. 100,102 Granules and organelles such as mitochondria traffic on these microtubule “tracks” to accumulate within the tips that will ultimately be released to become circulating platelets. 103 The coiled microtubules at the proplatelet tip become the marginal band that maintains the discoid shape of the platelet. 100,104 RanBP10 binds to microtubules and functions as a GEF for Ran, stabilizing microtubules and facilitating granule transport. 105,106 Remodeling of the megakaryocyte cytoskeleton is essential for proplatelet formation, and mutations affecting cytoskeletal proteins, including regulators of actin (WASp), filamin A, β1-tubulin, and nonmuscle myosin heavy chain IIA form the basis of several of the inherited thrombocytopenia syndromes. 55,107,108,109

Platelets are derived from the megakaryocyte cytoplasm. It has been estimated that each megakaryocyte gives rise to 1,000 to 5,000 platelets and 110,111 and before the residual nuclear material is engulfed and eliminated by marrow macrophages. 111 Stage IV megakaryocytes are wholly engaged in platelet formation. Careful microscopic studies have localized narrow megakaryocytes to the abluminal surface of sinusoidal endothelial cells. Fully mature megakaryocytes develop cytoplasmic processes constricted at platelet-sized intervals that extend through the endothelial barrier into the sinusoidal lumen, where platelets are released. 114 It is likely that both integrin-mediated cell-cell interactions and extracellular matrix degradation are required for this process. 115,116 and 117 It is also possible that the final stages of megakaryocyte fragmentation occur in the lung, at least for some megakaryocytes. Howell and Donahue reported in 1939 that platelet levels in pulmonary venous blood exceed those found in the pulmonary artery, suggesting platelet production in the lung. 118 Whether this represents the migration and fragmentation of intact megakaryocytes in the lung or merely the final size reduction of large fragments of megakaryocyte cytoplasm that are also released into the blood is not clear. Lung megakaryocytes have been characterized by Slater et al., who believe they contribute substantially to blood platelet production. 120 However, in preclinical studies of TPO, Kaushansky et al. did not detect any denuded megakaryocyte nuclei in the lungs of mice which at the time of sacrifice had platelet counts as high as 4 million/mm³. 121 One study found that dog lungs contain 2.5 megakaryocytes/cm² tavassoli 122; extrapolation of these data would suggest that human lungs contain approximately 6,000 megakaryocytes, only enough to account for a small proportion (<0.1%) of daily platelet production. Moreover, cultured megakaryocytes can form functional platelets in vitro by generating proplatelets in the absence of endothelial surfaces or the pulmonary circulation, 100 and the release of proplatelet fragments into bone marrow sinusoids has been visualized in living mice. 123 Thus, the role of pulmonary bed platelet production remains controversial.
FIGURE 15.4. Proplatelet formation in mature megakaryocytes. Noncentrosomal microtubules migrate to the cell periphery where they form bundles. Pseudopodia form and elongate into proplatelet processes, and the microtubules form bidirectional tracks within the processes that terminate in coiled ends. Granules and other organelles traffic along the microtubules and accumulate in the tips. Proplatelet processes are released and continue to remodel in the circulation, alternating between barbell-shaped proplatelets and large preplatelets, before the proplatelets finally divide into individual platelets.

Notably, the proplatelets and platelets released in experimental models are larger than typical circulating platelets. In addition, it has long been recognized that patients with disorders of increased platelet production, such as immune thrombocytopenia, have relatively large circulating platelets. Thus, it has been proposed that once released into the circulation, these larger platelet precursors undergo further remodeling. Using an in vitro model, Thon et al. demonstrated that platelet precursors shift back and forth between two morphologic states, discoid preplatelets and barbell-like proplatelets. Spectrin stabilizes the bridge between the ends of the barbell form. Furthermore, these precursor platelets can be observed to divide or undergo fission. Shear forces in the circulation likely contribute to the cleavage of barbell-shaped proplatelets into individual platelets, although it has been postulated that mechanisms similar to those driving cell separation in cytokinesis may also be involved.

Programmed cell death represents not only the end of the megakaryocyte life cycle and proteins that regulate the intrinsic apoptosis pathway influence megakaryocyte survival. Apoptosis has also been proposed to play a role in megakaryocyte functions such as proplatelet formation. Early studies found that focal activation of caspases accompanies megakaryocyte maturation and overexpression of Bcl2 inhibits proplatelet formation, suggesting that localized apoptosis is required for platelet shedding. However, a recent study found that targeted deletion of caspase 9, the initiator caspase in the intrinsic apoptotic pathway, has no effect on proplatelet formation. Additional data support the alternative hypothesis that inhibition of apoptosis in mature megakaryocytes is necessary for proplatelet formation. In mouse models, targeted loss of Bcl-xL in megakaryocytes leads to caspase activation and failure of proplatelet formation and release of morphologically abnormal, large platelets. Whereas isolated loss of Bcl-xL primarily affects mature megakaryocytes at the point of proplatelet formation, combined deletion of Bcl-xL.
and Mcl-1 has even more profound effects, with severe impairment of megakaryopoiesis in embryos lacking both apoptotic regulators.\textsuperscript{130} In addition, Bcl-xL inhibits apoptosis in circulating platelets. Mutation or pharmacologic inhibition of Bcl-xL leads to reduced platelet life span in mice.\textsuperscript{129,131} Apoptosis of aged platelets is mediated by Bak and Bax, whose activity is normally controlled by Bcl-xL; genetic deletion of Bak and Bax prolongs platelet survival and renders platelets resistant to the effects of Bcl-xL inhibition.\textsuperscript{129} Mutations of Bcl-xL or Mcl-1 have not been described in humans; however, a proapoptotic mutation of cytochrome c has been identified in a family with autosomal dominant thrombocytopenia.\textsuperscript{132}

**TRANSCRIPTIONAL REGULATION OF MEGAKARYOPOIESIS**

Several themes are emerging in models of transcriptional regulation of hematopoietic differentiation that are relevant to the discussion of megakaryopoiesis. Lineage priming refers to the concept that the HSC is competent to express multiple genetic programs and lineage choice is the consequence of progressive silencing of alternative possibilities.\textsuperscript{133,134} Similarly, anticipatory regulation refers to the concept that differentiation-associated transcription factors are already bound at target promoters in HSCs, allowing for low-level expression that increases with differentiation.\textsuperscript{23} Thus, as previously discussed, several transcription factors associated with megakaryocytes, as well as other lineages, are also expressed at low levels in HSCs, as well as in bipotential megakaryocytic/erythroid cells. As cells start to differentiate, lineage-specific transcription factors promote their own expression while suppressing factors that would favor other cell types, thus reinforcing lineage choice. For example, GATA1 activates its own promoter to increase its expression, and simultaneously inhibits PU.1, favoring megakaryocytic/erythroid differentiation, whereas in other cells, PU.1 might dominate, repressing the megakaryocytic/erythroid program and favoring myelopoiesis.\textsuperscript{135,136,137} Transcription factors do not act in isolation, however, but are typically present as components of cross-regulatory multiprotein complexes; their function may vary depending on the other factors that are present.

Recent studies have identified five core transcription factors, SCL/TAL1, GATA1, GATA2, RUNX1, and FLI1, as the promoters of hematopoietic genes in primary megakaryocytes. Genes next to regions bound by all five factors were highly enriched for known regulators of megakaryocytic differentiation or function.\textsuperscript{138} Additional factors of importance in megakaryopoiesis include NF-E2, FOG1, HOX family proteins, GFI-1b, and c-Myb. Mutant forms of several of these factors or their downstream targets have been found in inherited thrombocytopenia syndromes or leukemias. In addition, there is emerging recognition of the role of noncoding RNAs in megakaryocytic differentiation.

SCL/TAL1: Stem cell leukemia/T-cell acute lymphoblastic leukemia gene 1, or SCL/TAL1, is a basic helix-loop-helix transcription factor that is essential for early hematopoietic specification as well as definitive differentiation of the erythroid and megakaryocyte lineages.\textsuperscript{139} Loss of Scl/Tal1 expression in adult mice leads to defects in megakaryocyte cytoplasmic maturation and thrombocytopenia.\textsuperscript{140,141} In addition, progenitor cells from Scl/Tal1-deficient mice are unable to generate megakaryocytes in vitro.\textsuperscript{142,143} Among the transcriptional targets of SCL/TAL1 important for megakaryopoiesis are NF-E2 and MEF2C. Scl/Tal1 directly binds regulatory elements of Mef2C in megakaryocytic cells, and the platelet phenotype of Mef2C- knockout mice is similar to that of Scl/Tal1-deficient animals.\textsuperscript{144} In human CD34\textsuperscript{+} hematopoietic progenitor cells, expression of MEF2C increases with megakaryocytic differentiation.\textsuperscript{145} SCL/TAL1 has multiple partners, including E2A and LMO2. E2A binds canonical DNA elements called E-boxes represented by the motif CANNTG. E-boxes are frequently found along with GATA-binding motifs within the regulatory elements of erythroid and megakaryocytic cells.\textsuperscript{146,147} LMO2 is a LIM domain containing protein that forms a multiprotein complex with GATA1, SCL/TAL1, E2A, and another LIM domain protein LDB1\textsuperscript{148,149} and \textsuperscript{150}; the complex is critical for early hematopoietic specification. LDB1 can self-associate to form oligomers and may bind multiple GATA1 molecules simultaneously, thus facilitating long-range interactions between GATA-bound sites.\textsuperscript{152,153} and \textsuperscript{154}

GATA1: GATA1 is a zinc finger transcription factor critical in both erythroid and megakaryocytic development, with target genes including HBB (encoding β-globin), ALAS1, BCL2L1, NFE2, GP1Bβ, and GP9. Gata1 deficiency in mouse models leads to arrest of erythroid maturation at the proerythroblast stage and severe anemia,\textsuperscript{155} as well as defects in megakaryocyte maturation with hyperproliferation of low ploidy cells, impaired endomitosis and formation of the DMS, and release of large hypogranulated platelets.\textsuperscript{156,157} GATA-binding motifs (T/A)GATA(A/G) are found in the regulatory elements of nearly all erythroid and megakaryocytic genes.\textsuperscript{158,159} Furthermore, the co-occurrence of ETS and GATA motifs was significantly associated with expression of the megakaryocytic program over the erythroid program.\textsuperscript{160} GATA1 can function either as a transcriptional activator or repressor, depending on its binding partners. GATA1 contains two zinc fingers; the C-terminal zinc finger is responsible for high-affinity DNA binding, whereas the N-terminal finger stabilizes the interaction and binds to the co-factor FOG1.\textsuperscript{161} In addition to FOG1,\textsuperscript{162} GATA1 has interactions with other megakaryocytic core factors, including RUNX1 and FLI1.\textsuperscript{163,164,165} FOG1 contains 9 zinc fingers, 4 of which mediate interactions with GATA1.\textsuperscript{166} In mouse models, deletion of Fog1 results in a more severe defect in megakaryopoiesis than does deletion of Gata1,\textsuperscript{167,168} supporting the
conclusion that although GATA1 is required for erythroid lineage commitment, FOG1 is required for specification of both erythroid and megakaryocytic progenitors.\(^{168}\) The interaction of GATA1 with FOG1 and PU.1 is mutually exclusive,\(^ {169}\) thus GATA1 bound by FOG1 may be protected from repression by PU.1, favoring megakaryocytic/erythroid differentiation. Posttranslational modification of GATA1 by SUMOylation of amino acid K137 also disrupts FOG1 binding.\(^ {170}\) FOG1 can promote the function of GATA1 either as an activator or repressor of transcription. FOG1 contains an N-terminal nucleosome remodeling and histone deacetylase complex (NuRD) recruitment domain,\(^ {171}\) and can thus bind transcriptional repressors such as HDAC1 and HDAC2. Knockin mice expressing FOG1 mutated within its NuRD domain exhibited thrombocytopenia and anemia, suggesting that FOG1 function in megakaryopoiesis is mediated at least in part through recruitment of NuRD.\(^ {172}\) Although association with NuRD was linked with both gene activation and repression, NuRD binding by FOG1 was shown to repress the mast cell program in megakaryocytic/erythroid cells.\(^ {173}\) In humans, X-linked inheritance of mutations of GATA1 involving the N-zinc finger, abrogating interaction with FOG1, leads to macrothrombocytopenia and dyserythropoiesis\(^ {174,175,176,177}\) and \(^ {178}\) (Fig. 15.5). In Down syndrome, acquired mutations within exon 2 of GATA1 result in alteration of the translational start site and production of a shortened species, GATA1S. GATA1S binds DNA and interacts with FOG1, but lacks the N-terminal activation domain and has a reduced transactivation potential.\(^ {179}\) GATA1S is nearly always present in children with Down syndrome who develop transient abnormal myelopoiesis and megakaryoblastic leukemia and is thought to be an early event in the initiation of leukemogenesis.\(^ {180,181}\)

GATA2: Closely related to GATA1, GATA2 is an essential transcription factor for HSCs, MEPs, and megakaryocytes, but becomes down-regulated in mature erythroid cells.\(^ {182,183,184}\) and \(^ {185}\) GATA2 expression is down-regulated to a lesser extent during megakaryopoiesis,\(^ {186,187}\) and overexpression of GATA2 favors megakaryopoiesis in cell lines.\(^ {188}\) In maturing cells, expression of GATA2 is repressed by GATA1, reinforcing the differentiation program.\(^ {189}\) Thus, in experimental models, deletion of GATA1 is accompanied by overexpression of GATA2.\(^ {190}\) GATA1 and GATA2 have homologous zinc fingers, interact with FOG1, and bind overlapping sets of genes.\(^ {191,192}\) However, in general, GATA1 and GATA2 have opposite effects at target genes, either activating or repressing transcription. The exchange of GATA2 for GATA1 at regulatory elements during differentiation is referred to as the GATA switch.\(^ {193}\) Using an in vitro model of megakaryocyte maturation, Dore et al. recently found that as many as 30% of sites occupied by GATA2 are occupied instead by GATA1 in differentiated cells.\(^ {160}\) In contrast to GATA1 which is on the X-chromosome, GATA2 is on chromosome 3 and GATA2 mutations have not been described in human disease.

![FIGURE 15.5. GATA1 mutations associated with human disease. Wild-type GATA1 contains an activation domain (AD) and](image-url)
two zinc fingers (NF and CF) that mediate DNA binding. FOG1 interacts with the amino-terminal zinc finger (NF). Mutations in the N-finger have been discovered in males with macrothrombocytopenia and impaired erythropoiesis, either due to disruption of FOG1 binding or, in the case of R216Q, impaired DNA binding. In Down syndrome, mutations that lead to loss of the AD (GATA15) promote the development of transient myeloproliferative disorder and megakaryoblastic leukemia.

**RUNX1:** RUNX1 is a heterodimeric transcription factor of the Runt-domain family, consisting of core-binding factor α-2 (CBFA2) that binds DNA and CBF-β, which does not directly bind DNA. Although RUNX1 is critical for emergence of the HSC during embryogenesis, in the adult it is dispensable for maintenance of stem cells but required for megakaryopoiesis. In cell line and animal models, overexpression of RUNX1 induces megakaryocytic differentiation, whereas RUNX1 deficiency results in proliferation of immature megakaryocytes and thrombocytopenia. Mutations leading to haploinsufficiency of RUNX1 cause familial thrombocytopenia with absent CD41

**Expression of FLI1 influences cell fate decisions in the MEP;** increased expression of FLI1 favors megakaryocyte development, whereas RUNX1 suppresses megakaryopoiesis, whereas overexpression of FLI1 promotes megakaryocyte development while suppressing erythropoiesis.

**Homeobox Genes:** The homeobox genes, which include HOX and non-HOX genes, play key roles in body pattern development, and they are also expressed in adult HSC and play pivotal roles in their proliferation. In hematopoietic progenitors, TPO promotes expression of HOXB4 as well as nuclear localization of HOXA9 through up-regulation of its co-factor MEIS1. In addition to HOXA9, MEIS1 can interact with PBX1b and PBX2, and the complex of MEIS1 and PBX up-regulates megakaryocytic gene expression in cooperation with GATA1 and ETS. Mouse studies show that Meis1−/− mice have a severe abnormality of megakaryopoiesis and lack CD41+ cells in the fetal liver. Although its function in megakaryocytes is not understood, mutations of HOXA11 are associated with the congenital thrombocytopenia syndrome amegakaryocytic thrombocytopenia with radioulnar synostosis (ATRUS).

**FLI1, KLF1, and c-Myb:** Several changes in gene expression accompany the divergence of bipotential MEPs to committed megakaryocytic or erythroid cells. The ETS family member FLI1, in conjunction with SCL and GATA2, controls HSC specification, however, it is also critical for formation of the vasculature and for megakaryopoiesis. and FLI1 cooperates with GATA1 and regulates many genes important for terminal megakaryocytic maturation. Expression of FLI1 influences cell fate decisions in the MEP; increased expression of FLI1 favors megakaryocyte development, whereas FLI1 expression decreases in erythroid cells. In mouse models, loss of FLI1 suppresses megakaryopoiesis, whereas overexpression of FLI1 promotes megakaryocyte development while suppressing erythropoiesis.

Conversely, KLF1 (or EKLF), a target of GATA1, is up-regulated in erythroid-committed progenitors, but inhibits megakaryopoiesis. FLI1 and KLF1 inhibit each other’s activity directly through protein-protein interaction, and this cross-antagonism has been suggested to reinforce lineage choice between megakaryocytes and erythroid cells. Indeed, selective disruption of Klf1 in mouse models leads to anemia with thrombocytosis, whereas targeted deletion of FLI1 enhances erythropoiesis. Other transcription factors have been identified that act in the MEP, including GFI-1b and c-Myb. Growth factor independence-1 (GFI-1b) is a transcriptional repressor that is essential for both erythropoiesis and megakaryopoiesis. GFI-1b is expressed in the bipotential MEP and inhibits the expression of the TGF-β receptor III (TGFBR3) gene. This disrupts TGF-β/smad2 signaling which otherwise restrains proliferation and differentiation of erythro-megakaryocytic progenitors. The c-Myb gene encodes for a basic helix turn helix transcription factor composed of three functional domains: a DNA binding domain at the N terminus, a central transactivation domain,
and a C-terminal negative regulatory domain. c-Myb has critical roles both during early hematopoiesis and in differentiating cells. \(^{235,236}\) Down-regulation of c-Myb accompanies megakaryocytic differentiation, and hypomorphic c-Myb expression increases megakaryopoiesis at the expense of erythropoiesis. \(^{236,237}\) Silencing of c-Myb in human CD34\(^+\) progenitor cells in vitro is associated with loss of KLF1 and LMO2 (http://bloodjournal.hematologylibrary.org/content/116/22/e99.full, ref 22) expression and results in commitment toward the monomorphage and megakaryocyte lineages whereas erythroid differentiation is strongly impaired. \(^{238}\)

Recently, the role of noncoding RNAs has been recognized in hematopoiesis and megakaryocyte differentiation. \(^{239,240,241}\) MicroRNAs (miRNAs) are a class of approximately 22-nucleotide noncoding RNAs that have been highly conserved during evolution and modulate protein expression by degrading mRNA or repressing translation. There are over 400 human miRNAs, and several of them have been implicated in megakaryopoiesis using profiling, knockdown, or overexpression assays. In megakaryocytes, miR-155 expression is reduced as cells differentiate toward megakaryocytes, and overexpression of miR-155 inhibits megakaryopoiesis in vitro and mouse models, potentially by targeting Meis1 and Ets1 transcripts. \(^{242,243}\) \(^{244}\) In contrast, miR-150 levels increase during megakaryocyte differentiation, but not in erythroid cells. \(^{239}\) miR-150 targets c-Myb expression. Down-regulation of c-Myb promotes megakaryocytic differentiation at the expense of erythroid cells. \(^{236}\) TPO induces expression of miR-150, providing another mechanism by which it influences megakaryopoiesis. \(^{245}\) Additional regulatory miRNAs with potential roles in megakaryopoiesis include miR-34a which when overexpressed in CD34\(^+\) cells increases megakaryocyte colony formation, and miR-27a which targets the Runx1 transcript. \(^{246,247}\)

**CYTOKINES IN MEGAKARYOPOIESIS**

The identification of TPO and its receptor c-Mpl was a major advance in the study of megakaryocytes. The term thrombopoietin was first coined in 1958 to describe the putative primary regulator of platelet production; \(^{248}\) the anticipated factor was also referred to as megakaryocyte growth and development factor (MGDF). Over the four decades following its description, evidence both for and against the existence of TPO as a distinct entity was presented. \(^{249,250}\) Although not appreciated at the time, a major insight into megakaryocyte biology was provided in 1986 when Françoise Wendling et al. described a murine retrovirus, myeloproliferative leukemia virus, which induced a vast expansion of hematopoietic cells. \(^{251}\) The responsible viral oncogene was characterized in 1990, \(^{11}\) and its cellular homolog c-mpl was cloned in 1992. \(^{10}\) Based on the presence of two copies of the hematopoietic cytokine receptor motif, it was immediately apparent that c-mpl encoded a growth factor receptor. However, its ligand was not known. Using three distinct strategies, four separate groups were able to clone the complementary DNA for the corresponding hormone and reported their results in 1994. \(^{12,13,14}\) and \(^{15}\) The gene for this c-Mpl ligand was mapped to human chromosome 3q26-28, spans 6 to 8 kb, consists of seven exons, and encodes a predicted 36-kD polypeptide. \(^{252,253}\) and \(^{254}\) The recombinant and naturally occurring cytokines migrate as 70-kD proteins, indicating substantial posttranslational modification, a conclusion verified by the finding of six sites of N-linked carbohydrate and many sites of O-linked carbohydrate. \(^{255}\) Based on its biologic activities, the c-Mpl ligand was termed thrombopoietin (TPO). \(^{121}\)

TPO bears a striking homology to erythropoietin (EPO), the primary regulator of erythropoiesis, within the amino terminal half of the predicted polypeptide. \(^{12,13,14}\) and \(^{15}\) The two proteins are more closely related than any other two cytokines within the hematopoietic cytokine family, sharing 20% identical amino acids, an additional 25% conservative substitutions, and identical positions of three of the four cysteine residues. However, unlike any of the other cytokines in the family, TPO contains a 181-residue carboxyl terminal extension, which bears homology to no known protein. Two functions have been assigned to this region: it prolongs the circulatory half-life of the cytokine and it aids in the secretion of TPO from cells that normally synthesize it. \(^{256,257}\) and \(^{258}\)

The biologic activities of TPO are consistent with a primary role in megakaryopoiesis. Incubation of marrow cells from mice, rats, dogs, nonhuman primates, and humans with TPO leads to an impressive stimulation of megakaryocyte growth in both suspension and semi-solid culture. \(^{12,121,259,260}\) Compared to cultures initiated with other hematopoietic growth factors with promegakaryocytic activity such as IL-3, kit ligand (KL), IL-6, IL-11, or leukemia inhibitory factor (LIF), marrow cells grown in TPO contain greater numbers of megakaryocytes, and the cells are larger and more highly polypliod. When administered to animals or humans, TPO stimulates platelet production in a log-linear manner to levels tenfold higher than baseline. \(^{14,256,261,262,263}\) \(^{264}\) and \(^{264}\) without affecting the peripheral blood red or white cell counts. However, perhaps unexpectedly, the number of erythroid and myeloid progenitors and mixed myeloid progenitors in marrow and spleen were also increased in some studies, \(^{265,266}\) an effect that is especially impressive when the cytokine is administered to animals after myelosuppressive therapy \(^{265,267,268}\) and probably due to the synergy between TPO and the other hematopoietic cytokines circulating at high levels in this condition.
In the hopes of treating patients with thrombocytopenia, a number of clinical trials were conducted with recombinant TPO, using either recombinant human TPO (rHuTPO) or a truncated and pegylated form (PEG-MGDF); however, the development of antibodies to PEG-MGDF that cross-reacted with endogenous TPO halted further development of these first-generation agents. As an alternative strategy, second-generation agents, the TPO-receptor agonists, were designed that can stimulate c-Mpl but bear little homology to the native protein. These agents include peptidobodies that bind the extracellular domain of c-Mpl (Romiplostim) as well as small molecules that bind within the transmembrane domain of c-Mpl at a site distinct from TPO. Phase 3 studies have demonstrated the efficacy and safety of TPO-receptor agonists in adults with chronic immune thrombocytopenia, and additional clinical indications are under investigation.

The biologic effects of TPO in vitro and of its administration in vivo strongly suggest that the cytokine plays an important role in hematopoiesis. Based on genetic studies, it is now clear that TPO is the primary regulator of thrombopoiesis. Genetic elimination of c-mpl or tpo in mice leads to profound thrombocytopenia due to a greatly reduced number of megakaryocyte progenitors and mature megakaryocytes and the reduced polyploidy of the remaining megakaryocytes. The human disease related to deficiency of c-Mpl is CAMT. In CAMT, autosomal recessive inheritance of nonsense or missense mutations of MPL results in loss of TPO responsiveness. Both mice and humans with c-Mpl deficiency also have a HSC defect, with humans developing overt marrow failure. Restoration of Mpl expression in Mpl-deficient mice using transcriptionally targeted vectors results in restoration of the HSC pool and correction of thrombocytopenia. Although tpo-knockout mice phenocopy c-mpl-deficient animals, mutations eliminating TPO expression have not been described in humans.

TPO levels in the plasma are primarily regulated by platelet mass, although there is evidence for additional regulation at the level of gene transcription and protein translation. In most experimental and natural cases of thrombocytopenia, plasma concentrations of TPO vary inversely with platelet counts, rising to maximal levels within 24 hours of the onset of profound thrombocytopenia. TPO is produced at a constant rate by the liver, and to a minor extent the kidney, and once in the circulation its uptake and degradation (and, hence, the level remaining in the blood to affect megakaryopoiesis) are determined by the mass of c-Mpl receptors present on platelets and megakaryocytes. In this way, when platelet levels are high, more TPO is removed from the circulation and there is a compensatory reduction of megakaryopoiesis. Conversely, thrombocytopenia, particularly thrombocytopenia due to decreased platelet production, is associated with increased plasma TPO levels that stimulate megakaryopoiesis (Fig. 15.6). Although TPO expression by the liver is not regulated by thrombocytopenia, other stimuli can enhance TPO production. For example, IL-6 increases TPO expression through enhanced hepatic transcription, accounting for the thrombocytosis that is observed in clinical states of inflammation. In addition, transcription of TPO in marrow stromal cells has been shown to increase in states of thrombocytopenia and platelet proteins such as CD40 ligand, platelet-derived growth factor, fibroblast growth factor, TGF-β, PF4, and thrombospondin may also modulate TPO production from marrow stromal cells. The human TPO gene 5’ flanking region lacks a TATA box or a CAAT motif and directs transcription initiation at multiple sites over a 50-nucleotide region. Reporter gene analysis in a hepatocyte cell line identified an ETS2 transcription factor-binding motif responsible for high-level expression of the gene. Subsequent studies, though failing to confirm ETS factor interaction, identified binding of the C/EBP-δ. The 5’ flanking region also includes binding sites for specificity protein-1, activator protein-2 (AP-2), and nuclear factor-κB (NF-κB), although the contribution of these transcription factors to TPO gene expression, either under steady-state or stimulated conditions, has yet to be defined.
FIGURE 15.6. Regulation of plasma TPO levels. TPO is produced at a steady-state level by the liver, and to a lesser extent by the kidney. Plasma TPO is bound and internalized by c-Mpl receptors on circulating platelets, reducing the amount that reaches the bone marrow to stimulate megakaryopoiesis. In states of thrombocytopenia, more TPO reaches the marrow and thus platelet production is increased. When platelet levels are high, little TPO is available to stimulate megakaryopoiesis and platelet production decreases.

Although TPO is critically important for megakaryopoiesis, it is not essential, as mice lacking either the cytokine or its receptor retain approximately 10% of normal levels of megakaryocytes and platelets. Thus, other cytokines can support megakaryopoiesis. Prior to the discovery of TPO, it was known that IL-3, granulocyte-macrophage colony-stimulating factor (GM-CSF), and the c-KL (also called stem cell factor or steel factor) support the proliferation of megakaryocyte progenitors in plasma-containing cultures. IL-3 is a 25- to 30-kD protein produced primarily by T lymphocytes. The mature human polypeptide contains 133 amino acids, but significant amounts of N-linked carbohydrate modification account for the larger-than-expected relative molecular mass (Mr) of the cytokine. GM-CSF is an 18- to 30-kD protein also produced by T lymphocytes, but endothelial cells, monocytes, and fibroblasts also produce the protein and, like IL-3, GM-CSF is highly modified with both N-linked and O-linked carbohydrate.

Although the two polypeptides display essentially no primary sequence homology, their tertiary structures are highly related, and the receptors for the two cytokines share a common subunit. However, the physiologic relevance of IL-3 and GM-CSF for thrombopoiesis is uncertain because their administration to mice or humans has only minimal effects on platelet production, and the genetic elimination of either cytokine has no impact on megakaryopoiesis, even in combination with the elimination of other thrombopoietic cytokines. In contrast to the hematopoietic cytokine family, KL is more closely related to other hematopoietic proteins that use protein tyrosine kinase receptors, such as macrophage colony-stimulating factor and the flt-3 ligand (FL). Nevertheless, KL has been shown to stimulate megakaryocyte colony growth when used in combination with other cytokines. Moreover, genetic elimination of c-kit reduces megakaryocyte production and the rebound thrombocytosis that occurs after immunosuppressive therapy. In addition to early hematopoietic cells, KL also acts on primitive cells of the melanogenic and germ cell systems. KL is a dimeric protein composed of two identical noncovalently linked polypeptides; the soluble form monomer contains 165 residues, derived by proteolytic cleavage of a membrane-bound form of the molecule. The membrane-bound form is actually more active than the soluble cytokine because cell survival and proliferation signals derived from the former are prolonged in receptor-bearing cells. Moreover, a naturally occurring mutant allele of the gene (Sl()), which allows production of the soluble but not the membrane-bound form of KL, results in a phenotype nearly identical to deletion of the entire locus.

In the late 1980s and early 1990s, three molecules related by use of a common receptor subunit were characterized that display effects on megakaryocyte production. IL-6, cloned by several groups using multiple assays (hepatocyte growth,
myeloma cell growth, immunoglobulin secretion, and antiviral activity), was found to enhance megakaryocyte maturation. IL-6 is a 26-kDa polypeptide widely produced in response to inflammatory stimuli from T-cells, fibroblasts, macrophages, and stromal cells. The mature protein is composed of 184 amino acids, contains two disulfide bonds, and displays both N-linked and O-linked carbohydrate modification. Although IL-6 alone does not affect in vitro megakaryopoiesis, it augments the number of megakaryocyte colonies obtained in the presence of IL-3 or KL. In such culture systems, IL-6 primarily exerts a differentiating effect, as its levels correlate with megakaryocyte size and ploidy in long-term marrow cultures, and its neutralization reduces these parameters. The administration of IL-6 to mice, dogs, or humans results in a modest thrombocytosis.

Notch signaling is complex, as there are four single-pass transmembrane Notch receptors (Notch1-4) and five transmembrane ligands (Delta-like-1/3/4, Jagged-1/2). Notch signaling is initiated when the extracellular portion of a Notch receptor binds one of its cognate ligands, resulting in proteolytic cleavage that releases the intracellular domain of Notch from the membrane, allowing it to translocate to the nucleus and stimulate gene transcription. Although previously recognized for its role in T-cell development, Notch has more recently been shown to specify megakaryocyte development from hematopoietic stem and progenitor cells. Murine hematopoietic progenitors, cultured in the absence of cytokines on stroma expressing DL1, underwent megakaryocytic differentiation, whereas the same cells cultured on control stroma gave rise to erythroid and granulocyte-macrophage cells. Conversely, under megakaryocytic culture conditions, the presence of stromal cells expressing DL4 inhibited the later stages of megakaryocytic maturation without affecting earlier aspects of differentiation. The pathways are only partially understood; however, DL1 has been shown to cooperate with HOX84 in promoting HSC expansion; because TPO promotes HOX84 expression, this provides an opportunity for synergy between Notch and TPO signaling. In addition, both Notch and TPO signaling result in activation of PI3K and Akt, another potential synergy that would promote megakaryopoiesis.
In addition to positive regulators of megakaryopoiesis, several substances have been shown to inhibit megakaryocyte development. TGF-β is a family of five isoforms, all disulfide-linked homodimers each containing 112 residues. TGF-β1 is the predominant type of TGF found in hematopoietic tissues; platelet α-granules are a particularly rich source of this cytokine. TGFs are inhibitors of hematopoiesis in general, but particularly of megakaryocyte development. The two best understood TGF-β growth inhibitory effects are exerted on cell-cycle progression. After binding to one of five TGF receptors, two pathways that block cell-cycle progression are activated: pRb is hypophosphorylated, antagonizing the effects of G1-phase cyclin-dependent kinases, and the cell-cycle inhibitor p27 is upregulated, again halting cell-cycle progression at the level of S phase. It should be noted that TGF-β is not inhibitory only for megakaryopoiesis; rather, the cytokine appears to reduce hematopoiesis at many levels. In contrast to its effects on cell proliferation, evidence has been presented that TGF-β might enhance megakaryocyte differentiation by enhancing expression of the cell-cycle inhibitor p15, an effect that may be due to autocrine production of the cytokine. Additional platelet granule proteins found to inhibit megakaryocyte development include the chemokine PF4 and β-thromboglobulin. PF4 is a CXC chemokine, but unlike SDF-1 it does not act through a G protein-coupled CXCR; instead it forms a tetramer and binds to glycosaminoglycans on cell surfaces and to negatively charged domains of several membrane receptors. PF4 secreted by marrow megakaryocytes may act in a paracrine fashion to down-regulate megakaryopoiesis by binding to lipoprotein receptor-related protein-1 (LRP1). Although not demonstrated in megakaryocytes, LRP1 is required for growth inhibition in response to TGF-β in vascular cells, providing a potential mechanistic link between PF4 and TGF-β. Finally, interferon (IFN-α) inhibits megakaryopoiesis, and its use leads to modest to severe thrombocytopenia in a significant number of patients undergoing therapy for chronic hepatitis. Multiple mechanisms are responsible for the inhibitory effect of IFN-α on megakaryopoiesis, including a direct inhibitory effect of IFN-α on growth-factor-induced proliferation pathways. For example, IFN-α augments double-stranded RNA-activated protein kinase activity, inhibiting translation initiation factor-2 and implicating reduction of the growth-factor-induced protein synthesis necessary for cytokine response. Other investigators have reported that the functionally similar cytokine IFN-γ induces expression of the cell-cycle inhibitor p27, arresting cells in G0/G1. Wang et al. demonstrated that IFN-α induces a suppressor of the cytokine signaling-1 (SOCS1)-based feedback mechanism that negatively regulates TPO signaling. Consistent with these findings, TPO-receptor agonists have been used to ameliorate the thrombocytopenia resulting from IFN-α therapy in patients with hepatitis. Thus, in addition to the multiple positive mediators of megakaryopoiesis, several cytokines block the process and can lead to thrombocytopenia.

**SIGNAL TRANSDUCTION PATHWAYS IN MEGAKARYOCYTES**

c-Mpl is a typical hematopoietic receptor containing two cytokine receptor homology domains (marked by the distinctive WSXWS sequence motif), a transmembrane domain, and a cytoplasmic domain that mediates intracellular signaling. The extracellular domain is N-glycosylated, enhancing receptor secretion and cell surface expression. c-Mpl is secreted onto the cell surface as a pre-formed but inactive homodimer. Although c-Mpl does not have intrinsic tyrosine kinase activity, it associates with a cytoplasmic tyrosine kinase, Janus kinase (JAK)2 (Fig. 15.7). JAK2 binds to a short motif (termed box1) adjacent to the transmembrane domain of the receptor. Upon binding of TPO to its extracellular domain, c-Mpl undergoes a conformational change that brings the cytoplasmic tails of the receptor and the associated JAK2 closer together, initiating JAK2 kinase transactivation and downstream signaling events. Experimental manipulation of the receptor has identified three different states of the receptor, inactive, partially active, and active, related by receptor subunit rotation.

The state of the receptor depends in part on an amphipathic KWQFP motif at the junction between the transmembrane and cytoplasmic domains; deletion of this sequence experimentally results in a gain of function, in which the mutant receptor can signal in the absence of TPO. Naturally occurring mutations within the transmembrane domain (e.g., c-Mpl Ser505Asn, Trp508Ser, and Trp515Leu) also result in a constitutively active receptor and are associated with myeloproliferative disease. In addition, small molecule TPO-receptor agonists such as Eltrombopag bind to the transmembrane domain and may promote receptor activation through this type of allosteric mechanism. Following ligation, both c-Mpl and the bound TPO are then internalized through endocytosis, limiting the duration of signaling. Whereas a portion of the internalized receptor is degraded in the proteasome, a fraction is also recycled to the cell surface where it can again interact with TPO and participate in signaling. Enhanced proteosomal degradation and reduced receptor maturation and recycling of c-Mpl occurs in cells bearing the constitutively active Jak2 Val617Phe, present in the majority of patients with the myeloproliferative disease polycythemia vera (PV), leading to reduced surface expression of the receptor.
Janus family kinases are critical to megakaryopoiesis. Four JAK kinases have been identified in hematopoietic cells: JAK1, JAK2, JAK3, and TYK2. Of the cytokines that affect megakaryopoiesis, IL-3 activates JAK2; IL-6, IL-11, and LIF activate JAK1, JAK2, and TYK2 (although JAK1 is most important); and TPO leads to JAK2 and TYK2 phosphorylation (although JAK2 is most important) and . Moreover, even members of the receptor tyrosine kinase family that affect megakaryopoiesis, such as KI or FL, activate JAK kinases. Phosphorylation of JAKs leads to their activation, which, in turn, leads to phosphorylation of a number of substrates, including the receptors themselves and reversibly tethered signaling molecules. One of the best studied families of secondary signaling molecules is the signal transducers and activators of transcriptions (STATs); these latent transcription factors dock at P-Tyr residues of cytokine receptors and are phosphorylated by JAKs, and, once so modified, P-STATS dimerize, translocate to the nucleus, and bind to specific genetic elements altering transcription. Both P-Tyr and P-Ser modifications are required to fully activate STATs. Among the known targets of the STATs known to play an important role in megakaryocytic cell survival and proliferation are Bcl-X, c-myc, and with STAT1 displaying generally inhibitory effects on cell cycling and STAT3 and STAT5 displaying the opposite effect. Phosphorylation of tyrosine residues on c-Mpl by JAK2 creates docking sites for additional signaling intermediates via SRC homology 2 (SH2) domains, including the guanine nucleotide exchange factor Vav, adapter proteins such as Shc and the Gabs, and the phosphatase SHP2. Phosphorylation of JAK2 itself provides additional docking sites, providing binding sites for p85 and the adaptor protein Lnk. These interactions modulate signaling, activating the RAS-RAF-MAPK and PI3K-AKT pathways, or in the case of Lnk, down-regulating JAK2.

The RAS-RAF-MAPK pathway is critical in megakaryopoiesis. Activation of MAPK in cell lines promotes megakaryocytic differentiation, and MAPK pathway inhibitors block polyploidization and megakaryocyte maturation in primary cells. MAPKs are approximately 40-kD Ser/Thr kinases that are highly conserved in all eukaryotic cells from yeast to humans. At least six signaling cascades classified as MAPK pathways have been identified and have been found to mediate cell proliferation, survival, apoptosis, or differentiation. At present, three classes of MAPKs have been identified in megakaryocytes: extracellular stimulus response kinase (ERK) 1 and ERK2 (also termed p44 and p42, respectively); c-jun N-terminal kinase (JNK); and p38 kinase. MAPK activation requires phosphorylation both on threonine and tyrosine residues present on specific motifs (Thr-Xaa-Tyr). Receptors that activate MAPKs do so by activating Ras and initiating a kinase cascade. Thus, for c-Mpl, the adapter molecule Shc is recruited to the tyrosinephosphorylated receptor cytoplasmic domain, which is then phosphorylated by JAK2. Phospho-Shc then recruits the adapter protein Grb2, which activates the guanine nucleotide exchange factor SOS, which then charges Ras with GTP, thereby activating it. Active Ras, in turn, leads to the activation of an MAPK kinase kinase such as Raf-1, which phosphorylates an MAPK kinase such as MEK, which then phosphorylates MAPKs including ERK1 and ERK2. Because cells contain numerous MAPK kinase kinases and MAPK kinases, the potential for cross-talk between different MAPK pathways is large; this potential is reduced considerably through scaffolding proteins that sequester only the corresponding MAPK kinase kinase, MAPK kinase, and MAPK. Virtually every cytokine affecting megakaryocytes activates ERK1 and ERK2. Alternate pathways to MAPK activation have also been described in platelets, and integrin engagement in fibroblasts affects the cellular localization of ERK1/2, exerting a profound effect on its capacity to signal. Blockade of ERK1 and ERK2 has been shown to reduce cell proliferation in c-Mpl receptor-bearing cell lines and both cell proliferation and the generation of highly polyploid cells in megakaryocytic progenitors, but, curiously, to enhance proliferation of more primitive megakaryocytic progenitors from cord blood. The molecular targets of active MAPKs in megakaryocyte progenitors that mediate the effect of ERK1 and ERK2 on cell survival, proliferation, and differentiation are presently a topic of intense research; most studies in other cell systems suggest that ERK affects nuclear transcription factors, such as c-jun, c-myc, and the ets family member Elk-1, which then modulate activity of the cell-cycle machinery. For example, stimulation of ERK1 and ERK2 leads to increased levels of cyclin D in fibroblasts. The strength and duration of MAPK activation may be important in whether the cell responds by proliferation or differentiation. Transient or acute MAPK activation that occurs in the cell cytoplasm (minutes to hours) is typical of cell-cycle progression and proliferation, whereas sustained MAPK activation into the nucleus (lasting many hours or several days) is characteristic of cell-cycle arrest and differentiation. Activation of the Ras-like small GTPase Rap1 activates the MAPK kinase kinase B-Raf and leads to a sustained activation of ERK1/2 in cell lines. The Rap1 ERK signaling pathway responds to Src kinases and cAMP via activation of PKA and is linked to cell receptors via adaptor and scaffold proteins such as c-Cbl and CrkL. MAPKs also act on additional kinases, including the 90
kD ribosomal S6 kinase and the NF-κB activator AP-1. Despite their apparent importance, a requirement for either Raf-1 or B-Raf in megakaryopoiesis has not been proven in mouse models. Although TPO activates JNK and p38 in c-Mpl-bearing cells, primary megakaryocytes, and platelets, less is known of their effects on megakaryocyte development.

FIGURE 15.7. Representative pathways in TPO signaling. TPO binds to the homodimeric c-Mpl, leading to a conformational change that leads to transactivation of the associated JAK2 molecules. Active JAK2 then phosphorylates tyrosine residues on the receptor, including Y112 and Y117, which form docking sites for SH2-domain-containing proteins and adaptors. JAK2 phosphorylates STATs 3 and 5, which form homodimers and translocate to the nucleus where they activate transcription. Formation of a complex between SHC, SOS, and GRB2 leads to activation of the RAS/RAF/MAPK pathway. Engagement of p85 through adaptor proteins in conjunction with RAS activation leads to activation of PI3K and its downstream effectors. Negative regulators of TPO signaling, including SOCS, Lnk, Lyn, and PTEN, are shown in red.

P. 384

The PI3K pathway also has a critical role in megakaryopoiesis and is activated in response to multiple cytokines, including TPO, IL-3, GM-CSF, KL, and IL-6. PI3K is a heterodimeric lipid kinase composed of an 110-kD kinase (p110) and an 85-kD (p85) regulatory subunit. PI3K activity is initiated by the engagement of the two SRC homology 2 domains of p85, either by a phosphorylated cytokine receptor (usually in the context of a YXXM or YVAC motif) and an adapter molecule, resulting in conformational changes allowing activation of p110 and relocation of the kinase to the lipid membrane. Although p85 interacts directly with some hematopoietic cytokine receptors, the mechanism by which it is activated in TPO signaling is not clear; it may involve interaction with an adaptor molecule. Once in proximity to its membrane lipid substrates and its coactivator, membrane-bound activated Ras, active PI3K then generates PI 4,5 phosphate (PIP2) and PI 3,4,5 phosphate (PIP3), and pleckstrin homology (PH) domain-containing proteins are recruited to these phospholipids to initiate signaling cascades. Lipid phosphatases, including SRC homology 2-containing inositol phosphatase (SHIP2) and PTEN, negatively regulate PI3K signaling.

Central to the PI3K signaling cascade is 3-phosphoinositide-dependent protein kinase-1, also known as PDPK1. PDPK1 is recruited to PIP2 and PIP3 in the cell membrane through its PH domain where it can interact with its effector substrates.
including Akt, ribosomal protein p70 S6 kinase (p70S6K), and PKC. Akt is a serine-threonine kinase with multiple targets that have roles in cell survival and growth. TPO promotes phosphorylation and activation of Akt which is blocked by inhibitors of PI3K, and inhibition of PI3K in cell line models as well as in primary megakaryocytes leads to reduced cell survival and proliferation; furthermore, expression of a constitutively active Akt restores proliferation and survival in the presence of PI3K inhibitors.\(^{366}\) Akt promotes cell survival by phosphorylation of the proapoptotic protein Bad. Phosphorylated Bad binds to protein 14-3-3 and is thus targeted for proteolysis, removing its inhibitory effect on the pro-survival protein Bcl-X\(_L\).\(^{476,477,478}\) GSK-3\(\beta\) is also phosphorylated by Akt, leading to inhibition of GSK-3\(\beta\) activity and enhanced survival and proliferation.\(^{479,480}\) Forkhead family members, including FOXO3a, are also phosphorylated by Akt, preventing their translocation to the nucleus where they promote cell-cycle arrest and apoptosis by induction of p27, Bim, Fas ligand, and GADD45. TPO promotes down-regulation of p27 in megakaryocytic cells through a PI3K/Akt/FOXO3a pathway.\(^{481}\)

In addition, PI3K and Akt signaling activate the mammalian target of rapamycin (mTOR) through inhibition of the GTPase TSC2 and subsequent activation of the small GTP-binding protein Rheb.\(^{482,483}\) mTOR is a serine-threonine kinase and a member of the PI3K-related kinase family that functions in the regulation of cell size and cell-cycle progression. mTOR controls the phosphorylation status of proteins involved in initiating translational control, including p70S6K and eukaryotic translation initiation factor 4E-binding protein (4E-BP). Multiple signaling pathways converge on p70S6K and it has multiple sites of inducible phosphorylation; however, phosphorylation by PDPK1 and mTOR are essential for its activity.\(^{484}\) The Ras-MAPK pathway also modulates mTOR activity. TPO induces activation of the mTOR/p70S6K pathway in megakaryocytes, and inhibition of mTOR signaling by rapamycin leads to reduced proliferation of megakaryocytic progenitors and, in some studies, megakaryocyte polyploidization and maturation.\(^{485,486,487}\) mTOR signaling may be particularly important in neonatal megakaryopoiesis.\(^{488}\)

Although JAK2 has been studied the most, other tyrosine kinases are activated by TPO and play a role in megakaryopoiesis. The src family kinase Lyn is activated in TPO-stimulated megakaryocytes.\(^{489}\) Mutagenesis experiments identified tyrosine 112 of c-Mpl as critical for Lyn activation.\(^{490}\) Unlike Lyn, JAK2 is a cytokine receptor protein tyrosine kinase that is not membrane-bound. JAK2 stimulates cytokine signaling via activation of its associated tyrosine kinase-associated protein (TAP) and STAT proteins, including STAT5. However, JAK2 is not expressed in megakaryocytes.\(^{490}\)

In vivo, megakaryocytes are affected both by soluble cytokines and activation of adhesive receptors in the marrow microenvironment; similarly, focal adhesion kinase (FAK) activation in platelets requires the co-stimulation of growth factor receptors and integrins. In megakaryocytic cell lines, TPO stimulates phosphorylation of FAK.\(^{493}\) Targeted deletion of Fak in a mouse model resulted in enhanced megakaryopoiesis, with increased numbers of megakaryocytic progenitors, mature megakaryocytes, and circulating platelets. Fak\(^{-/-}\) megakaryocytes were impaired in their ability to active Lyn in response to TPO, but in contrast showed increased activation of MAPK and Akt signaling, and lyn\(^{-/-}\) mice show increased megakaryopoiesis.\(^{490,491}\)

As should be clear from the previous discussion, the megakaryocyte (and probably all hematopoietic cells) uses multiple molecular pathways to affect cell survival and proliferation. Recent work with c-Mpl has helped to clarify the nature and teleology behind this seeming redundancy. Phosphorylation of the penultimate tyrosine residue in the cytoplasmic domain of c-Mpl leads to Shc, STAT3, and STAT5 activation.\(^{419}\) Moreover, MAPK activation is also thought to emanate from the distal half of the receptor.\(^{430}\) Nevertheless, a truncated form of c-Mpl bearing neither of these regions continues to modestly activate STAT5, MAPK, and PI3K in a TPO-dependent manner,\(^{419}\) and introduction of a similarly truncated receptor into the germline in place of the full-length receptor affords the resultant mice a normal steady-state platelet count throughout life.\(^{494}\) However, these mice do not respond properly to stress; compared with normal mice, platelet recovery after immune-mediated or chemotherapy-induced thrombocytopenia is substantially delayed. Thus, the seeming redundancy in cytokine signaling appears to reflect a capacity of the cell to grade the TPO response into steady-state and emergency thrombopoiesis. A similar conclusion regarding signaling via STAT5 in erythropoiesis has been presented.\(^{495}\)

The signaling cascades initiated by TPO are of limited duration. Multiple mechanisms exist to govern this process. As discussed above, following initiation of signaling, the ligated c-Mpl is internalized and degraded.\(^{498,499}\) Another mechanism of feedback inhibition of cytokine receptor signaling is mediated by STAT-mediated induction of SOCS proteins.\(^{496}\) At present, five members of this STAT-induced family of signaling proteins have been found to inhibit signaling, either by directly blocking JAK kinase function or by competing for binding to phosphorytrosine receptor-signaling sites with secondary signaling mediators. Hence, when STAT is activated, it ultimately feeds back to inhibit JAK2 signaling. This mechanism can also account for receptor cross-talk (i.e., the ability of one cytokine signal to negatively affect another), because SOCS proteins induced by one receptor can interact with others.\(^{385,497}\) The SH2-domain-containing adaptor protein Lnk also binds to and negatively regulates JAK2 that has been phosphorylated in response to TPO. In the absence of Lnk, mice exhibit thrombocytosis and over time develop a myeloproliferative disorder.\(^{325,426,498}\)
Naturally occurring mutations that disrupt regulation of JAK2 are associated with the development of myeloproliferative disorders and leukemia.

**CLINICAL DISORDERS OF MEGAKARYOPOIESIS**

A number of disorders of megakaryopoiesis, including congenital thrombocytopenias and thrombocythemas, as well as acquired myeloproliferative disorders and leukemias, involve mutation of transcription factors and signaling molecules that have been discussed in this chapter as having a role in megakaryocyte development (Table 15.2). A brief review of several instructive disorders follows.

ATRUS, amegakaryocytic thrombocytopenia with radioulnar synostosis; BSS, Bernard-Soulier syndrome; CAMT, congenital amegakaryocytic thrombocytopenia; DS-AMKL, Down syndrome, acute megakaryoblastic leukemia; DS-TMD, Down syndrometranient myeloproliferative disorder; ET, essential thrombocythemia; FPD-PMM, familial platelet disorder with predisposition to myeloid malignancy; GPS, gray platelet syndrome; HPS, Hermansky Pudlak syndrome; PMF, primary myelofibrosis; PTS, Paris-Trousseau syndrome; PV, polycythemia vera; vWD, von Willebrand disease; WAS, Wiskott-Aldrich syndrome; XLT, X-linked thrombocytopenia; XLTT, X-linked thrombocytopenia with thalassemia.

CAMT: CAMT is the quintessential defect of megakaryocyte production, resulting from homozygous or compound heterozygous mutations of MPL encoding c-Mpl. The clinical course of CAMT confirms the critical role of TPO in both megakaryocytes and HSCs. Although children with CAMT are typically born with isolated thrombocytopenia and deficiency of megakaryocytes, over time they develop pancytopenia and bone marrows performed later in their course will show a severe depletion of megakaryocytes and trilineage hypocellularity. In addition, children with CAMT are at risk to develop clonal disease including myelodysplastic syndrome (MDS) or leukemia. Serum TPO levels are highly elevated.
due to the absence of receptor-mediated uptake.\textsuperscript{274} Whereas the majority of described mutations are in exons 1 to 3 of MPL, mutations have been described throughout the coding sequence. Mutations that result in complete disruption of the receptor (type I) are associated with an earlier onset of marrow failure (median age 22 months), whereas mutations that encode amino acid substitutions that result in partial receptor function (type II) are associated with transient improvement in platelet counts and a later onset of marrow failure (median age 48 months).\textsuperscript{500}

TAR and ATRUS: As in CAMT, thrombocytopenia with absent radii (TAR) also presents at birth with thrombocytopenia, but affected infants have the characteristic finding of bilateral absent radii. Additional skeletal and nonskeletal defects are frequent, including lower extremitiy, cardiac, renal, and gastrointestinal abnormalities.\textsuperscript{502} Unlike CAMT, thrombocytopenia in TAR tends to improve over the first 2 years of life, and children do not usually develop other cytopenias. TAR remains enigmatic with an incomplete understanding of its genetic etiology, and current evidence suggests a complex pattern of inheritance. Platelets from young patients with thrombocytopenia have impaired responses to TPO and impaired megakaryocyte differentiation, but TPO signaling is restored in platelets from adults.\textsuperscript{503} No defects in THPO (the gene for TPO), MPL, or JAK2 have been identified.\textsuperscript{504,506} A large study involving 30 patients with TAR identified a common interstitial microdeletion of 200 kb on chromosome 1q21.1 including several candidate genes.\textsuperscript{507} However, in approximately 75% of the patients, the deletion was inherited from an unaffected parent, suggesting that a second genetic change must be co-inherited in order for the phenotype to be expressed. The treatment of thrombocytopenia in TAR is largely supportive, as platelet counts typically improve with age.

ATRUS shares features with both CAMT and TAR. Thrombocytopenia is present at birth, and like TAR, there are radial abnormalities, in this case bilateral fusion of the proximal radius and ulna. However, platelet counts do not improve with age and similar to CAMT, most affected children develop bone marrow failure. Autosomal dominant inheritance of a mutation in the HOX family member HOXA11 was reported in two unrelated families with ATRUS\textsuperscript{216,508}; it is intriguing that mice lacking expression of HOXA11 show skeletal abnormalities but lack a hematologic phenotype.\textsuperscript{509} Additional patients with clinical features of ATRUS have been reported who do not have identifiable mutations in HOXA11,\textsuperscript{510,511} suggesting other loci may also be involved.

RUNX1: Reflecting the role of RUNX1 in hematopoiesis and megakaryocyte development, autosomal dominant mutations resulting in haploinsufficiency of RUNX1 are found in the familial platelet disorder with a propensity for myeloid malignancy (FPD-PMM).\textsuperscript{197,512} In FPD-PMM platelets are normal in size and thrombocytopenia is typically moderate, but bleeding may be more prominent than expected due to associated platelet dysfunction. The major complication of this disorder is not bleeding but the development of myelodysplasia or leukemia. The rate of myeloid malignancies in affected individuals ranges between 20% and

65% and peaks at the fourth decade of life. T-cell malignancies have been reported as well.\textsuperscript{513} Heterozygous mutations of RUNX1 described in this disorder range from substitutions or large deletions and most commonly affect the RUNX homology domain; although most result in haploinsufficiency, some mutations may have a dominant negative effect. Additional acquired mutations in RUNX1 or karyotypic abnormalities are frequently detected in the malignant clone at the time of acute myeloid leukemia/MDS diagnosis.

GATA1: As discussed above, GATA1 is essential for differentiation of both erythrocytes and megakaryocytes; thus, mutations affecting this transcription factor are associated with red cell abnormalities as well as thrombocytopenia. GATA1 mutations are associated with several phenotypes, including X-linked thrombocytopenia (XLT) with dyserythropoiesis, X-linked thrombocytopenia with thalassemia (XLTT), and rarely congenital erythropoietic porphyria.\textsuperscript{514} All mutations described to date are within the N-terminal zinc finger of GATA1; mutations altering the interaction of GATA1 and its co-factor FOG1 are associated with XLT, whereas mutations altering the interaction of GATA1 and DNA are associated with XLTT. Features suggestive of a GATA1 mutation include X-linked recessive inheritance, macrothrombocytopenia, “gray platelets” with deficient alpha granules, red cell abnormalities including dyserythropoiesis or thalassemia, and hyperproliferation of megakaryocytes in the bone marrow. Although inheritance is X-linked, a mild phenotype due to skewed X-inactivation in female family members has been described.\textsuperscript{515}

FLI1: Although no specific FLI1 mutations have been described in patients with inherited thrombocytopenia, in Paris-Trousseau syndrome there is deletion of the terminal portion of chromosome 11q (11q23), and within the critical deleted region are several genes important to megakaryopoiesis, most notably ETS and FLI1.\textsuperscript{218} Affected infants may have severe thrombocytopenia, congenital heart defects, and neurologic abnormalities.\textsuperscript{516} Platelets are normal in size, but Romanovsky staining or electron microscopy reveals abnormal giant alpha granules and may show deficiency of dense

P. 386
granules. Over time platelet counts improve and can reach near-normal levels, but a bleeding tendency that is out of proportion to the degree of thrombocytopenia frequently remains. Multiple genes are deleted; however, thrombocytopenia in Paris-Trousseau syndrome can be traced to the hemizygous loss of FLI1.

Macrothrombocytopenias: Giant platelet disorders include BSS and MYH9-related disease, although other thrombocytopenias are also characterized by large platelets. BSS is an autosomal recessive macrothrombocytopenia with significant platelet dysfunction due to the deficiency of GP Ib, the platelet receptor for vWF. GP Ib is composed of four subunits, encoded by four separate genes: GPIBA, GPIBB, GPS, and GP9. To date, mutations in BSS have been found in GPIBA, GPIBB, and GP9. Although BSS is classically inherited in an autosomal recessive fashion, the Bolzano mutation (c.515C>T transition in the GPIBA gene) is associated with mild macrothrombocytopenia in the heterozygous state. The mechanism of macrothrombocytopenia in BSS has been attributed at least in part to the interaction of GP Ib with filamin A, a dimeric scaffolding protein. This interaction may be critical for maintaining the platelet shape, as platelets from Flna- knockout mice are large and fragile despite normal GP Ib expression. Macrothrombocytopenia associated with mutation of FLNA has also been described in X-linked periventricular nodular heterotopia. Gain-of-function mutations of GP Ib are also associated with thrombocytopenia, due to inappropriate binding of platelets to vWF and consumption. This disorder resembles type 2B von Willebrand disease and is called platelet-type von Willebrand disease. In contrast to BSS, MYH9-related disease is inherited as an autosomal dominant disorder, and MYH9-related disease is also associated with progressive sensineural deafness, nephropathy, and cataracts. Prior to discovery of the underlying gene defect, affected patients were diagnosed with various disorders, including May-Hegglin anomaly, Sebastian syndrome, Ebstein syndrome, and Fechtner syndrome. MYH9 encodes the heavy chain of myosin IIA, which is active in the organization of the DMS and in proplatelet formation. Review of the peripheral blood smear may reveal Dohle-like bodies within neutrophils, which represent the abnormal precipitated myosin.

Wiskott-Aldrich Syndrome: Wiskott-Aldrich syndrome is caused by mutations involving the WASp, which is a hematopoietic-specific regulator of actin polymerization encoded on the X-chromosome. The full syndrome is manifested by microthrombocytopenia and impaired T-cell function, with eczema, frequent viral and bacterial infections, autoimmune phenomena, and predisposition to lymphoma. Mutations that only partially impair WASp function are associated with a less severe clinical course, typically X-linked microthrombocytopenia in the absence of significant immunodeficiency. This has been called X-linked thrombocytopenia or XLT, but it must be distinguished from XLT related to GATA1 mutations.

Granule Disorders: The study of disorders involving platelet α-granules (gray platelet syndrome) or dense granules (Hermansky Pudlak syndrome) has provided insights into the cellular mechanisms involved in granule formation in the megakaryocyte. Gray platelet syndrome (GPS) is characterized by thrombocytopenia with large platelets that appear pale on the peripheral blood smear due to a deficiency of α-granules. Families with X-linked disease are likely to have GATA1 mutations that can phenotypically resemble GPS (see above). Recently, mutations in NBEAL2 (neurobeachin-like 2) were identified as the genetic cause of autosomal recessive GPS. The function of NBEAL2 is not understood but it is a member of a family of proteins that are involved in vesicular trafficking. In Hermansky Pudlak syndrome, defects in the biogenesis and trafficking of lysosome-related organelles, including melanosomes and platelet dense granules, underlie the hypopigmentation and bleeding manifestations characteristic of the disorder. At least seven mutations in human disease, as well as additional mutants in mouse models have been described, involving members of multiprotein complexes that function to regulate formation of, and cargo recruitment into, membrane-bounded transport carriers (AP-3), in the tethering and regulation of fusion between endosomal compartments (HOPS), and the intracellular positioning and movement of late endocytic organelles (HOPS and BLOC-3). Both α- and dense granules are deficient in gunmetal mice, in which mutation of Rab geranylgeranyl transferase disrupts membrane remodeling and granule packaging; the human mutation has not been identified.

BCR/ABL-Negative Myeloproliferative Disorders: BCR/ABL-negative myeloproliferative disorders include PV, essential thrombocythemia (ET), and primary myelofibrosis (PMF). Acquired activating mutations in JAK2, typically Val617Phe but rarely alternative exon 12 mutations, can be found in most patients with PV, and nearly half of those with ET or PMF. Activating mutations in the transmembrane domain of c-Mpl, including Trp515Leu or Trp515Lys, are also found in a small proportion of patients with PMF and ET. JAK2 contains two Jak homology domains: JH1, which represents the active kinase domain, and JH2, which lacks kinase activity and negatively regulates JH1. The Val617Phe mutation within JH2 disrupts this negative regulation. In addition, JAK2 Val617Phe is not downregulated normally by Lnk.

In addition to these acquired conditions, familial thrombocytopenia has also been linked to inherited mutations that alter TPO signaling. The mutation Ser505Asn within the transmembrane domain of c-Mpl was identified in a large Japanese
family with thrombocytosis, and the mutant c-Mpl was shown to confer cytokine independence in a Ba/F3 cell line. Mutations leading to overproduction of TPO have also been identified in families with thrombocytosis. The TPO gene displays an unusual 5’ untranslated region structure. Unlike the majority of genes that initiate translation of the encoded polypeptide from the first ATG codon present in the mRNA, TPO translation initiates at the eighth ATG codon, located within the third exon of the full-length transcript. Moreover, the eighth ATG is embedded in the short open reading frame (ORF) of the seventh ATG, a particularly inefficient circumstance for translation initiation. As such, little TPO protein is produced for any given amount of mRNA. Although it is not yet certain whether this molecular arrangement has physiologic consequences (i.e., if it can be differentially regulated), mutation of the TPO gene in noncoding sequences can lead to enhanced translation efficiency and thrombocytosis. Four pedigrees of familial, autosomal dominant thrombocytosis have been linked to mutations in the region surrounding the initiation codon. In two families, a single mutation in different nucleotides of the intron 3 splice donor sequence results in alternate splicing of the primary TPO transcript, eliminating the seventh and eighth ATG codons, and in the creation of a new amino terminus by the fusing of the fifth ORF with the TPO coding sequence. This novel TPO mRNA is efficiently translated, resulting in supraphysiologic levels of cytokine production and polyclonal expansion of thrombopoiesis. In another mutant TPO allele, the deletion of a single nucleotide within the seventh ORF leads to its fusion with the TPO coding sequence and to now-enhanced translation of TPO from the seventh ATG codon. Finally, another mutation within the seventh ORF leads to its premature termination, preventing its interference with translation initiation from the usual eighth initiation codon and again enhancing TPO production.

Transient Myeloproliferative Disorder and Acute Megakaryoblastic Leukemia: Approximately 10% to 20% of infants with Down syndrome develop transient myeloproliferative disease (TMD), in which immature megakaryoblasts accumulate in the liver, bone marrow, and peripheral blood. Although almost indistinguishable from acute megakaryoblastic leukemia (AMKL), this disorder undergoes spontaneous remission in most cases. However, approximately 30% of children with a history of TMD go on to develop AMKL within 3 years. Certainly an extra copy of chromosome 21, which contains the gene RUNX1, predisposes these children to megakaryocytic proliferative disorders, although the exact role of trisomy 21 is unclear. However, acquired mutations of GATA1, resulting in the production of GATA1S, have been detected in the majority of Down syndrome patients with TMD and AMKL and represent an early step in leukemic transformation. Note that GATA1 mutations are not found in children with AMKL in the absence of Down syndrome, suggesting an important interaction between GATA1S and trisomy 21. Instead, a translocation between chromosomes 1 and 22, resulting in the fusion protein OTT-MAL, has been detected in AMKL occurring in children without Down syndrome. Expression of the OTT-MAL fusion protein in a conditional knockin mouse model led to expansion of multipotent myeloid progenitors, enhanced self-renewal of megakaryocytic progenitors, extramedullary hematopoiesis, and eventual development of AMKL. Further studies showed that expression of OTT-MAL activates RBPIJ, which normally serves as a transcriptional coactivator of Notch, thus deregulating Notch signaling. The activation of RBPIJ-mediated transcription by OTT-MAL is required for the growth of AMKL cells derived from leukemic animals.

Platelet Structure and Function in Hemostasis and Thrombosis
Susan S. Smyth

PLATELET STRUCTURE
Structural and Functional Anatomy

Light Microscopy
Light microscopy of Wright-stained smears (Fig. 16.1) reveals platelets as small, anucleate (i.e., lacking a nucleus) fragments with occasional reddish granules, measuring approximately 2 µm in diameter with a volume of approximately 8 fl and exhibiting considerable variation in size and shape. Platelets released from the marrow under "conditions of stress" such as thrombocytopenia and termed stress platelets are large and often beaded in shape, whereas young platelets, recently released from the marrow, are termed reticulated in reference to their RNA content and in analogy to young red cell reticulocytes.

Electron Microscopy and Subcellular Features
Platelets exist in two distinct forms, resting and activated, with the resting state marked by baseline metabolic activity and the activated form resulting from agonist stimulation (e.g., response to thrombin). By scanning electron microscopy, circulating resting blood platelets appear as flat discs with smooth contours, rare spiny filopodia (Fig. 16.2), and random openings of a channel system, the surface-connected canalicular system (SCCS), which invaginates throughout the platelet and is the conduit by which granule contents exocytose after stimulation. Although the platelet is anucleate, transmission electron microscopy reveals a complex surface and a cytoplasm packed with a number of different subplatelet structures and organelles that are essential to the maintenance of normal hemostasis (Figs. 16.3 and 16.4). Initial descriptions of platelet anatomy stem from studies employing transmission electron microscopy; and platelet structure is classified into four general areas: the platelet surface, membranous structures, cytoskeleton, and granules.

Platelet Surface
Plasma Membrane
The platelet plasma membrane separates intra- from extracellular regions and, in thin sections, exhibits a typical 20-nm-thick trilaminar structure whose overall appearance does not differ from that of other blood cells. The platelet membrane is exceptionally complex in composition, distribution, and function, incorporating a number of glycoproteins (GPs) and lipids into its phospholipid bilayer and integrating a variety of extra- and intraplatelet events such as permeability, agonist stimulation, and platelet adhesion, activation/secretion, and aggregation.

The lipid composition of the membrane is distributed in an asymmetric manner, with neutral species located mainly in the outer layer, and anionic forms, such as phosphatidylserine (PS), concentrated on the inner side. This sequestration of PS, which promotes plasma coagulation by contributing to the prothrombinase complex, on the inner side of the membrane may account for the fact that resting platelets are essentially nonreactive in terms of thrombin generation. On the other hand, activated platelets make a major contribution to thrombin formation through the interactions of factors Xa and Va and prothrombin on their surface. The plasma membrane also contains sodium and calcium adenosine triphosphatase (ATPase) pumps, which are important for maintaining ionic homeostasis.

Platelet Membranous Systems
Platelets have features of muscle-related cells in terms of their high content of actin and their contractile response during activation. Similar muscle-like qualities are found in the two membranous systems of platelets, the SCCS and the dense tubular system, which resemble transverse tubules and sarcotubules, respectively.

Surface-connected Canalicular System
The SCCS, also called the open canalicular system, is fenestrated and contiguous with the surface plasma membrane. The SCCS has several prominent functional roles: first, as an internal reservoir of membrane to facilitate platelet spreading and filopodia formation after adhesion; and second, as a storage reservoir for membrane GPs, such as αIIbβ3 (GPIIb-IIIa), that increase on the platelet surface after activation. The system also provides a route for granule release during the secretory phase of platelet activation and serves as a route of ingress and egress for molecules as they translocate between the plasma and the platelet.

Dense Tubules
Unlike the SCCS, the dense tubular system is a closed-channel system consisting of narrow, membrane-limited tubules, approximately 40 to 60 nm in diameter.\textsuperscript{17} It contains residual smooth endoplasmic reticulum from the megakaryocyte.\textsuperscript{18,19} Peroxidase,\textsuperscript{20,21} acetylcholinesterase (in cat, rat, and mouse but not human platelets or megakaryocytes),\textsuperscript{24} adenylate cyclase, and Ca\textsuperscript{2+} and Mg\textsuperscript{2+}-activated ATPases\textsuperscript{25} have been cytochemically demonstrated in the dense tubular system.

This channel system is involved in the regulation of intracellular calcium transport because it has been reported to selectively bind, sequester, and release divalent cations after activation.\textsuperscript{25}

P.390

The dense tubular system is also the site of prostaglandin (PG) synthesis in platelets.\textsuperscript{26,27}

FIGURE 16.1. A human peripheral blood smear stained with Wright-Giemsa. Platelets, indicated by arrows, are interspersed between erythrocytes and a few leukocytes. The pale, grayish-blue cytoplasm contains purple-red granules. Original magnification of 35-mm slide x100.
FIGURE 16.2. Scanning electron micrograph of unstimulated human platelets. Most are discoid (d) in shape. Many surface indentations, indicated by arrows, are present; these correspond to openings of the surface-connected canalicular system to the external milieu. Magnification ×15,000. (Data from Stenberg PE, Shuman MA, Levine SP, Bainton DF. Optimal techniques for the immunocytochemical demonstration of β-thromboglobulin, platelet factor 4, and fibrinogen in the alpha granules of unstimulated platelets. Histochem J 1984;16:983-1001.)

Platelet Cytoskeleton
The shape of platelets and their ability to contract and spread depend on an organized cytoskeleton. The cytoskeleton can direct platelet shape change, send out extracellular extensions, collect and then extrude secretory granules, and affect surface reactivity (Fig. 16.5). These varied functions are performed by three distinct structures: first, the membrane skeleton, which buttresses the inner side of the plasma membrane; second, the mass of actin and intermediate filaments, which fills the cytoplasm; and third, the circumferential microtubule band, which encircles the substance of the platelet to produce the resting disclike form. Three different protein filaments/tubules contribute to the overall network: 5- to 6-nm-diameter microfilaments of actin, 10- to 12-nm intermediate filaments of desmin and vimentin, and 25-nm microtubules composed mainly of tubulin. Together, these filaments, depending on the activation state of the platelet, comprise 30% to 50% of total platelet protein.

FIGURE 16.3. Diagram of a human platelet displaying components visible by electron microscopy and cytochemistry. In addition to membranous components (plasma membrane, surface-connected canalicular system, and dense tubular system), mitochondria, microtubules, and glycogen, four types of storage organelles are identified: α-granules, dense bodies, lysosomes, and microperoxisomes. Whereas the first two can be identified morphologically, microperoxisomes and lysosomes are recognizable only by cytochemical stains. (From Bentfeld-Barker ME, Bainton DF. Identification of primary lysosomes in human megakaryocytes and platelets. Blood 1982;59:472-481, with permission.)

Membrane Skeleton

The membrane skeleton was first described more than 30 years ago by electron microscopy and then analyzed biochemically by detergent lysis in Triton X-100. The membrane skeleton contains short actin filaments that connect surface receptors with the bulk of cytoplasmic actin filaments. Filamin-A, a component of the membrane cytoskeleton, links the cytoplasmic domain of GPIbα with actin filaments and also binds integrins. Other components of the membrane skeleton include structural and signaling molecules such as spectrin, talin, migfilin, Src, and small GTPase family members (Table 16.1). Through tight regulation, the interactions of these proteins allow platelets to sense and to respond to environmental cues.

Cytoplasmic Actin and Intermediate Filaments

The bulk of the platelet cytoskeleton consists of a large amount of actin (M_r = 42,000) that comprises approximately 25% of total platelet protein. Other platelet cytoskeletal proteins, such as tropomyosin and α-actinin, are present in lower amounts (2% to 5% of total platelet protein). The actin exists in soluble, monomeric (G-actin), and filamentous (F-actin) forms and connects to both the membrane skeleton and the microtubules. In resting platelets, approximately 40% of actin is in microfilaments, which are dispersed throughout the cytoplasm and obscured by their small size and the
many other subplatelet structures present, such as granules. The intermediate filaments are more stable, resistant structures, rich in vimentin, that appear to bear tension within the cytoplasm.

Platelet stimulation results in profound changes in cytoskeletal organization. Morphologically, platelets rapidly lose their discoid shape, become rounded, and extend filopodia. With the rise in intracellular calcium, the proportion of F-actin increases rapidly to 60% or 70%. Actin monomers polymerize into filaments at platelet peripheries, and bundles of new filaments form to fill developing filopodia. Phosphorylation of myosin light chain results in binding of myosin to actin, providing the tension required for granule centralization and retraction of filopodia. Additional proteins, such as talin and surface αIIbβ3, join the developing electron-dense actin filaments, and the structure is remodeled through the action of an associated calcium-dependent protease, calpain. The sum of these events in platelet function is critical because the combination of various additions, rearrangements, and remodeling steps underpins shape change and spreading (filopodia and lamellipodia formation), along with platelet secretion and clot retraction.
FIGURE 16.4. Ultrastructure of unstimulated human platelets. Membranous organelles, including the surface-connected canalicular system (SCCS) and dense tubular system (DTS), and cytoplasmic organelles, including mitochondria (M), α-granules (G), dense bodies (DB), coated vesicles (CV), and glycogen (GLY), are visualized at the ultrastructural level. Microtubules (MT) are present as cross-sectional and longitudinal profiles at the poles of the discoid platelets.
Magnification ×46,000. Bar = 0.5 µm.

Microtubules

A circumferential microtubule band that supports the discoid form of the platelet\textsuperscript{33,34} is made of two nonidentical subunit proteins (α- and β-tubulin), associated with microtubule-associated proteins. The 25-nm-diameter microtubule coil lies adjacent to, but does not touch, the plasma membrane.\textsuperscript{56} Platelet microtubules comprise 13 protofilaments of αβ tubulin dimers and are primarily polymerized in unstimulated platelets. Platelet activation results in microtubule disassembly and then reassembly; such alterations in the marginal microtubule bundle result in platelet shape changes.\textsuperscript{56} Microtubules appear to be key determinants of platelet size\textsuperscript{57} and may be disorganized in giant platelet disorders.\textsuperscript{58}

Platelet Granules and Organelles

Platelets possess secretory granules and mechanisms for cargo release to amplify responses to stimuli and influence the surrounding environment. Platelet granule structures include α- and dense granules, lysosomes, and peroxisomes. α-Granules and the dense bodies are the main secretory granules that release cargo (e.g., fibrinogen and adenosine diphosphate [ADP]) upon platelet activation.
FIGURE 16.5. Human platelet cytoskeletons prepared by simultaneous fixation and lysis in Triton X-100 detergent. Single actin filaments, indicated by short arrows, course throughout the platelet cytoplasm. Clusters of filaments, indicated by
long arrows, also are present. Note the microtubule coils at the platelet peripheries (arrowheads). Magnification ×30,000. (From Boyles J, Fox JEB, Phillips DR, Stenberg PE. Organization of the cytoskeleton in resting, discoid platelets: preservation of actin filaments by a modified fixation that prevents osmium damage. J Cell Biol 1985;101:1463-1472, with permission.)

Platelet granule secretion begins with a dramatic increase in platelet metabolic activity, set off by a wave of calcium release and marked by increased adenosine triphosphate (ATP) production. After platelet stimulation by agonists, a “contractile ring” develops around centralized granules, the granules fuse with the surface membranes, and then they extrude their contents. The molecular events underlying platelet granule release involve many of the same proteins and processes observed in other systems of membrane docking, fusion, and extrusion. Granule secretion in platelets is a graded process that depends on the number, concentration, and nature of the original stimulus/stimuli, either strong (e.g., thrombin and collagen) or weak (e.g., ADP and epinephrine).

α-Granules

α-Granules, with a cross-sectional diameter of approximately 300 nm and numbering approximately 50 per platelet, are the predominant platelet granules. They are approximately spherical in shape, with an outer membrane enclosing two distinct intragranular zones that vary in electron density. The larger, electron-dense region is often eccentrically placed and consists of a nucleoid material that is rich in platelet-specific proteins such as β-thromboglobulin. The second zone, of lower electron density, lies in the periphery adjacent to the granule membrane and contains tubular structures with adhesive GPs such as von Willebrand factor (vWF) and multimerin.

P.392

along with factor V. Platelets take up plasma proteins and store them in their α-granules. Select α-granule proteins are discussed below and listed in Table 16.2.

Three proteins, β-thromboglobulin, PF4, and thrombospondin, are synthesized in megakaryocytes and highly concentrated in α-granules. The first two, β-thromboglobulin and PF4, show homology in amino acid sequence and share the additional features of localization in the dense nucleoid of α-granules, heparin-binding properties, and membership in the CXC family of chemokines. \(^{14,71,72,73}\) and \(^{74}\) Together, they constitute approximately 5% of total platelet protein, and they can serve as useful markers for platelet activation in serum or plasma. \(^{75,76}\) Thrombospondin may comprise up to 20% of the total platelet protein released in response to thrombin, and likely participates in multiple biologic processes. \(^{77,78}\)

vWF is also synthesized by megakaryocytes and is present in the tubular structures of the α-granule peripheral zone, similar to its localization within Weibel-Palade bodies of vascular endothelial cells. \(^{66,79}\) Factor V and multimerin, a factor V/Va-binding protein, \(^{67,80}\) co-localize with vWF in platelets but not in endothelial cells. Fibrinogen is also found in α-granules, but is incorporated actively from plasma and not synthesized by megakaryocytes. \(^{69}\) In fact, small amounts of virtually all plasma proteins, such as albumin, immunoglobulin G (IgG), fibronectin, and β-amyloid protein precursor, may be taken up into the plateau α-granules. \(^{79,81,82}\) and \(^{83}\) α-Granules also contain many growth factors, including platelet-derived growth factor, transforming growth factor-β (TGF-β), and vascular endothelial growth factor. These signaling molecules may contribute to the mitogenic activity of platelets. \(^{84,85}\) A role for platelet α-granule proteins in angiogenesis has been recently reported. Both pro- (e.g., VEGF) and antiangiogenesis proteins (e.g., endostatin) are stored within α-granules. How populations of angiogenesis regulatory proteins may be selectively compartmentalized and released from platelets is an area of active investigation. \(^{86,87,88,89}\) and \(^{90}\) Likewise, the activation and functions of platelet-derived TGF-β in cardiac fibrosis and other conditions have been described. \(^{91,92}\)

Platelet α-granules serve as an important reservoir for α\(_\text{IIb}β\_3\) that contributes significantly to the surface fibrinogen receptors present on activated platelets. \(^{93,94,95}\) The α-granule membrane protein, P-selectin (granule membrane protein-140) is translocated to the plasma membrane after platelet activation. \(^{96,97}\) Finally, a number of additional proteins have been located to the surface of α-granules alone, including CD9, platelet endothelial cell adhesion molecule-1 (PECAM-1), Rap 1b, GPIb-IX-V, and osteonectin. \(^{98,99}\) and \(^{100}\) (Table 16.2).

The platelets and megakaryocytes of patients with gray platelet syndrome have decreased numbers of α-granules and reduced levels of some proteins. It is proposed that there is incorrect targeting of α-granule proteins to the α-granule in the megakaryocyte in this disease. \(^{101,102}\)

Dense Bodies

Dense bodies, numbering approximately five per platelet, are exceptionally electron-dense and easily distinguished by electron microscopy because of their distinctive “bull’s-eye” appearance. \(^{103,104}\) With an approximate diameter of 250 nm, these granules contain a large reservoir of ADP, a critical agonist for platelet activation that amplifies the effect of other stimuli. \(^{132}\) In addition to this nonmetabolic pool of ADP, the dense bodies are rich in ATP, pyrophosphate, calcium, and serotonin (5-hydroxytryptamine), with lesser amounts of guanosine triphosphate (GTP), guanosine diphosphate (GDP), and magnesium. \(^{74}\) The adenine nucleotides are synthesized and segregated by megakaryocytes, whereas serotonin is incorporated into dense granules from the plasma by circulating platelets. \(^{133,134,135}\) There is more ADP than ATP in dense bodies, and both can lead to adenosine monophosphate (AMP). In turn, AMP can be dephosphorylated to adenosine or cyclized to produce cyclic AMP, an inhibitor of the platelet-stimulatory response. The dense granule membrane contains P-selectin and granulophysin. \(^{136}\)

Lysosomes

Lysosomes are small, acidified vesicles, approximately 200 nm in diameter, \(^{105}\) that contain acid hydrolases with pH optima of 3.5 to 5.5, including β-glucuronidase, cathepsins, aroyl P.393

sulfatase, β-hexosaminidase, β-galactosidase, haperitinase, and β-glycerophosphatase. Additional proteins found in lysosomes include cathepsin D and lysosome-associated membrane proteins (LAMP-1/LAMP-2), which are expressed on the plasma membrane after activation). \(^{106,107}\) Lysosomal constituents are released more slowly and incompletely (maximally, 60% of the granules) than α-granules or dense-body components after platelet stimulation, and their release also requires stronger agonists such as thrombin or collagen.

conc., concentration.
Note: A number of additional elements are released or secreted from within the platelet. For example, α-granules also contain the major platelet surface glycoproteins (GPs) GPIIb-IIIa and GPIb-IX along with albumin and immunoglobulin G, adhesive glycoproteins (fibronectin, vitronectin), fibrinolytic components (α2-antiplasmin, plasminogen activator), and coagulation-related proteins (high-molecular-weight kininogen, α2-macroglobulin). In addition, dense granules contain guanosine triphosphate/guanosine diphosphate and high concentrations of pyrophosphate, phosphate, and magnesium, much of which is secreted with activation. A number of additional proteins are present, some released and some retained in the platelet cytosol, such as a subunit of factor XIII, amyloid β-protein precursor, protease nexin I, and tissue factor pathway inhibitor.

Organelles: Microperoxisomes, Coated Vesicles, Mitochondria, and Glycogen

Peroxisomes are rare, small (90 nm in diameter) granules, demonstrable with alkaline diaminobenzidine as a result of their catalase activity. The structure may participate in the synthesis of platelet-activating factor. Mitochondria in platelets are similar, with the exception of their smaller size, to those in other cell types. There are approximately seven per human platelet, and they serve as the site for the actions of the respiratory chain and the citric acid cycle. Glycogen is found in small particles or in masses of closely associated particles, playing an essential role in platelet metabolism.

Platelet Biochemistry and Metabolism

Composition

The platelet is composed of approximately 60% protein, 15% lipid, and 8% carbohydrate by dry weight. Platelet minerals include magnesium, calcium, potassium, and zinc. Platelets contain substantial amounts of vitamin B12, folic acid, and ascorbic acid. The concentrations of sodium and potassium within the platelet are 39 and 138 mEq, respectively. This gradient against plasma, apparently distributed in two discrete metabolic compartments, is maintained by an active ion pump, which derives energy from a membrane ATPase of the ouabain-sensitive, Na+/K+-dependent type.

Unstimulated platelets maintain a low cytoplasmic Ca2+ concentration (~100 to 500 nmol/L) by limiting Ca2+ transport from plasma and promoting active efflux of this ion from the cell. Two pools of calcium are present in platelets: a rapidly turning over cytosolic pool regulated by a sodium-calcium antiporter in the plasma membrane and a more slowly exchanging pool regulated by Ca2+/Mg2+-ATPase and sequestered in the dense tubular system. Platelets are therefore able to transport calcium from the cytosol by moving it against a gradient into the extracellular space or by sequestration in the dense tubular system.

Energy Metabolism and Generation of ATP

There are several similarities between the energy metabolism of the platelet (Fig. 16.6) and that of skeletal muscle. Both involve active glycolysis and the synthesis and use of large amounts of glycogen, and in both, the major mediator of intracellular energy use is an actomyosin-like ATPase. The platelet, like muscle, is metabolically adapted to expend large amounts of energy rapidly during aggregation, the release reaction, and clot retraction.

The major energy source for the platelet is glucose, which is rapidly taken up from the plasma (Fig. 16.6, Step 1). Under basal conditions, 40% to 50% of the absorbed glucose is used to provide energy for synthetic functions or is converted into glycogen. Electron microscopy reveals prominent masses of glycogen in some platelets. The glycolytic pathway with its regulatory enzymes (phosphorylase, pyruvate kinase, hexokinase, phosphofructokinase, and glyceraldehyde 3-phosphate dehydrogenase), the citric acid cycle, the pentose phosphate shunt, and the NAD-NADH (nicotinamide adenine dinucleotide-nicotinamide adenine dinucleotide [reduced form]) system are all active in the platelet. Ninety-eight percent of platelet pyruvate is converted to lactate, which leaves the platelet. In addition to glycolysis, platelets contain enzymes for oxidative phosphorylation and fatty acid oxidation (Fig. 16.6, Step 2).
FIGURE 16.6. Simplified scheme of platelet energy metabolism. Platelet energy is derived from the metabolism of glucose and, to a lesser extent, from the metabolism of fatty acids. Energy is provided in approximately equal amounts by glycolysis and the citric acid cycle. The platelet energy reserve is provided by the metabolic pool of platelet nucleotides that is in a state of continuous turnover. This energy is used for the maintenance of the platelets' structural integrity and in the reactions accompanying the response of platelets to stimuli. The granule-bound storage (nonmetabolic) nucleotide pool is discharged during the release reaction. ADP, adenosine diphosphate; AMP, adenosine monophosphate; ATP, adenosine triphosphate; IMP, inosine monophosphate. (Adapted from Hirsh J, Doery JCG. Platelet function in health and disease. Prog Hematol 1972;7:185-234.)

ATP production in platelets is affected greatly by the suspending medium, chelating agents, and in vitro manipulation of platelets. In plasma, oxidative ATP production by unstimulated platelets is predominant, and all ATP formed by oxidative phosphorylation may be the product of β-oxidation of fatty acids, glycogen turnover, the hexose monophosphate shunt, and the citric acid cycle are virtually inactive. Glycolysis is capable of completely compensating for reduced ATP production when oxidative phosphorylation is inhibited. Platelet stimulation by agents that induce aggregation and release is associated with a marked increase in metabolic activity involving glycogenolysis, as well as with glycolysis and oxidation to varying degrees.

The total amounts of ATP synthesized by the two pathways are approximately equal because of the greater ATP yield per mole of glucose provided by oxidation. ATP energy is used in unstimulated platelets to maintain homeostatic levels of H⁺, K⁺, Na⁺, and Ca²⁺. Nucleotide Metabolism and the Nonmetabolic Role for ADP

Adenine nucleotides constitute 90% of free platelet nucleotides and are partitioned into at least two different pools, which undergo minimal interchange (Fig. 16.6). The metabolic or
cytoplasmic pool makes up 40% of total adenine nucleotides; it is used for the maintenance of various energy-consuming cell functions and is retained during platelet release. In large part made up of ATP, this pool is constantly turning over, as revealed by the rapid incorporation of $^{14}$C-adenine and $^{32}$P-phosphate into ATP. In unstimulated platelets, the relative concentrations of metabolic AMP, ADP, and ATP are maintained by the enzyme adenylate kinase (Fig. 16.6, Step 3). The storage pool, which is present in the dense bodies, contains approximately two-thirds of the total platelet nucleotides, mainly in the form of ADP and ATP. It is metabolically inactive, does not rapidly incorporate exogenous adenine or phosphate, and equilibrates slowly with the metabolic pool. Nucleotides in this pool are extruded from the platelet during the release reaction (Fig. 16.6, Step 4) and cannot be replenished after release. ATP hydrolysis is required for conversion of G-actin to F-actin, and the resultant ADP becomes associated with F-actin; this small percentage of platelet ADP bound to actin constitutes one-third of the nucleotide compartment. Perhaps as much as 40% of all ATP produced is used during the process of actin treadmilling, and as much as 7% is used in the turnover of the phosphoinositides PIP and PIP$_2$.

The ATP that is broken down to provide energy for the release reaction is not rephosphorylated; rather, it is irreversibly degraded to hypoxanthine (Fig. 16.6, Step 5), which diffuses out of the cell. This reaction also proceeds slowly in stored normal platelets. Hypoxanthine in the plasma may be reincorporated slowly into metabolic AMP by the salvage pathway (Fig. 16.6, Steps 6 and 7). Platelet stimulation results in marked activation of ATP-producing pathways. The steady-state level of ATP decreases and hypoxanthine accumulates. In addition, a transient but greatly increased uptake of phosphate by platelets occurs. Although ATP-requiring processes are activated by platelet stimulation, it is unknown whether or how these are coupled to signal processing in platelets.

Lipid Composition and Metabolism and the Generation of Arachidonic Acid

Phospholipids constitute 80% of total platelet lipid, with neutral lipids and glycolipids comprising the remainder. The five major phospholipids identified in human platelets are phosphatidylcholine (PC, 38% of total phospholipids), phosphatidylethanolamine (PE, 27%), sphingomyelin (17%), PS (10%), and phosphatidylinositol (PI, 5%). Studies of platelet subcellular fractions reveal that 57% of total human platelet phospholipids are present in the plasma membrane. Most of the negatively charged phospholipids (i.e., PE, PI, and PS) are contained in the inner leaflet and an asymmetric arrangement that prevents inappropriate coagulation by sequestering the phospholipids that accelerate plasma coagulation (mainly PS) away from the platelet surface. This asymmetry collapses when platelets are activated. These same phospholipids (i.e., PS and PE, which interact with coagulation proteins) redistribute with platelet activation and are thereby exposed on the surface to function in promoting clot formation. The asymmetric distribution of phospholipids on the platelet surface appears to be maintained by one or more membrane scramblase enzymes; and a “floppase” has been proposed to reverse the phospholipid asymmetry with activation.

Almost all platelet fatty acids are esterified in phospholipids, leaving only trace amounts in the free form. Platelet phospholipids are enriched in arachidonate, the precursor of prostaglandins, at their “sn-2” position. After agonist stimulation, phospholipase A$_2$ activity rises, and arachidonic acid is released from membrane phospholipids, predominantly PC. After release, arachidonic acid is oxygenated to form the cyclic endoperoxide intermediate, PGH$_2$, by cyclo-oxygenase-1, which leads to TXA$_2$ formation. The lipoxigenase pathway accounts for a small proportion of arachidonate metabolism, producing mainly 12-HETE (12-hydroxyicosatetraenoic acid).

Neutral lipids, mainly cholesterol, make up approximately 28% of total platelet lipids. Cholesterol is a major constituent of platelet membranes and is also present in the platelet cytoskeleton. It is synthesized by megakaryocytes but not by platelets. Finally, neutral glycolipids, gangliosides, and ceramides have been detected in platelets.

Platelet Microparticles and Kinetics

Microparticles

Platelet microparticles are tiny structures rich in surface PS that are generated during platelet activation and can contribute significantly to the acceleration by platelets of plasma coagulation, specifically factor Xa and thrombin generation. The composition of microparticles varies with the agonist or stimulus (C5b-9, ionophore A23187, thrombin, tissue factor, shear) involved in their formation, and have been found to bind factors Xa, VIII, and Va, along with protein S. Physiologically, microparticles appear to be an important contributor to procoagulant activity as their defect in patients is associated with clinical bleeding.

Platelet Heterogeneity
The normal platelet count varies between 150,000 and 400,000/µl, and normal platelet size (mean platelet volume) varies between 7.5 and 10.5 fl. Platelets are released into the blood from long proplatelet extensions of megakaryocytes. 

Young platelets, that is, those recently released by megakaryocytes, are larger and more dense, and undergo remodeling in circulation, in part by shedding some of their surface components. Macrothrombocytopenias may reflect a disturbance in the steps of platelet production, and the properties of large platelets may reflect unique attributes of platelets recently released from the bone marrow or proplatelets produced under conditions of accelerated or abnormal production.

Platelet Distribution and Survival Kinetics

Labeling

Platelets labeled with $^{51}$Cr (chromate) have been used to estimate platelet lifespan in humans at 8 to 12 days, and the method has been widely validated. Other methods reported for platelet labeling include $^{111}$In (indium) chelated with 8-hydroxyquinoline and $^{32}$P-labeled diisopropylfluorophosphate, $^{68}$Ga (gallium). Platelet labeling is not commonly used for clinical evaluations, but all of the published studies give the same approximate values for distribution and survival.

Distribution

Approximately one-third of the total platelet mass appears to pool in the spleen. The splenic pool exchanges freely with the platelets in the peripheral circulation. Transfusion of $^{51}$Cr-labeled platelets into normal subjects results in approximately two-thirds remaining in the circulation—in contrast to nearly 100% in splenectomized patients. In addition, administration of epinephrine, which evacuates platelets from the spleen, increases the peripheral platelet count 30% to 50%. Platelet counts in asplenic patients are not affected by epinephrine. Some studies suggest that the splenic pool consists of the youngest, largest platelets. The mechanism of splenic sequestration has been hypothesized to result from a longer transit time through the splenic cords (which platelets enter because of their small size) or from binding to the reticular and endothelial cells of the spleen.

Pathophysiologic states can result in 80% to 90% of platelets being sequestered in the spleen, resulting in thrombocytopenia. Release of platelets from the lungs after intracardiac administration of epinephrine has been reported. Also, platelet counts rise after vigorous exercise, and this rise is not affected by splenectomy. This nonsplenic pool represents approximately 16% of the total platelet mass.

Life Span

Platelet life span, based on the time required to clear labeled platelets from the circulation, has been estimated to be 8 to 12 days in humans. In steady state, when platelet production equals destruction, platelet turnover has been estimated at 1.2 to 1.5 x $10^{11}$ cells per day. Recommendations for estimation of platelet lifespan have been published by the Panel on Diagnostic Application of Radioisotopes in Hematology, International Committee for Standardization in Hematology, and multiple models for analysis of platelet lifespan have been proposed. As discussed above, platelets may be removed from circulation by pooling in the spleen, the liver, and the lung.

Platelet life span is regulated by Bcl-2 proteins. Platelet Bcl-x(L) is required for survival by suppressing Bak. Bak activation results in classic apoptosis pathways that result in mitochondrial damage, caspase activation, and PS exposure. Platelets from Bak-deficient animals live longer than normal, indicating a predetermined program of platelet death.

Interactions beyond Platelets: The Coagulation System

Platelet Interactions with the Plasma Coagulation System

Activated platelets accelerate thrombin generation. The production of factor Xa and thrombin is the result of the coagulation “cascade” in which a series of successive calcium-dependent complexes is generated by the extrinsic and intrinsic pathways. The complex development occurs primarily on phospholipid surfaces. Soluble Xa binds avidly to Va on the surface of activated platelets, indicating that the surface of activated platelets is likely a major site for coagulation reactions. The precise elements involved in “platelet-based coagulation” remain to be elucidated. Platelet-bound VIIIa may serve as a binding site for IXa and, in addition to factor Va, the effector cell protease receptor-1 (EPR-1) has been identified as a factor Xa-binding site. An additional receptor(s) for IXa may also exist. Whether specific receptors for VIIIa and Va exist or if they bind to exposed PS is not entirely established. Unlike factor V, it is not clear if factor VIII is present within resting, unactivated platelets. Platelets do not appear to take up significant amounts of plasma vWF with bound factor VIII—a clear difference from their active uptake of plasma fibrinogen.
Thrombin can activate factor XI, particularly on platelet surfaces or in the presence of proteoglycans. In this instance, traces of thrombin, generated through tissue factor from sites of cellular injury, activate plasma factor XI (bound to platelets through the presence of prothrombin itself), which, in turn, activates plasma factor IX and leads to a subsequent dramatic increase in thrombin production. Such a sequence of events is favored by the presence of platelets that protect any surfacebound reactants from soluble inhibitors. The process may also conserve a small amount of initial thrombin by linking it to immobilized protein substrates, away from plasma inhibitors. The data are consistent with the clinical observation that the amount of platelet factor XI, rather than plasma factor XI, determines the bleeding severity in deficient patients, and the information explains how factor XI can be activated regardless of other contact factors.

This work illustrates that platelets play a multifaceted role in coagulation and emphasizes the fundamental difference between resting platelets with no ability to accelerate coagulation and agonist-activated platelets, which are intensely active participants. Both intact platelets and platelet microparticles may contribute to these processes. Regardless of the exact mechanisms involved, the binding of any coagulation factor to a high-affinity binding site on the platelet plasma membrane concentrates that factor locally and can orient it with respect to other factors. Also, multiple studies show that platelet surface-bound coagulation proteins are generally protected from their usual plasma inhibitors. Finally, such binding (e.g., factor Xa to activated platelets) can facilitate the rapid delivery of a potent coagulant and potential agonist to a site of vessel injury, where it may be most valuable in hemostasis.

Platelet Forms of Plasma Proteins

Three factors (factor V, fibrinogen, and vWF) found in platelet α-granules contribute significantly to coagulation (Table 16.3). Platelets have particularly large amounts of fibrinogen, which they do not synthesize, and lesser amounts of vWF, which they do. The origin of FV appears to be a combination of incorporation from plasma and de novo synthesis in megakaryocytes. The bulk of FV (20% of total factor V in blood) is located in the α-granules, and the thrombin-activated form, factor Va, is the major secreted platelet phosphoprotein.

The distinct and critical role of FV in hemostasis is underscored by the findings in two kindreds of factor V Quebec, in which a selective defect in α-granule factor V (plasma factor V is nearly normal), probably due to excessive granule-based proteolysis, is accompanied by a severe bleeding diathesis. Platelet fibrinogen constitutes up to 10% of total platelet protein. Platelet vWF is present in relatively large amounts in α-granules, and may play a role in platelet adherence to subendothelium.

Other Platelet-associated Coagulation Factors

The numerous platelet proteins that participate in plasma coagulation are listed in Table 16.3. Several additional plasma coagulation factors are associated with platelets, along with a variety of coagulation inhibitors as noted in the following.

FXIII is contained in the cytosol and is not organelle-associated; it is a fully active subunit of plasma factor XIII. FXIII makes up 50% of the total amount of factor XIII activity in blood. It has been suggested that it provides a subunit for plasma factor XIII. High-molecular-weight kininogen is present in α-granules and is secreted and expressed on the platelet plasma membrane after thrombin activation. Platelets contain 2.5% of protein S found in whole blood. This protein is synthesized in megakaryocytes, stored in α-granules, and released from platelets on thrombin stimulation. Additionally, platelet-dense granules contain polyphosphate at a concentration of approximately 130 mM, which is released upon platelet activation. Polyphosphate, a highly anionic polymer, activates the contact pathway, heightens Va activation, and accelerates thrombin generation. Polyphosphates also incorporate into fibrin clots and may alter clot structure.

Protease Inhibitors

All known plasma protease inhibitors are also localized to platelet α-granules. These include α1-protease inhibitor, α2-macroglobulin, C1 inhibitor, α2-antiplasmin, plasminogen activator inhibitor-1, lipoprotein-associated coagulation inhibitor, protease nexin I (thrombin inhibitor), and protease nexin II (factors IXa and Xa inhibitors).

Clot Retraction

When whole blood is placed in a glass tube and simply left to clot for several hours at ambient temperature, clear serum is expressed from the bulk of the fibrin-red cell mass as platelets exert their global contractile potential. Clot retraction in vitro requires the major surface integrin αIIbβ3 (or GPIIb-IIIa) and P.397

contractile proteins actin and myosin, including the non-muscle myosin heavy chain IIA. Integrin activation by talin is required for clot retraction, however, beyond these broadly based studies, relatively few additional details are available to translate this dramatic laboratory event into a physiologic mechanism.

**PLATELET ADHESION AND ACTIVATION**

Primary hemostasis and arterial thrombosis are the results of a complex series of cell-cell, cell-protein, and protein-protein reactions that involve platelets, leukocytes, endothelium, subendothelial matrix, and plasma proteins, such as fibrinogen, vWF, and others. The consequences of arterial thrombosis include such events as myocardial infarction (MI), unstable angina, and stroke. These clinicopathologic entities and their associated cellular physiologic mechanisms that are outlined in this chapter, collectively account for the largest cause of morbidity and mortality in the Western world.

Platelet adhesion to exposed subendothelium is a complex multistep process that involves a diverse array of adhesive ligands (vWF, collagen, fibronectin, thrombospondin, and perhaps laminin) and surface receptors (GPIb/V/IX, GPVI, integrins α<sub>IIb</sub>β<sub>3</sub>, α<sub>IIb</sub>β<sub>1</sub>, α<sub>5</sub>β<sub>1</sub>, and α<sub>6</sub>β<sub>1</sub>).<sup>200,201,202,203</sup> The specific ligand/receptor players in primary platelet adhesion are largely dependent on the arterial flow conditions present.<sup>204</sup> As such, in larger arteries and veins, platelet adhesion to the vessel wall is thought to involve fibrillar collagen, fibronectin, and laminin. There are at least 25 forms of collagen, and several of these are present in the blood vessel wall, while one (type IV) is present in the subendothelial basement membrane.<sup>205,206</sup> In high shear conditions, platelet tethering is dependent on the unique shear-dependent interaction between GPIb/V/IX and subendothelial vWF, derived either from plasma or released by endothelial cells and/or platelets.<sup>207</sup> A tether forms between GPIb and vWF that either halts platelet movement or reduces it such that other interactions can proceed. Subsequent interactions are mediated by GPVI binding to glycineproline-hydroxyproline sites on...
collagen and perhaps to exposed laminin. The interaction of GPVI with collagen strongly activates platelets such that integrins, including αIβ1 and αIIbβ3 (GPIIb-IIIa), can engage in high-affinity interactions with ligands.

Following initial platelet adhesion, subsequent platelet-platelet interactions are initially mediated by two receptors, GPIb/V/IX and αIIbβ3, and their respective contributions are dependent on the flow conditions present. In high shear stress conditions, GPIb/V/IX receptor and vWF ligand action are predominant, with fibrinogen playing a stabilizing role. At low shear conditions, fibrinogen is thought to be the primary ligand supporting platelet plug formation through its interaction with αIIbβ3, although thrombus formation can take place in the absence of vWF and fibrinogen, so other ligands may also be involved.

Platelet Glycoprotein Ib Complex-von Willebrand Factor Interaction and Signaling

The interaction of the platelet GPIb “complex” (the polypeptides GPIbα, GPIbβ, GPIX, and GPV) with its primary ligand, vWF, is the receptor-ligand pairing that initiates platelet adhesion followed by a cascade of events leading to pathologic thrombosis or physiologic hemostasis. A unique aspect of this receptor-ligand interaction is that it requires the presence of high arterial shear rates to take place, thus explaining the predisposition of platelet-rich “white clots” in the arterial circulation over clots found in the venous circulation, with its relatively lower shear forces, in which clot formation takes place independent of the GPIb complex.

The GPIb complex consists of four transmembrane subunits, each of which is a member of the leucine-rich repeat protein superfamily that participates in cell-matrix interactions throughout nature. Each of the four subunits contains one or more tandem, 24-amino acid leucine-rich repeats flanked by conserved disulfide loop structures at both the N and C termini of the repeats. GPIbα is covalently associated with the GPIbβ chain through disulfide linkage of cysteine residues, and both of these chains are noncovalently associated with GPIX in a 1:1 ratio and with GPV in a 2:1 ratio (Fig. 16.7). GPIb contains multiple O-linked carbohydrate groups with sialic acid residues. The complex appears as a long rod with globular domains by electron microscopy and is predicted to extend far out from the platelet surface, a feature which may make it sensitive to shear-induced conformational changes.

vWF is a large, multimeric GP that circulates in plasma and is also found in platelets and the Weibel-Palade bodies of endothelial cells. Mature vWF is a 2,050-amino acid subunit that is disulfide linked into large multimers. It contains three adjacent A domains in the N-proximal half of the peptide that collectively regulate the adhesion of platelets to subendothelial matrix. In this respect, the A1 and A3 domains bind to different matrix collagens, whereas the A2 domain contains the binding site for the GPIb complex. The A1 domain is the primary role player in platelet adhesion, because this part of the molecule is believed to change its conformation in response to immobilization and high shear forces, thus making it a high-affinity ligand for the GPIb complex receptor.
The binding site for vWF is present in the N-terminal 282 residues of GPIb. Important to the interactions are a cluster between residues Asp 252 and Arg 293 containing sulfated tyrosine residues and important anionic residues, a disulfide loop between Cys 209 and Cys 248, and an N-terminal flanking sequence of the leucine-rich repeats (LRG). Mutations involving single amino acid residues within these LRGs account for some cases of the congenital bleeding disorder Bernard-Soulier syndrome, in which the GPIb complex binds poorly, or not at all, to vWF. The crystal structure of the N terminus of GPIbα in complex with the A1 domain of vWF reveals an elongated complex with interactions of the globular A1 domain with the concave face of GPIbα.

Unlike other receptors, GPIb does not require platelet activation for its interactions with vWF. In vitro, the interactions of vWF and binding with the GPIb complex occur with generally very low affinity in the absence of shear. The presence of the vancomycinlike antibiotic ristocetin or viper venom proteins, such as botrocetin, promotes the interactions. Mobilization may uncoil vWF to promote interactions with GPIb. The addition of shear, in a parallel-plate flow system, results in a biphasic fashion. Likewise, the rate of translocation of platelets from blood to the endothelial cell surface, which is dependent, increases linearly up to wall shear rates of 1,500 s⁻¹, whereas the translocation rate remains relatively constant with the wall shear rate between 1,500 and 6,000 s⁻¹. Thus, the presence of shear is important for promoting the interactions between the GPIb complex and vWF. Studies of real-time thrombus formation in the absence of platelet GPIb complex and in blood from individuals with severe (type 3) von Willebrand disease indicate that GPIb and vWF interaction are required for platelet surface interaction at high shear rates (>1,210 s⁻¹), whereas GPIb deficiency results in poor platelet adhesion at lower shear.

Shear accelerates thrombus formation likely by promoting this receptor-ligand interaction.
The GPIb complex serves as an α-thrombin binding site on platelets, although the physiologic relevance of the interactions is not clear. The density of GPIb complexes (~20,000/platelet) far exceeds the number of thrombin binding sites reported on platelets (~6,000/platelet). Both exosites I and II of thrombin have been implicated in the interactions. Two independently solved crystal structures had significant differences. Involvement of exosite I could have important ramifications for thrombin activity, as most substrates need to bind exosite 1 to be efficiently cleaved. Thrombin binding may influence vWF interactions, although this has not been definitively established. Thrombin is also capable of cleaving GPV near the surface to release a soluble fragment.

P. 399

Studies have identified interaction of the GPIb complex with ligands other than vWF. These include a study of a reversible association of GPIb with P-selectin, which is examined in more detail in the section “Platelets and Endothelium.” The interaction of platelet GPIb with the neutrophil adhesion receptor αMβ2 (Mac-1) is discussed in the section “Platelets and White Blood Cells.” Additionally, GPIb reportedly interacts with high-molecular-weight kinogen, factor XII, and factor XI.

Glycoprotein Ib Complex Signaling

When the GPIb complex interacts with its vWF ligand under conditions of elevated shear stress, signals are initiated that activate integrin αIβ3. The pathways involved lead to (a) elevation of intracellular calcium; (b) activation of a tyrosine kinase signaling pathway that incorporates nonreceptor tyrosine kinases such as Src, Fyn, Lyn, and Syk, phospholipase Cy2, and adaptor proteins such as SHC, LAT, and SLP-76; (c) inside-out signaling through the αIβ1 integrin followed by platelet aggregation; and (d) activation of protein kinase C (PKC), protein kinase G (PKG), and phosphoinositide 3-kinase (PI3K). Other downstream players and events that play roles after GPIb receptor occupancy include: (a) the homodimeric signaling protein 14-3-3 and calmodulin, (b) receptor cross-linking, and (c) the immunoreceptor tyrosine-based activation motif (ITAM)-containing proteins Fcγ receptor IIA (FcγRIIA) and Fc receptor (FcR) y chain. Signaling through the GPIb complex can release ADP and generate thromboxane A2 generation, which in turn activate integrin αIIβ3.

Binding sites for 14-3-3 have been identified in the cytoplasmic domains of GPIbα, GPIbβ, GPIX, and GPV, and yeast two-hybrid studies documented in vivo interaction between 14-3-3ζ and both GPIbα and β. Phosphorylation of Ser 166 of the 14-3-3ζ consensus sequence in the GPIbβ cytoplasmic domain is required to permit high-affinity 14-3-3 binding. The GPIb complex appears to physically associate with the 14-kDa Fcγ-chain and with the 40-kDa FcγRIIA receptor. Both of these proteins contain nonidentical, but similar ITAM domain sequences and may play roles in signaling by GPIb. The lipid kinase PI3K has been found to play a role in GPIb-IX mediated activation of αIβ3 by participation in complex formation with the GPIb and 14-3-3. Thus, once vWF binds to GPIb-IX, signaling complexes form in the vicinity of the GPIbα cytoplasmic tail consisting of cytoskeletal proteins such as 14-3-3ζ as well as signaling proteins like Src and PI 3-kinase. This process leads to Syk activation, protein tyrosine phosphorylation, and recruitment of other cytoplasmic proteins with pleckstrin homology domains that can support interactions with 3-phosphorylated phosphoinositides and ultimately activation of integrin αIβ3.

Platelet-Collagen Interaction and Signaling

Collagens, one of the most thrombogenic substances in vessels, are very important activators of platelets in the vascular subendothelium and vessel wall, and thus are prime targets for therapeutic intervention in patients experiencing a pathologic arterial thrombotic event such as MI or stroke. Platelets have two major surface receptors for collagen, the immunoglobulin superfamily member GPVI and the integrin αIIβ3. The former is considered to be the primary player in platelet adhesion, initiating signaling and subsequent platelet activation. In addition to these two surface receptors, the GPIb complex can also be considered an indirect collagen receptor because its subendothelial vWF ligand essentially acts as a bridging molecule between platelets and collagen by fixing itself to the latter, which, in turn, acts as scaffolding for the multimers. Collagen adhesion also results in indirect activation of the protease-activated receptor 1 via MMP-1. Other molecules, such as CD 36, may also sustain collagen interactions.

Glycoprotein VI Receptor

The GPVI receptor, a member of the IgG superfamily, is expressed in platelets in close association with the 14-kDa Fcγ-chain, which serves as the signaling subunit for GPVI. The receptor exists as a dimer in stable association with the Fcγ-chain. Expression of GPVI on mouse platelets appears to be dependent on Fcγ-chain expression, and the latter has also been found to be critical for collagen-mediated platelet activation.
GPVI has two Ig C2 loops, and the N-terminal loop likely contains the collagen-binding domain. The crystal structure indicates that the GPVI dimers assume a parallel orientation of the collagen-binding domains to fit the helix structure of collagen.

GPVI is the main receptor involved in collagen-mediated platelet activation. Studies of mice lacking platelet GPVI show that they lose collagen-induced platelet activation due to a defect in platelet adhesion. Thus, GPVI appears to serve as the initial receptor involved in platelet adhesion, and it activates integrin binding. GPVI alone supports adhesion to insoluble collagens, and works with α2β1 to promote platelet adhesion to soluble collagen microfibrils. GPVI can also be engaged by collage-related peptides (arranged in triple helical structures with sequences similar to collagen) and the snake venom convulxin, which elicit signals through GPVI.

α2β1 Receptor

The first platelet collagen receptor identified was the integrin α2β1 receptor, also known as platelet GPIa/IIa and lymphocyte VLA-2. In all α subunits of integrins, seven tandem repeats are localized to the N-terminal end and folded into a sevenbladed β-propeller structure. The α2 subunit also contains an I domain between the second and third repeats that includes a metal coordination site for Mg²⁺ that is critical for interaction with collagen. As with other integrins, activation increases the affinity of the α2β1 and collagen. Currently, α2β1 is believed to mediate stable adhesion following GPIb- and GPVI-initiated interactions with vWF and collagen, respectively.

Platelet-Collagen Signaling

When compared to vWF, collagen is a more efficient substrate when it comes to supporting stable platelet adhesion and thrombus formation. The fact that initial platelet tethering to collagen under high shear flow first requires interaction between vWF and platelet GPIb serves to underscore the importance of the two major collagen receptors, GPVI and α2β1, in promoting platelet adhesion and activation under shear conditions.

Many of the early signaling events that follow GPVI stimulation have been characterized. Synergism between GPVI pathways and those related to other adhesion receptors such as GPIb-V-IX and soluble agonists released by activated platelets are likely necessary for the full repertoire of platelet-collagen signaling. Exposure of platelets to collagen surfaces likely results in GPVI clustering that in turn triggers the tyrosine phosphorylation of the FcRγ chain. GPVI signaling may also be influenced by its association with glycolipid-enriched microdomains (GEMS, membrane rafts) in the plasma membrane. The GPVI/FcRγ-chain complex leads to platelet activation through a pathway that has many aspects in common with signaling by immune receptors, such as the Fc receptor family (of which FcγRIIA is the lone family member found in platelets) and the B- and T-cell antigen receptors (Fig. 16.8). Immunoreceptors like the Fc receptors and the FcRγ chain all have the ITAM (immunoreceptor tyrosine-based activation motif) in common. Tyrosine phosphorylation of the ITAM by Lyn and Fyn of the Src family of tyrosine kinases takes place after activation of GPVI. The phosphorylated Src kinase, in turn, leads to activation of the tyrosine kinase Syk after its autophosphorylation. Syk then initiates a downstream signaling cascade involving the LAT and SLP-76 adapter proteins, which leads to formation of a signaling complex by virtue of its multiple phosphorylation sites that also act as docking sites, leading to recruitment of additional proteins to the plasma membrane. The signaling complex activates cytosolic second messengerproducing enzymes PI3K and phospholipase Cγ2, facilitated by tyrosine phosphorylated LAT. PI3K leads to the generation of PI3,4P2 and PI3,4,5P3 (PIP3), and this, in turn, supports recruitment of proteins to the membrane signalosome complex with specific pleckstrin homology (PH) domains, including a member of the Tec kinase family, Btk, along with PLCγ2. Syk is critical for collagen-mediated platelet activation through the GPVI/FcRγ-chain complex, and knockout mouse studies have shown that absence of this enzyme leads to loss of phosphorylation of LAT, the adapter SLP-76, and PLCγ2.
FIGURE 16.8. Collagen activates platelets through the same pathway as an immune receptor. Cross-linking of the glycoprotein (GP) VI/Fc receptor (R) γ chain leads to tyrosine phosphorylation of the immunoreceptor tyrosine-based activation motif (ITAM) sequence, enabling recruitment of the tyrosine kinase (Syk) through its tandem Src-homology 2 (SH2) domains. This leads to autophosphorylation and subsequent activation of Syk, which in turn leads to tyrosine phosphorylation of phospholipase Cγ2 (PLCγ2). A large number of proteins are implicated in the regulation of PLCγ2, as discussed in the text. YP, phosphotyrosine. (From Watson SP. Collagen receptor signaling in platelets and megakaryocytes. Thromb Haemost 1999;82:367, with permission.)

PLCγ2 plays a critical role in aggregation and secretion responses to collagen, as demonstrated in PLCγ2 knockout mice. The major role of PLC isoforms is concerned with the generation of the second messengers inositol 1,4,5-triphosphate and 1,2-diacylglycerol (DAG), which participate in intracellular calcium homeostasis and activation of many isoforms of PKC. The former process culminates in a robust calcium signal that promotes efficient platelet activation, via α2β1 as well as αIIbβ3. Along with the proteins noted above, PI3K and its associated second messenger pathway also play a very important role in the regulation of PLCγ2 through activation of other signaling proteins such as protein kinase B (also known as Akt). Platelets contain several isoforms of Akt that are important for normal platelet function and thrombus formation along with granule secretion. Other downstream events include activation of Rap1 and Pyk2. In addition to GPVI, the α2β1 receptor also propagates signaling. The use of α2β1-selective ligands has demonstrated calcium-dependent spreading and tyrosine phosphorylation of several proteins when interaction with platelets takes place, including Src, Syk, SLP-76, PLCγ2, p38 MAP kinase, ILK, Rac, and PAK.

Physiologic Inhibition of Platelet Adhesion
Negative regulation of platelets is essential to set the stimulus threshold for thrombus formation, determine final clot size and stability, and prevent uncontrolled thrombosis. The mechanisms behind the negative regulation of platelet activation are described later in the chapter, and in this respect, roles of players such as nitric oxide and prostacyclin have been well characterized. Platelet activation can also be inhibited by signaling through the adhesion molecule PECAM-1 (CD31).\textsuperscript{257,258,259,260} Expressed on a number of blood cells and endothelial cells, PECAM has a wide array of regulatory functions in processes such as apoptosis and cell activation. Following homophilic interactions and/or clustering, PECAM-1 is tyrosine phosphorylated in its cytoplasmic tail ITIM domain (immunoreceptor tyrosine-based inhibition motif) by Src family kinases, and this engenders recruitment of tyrosine, serine/threonine, or lipid phosphatases with resultant kinase-dependent signaling inhibition.\textsuperscript{258} Phosphorylation of PECAM-1 recruits and activates the SH2 domain-containing protein-tyrosine phosphatase, SHP-2.\textsuperscript{260} Studies suggest that the PECAM-1/SH2 complex functions to counteract platelet activating, most particularly for collagen by inhibiting GPVI/FcRγ chain signaling.\textsuperscript{260} However, PECAM-1 has also been observed to attenuate G-protein mediated signaling by thrombin and other agonists. The Src family kinase Lyn also inhibits platelet activation by GPVI, and appears to do so independently of PECAM.\textsuperscript{261} Other platelet proteins with ITIM-domains that also inhibit platelet function include carcinoembryonic antigen cell adhesion molecule 1 (CECAM1) and G6B.\textsuperscript{262}

Platelet Thrombin (Protease-activated) Receptors and Signaling

PARs are G-protein-coupled receptors that use a unique mechanism to convert an extracellular protein cleavage event into an intracellular activation signal. In this case, the ligand is already part of the receptor per se, by virtue of the fact that it is represented by the amino acid sequence SFLLRN (residues 42 through 47) and is unmasked as a new amino terminus after thrombin cleaves the peptide bond between Arg 41 and Ser 42. This “tethered ligand” then proceeds to irreversibly dock with the body of its own receptor to effect transmembrane signaling, as shown in Figure 16.9.

Thrombin signaling in platelets is mediated, at least in part, by four members of a family of G-protein-coupled PARs (PAR-1, -2, -3, and -4) (see previous section for a discussion of the GPIb complex as a thrombin receptor).\textsuperscript{263} Human platelets express PAR-1 and PAR-4, and activation of either is sufficient to trigger platelet aggregation.\textsuperscript{264,265} Mouse platelets express PAR-3 and PAR-4.\textsuperscript{266} PAR-1, -3, and -4 can be activated by thrombin, whereas PAR-2 can be activated by trypsin, tryptase, and coagulation factors VIIa and Xa. Presumably, other proteases are capable of recognizing the active sites of these receptors and can thus also trigger PAR signaling. PAR-1 is the prototype family member and was the first to be cloned and characterized in the human and hamster.\textsuperscript{264} A synthetic peptide that mimics the PAR-1-tethered ligand (SFLLRN) is capable of functioning as an agonist by activating the receptor independent of cleavage of the 41-residue N-terminal exodomain.

The mechanism by which G-protein-coupled receptors, such as PAR-1, signal through the G proteins is shown in Figure 16.10. PAR-1 is capable of coupling to members of the G12/13, Gq, and Gz families and thus is connected to a significant number of intracellular signaling pathways. The α subunits of G12 and G13 are believed to be involved in mediating platelet shape change,\textsuperscript{267} and downstream signaling mediators include Rho family members, among others. The α subunit of Gq is needed for platelet secretion and aggregation and participates in activation of PLCβ that leads to calcium mobilization and PKC activation.\textsuperscript{268} The α subunit of Gz is a Gi family member that has been speculated to play an epinephrinelike role in human platelets through inhibition of adenylate cyclase.\textsuperscript{269}
FIGURE 16.9. Structure and features of PAR-1. Cleavage of PAR-1 by thrombin between arginine 41 and serine 42 exposes a new N terminus that serves as a tethered ligand. Activation of PAR-1 is followed by a rapid burst of signaling before the receptor is desensitized and, in some cases, cleared from the cell surface. (From Brass LF. Thrombin and platelet activation. Chest 2003;124:18S-25S.)

The β-γ subunit counterparts of G proteins involved in PAR signaling are involved in a plethora of activities, including activation of protein kinases, channels, and lipid-modifying enzymes, such as PI3K, which provide attachment for multiple signaling protein complexes close to the inner leaflet of the cell membrane, potentially through surface “hot spots.”

Thus, this vast network of signaling pathways mediated through several G-protein families is in keeping with the pleiotropic roles that thrombin has been shown to exhibit in cellular homeostasis, which extends beyond platelet activation to include endothelial cells, leukocytes, smooth muscle cells, and T lymphocytes, along with physiologic processes such as tissue injury, inflammation, angiogenesis, and embryonic development.
FIGURE 16.10. Signaling through G proteins and G-protein-coupled receptors. Agonist binding to the receptor causes the exchange of guanosine triphosphate (GTP) for guanosine diphosphate (GDP) on the guanine nucleotide-binding site of the G-protein α subunit. This causes the dissociation of Ga from Gβγ, both of which can activate intracellular effectors and ion channels. (From Brass LF. Molecular basis of platelet activation. In: Hoffman R, Benz EJ, Shattil SJ, et al., eds. Hematology: basic principles and practice. New York: Churchill-Livingstone, 2000:1754, with permission.)

Physiologic differences exist between PAR-1 and PAR-4 on human platelets. PAR-1 appears to mediate a substantial portion of thrombin signaling and appears to be most efficient at mediating platelet activation at low concentrations of thrombin, whereas PAR-4 can function in the absence of PAR-1, but only at high thrombin concentrations. The rate of platelet activation through PAR-4 is significantly slower and more sustained than that through PAR-1.271,272 Given the importance of this system with respect to normal hemostasis, PAR-4 may serve as a redundant, backup receptor to PAR-1, or it may serve as an important receptor for one or more proteases other than thrombin.

Once activated, PAR-1 is rapidly uncoupled from signaling and internalized into the cell.273 It is then transported to lysosomes and degraded.268,269 Platelets presumably have no need for a thrombin receptor recycling mechanism, because once activated, they are irreversibly incorporated into blood clots. Conversely, in cell lines with characteristics similar to megakaryocytes, new protein synthesis is needed for recovery of PAR-1 signaling,274 and in endothelial cells, sensitivity to thrombin is maintained by delivery of naive PAR-1 to the cell surface from a preformed intracellular pool.275

Subsequent studies employing PAR3 and PAR4 knockout mice have also demonstrated defective thrombus formation under high shear conditions in vivo, suggesting the possible existence of shear-based functional differences between protease-activated receptors.276,277

Platelet ADP (Purinergic) Receptors and Signaling

Evidence that ADP plays an important role in both the formation of the platelet plug and the pathogenesis of arterial thrombosis has been accumulating since its initial characterization in 1960 as a factor derived from red blood cells that influences platelet adhesion.278 ADP is present in high (molar) concentrations in platelet-dense granules and is released when platelet stimulation takes place with other agonists, such as collagen; thus, ADP serves to further amplify the biochemical and physiologic changes associated with platelet activation and aggregation. Inhibitors of this ADP-associated aggregation include commonly used clinical agents, including ticlopidine, clopidogrel, prasugrel, and ticagrelor, proven to be very effective antithrombotic drugs.278,279

Platelet P2Y1 and P2Y12 and P2X1 Receptors

Adenine nucleotides interact with P2 receptors that are ubiquitous among different cell types and have been found to regulate a wide range of physiologic processes. They are divided into two groups, the G-protein-coupled superfamily named P2Y and the ligand-gated ion channel superfamily termed P2X.280 Two G-protein-coupled P2Y receptors contribute to platelet aggregation. The P2Y1 receptor initiates aggregation through mobilization of calcium stores, and the P2Y12 receptor is coupled to inhibition of adenylyl cyclase and is essential for a full aggregation response to ADP with stabilization of the platelet plug. P2X1 is a third purinergic receptor present in platelets that may largely recognize ATP.
The P2Y₁ receptor was first cloned in 1993 from a chick brain complementary DNA library. The P2Y₁ receptor has 373 amino acid residues and the prototype structure of a G-protein-coupled receptor. It is distributed in various tissues such as heart, blood vessels, testis, and ovary. P2Y₁ couples to Gαq, and platelets from mice deficient in P2Y₁ are unable to change shape or aggregate in response to ADP; likewise, platelets from mice lacking Gαq do not aggregate to ADP. After the characterization of P2Y₁, it became clear that a second platelet ADP receptor had to exist that was responsible for the inhibition of cAMP production by ADP, and that was the target for antithrombotic drugs (at the time, ticlopidine and clopidogrel) that interfered with ADP-activation. The P2Y₁₂ receptor was cloned in 2001 from human and rat platelet complementary DNA libraries using Xenopus oocytes. The receptor indeed showed the ability to display ADP-mediated inhibition of platelet cyclic AMP (cAMP) formation that was not blocked by P2Y₁ antagonists.

Inhibition of either of the P2Y₁ or P2Y₁₂ receptors is sufficient to block ADP-mediated platelet aggregation, and coactivation of both receptors is therefore necessary, through the G proteins Gαq and Gxi, respectively, for ADP to activate and aggregate the platelet (Fig. 16.11). A series of studies involving the use of selective P2Y₁ and P2Y₁₂ receptor antagonists, a cAMP inhibitor, gene targeting, and Gαq and Gxi protein agonists that would theoretically activate the two main G-protein pathways associated with ADP stimulation (see below) has led to the conclusion that signaling events downstream of both receptors are needed to elicit full activation.

Studies done with platelets from patients who manifest defective P2Y₁₂, along with experiments involving the study of P2Y₁ receptor function in platelet-rich plasma that has high fibrinogen concentrations, indicate that the P2Y₁ receptor has roles in activation and aggregation in in addition to shape change. Platelet shape change is dependent on two separate G signaling pathways, a Gαq-linked release of calcium from internal stores, and a G₁₂/G₁₃ link to activation of Rho kinases and Rho guanine nucleotide exchange factors that activate small G proteins. The primary role of the P2Y₁₂ receptor in platelet activation and aggregation is to amplify and complete the aggregation response to ADP. Individuals with congenital defects in P2Y₁₂ display a mild to moderate bleeding diathesis. Platelets from P2Y₁₂-deficient mice aggregate poorly, or not at all, in response to ADP, display a shift in the dose-response curves for collagen and thrombin, and lack ADP-induced repression of cAMP levels. The bleeding time of homozygous knockouts was markedly prolonged compared with near normal results in heterozygotes. Current data indicated that the P2Y1 receptor elicits a transient platelet response (manifested by a rise in cytoplasmic calcium, shape change, and reversible aggregation), and the P2Y₁₂ receptor, via inhibition of adenylyl cyclase, amplifies the ADP response. The central role of the P2Y₁₂ receptor in the formation and stabilization of thrombi has been demonstrated by the therapeutic efficacy of antithrombotic drugs that are antagonists.

FIGURE 16.11. Current view of the interplay between the platelet P2 receptors. Two G-protein-coupled receptors are involved in adenosine diphosphate (ADP)-induced platelet aggregation, P2Y₁ and P2Y₁₂. The former is responsible for intracellular calcium mobilization, shape change, and transient aggregation, whereas the latter is coupled to adenylate cyclase.
cyclase (AC) inhibition and is responsible for amplification of platelet aggregation and potentiation of platelet secretion. Both receptors are required for normal platelet response to ADP. A P2X receptor is also present on platelets and is responsible for rapid calcium influx. It therefore synergizes with the P2Y receptor. Both the P2Y₁₂ and P2X₁ receptors have been shown to play key roles in platelet activation and aggregation under high shear stress conditions. ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; MLC, myosin light chain; P, phosphorylated; PLC, phospholipase C; Y, phosphorytrosine. (Modified from Gachet C. ADP receptors of platelets and their inhibition. Thromb Haemost 2001;86:227, with permission.)

The P2X₁ is an ATP-gated ion channel known to mediate rapid and selective permeability to cations. On platelets, the P2X₁ receptor has been shown to mediate fast calcium entry stimulated by ADP, although ATP may be the physiologically relevant agonist. P2X₁ is a 399-amino acid protein composed of two transmembrane domains, intracellular N and C termini, and an extracellular loop with 10 conserved cysteine residues. At least three P2X subunits are required to constitute a membrane pore. A study of P2X₁-deficient mice has further indicated that this receptor contributes to the thrombosis of small arteries. Conversely, increased systemic thrombosis has been reported in mice overexpressing the human P2X₁ receptor.

ADP Receptor Signaling

Although considered a weak agonist in comparison to collagen or thrombin, ADP clearly plays an important role in thrombus stabilization, likely by contributing to the recruitment of additional platelets to growing thrombi. Aggregation is often reversible when platelets are stimulated by ADP alone. In addition, low concentrations of ADP serve to amplify the effects of both strong and weaker agonists, the latter including serotonin and adrenaline, among others. As noted in the preceding paragraphs, ADP signal transduction downstream from the P2Y₁ receptor leads to a transient rise in free cytoplasmic calcium as a result of mobilization from internal stores, and this is followed by a secondary store-mediated influx, while a concomitant inhibition of adenylate cyclase is initiated by ADP stimulation of the P2Y₁ receptor (Fig. 16.11). The G-protein family member responsible for signaling through P2Y₁ to PICβ is Gq, whereas the member responsible for signaling through P2Y₁₂ to inhibit adenylate cyclase is Gi. While ADP-mediated platelet activation via the P2Y₁ receptor incorporates the Gq-dependent PLC-β second messenger pathway, the P2Y₁₂ receptor mediates its postoccupancy signaling through Gi-dependent PI3 kinase activation and subsequent repression of cAMP levels. In addition to the PI3K role, several groups have reported a role for Rap1b in P2Y₁₂ signal transduction. Rap1b is a small GTPase that is highly expressed in platelets, and its ADP-stimulated increased activation is abolished by P2Y₁₂ antagonists and G knockout mice. Rap1b, in turn, is an important intermediate in activation of platelet integrins. P2Y₁₂ activation has been found to play an important role in activation of α₁β₃. Using P2Y₁₂ knockout mice, Andre et al. noted that platelets activated with PAR-4 or ADP were defective in binding soluble fibrinogen relative to wild-type mice.

Platelet Activation by Soluble Agonists

α₂-Adrenergic Receptors and Epinephrine

Epinephrine is unique among platelet agonists because it is considered to be capable of stimulating secretion and aggregation, but not cytoskeletal reorganization responsible for shape change. Platelet responses to epinephrine are mediated through α₂-adrenergic receptors, and these responses have been found to vary among individuals, with some donors with otherwise normal platelets manifesting delayed or absent responses. The α₂A-adrenergic receptor couples to Gαi members, most notably Gαz in platelets. Epinephrine synergizes with other agonists, although whether ADP or thromboxane is necessary for epinephrine’s actions is not entirely clear. Epinephrine may mediate sympathetic stimulation of platelets.

Arachidonic Acid, Thromboxane A₂, and Thromboxane Receptors

After platelet stimulation by a number of agonists, arachidonic acid is generated directly by phospholipase A from its membrane phospholipid precursors (PC, PS, and PI) and indirectly by PLC generation of DAG followed by DAG lipase action. Most platelet agonists are believed to activate this pathway. Three known eicosanoid subsets of biochemical compounds are known to be derived from the formation of arachidonic acid—the prostanoids, leukotrienes, and epoxides. The prostanoids are formed by the cyclooxygenase pathway and include endoperoxides and thromboxanes along with prostaglandins. The leukotrienes are formed by the lipooxygenase pathway and the epoxides by the cytochrome
P450 epoxygenase pathway. Although all three of these pathways are present in platelets, most arachidonic acid ends up being metabolized to thromboxane A2 (TxA2).²⁹⁹

TxA₂ is produced in platelets from arachidonic acid through the generation of PGH₂ by the enzyme cyclo-oxygenase, which is irreversibly inhibited by aspirin through acetylation of a serine residue near its C terminus.³⁰⁰,³⁰¹ PGH₂ is the parent compound for both biologically active prostaglandins, such as PGE₂ and PGI₂, and TxA₂. The former two compounds act to inhibit platelet activation by generating intracellular cAMP, whereas TxA₂ activates platelets. Although prostaglandin and thromboxane pathways can be present in the same cell, platelets primarily synthesize thromboxane, and endothelial cells mainly synthesize prostaglandins such as PGI₂, which acts as a local vasodilator and thus indirectly opposes platelet activation and vasoconstriction.³⁰²

Like ADP and epinephrine, TxA₂ is also capable of activating nearby platelets after its release into plasma. It has a very short half-life of 30 seconds before its conversion to the inactive metabolite thromboxane B₂ prevents widespread platelet activation beyond the vicinity of thrombus formation.³⁰³ Both arachidonic acid and analogs of TxA₂ have been found to activate and aggregate platelets by mediating shape change and phosphorylation of signaling enzymes, such as PLCβ, PKC, and so forth.³⁰⁴ The thromboxane receptor (TP) is a member of the seven-transmembrane G-protein-coupled receptor family and has been localized to the plasma membrane. Two isoforms of the receptor have been identified in platelets—TPα and TPβ—and they activate platelets through the Gq pathway to PLCβ and Gi₁/Gi₂ to myosin light chain phosphorylation through activation of Rho kinase.³⁰⁵ In addition, the α receptor is associated with activation of adenylate cyclase that leads to generation of cAMP, known to inhibit platelet activation, whereas the β receptor inhibits adenylate cyclase activation after its stimulation.

Coordination between Platelet Adhesion Events and Soluble Agonist Stimulation in Thrombus Growth

The mechanism by which soluble agonists coordinate their actions with platelet adhesion-related processes is an important consideration in the context of the steps required to facilitate thrombus growth.³⁰⁶ The application of advanced imaging techniques for visualizing individual platelets and thrombus development in live animals has dramatically improved understanding of the underlying mechanisms.³⁰⁷ Depending on the type and degree of vessel injury, exposure of collagen and generation of thrombin appear to serve as initiators of thrombus formation. Thrombus propagation appears to be a dynamic process, with platelets adhering and separating from the core. The bulk of the data supports a role for soluble mediators, such as ADP, in the additional accumulation of platelets within the growing thrombus. Rapid blood and high shear exert complex prothrombotic properties (e.g., by enhancing GPIb adhesions) and antithrombotic properties (e.g., by clearing soluble mediators). Within the platelet, initial platelet/vessel wall interactions characterized by contact between platelet GPIb and matrix vWF result in subsequent conformational changes in GPIbβ₃. Costimulation of platelets by these adhesion events and soluble agonist receptors may then potentiate and sustain early activation signals initiated by the early GPIb/vWF/α₂β₃. The costimulation may then lead to arrest of platelets. Once platelets are in close contact, molecules on the surface of one platelet can interact directly with those on an adjacent platelet. These contact-dependent events can promote or inhibit platelet functions.³⁰⁸ Major receptor pairs that amplify signaling include the Eph receptor tyrosine kinase and its ephrin ligands, semaphoring 4D, which reinforces signaling downstream of GPVI. Several adhesion/junction receptors participate in contact-dependent signaling, including PECAM-1, CEACAM1, ESAM, and JAM-A, and the bulk of the evidence indicates that they limit platelet activation and thrombus growth. Platelets also express connexins, which appear to form functional pores in closely attached platelets, but their function remains to be established definitively.³⁰⁹

Physiologic Inhibition of Platelet Activation

One of the many remarkable features of platelets is their ability to remain in a physiologic resting state and resist becoming activated while navigating the heart, arterial, and venous circulations.

P.404

Indeed, the pathologic consequences associated with widespread inappropriate platelet activation are life- and limb-threatening in the settings of well-characterized clinical disorders, such as thrombotic thrombocytopenic purpura and heparin-induced thrombocytopenia. The mechanisms responsible for maintaining the fine balance of keeping platelets in a resting state until they encounter a genuine need to undergo adhesion, activation, and aggregation at the site of vascular injury are nearly as diverse as those responsible for mediating these physiologic phenomena.

Some general mechanisms involved in physiologic inhibition of platelet activation include phenomena such as (a) generation of negative-regulating molecules by the platelet (e.g., cAMP), endothelium (e.g., PGI₂, nitric oxide [NO], heparan sulfate), and at distant sites (e.g., antithrombin); (b) barrier of endothelial cells that prevents direct contact of
circular platelets with collagen; (c) ecto-ADPase (CD39) expression by endothelial cells that metabolizes ADP secreted from platelets; (d) tendency for blood flow to wash away unbound thrombin and other soluble mediators from the site of platelet plug formation; (e) brief half-life of certain key platelet activators such as TxA2; (f) tight regulation of the affinity state of receptors such as αIIbβ3; (g) downregulation of signaling receptors to limit their actions; and (h) inhibitory pathways mediated by ITIM-containing and/or contact-dependent adhesion receptors, such as PECAM, CECAM-1, JAM-A, and potentially others. Some of the physiologic and biochemical phenomena related to inhibition of platelet activation are described in the following.

Receptor Downregulation and Desensitization

Signaling through G-protein-coupled receptors present on the surface of platelets is limited by their phosphorylation, which triggers desensitization, that is, uncoupling from G proteins, and internalization via Claritin-mediated endocytosis. G-protein kinases and β-arrestin are central to these processes. In addition, G-protein-coupled receptors interact with a myriad of other molecules that finely tune their signaling, including regulators of G-protein signaling (RGS) and GPCR-associated sorting proteins.

Inhibitory Prostaglandins

Generation of the prostaglandins from arachidonic acid metabolism, such as PGI2 and PGE2 (at high concentrations), results in inhibition of platelet activation and aggregation, and counterbalances the actions of thromboxanes derived from the same pathway. While PGI2 and PGD2 inhibit platelet function at low doses, PGE2 displays a biphasic response, and inhibits platelet function only at high concentrations, likely via the EP4 receptor. The inhibitory effects are mediated via G-protein-coupled receptors (IP and EP receptors, respectively) that couple to the Gs subunits of Gs to regulate adenylate cyclase-mediated generation of cAMP. cAMP levels in platelets are also governed by the activity of phosphodiesterase, the enzyme responsible for cAMP metabolism. This enzyme activity is inhibited by drugs such as the weak antiplatelet agent dipyridamole, the bronchodilator theophylline, and sildenafil, used to treat erectile dysfunction in men.

Raising cAMP levels causes a number of specific changes in platelet function, mediated in large part by activation of protein kinase A (PKA). Targets for PKA include vasodilator-stimulated phosphoprotein (VASP), the IP3 receptor, which reduces intracellular calcium mobilization, and the cytoplasmic domain of GPIbβ. Phosphorylation of the IP3 receptor reduces intracellular calcium mobilization, whereas Gα13 phosphorylation downregulates TxA2 signaling. Phosphorylation of GPIbβ may reduce platelet activation through its increased interaction with the 14-3-3ζ protein. Other targets include small G proteins of the Rho family, filamin, myosin light chain, VASP, and Rap1b. The net effect is inactivation of signaling pathways and modulation of actin cytoskeletal dynamics to block adhesion, granule release, and aggregation.

Nitric Oxide

NO is generated by endothelial cells and platelets from L-arginine in response to shear stress forces and other platelet agonists, such as thrombin and ADP. The bulk of the evidence suggests that at high concentrations NO functions to inhibit platelet activation through the cyclic guanosine monophosphate (cGMP) second messenger generated by guanylate cyclase activation. Elevations in cGMP, by modulating phosphodiesterase activity, can raise intraplatelet cAMP. Paradoxically, low levels of NO may elicit platelet activation pathways. Endothelial NO synthase activity is enhanced during platelet activation, presumably as an additional means for limiting platelet aggregation.

Other Inhibitory Processes of Platelet Activation

Increasingly, a number of surface receptors are being identified that negatively regulate platelet signaling. Among these include the immunoglobulin (Ig)-immunoreceptor tyrosine-based inhibitory motif (ITIM) superfamily members, PECAM-1, CEACAM-1, and G6b-B. While the ITIM members clearly suppress immunoreceptor tyrosine-based activation motif (ITAM)-associated Fcy receptor IIa and glycoprotein VI (GPVI)/Fcγ-chain signaling pathways in platelets, they also appear to have broader effects at multiple levels on platelet function.

Platelet Secretion

The extent of secretion of α-, dense-, and lysosomal-granule contents is dependent on the strength of the agonist, occurs in association with platelet activation, and is one of the many downstream consequences mediated by the activation and transport to the internal leaflet of the plasma membrane of PKC. In turn, release of cargo, such as ADP, vWF, fibrinogen, and calcium ions, enhances activation and aggregation. To date, over 300 proteins have been identified that are released by platelets and may alter the local environment and have important downstream consequences.
The strongest responses a platelet can mount to agonist stimulation include activation, secretion, and aggregation. The granule secretory (release) phase is most readily documented in vitro by the “secondary wave” that denotes a second surge of aggregation activity of a fixed number of platelets in response to release of proaggregatory granule contents. These platelets are exposed to an agonist under the controlled in vitro conditions associated with platelet aggregation studies, in which clinical defects in primary hemostasis due to platelet perturbations are further characterized. The secondary wave is typically seen best when the agonist is a weaker one, such as epinephrine, or is a relatively lower concentration of another relatively weak agonist, ADP. These two agonists require both cyclo-oxygenase activity and a primary wave of aggregation to induce secretion at low calcium concentrations.\(^{314}\)

Several studies suggest that the mechanism by which platelet granules (vesicles) fuse with the cell membrane to release their granule contents involves soluble N-ethylmaleimide-sensitive factor (NSF) attachment protein (SNAP) receptor (SNARE) complexes that are formed between vesicle-associated membrane proteins (VAMPs; v-SNAREs), and proteins in the target membranes (different members of the syntaxin, SNAP, and vesicle-associated membrane protein [VAMP] gene families; t-SNAREs) in a lock-and-key form of docking.\(^{61,315}\) These SNARE complexes are crucial for membrane trafficking and fusion events such as secretion and exocytosis. In platelets, the specific isoforms VAMP-2, VAMP-3, and VAMP-8 form SNARE complexes with platelet syntaxin 2, 4, and SNAP-23 to mediate platelet secretion.\(^{61,315}\) A number of SNARE regulators, such as members of the Munc family, Doc2\(\alpha\), and tomosyn, regulate SNARE function. Simultaneous with the exocytosis of platelet granules, it is apparent that there is also inward (centripetal) movement of other intracellular contents, and this may play a role in transporting proaggregatory proteins away from the membrane surface and thus serve as another counterbalancing mechanism for limiting the extent of thrombus formation. Examples of this phenomenon include the internalization of fibrinogen from the surface of activated platelets, along with \(\alpha_{III}\beta_3\) receptors from the surface of resting and activated platelets, as noted earlier.\(^{316}\)

**PLATELET AGGREGATION: \(\alpha_{III}\beta_3\) RECEPTOR AND ITS SIGNALING MECHANISMS**

Platelet aggregation is a complex phenomenon that is the end result of a series of adhesion- and activation-related processes. The molecular mechanisms involved in platelet aggregation continue to be an area of very active research that also periodically reminds us that there is still much to be characterized about this important aspect of platelet function. Essential components of this process include an agonist, calcium, and the adhesive proteins fibrinogen and vWF. Divalent cations, such as calcium and magnesium, are required for platelet aggregation in trace amounts, and these alter the specificity of the integrin \(\alpha_{III}\beta_3\) for its ligands. Fibrinogen and vWF play dominant roles in platelet aggregation through binding to \(\alpha_{III}\beta_3\) and also by the ability of the former to generate polymerized fibrin as support for the platelets in a thrombus. The multivalent nature of fibrinogen and vWF allows them to cross-link platelets on binding to \(\alpha_{III}\beta_3\) on stimulated platelets to initiate platelet aggregation.

The molecular basis of integrin signaling that occurs in platelet \(\alpha_{III}\beta_3\) is an integral part of thrombus formation and is important in understanding this process. GPIIb (\(\alpha_{II}\)) and GPIIIa (\(\beta_3\)) were identified as the abnormal proteins present in patients with Glanzmann thrombasthenia in the 1970s.\(^{316,317}\) They represent the most abundant receptor on the platelet surface. Like all integrin receptors, this complex is composed of noncovalently linked subunits. Each subunit is encoded by separate genes on the long arm of chromosome 17. Both subunits consist of a large extracellular domain and very short cytoplasmic domains, and together they form a heterodimer. Within their combined extracellular domains is the ligand-binding pocket, with surrounding subunit domains conferring specificity. Equally important are the short cytoplasmic domains critical for transmembrane signaling. These domains act to regulate the affinity of the receptor, transmit intracellular signaling, and anchor the receptor to the cytoskeletal elements.\(^{318}\)

The signaling pathways of \(\alpha_{III}\beta_3\) are complex and have been extensively studied. Central concepts of the signaling pathway include inside-out signaling, which involves the processes termed affinity and avidity modulation,\(^{318,319,320,321}\) and outside-in signaling, in which messages are transmitted to the inside of the platelet via the events occurring outside the membrane through \(\alpha_{III}\beta_3\) activation. Primary platelet agonists such as ADP, thrombin, and matrix proteins collagen and vWF affect platelet aggregation through a process known as inside-out signaling. This term denotes an integrin property that involves the binding action of agonists and extracellular matrix ligands to their receptors, leading to activation of numerous platelet functions, including the conformational change of \(\alpha_{III}\beta_3\) to a high-affinity state, referred to as affinity modulation. The relative contribution of soluble and extracellular matrix stimuli to inside-out signaling likely varies with flow conditions and other factors related to vascular perturbation. For example, GPIb/V/IX function is most relevant under
high shear stress conditions such as those associated with arterioles and capillaries and in stenotic arteries. One of the effects of inside-out signaling on \( \alpha_{\text{IIb}}\beta_3 \) is exposure of the fibrinogen-binding site through signal transduction involving the cytoplasmic domains (Figs. 16.12 and 16.13). The process involves a cascade of intracellular pathways that converge on Rap1, the Rap1-adaptor molecule RIAM, talin, and kindlin. The association between subunit cytoplasmic tails, and likely also the integrin subunit transmembrane domains, maintains the \( \alpha_{\text{IIb}}\beta_3 \) complex in a resting, nonadhesive conformation. Likewise, talin appears to be “auto-inhibited” in resting cells. Inside-out signals release talin auto-inhibition to expose a FERM domain in the talin head. This domain interacts with the integrin \( \beta \) subunit cytoplasmic domains, which causes separation of the integrin tails with consequent changes in the extracellular domains to increase \( \alpha_{\text{IIb}}\beta_3 \) affinity. Activation of \( \alpha_{\text{IIb}}\beta_3 \) also requires kindlin-3, an adaptor protein that interacts with a distinct site on \( \beta_3 \) integrin tails. The precise relationship between talin and kindlin remains to be elucidated.

The crystal structure of the \( \alpha_{\text{IIb}}\beta_3 \) headpiece provides evidence that the receptor can assume different conformations, and complexes of the receptor with the drugs eptifibatide and tirofiban have been reported. Two major conformational changes of \( \alpha_{\text{IIb}}\beta_3 \) have been reported—headpiece extension and domain swing-out—both of which may enhance integrin ligand binding. Thiol-disulfide exchange may also influence \( \alpha_{\text{IIb}}\beta_3 \) activation.

Avidity modulation, the less dominant action, acts to cluster the \( \alpha_{\text{IIb}}\beta_3 \) heterodimers into oligomers through lateral diffusion. These conversions are critical in allowing \( \alpha_{\text{IIb}}\beta_3 \) to engage soluble adhesive ligands. These ligands contain the classical integrin-recognition sequence RGD, Arg-Gly-Asp, which acts as a bridge between adjacent platelets, allowing aggregation to proceed. In addition, more \( \alpha_{\text{IIb}}\beta_3 \) translocates to the platelet surface membrane from the degranulating \( \alpha \)-granule pool, where additional receptors are stored. These changes facilitate irreversible binding to fibrinogen.

**FIGURE 16.12.** Integrin activation is bidirectional and reciprocal. The \( \alpha_{\text{IIb}}\beta_3 \) complex equilibrates between resting and activated states, the resting state predominating in unstimulated platelets and the activated state in stimulated platelets. Conversion from resting to activated does not imply a single, abrupt change but rather a series of coordinated and linked conformational transitions. A: Inside-out signaling. Agonist-dependent intracellular signals stimulate the interaction of key regulatory ligands (such as talin) with integrin cytoplasmic tails (in this case the \( \beta_3 \) tail). This leads to conformational changes in the extracellular domain that result in increased affinity for adhesive ligands such as fibrinogen, von Willebrand factor (vWF), and fibronectin. Plasma fibrinogen and vWF support platelet aggregation at low and high shear rates, respectively, by bridging \( \alpha_{\text{IIb}}\beta_3 \) receptors on adjacent platelets. Studies in mice deficient in fibrinogen and vWF indicate that plasma fibronectin can also promote thrombus initiation, growth, and stability at high shear rates. B: Outside-in signaling. Extracellular ligand binding, initially reversible, becomes progressively irreversible and promotes integrin clustering and further conformational changes that are transmitted to the cytoplasmic tails. This results in the recruitment and/or activation of enzymes, adaptors, and effectors to form integrin-based signaling complexes. (From Shattil SJ, Newman PJ. Integrins: dynamic scaffolds for adhesion and signaling in platelets. Blood 2004;104:1606-1615.)
FIGURE 16.13. Schematic illustration of αIIbβ3 receptor regulation via inside-out and outside-in signaling. ADP, adenosine diphosphate; ADPase, adenosine 5’-diphosphatase; NO, nitric oxide; PGE2, prostaglandin E2; PGI2, prostacyclin; TxA2, thromboxane A2. (From Casserly IP, Topol EJ. Glycoprotein IIb/IIIa antagonists—from bench to practice. Cell Mol Life Sci 2002;59:481, with permission.)

After ligand binding occurs, a multitude of intracellular signals are generated that are collectively referred to as outside-in signaling. This “contact-dependent signaling” determines the extent to which platelets will spread on a vascular matrix and how resistant to detachment they are.318,325 Outside-in signaling occurs in a discrete pattern in which ligand binding initiates integrin clustering and assembly of a “nascent” signaling complex proximal to the αIIbβ3 cytoplasmic tails, and this is followed by the growth of a larger “actin-based” signaling complex. It can be envisioned that the nascent complex is characterized temporally by (a) activation of Src kinases bound to the β3 cytoplasmic tail by fibrinogen engaging and facilitating integrin clustering, then (b) recruitment and activation of Syk by Src, then (c) Src and/or Syk phosphorylation of various substrates including adaptor proteins SLP-76 and c-Cbl along with the Rac GTPase Vav; and these substrates in
turn act by participating in signaling to the actin cytoskeleton. As the nascent complex assembles, many additional proteins are recruited that can influence actin reorganization, including Rac, the adaptor Nck, PAK, PI3-kinase, and VASP, an actin-bundling protein. All these signaling events during platelet aggregation are further supported by release of granules induced by the binding of adhesive proteins to the extracellular domain of β3. This complex series of events serves as a determinant of the final clot size. Once full spreading and aggregation of platelets occurs, usually within several minutes, focal adhesion kinase is phosphorylated. The PI3K system is activated once αIIbβ3 is engaged, leading to generation of D3 phosphoinositides. These proteins act to prevent the depolymerization of the actin cytoskeleton, with the result that the platelet aggregate is stabilized. The end result of this outside-in signaling is a stable platelet clot. Not only does the αIIbβ3 receptor have important roles with respect to platelet function, it affects coagulation and may influence inflammatory processes as well.

Antithrombotic agents that act on the αIIbβ3 receptor have had a significant impact on clinical outcomes of patients with acute coronary syndromes (ACS) and those requiring percutaneous coronary interventions (PCI). The three parental agents used in the United States are the chimeric monoclonal antibody abciximab, the cyclic heptapeptide (based on the RGD sequence) eptifibatide, and the synthetic nonpeptide tirofiban. Disappointing clinical trial results were seen with the oral αIIbβ3 inhibitors used for longer term indications, and this even includes an increased all-cause mortality rate. The reasons for these results are not entirely known.

ROLE OF THE CYTOSKELETON IN PLATELET FUNCTION

(See additional cytoskeleton structure information in the section on platelet structure earlier in the chapter.)

Once an agonist has interacted with its platelet membrane receptor and triggered second messenger formation, a key event in platelet activation and subsequent aggregation is the transition of the platelet’s shape from the discoid appearance associated with its circulating, resting state to the amorphous, amebalike appearance with multiple pseudopodial projections that denote its activation state and readiness to participate in platelet plug formation. The platelet cytoskeleton and its associated signaling proteins are responsible for mediating shape change associated with activation, spreading, secretion, and aggregation. This cytoskeleton is associated with at least 14 different structural proteins that function interdependently as a single unit but can be seen as consisting of three major functional units: (a) a cytoplasmic network consisting mainly of actin, (b) a meshwork of proteins immediately proximal to the cytoplasmic leaflet of the platelet membrane referred to as the membrane skeleton (because they contain surface-associated proteins such as the GPIb complex), and (c) the microtubule coil that encircles the platelet to contribute to its resting, discoid state.

Transmembrane receptors such as GPIb participate in anchoring the platelets to extracellular matrix in the arterial subendothelium through their extracellular domains, while their cytoplasmic domains are almost simultaneously associating with membrane skeletal proteins in response. In doing so, these surface receptors are providing sites at which tension can be generated by intracellular contractile elements that subsequently lead to shape change and activation of signaling proteins.

The cytoplasmic network consists of actin filaments and their associated proteins, referred to as intermediate filaments. In resting platelets, approximately half of the actin is structurally filamentous in nature, and this fraction increases to approximately three-fourths during platelet activation. During this process, the actin filaments are reorganized into longer filaments after their initial breakdown into smaller units. Simultaneously, myosin is phosphorylated by myosin light chain kinase and then associates with F-actin, with the resultant filament then attaching itself to the α subunit of the GPIb complex through filamin. These filaments are also anchored at sites called focal adhesions, where the tyrosine kinase Fak becomes activated after platelet stimulation. Focal adhesions assemble around the αIIbβ3 integrin on its conformational change (activation) and so play a very important role in signaling pathways associated with platelet activation by drawing together membrane receptors, the cytoskeleton, and signaling phosphoproteins, such as members of the Src family, PI3K, and Syk, into close physical proximity. Other platelet integrin receptors, such as α5β3, also organize focal adhesions after binding to their respective extracellular ligands.

It was noted in the section on GP Ib complex signaling that phosphorylation of Ser 166 in the cytoplasmic domain of the GPIb complex β chain has been observed to be mediated by cAMP-associated activation of PKA and that this phosphorylation reduced interaction of GPIbβ and the signaling molecule, 14-3-3ζ. The phosphorylation of GPIbβ has also been demonstrated to have a direct inhibitory effect on actin polymerization.
The membrane skeleton consists of actin, filamin-A, talin, vinculin, spectrin, cortactin, α-actinin, and several membrane GPs, as noted previously. Filamin-A (previously termed actin-binding protein), a 280-kDa elongated dimer, serves as a scaffold for many proteins, including GPIbα and is important to the latter’s signaling and expression, and together they control platelet size. After platelet activation, cytoskeletal proteins, in particular filamin and talin, are preferentially cleaved by calpains, which are calcium-dependent proteases. Calpain-mediated cleavage of the β3 tail of αIIbβ3 may modulate its functions.

The marginal microtubule band maintains a platelet discoid shape and appears to be an essential intermediate in the microtubule-driven process of proplatelet formation and platelet release. This single microtubule polymer is wound in 8 to 12 coils in the cytoplasmic periphery and is located just beneath the plasma membrane. About 90% of β-tubulin in the marginal band is of the divergent, megakaryocyte (MK)/platelet-restricted β1 isoform. β1-tubulin-null mice show reduced proplatelet formation, thrombocytopenia, and platelet spherocytosis.

**PLATELET-CELL INTERACTIONS**

**Platelets and Endothelium**

The mechanisms behind platelet interaction with vWF, collagen, and other subendothelial matrix molecules exposed as a result of damaged endothelium have been well studied and described in earlier sections of this chapter. In addition to these platelet- subendothelial interaction paradigms, platelets (like neutrophils) roll on intact, activated endothelium in vivo and then reversibly adhere to it in a process that is dependent on endothelial cell expression of P-selectin. This sequence of molecular interactions is a well-controlled multistep process involving platelet tethering and interaction of platelet P-selectin glycoprotein ligand-1 (PSGL-1) or GPIbα with endothelial P-selectin (“rolling”), followed by subsequent “firm adhesion” to the vascular wall mediated through β3 integrins. Platelets rolling on activated endothelium can be inhibited by both anti-P-selectin and anti-GPIbα antibodies. GPIbα and PSGL-1 have structural similarities, including similar ligand-binding domains, and both are present on platelets and may interact with P-selectin. Endothelial P-selectin is rapidly expressed on the surface in response to inflammatory stimuli by translocating from membranes of storage granules (Weibel-Palade bodies) to the plasma membrane within seconds.

Along with endothelial P-selectin, vWF expressed on activated venous endothelium promotes platelet adhesion and translocation. When released along the endothelial surface as ultralarge vWF, platelets adhere like beads on a string. Platelets are released by cleavage of vWF by the metalloprotease, a disintegrin-like metalloproteinase with thrombospondin repeats-13 (ADAMTS13), that proteolyses vWF within the A2 domain under conditions of increased shear stress. Dysfunction in ADAMTS13 function underlies thrombotic thrombocytopenic purpura (TTP). In the absence of ADAMTS13, the platelet beads along the endothelial cell’s coalesce to form thrombi.

Firm platelet adhesion to intact endothelial cells following rolling is a process dependent on αIIbβ3 bridging to endothelium that involves endothelial receptors such as αβ3 and intercellular adhesion molecule-1 interacting with platelet-bound fibrinogen, fibronectin, and vWF. This firm adhesion is strengthened by inflammatory cytokines, such as RANTES, and additional receptor pairs, such as CD40-CD40L.

**Platelets and White Blood Cells**

Platelets contribute to leukocyte rolling and extravasation, which are two well-characterized steps involved in the translocation of the latter cell from the circulation to sites of infection. Leukocytes are also capable of tethering and rolling on adherent and activated platelets by interacting with P-selectin expressed on the platelet surface, and they will subsequently display extravasation asactivation of Mac-1. The α subunits of certain integrins, such as Mac-1, have been found to contain “insert” (I) domains, homologous to the Aβ domain of vWF. This observation has taken on added interest since it has been shown that Mac-1 is capable of binding to the GPIb complex and that this interaction requires the I domain of Mac-1 and the leucine-rich repeat region of GPIbα. The Mac-1-GPIb complex interaction may be important to initiate and propagate inflammation associated with the progression of atherosclerotic, purely thrombotic, or atherothrombotic processes.

Mac-1 has also been found to associate with other receptors of the platelet membrane, including the junctional adhesion molecule-3 (JAM-3), intercellular adhesion molecule-2 (ICAM-2), fibrinogen bound to αIIbβ3, and high-molecular-weight kininogen bound to GPIbα. During this adhesive process, the association of platelet membrane PSGL-1 and Mac-1 stimulates the release of inflammatory cytokines from platelets, which in turn induces inflammatory cascades in monocytes. This
integrin-, selectin-, and cytokine-based set of coordinated reactions linking neutrophils, platelets, and monocytes leads to circulating activated platelets and platelet-white cell aggregates that promote formation of atherosclerotic lesions.

ROLE OF PLATELETS IN SYSTEMIC DISORDERS

Inflammation and Immunity

The binding of platelets to leukocytes influences important white cell effector responses, such as cell activation, signaling associated with integrin activation, chemokine synthesis, and so forth. Thus, it has become clear that inflammation is capable of leading to local thrombosis, and thrombosis is capable of initiating and propagating inflammation. Leukocyte interactions with platelets result in immediate events, including activation of adhesion receptors, reactive oxygen species generation, and thrombin formation, but also in delayed responses such as alterations in gene expression and protein synthesis. The molecules regulated by platelet adhesion include cyclo-oxygenase 2 and tissue factor expression. Platelets and leukocytes participate in transcellular metabolism of arachidonic acid to generate novel mediators that either cell type alone could not generate. Platelets also stimulate the formation of neutrophil extracellular traps (nets) composed of DNA and proteases. Nets trap and kill bacteria and may also form scaffolds for thrombus formation. Platelets can also promote class switching of B cells through CD40L. The interactions of platelets with leukocytes may regulate the development of intimal hyperplasia, inflammatory lung and bowel disease, and arthritis.

Platelets in Atherogenesis

Atherosclerosis is the major cause of vascular occlusive disorders such as coronary artery disease, stroke, and peripheral arterial disease. Many of the molecular players mediating leukocyte-endothelium interactions that underscore the development of atherosclerosis have also been found to play important roles coordinating leukocyte attachment and transmigration across layers of platelets adherent to injured vascular intima. Animal models have recently provided strong evidence linking platelets to early events of atherogenesis. An atherosclerosis mouse model lacking α1b, exhibited substantial reduction in atherosclerotic lesion formation.341 The importance of P-selectin in atherosclerosis lesion formation has been well described.342,343 Platelet adhesion has been found to activate endothelial cell nuclear factor-κB and its regulated genes, many of which play key roles in platelet-endothelium-extracellular matrix molecular events that support inflammatory and proatherogenic phenotypes. This includes events that contribute to lesion maturation such as smooth muscle cell and fibroblast proliferation and promotion of collagen synthesis, among others. Inhibition of COX-1, an enzyme with expression restricted to platelets, in turn inhibits lesion formation in an atherosclerosis mouse model.344,347 Another atherosclerosis mouse model demonstrates that prolonged antibody blockade of GPIIbα leads to reduced arterial leukocyte accumulation in carotid arterial intima and subsequent reduced atherosclerosis lesion formation.345 VWF may also have a role in atherogenesis.346

In contrast to animal data, conclusions regarding the role of human platelets in atherogenesis are not nearly as extensive. Mouse data cannot be unequivocally applied to humans, because mouse platelets differ from human with respect to expression levels of certain surface receptors. Systemic platelet activation in humans has been described in a variety of atherosclerosis disease presentations. Antiplatelet agents do not obviously influence disease progression when applied in the secondary disease prevention setting in humans in which atherosclerosis is likely advanced, as opposed to the possibly preventable progression of early lesions that are present before an initial atherosclerosis clinical event.347

Platelets in Atherothrombosis

The interior of intact atherosclerotic plaques is rich in components that are highly thrombogenic (e.g., collagen types I and III, fibrinogen/fibrin, thrombospondin), and the luminal surface is relatively nonthrombogenic. In contrast to these observations, the thrombotic response to plaque disruption is dynamic. In this respect, thrombosis, repeat thrombosis, and thrombolysis, along with embolization, all occur simultaneously in many patients with acute coronary syndrome, and this is considered responsible for intermittent flow obstructions.348 The initial flow obstruction is acknowledged as being due to platelet aggregation, but subsequent fibrin stabilization is important to the longevity of the early and fragile platelet thrombus.349 As a result of reduced flow caused by the platelet thrombus at the plaque rupture site, an erythrocyte- and fibrin-rich thrombus may form and propagate up and down the artery in both directions.348 There is evidence that alteration of the endothelium such as may occur with early atherogenesis (particularly when under the influence of atherosclerosis risk factors) or plaque disruption may cause the endothelium to generate more mediators that enhance constriction, such as endothelin-1, and fewer mediators that enhance dilation, such as PG12 and NO.

Platelets in Vessel Integrity and Development

Platelets are essential to maintain the integrity of the vasculature, although the mechanisms are unknown. Platelets store a number of barrier stabilizing cytokines and growth factors which may be released constitutively or in a stimulus-
dependent manner, including sphingosine-1-phosphate (S1P) is essential for barrier function, ADP, serotonin, VEGF, and thrombospondin. Platelets recruit and promote the differentiation of bone marrow-derived and circulating endothelial progenitor cells, which may contribute to the vessel response to injury. Finally, platelets regulate lymphangiogenesis through interactions between platelet C-type, lectin-like receptor 2 (CLEC-2) expressed by platelets and podoplanin on lymphatic endothelial cells. Disruptions in these interactions in mice result in severe lymphatic vascular defects.

Platelet Function in Hemostasis and Thrombosis
David C. Calverley

PLATELET ADHESION AND ACTIVATION

Primary hemostasis and arterial thrombosis are the results of a complex series of cell-cell, cell-protein, and protein-protein reactions that involve platelets, leukocytes, endothelium, subendothelial matrix, and plasma proteins, such as fibrinogen, von Willebrand factor (vWF), and others. The consequences of arterial thrombosis include such events as myocardial infarction (MI), unstable angina, and stroke. These clinicopathologic entities and their associated cellular physiologic mechanisms that are outlined in this chapter collectively account for the largest cause of morbidity and mortality in the Western world.

Platelet adhesion to exposed subendothelium is a complex multistep process that involves a diverse array of adhesive ligands (vWF, collagen, fibrinogen/fibrin, fibronectin, thrombospondin, laminin, and vitronectin) and surface receptors (gplb/V/IX, gpVI, integrins αIIbβ3, αIIbβ2, αIbβ1, and α6β1). The specific ligand/receptor players in primary platelet adhesion are largely dependent on the arterial flow conditions present.
veins, platelet adhesion to the vessel wall is thought to involve fibrillar collagen, fibronectin, and laminin. There are at least 25 forms of collagen, and several of these are present in the blood vessel wall, whereas one (type IV) is present in the subendothelial basement membrane. In the high-shear conditions present in smaller arteries, platelet tethering is dependent on the unique shear-dependent interaction between gpIb/V/IX and subendothelial vWF. The subsequent rapid platelet deceleration allows for other ligand-receptor interactions such as collagen and αIβ3, that have slower binding kinetics and take on the role of mediating firm platelet adhesion. A metalloprotease, ADAMTS13, cleaves vWF; this cleavage prevents the accumulation of ultrahigh-molecular-weight multimers that would otherwise cause spontaneous platelet clumping and arterial thrombosis.

Following initial platelet adhesion, subsequent platelet-platelet interaction (aggregation) is mediated by two receptors, gpIb/V/IX and αIβ3, and their respective contributions are dependent on the flow conditions present. In high-shear stress conditions, gpIb/V/IX receptor and vWF ligand action are predominant, with fibrinogen playing a stabilizing role. At low-shear conditions, fibrinogen is thought to be the primary ligand supporting platelet plug formation through its interaction with αIβ3. It has been shown that thrombus formation can take place in the absence of vWF and fibrinogen, and this supports the idea that a third ligand directed to the αIβ3 receptor may also exist in vivo.

Platelet Glycoprotein Ib Complex-von Willebrand Factor Interaction and Signaling

It has long been recognized that the interaction of the platelet glycoprotein (gp) Ib “complex” (including the single-chain polypeptides gpIba, gpIbβ, gpIX, and gpV) with its primary ligand, vWF, is the receptor-ligand pairing that initiates platelet adhesion followed by a cascade of events leading to pathologic thrombosis or physiologic hemostasis. A unique aspect of this receptor-ligand interaction is that it requires the presence of high arterial shear rates to take place, thus explaining the predisposition of platelet-rich “white clots” in the arterial circulation over clots found in the venous circulation, with its relatively lower shear forces, in which clot formation takes place independent of the gpIb complex.

Using a parallel-plate flow cytometer, platelet interaction with subendothelial vWF has been characterized as occurring in a biphasic fashion. In this respect, the rate of translocation of platelets from blood to the endothelial cell surface increased linearly up to wall shear rates of 1,500 s⁻¹, whereas the translocation rate remained relatively constant with the wall shear rate between 1,500 and 6,000 s⁻¹. This ability to mediate translocation or rolling of the platelet on vWF is contingent on the gpIb complex, and mammalian cells expressing either the full complex or a complex lacking the gpV subunit were able to roll onto vWF in a gpIba-chain-dependent manner.

It is clear that arterial thrombus formation is contingent on both the presence of high wall shear rates and interaction between the gpIb complex and vWF. Studies involving the endpoint of realtime thrombus formation that involved comparison of blood from both patients with Bernard-Soulier syndrome (which lacks platelet gpIb complex) and severe (type 3) von Willebrand disease versus normal blood led to the conclusion that gpIb and vWF interaction was required for platelet surface interaction at high shear rates (>1,210 s⁻¹), whereas normal thrombus formation at lower shear rates (<340 s⁻¹) was possible with blood deficient in either gpIb or vWF. In normal blood, thrombus formation was accelerated as shear rate increased, and this served to verify the unique shear flow dependence of this receptor-ligand interaction.

The gpIb complex consists of four transmembrane subunits, each of which is a member of the leucine-rich repeat protein superfamily that participates in cell-matrix interactions throughout nature. Each of the four subunits contains one or more tandem, 24-amino acid leucine-rich repeats flanked by conserved disulfide loop structures at both the N and C termini of the repeats. gpIba is covalently associated with the gpIbβ chain through disulfide linkage of cysteine residues, and both of these chains are noncovalently associated with gpIX in a 1:1 ratio and with gpV in a 2:1 ratio and 24 (Fig. 17.1). vWF is a large multimeric glycoprotein that circulates in plasma and is also found in platelets and the Weibel-Palade bodies of endothelial cells. Mature vWF is a 2,050-amino acid subunit that is disulfide linked into large multimers. It contains three adjacent A domains in the N-proximal half of the peptide that collectively regulate the adhesion of platelets to subendothelial matrix. In this respect, the A₁ and A₃ domains bind to different matrix collagens, whereas the A₂ domain contains the binding site for the gpIb complex. The A₁ domain is the primary role player in platelet adhesion, because this part of the molecule is believed to change its conformation in response to immobilization and high-shear forces, thus making it a high-affinity ligand for the gpIb complex receptor. It has also been suggested that shear stresses may induce conformational changes in the gpIb complex that may be important in increasing its affinity for vWF. Through the simultaneous binding of collagen and platelets, vWF can serve as a molecular bridge between platelets and the subendothelial matrix mediating platelet adhesion to the vessel wall. Thus by associating with matrix proteins vWF mediates rapid and reversible platelet adhesion that promotes the rolling of these cells along the surface of vascular injury.
To further add to the mystery behind the mechanism of shear dependence in gpIb-vWF interaction, in vitro activation of vWF and binding to the gpIb complex occur with generally very low affinity without shear, whereas this shear-free binding exhibits high affinity in the presence of the vancomycin-like antibiotic ristocetin, and viper venom proteins, such as botrocetin. It is interesting that studies incorporating anti-gpIbα and anti-vWF domain A1 antibodies have suggested that ristocetin and botrocetin each appear to use different receptor and ligand-binding sites to facilitate the vWF-gpIb complex interaction.²⁹,³⁰ and ³¹

FIGURE 17.1. Schematic illustration of the glycoprotein (GP) Ib/V/IX complex and associated proteins. The N-terminal domain of GP Ibα contains binding sites for von Willebrand factor (vWF) and thrombin. The cytoplasmic domain of GP Ibα contains the phosphorylation-dependent 14-3-3 binding sites, and also the binding site for filamin that links GP Ib-IX to the actin cytoskeleton underlining the membrane. The cytoplasmic domain of GP Ibβ is phosphorylated by protein kinase A (PKA) and this phosphorylation is required for 14-3-3 binding. The membrane proximal region in the cytoplasmic domain of GP Ibβ and GP IX contains calmodulin-binding sites. From Du, X. Signaling and regulation of the platelet glycoprotein Ib-IX-V complex. LWW, Curr Opin Hematol 2007;14:262, Figure 2, with permission.
The binding interaction between vWF and gpIb appears to involve at least three distinct regions within the N-terminal 282 residues of gpIb. Each of these regions appears to be responsible for either direct binding to vWF or modulating its affinity for the ligand. In this respect, one region (His 1 to Glu 282), which includes a cluster between residues Asp 252 and Arg 293 containing sulfated tyrosine residues and important anionic residues, appears to be predominantly responsible for vWF-gpIb complex interaction in the presence of botrocetin over ristocetin. The second region contains the disulfide loop between Cys 209 and Cys 248 along with two naturally occurring mutations (Gly 233 to Val and Met 239 to Val) and two additional mutation sites identified in the laboratory (Asp 235 to Val and Lys 237 to Val) that can individually lead to expression of the pseudo- or platelettype von Willebrand disease phenotype. This disorder is associated with a gain-of-function gpIbα on platelets that adheres to vWF in the presence of lower concentrations of ristocetin (0.3 to 0.5 mg/ml) than are required for the wild-type phenotype (1.5 g/ml). It is analogous to type 2B von Willebrand disease, in which high-molecular-weight vWF multimers are absent from the plasma, and similar gain-of-function mutations have been localized to the Cys 509 to Cys 695 disulfide loop of vWF exon 28.

The third region includes the N-terminal flanking sequence of the leucine-rich repeat (LRG) motifs and the LRGs themselves. Mutations involving single amino acid residues within these LRGs account for some cases of the congenital bleeding disorder, Bernard-Soulier syndrome, in which the gpIb complex binds poorly or not at all to vWF. Evidence using mammalian Chinese hamster ovary cells expressing loss-of-function proteins and anti-gpIbα monoclonal antibodies has suggested that the more N-terminal LRGs may play a more direct role in interaction with vWF.

Glycoprotein Ib Complex Interaction with Thrombin

Recent studies have examined the potential role of the gpIb complex in thrombin-mediated platelet activation. The physiologic significance of the interaction of thrombin with the complex has remained relatively controversial. gpIbα contains a well-characterized high-affinity binding site for thrombin, and thrombin is also capable of cleaving gpV near the surface to release a soluble fragment.

Recent studies have suggested that a relationship exists between thrombin binding to the gpIb complex and cleavage of the seven-transmembrane G-protein-coupled protease-activated thrombin receptor, protease-activated receptor (PAR)-1 (see section “Platelet Thrombin [Protease-Activated] Receptors and Signaling”), and that accelerated coagulation on the surface of a developing thrombus is a downstream consequence of thrombin-gpIb interaction because of enhanced phospholipid exposure. These studies support a procoagulant role of this thrombin-gpIb pairing and this activity also plays an important role in the generation of platelet microparticles. In contrast, studies using gpV-null mice have suggested that the gpV subunit may act as a negative regulator of thrombin-mediated platelet activation, whereas data from another study suggest that thrombin-gpIb interaction leads to conformational changes in thrombin that reduce its cleavage of fibrinogen.

The phenotype of a gpIbα knockout mouse has been reported and was similar in many ways to human Bernard-Soulier syndrome. This mouse was then capable of having the wild-type phenotype restored by a human gpIbα transgene. Future use of this mouse model might be helpful toward further elucidation of the physiologic role of platelet gpIb complex interaction with thrombin. In the meantime, the current data extend further support for a role for the gpIb complex as a thrombin receptor on platelets, whereas, recent insights not withstanding, elucidation of the downstream consequences of that interaction with respect to platelet activation and thrombus formation will remain the subject of further investigation.

Studies have focused on interaction of the gpIb complex with activated intact endothelium through ligands other than vWF adherent to subendothelial matrix. These include a study of a reversible association of gpIb with endothelial cell P-selectin, which is examined in more detail in the section, “Platelets and Endothelium.” The interaction of platelet gpIb with the neutrophil adhesion receptor Mac-1 is discussed in the section, “Platelets and White Blood Cells.” These interactions may contribute more to inflammatory responses than platelet thrombus formation. The dependence of fibrin-associated platelet procoagulant activity on both the gpIb complex and vWF has also been documented.

Glycoprotein Ib Complex Signaling

For some time, controversy surrounded the question of whether the gpIb/V/IX complex signals. This was likely a result of variations in experimental strategies that involve differences with respect to vWF preparations, the use of conformational modulators in experimental work such as botrocetin, cell lines used, and other causes. It is reasonable to assume that the receptor is capable of signaling, although a lot of questions remain to be answered, and the many molecules that are known to participate in the process remain to be assembled into a defined pathway.
When the gplb complex interacts with its vWF ligand under conditions of elevated shear stress, there is abundant evidence that signaling pathways are activated that lead to (a) elevation of intracellular calcium; (b) activation of a tyrosine kinase signaling

P.413

pathway that incorporates nonreceptor tyrosine kinases such as Src, Fyn, Lyn, and Syk, phospholipase C (PIC)γ2, and adaptor proteins such as SHC, LAT, and SLP-76; (c) GTPase activating protein; (d) tyrosine phosphatases (PTP-1B and SHPTP10); (e) inside-out signaling through the αIIbβ3 integrin followed by platelet aggregation; and (f) activation of protein kinase C (PKC), protein kinase G (PKG), and phosphoinositide 3-kinase (PI3K). vWF binding also up-regulates integrin αIIbβ3 affinity indirectly through stimulation of adenosine diphosphate (ADP) secretion. Other downstream players and events that play roles after gplb receptor occupancy include (a) the homodimeric signaling protein 14-3-3 and calmodulin, (b) receptor cross-linking, and (c) the immunoreceptor tyrosine-based activation motif (ITAM)-containing proteins Fcy receptor IIa (FcyRIIA) and Fc receptor (FcR) γ chain. In addition to the above-mentioned components, the effect of shear force itself on gplb signaling, including the affinity and number of bonds between vWF and gplb, play potentially important roles as well.

Evidence has also been presented suggesting that indirect mechanisms may also be involved in gplb signaling, that are linked to ADP release and/or thromboxane A2 (TxA2) generation. The increase in intracellular calcium prompted by vWF-gplb interaction promotes dense granule secretion of ADP, which then activates integrin αIIbβ3 through the P2Y1 and P2Y12 purinergic receptors (see the section on “Platelet P2Y1 and P2Y12 Receptor Roles in ADP-Mediated Activation” later in the chapter).

14-3-3ζ is among the 10 isoforms of the 14-3-3 family of proteins that is named according to its electrophoretic gel migration position. Functionally, this family has a wide range of activities, including participating as a DNA damage, cell-cycle checkpoint protein, regulation of PKC activity, formation of heterotrimers with the signaling kinase Raf and the guanosine triphosphate exchange factor Ras, and so forth. Binding sites for 14-3-3 have been identified in the cytoplasmic domains of gplbα, gplbβ, gpIX, and gpV. In this respect, peptide fragments corresponding to overlapping cytoplasmic sequences of the four subunits demonstrated binding in vitro, whereas yeast two-hybrid studies documented in vivo interaction between 14-3-3ζ and both gpIbα and -β. Site-directed mutagenesis and protein-binding experiments confirmed the need for phosphorylation of Ser 166 of the 14-3-3 consensus sequence in the gplbβ cytoplasmic domain to permit high-affinity 14-3-3 binding. Findings that have evolved in lieu of the above observations include the binding of fibrinogen to mammalian-cell-transfected αIIBβ3 in response to vWF binding to co-transfected gplb-IX that was inhibited when the 14-3-3-binding domain was deleted from the gpIb-IX transfectant. Also, the lipid kinase PI3K has been found to play a role in this gplb-IX dependence of αIIBβ3 activation through its participation in complex formation with the gplb complex and 14-3-3. The reason for these associations would be to regulate, in short order, the formation of inositol phosphorylated in the 3-position within the reorganizing cytoskeleton in response to platelet activation (see section "Role of the Cytoskeleton in Platelet Function").

Many adhesion receptors initiate signaling through cross-linking, and there is evidence to suggest that the gplb complex may also use this mechanism. The gpV subunit surface expression on platelets is roughly half that of the other three subunits (12,000 vs. 25,000 copies per cell). It has also been suggested that two or more gplbα subunits cluster into a complex with the other glycoprotein subunits. The fact that there is one gpV subunit available in this complex for every two of the other subunits, and that both actin-binding protein (ABP or filamin; a membrane skeleton protein that associates with gplbα; see later in the chapter) and 14-3-3 exist as dimers, lends support to the concept of a complex consisting of a pair of gplbα-gplbβ-gpIX trimers joined noncovalently by a single gpV monomer (Fig. 17.1). Several studies document a physical association of the gplb complex with the 14-kDa FcRy-chain and with the 40-kDa FcRyIA receptor, suggesting that platelet activation may also occur through gplb-mediated triggering of Src-family-kinase phosphorylation. Both of these proteins contain nonidentical but similar ITAM domain sequences. The FcRy-chain forms a complex with the gpV1 monomer and plays an essential role in collagen-mediated platelet activation, as reviewed in the next section. The FcRyIA receptor is a member of the immunoglobulin (Ig) superfamily and is without a clearly defined physiologic role in platelets. Occupancy of this receptor by the C-terminal Fc domains of immunoglobulin leads to platelet activation, and this is blocked by anti-gplbα antibodies, whereas signaling through vWF is also blocked with anti-FcRyIA antibodies. Both ITAM-containing receptors can be coimmunoprecipitated with gplb and both have very similar signaling pathways that involve the tyrosine kinase Syk and PICγ2 and SHPTP10. Although the physical proximities of these three players have recently become apparent, the nature and significance of any physiologic
relationships that exist between the gpIb complex and these two ITAM receptors with respect to vWF-dependent platelet activation remains unclear.

Shear flow studies have demonstrated an important role for calcium signals that in turn promote αIIbβ3 activation necessary for stable platelet adhesion to vWF (34,35). This phenomenon occurs independently of extracellular calcium and is thought to involve αIIbβ3-mediated calcium release from intracellular stores. One proposed mechanism to explain this observation involves signaling pathways such as those used by ITAM-bearing receptors, because the enzyme and adaptor protein components used in both αIIbβ3 and ITAM signaling are very similar. These components are likely to be important in the positive feedback loop linking αIIbβ3 activation and calcium flux under high shear, which in turn promotes the efficient conversion of translocating platelets into firmly adhesive cells.64

Once vWF binds to gpIB-IX, signaling complexes form in the vicinity of the gpIbα cytoplasmic tail consisting of cytoskeletal proteins such as 14-3-3ζ as well as signaling proteins such as Src and PI 3-kinase. This process leads to Syk activation, protein tyrosine phosphorylation, and recruitment of other cytoplasmic proteins with Pleckstrin homology domains that can support interactions with 3-phosphorylated phosphoinositides.65,66,67,68 and 69

Platelet-Collagen Interaction and Signaling

Collagens are very important activators of platelets in the vascular subendothelium and vessel wall, and thus are prime targets for therapeutic intervention in patients experiencing a pathologic arterial thrombotic event such as MI or stroke. Platelets have two major surface receptors for collagen, the integrin αIIbβ3 and the immunoglobulin superfamily member gpVI. In addition to binding collagen with high affinity, αIIbβ3 binds laminins, E-cadherins, matrix metalloproteins, C1q, echovirus, and rotavirus. In addition to these two surface receptors, the gpIb complex can also be considered an indirect collagen receptor because its subendothelial vWF ligand essentially acts as a bridging molecule between platelets and collagen by fixing itself to the latter, which, in turn, acts as scaffolding for the multimers.

Collagen supports platelet adhesion through interaction with the integrin surface receptor αIIbβ3, although this interaction alone does not support platelet activation.72 Laboratory evidence suggests that gpVI and the 14-kDa FcRγ-chain signaling subunit (FcRγ chain) with which gpVI forms a complex are both required for collagen-mediated platelet adhesion and activation.61,69,70,71,72,73,74,75,76,77,78,79 and 80 Thus platelet adhesion to collagen is a multistep process. Once exposed to an injured vascular wall, vWF adheres to subendothelial collagen and undergoes a conformational change allowing its A1 domain to bind to GP Ib/IX under high-shear flow conditions. This rapidly formed bond is quickly broken and re-established and this leads to the platelet rolling along the vascular wall. This

in turn slows down the platelet and allows the signaling receptor GPVI to bind collagen, more specifically the repeating sequence Gly-Pro-Hyp (where Hyp is hydroxyproline). Both receptors can signal but the role of GPVI is considered predominant in this respect.81 A series of signaling events then leads to the inside-out signaling activation of αIIbβ3, and interaction of this receptor with collagen is stable and allows the platelet to form a high-affinity strong adhesive bond with the vessel wall.

The above notwithstanding, of many receptors studied only αIIbβ3 and GPVI have a defined role in platelet-collagen interactions although, in spite of extensive studies, their relative importance with respect to both adhesion and activation continues to be debatable. Problems associated with the isolation of collagen from extracellular matrices and possible bu

2. Integrins are a family of α-β heterodimers on the surface of cells that carry out diverse interactions between the cell surface and its environment that ultimately lead to changes in cell behavior in response to the ligand-receptor interaction. In all α subunits of integrins, seven tandem repeats are localized to the N-terminal end and folded into a seven-bladed β-propeller structure.84 The αI subunit also contains an I domain between the second and third repeats that includes a metal coordination site for Mg2+ that is critical for interaction with collagen.85 Similar domains are found on the β subunit, although less is known about these, and it appears that the interaction of αIβ1 with collagen involves only the I domain of α. The β1 subunit exhibits a cysteine-rich domain containing CGXC sequences that is close to the membrane surface. This region has protein disulfide isomerase activity responsible for regulating
conformational changes of the β1 subunit (which, in turn, alters α2 conformation, increasing its avidity for collagen) in response to inside-out signaling through the cytoplasmic domain.  

Glycoprotein VI Receptor

Although the gpVI receptor was identified on the surface of platelets in 1982, its role in collagen-mediated platelet activation was not appreciated until much later.  

The human and murine genes were cloned and characterized, and gpVI was found to be a member of the immunoglobulin superfamily.  

The expression of gpVI in platelets is very closely associated with that of the 14-kDa FcRγ-chain, which also serves as the signaling subunit for gpVI.  

Expression of gpVI on mouse platelets appears to be dependent on FcRγ-chain expression, and the latter has also been found to be critical for collagen-mediated platelet activation.  

GpVI has two Ig C2 loops, and the N-terminal loop likely contains the collagen-binding domain. It appears that gpVI has a requirement for the quaternary structure of collagen to be in a triple-helical conformation for the two to associate.  

Following the cloning of gpVI, mouse knockout studies have suggested GPVI may be the primary receptor involved in collagen-mediated platelet activation.  

Further studies have enabled the collagen-binding site on gpVI to be characterized.  

Studies incorporating collagen-related peptides (arranged in triple helical structures with sequences similar to collagen) and the snake venom convulxin as agonists have been shown to signal by clustering gpVI molecules on the surface.  

However, the idea of gpVI receptor clustering as a platelet activation mechanism applicable to collagen is tempered by consideration of the theoretically much greater distances that would exist between adjacent gpVI-binding sites along fibrillar collagen compared with the larger, noncovalently linked structures of convulxin, in which gpVI-binding site distribution is much different.  

Platelet-Collagen Signaling

When compared to vWF, collagen is a more efficient substrate when it comes to supporting stable platelet adhesion and thrombus formation. The fact that initial platelet tethering to collagen under high-shear flow first requires interaction between vWF and platelet gpIb serves to underscore the importance of the two major collagen receptors, α2β1 and gpVI, in promoting platelet adhesion and activation under shear conditions.  

Many of the early signaling events that follow gpVI stimulation have been characterized, although synergism between these gpVI mediators and those related to other adhesion receptors such as gpIb-V-IX and soluble agonists released by activated platelets further complicates full elucidation of the players and pathways associated with platelet-collagen signaling.  

The gpVI signaling pathway has been found to be essential for collagen-mediated platelet activation, and mouse platelet studies have shown a central role for this receptor in promoting platelet-collagen interaction. Integrin α2β1 also contributes to platelet adhesion through amplification of signals from gpVI.  

As noted in the last section, exposure of platelets to collagen surfaces is thought to result in gpVI clustering that in turn triggers the tyrosine phosphorylation of the Fcγ chain. gpVI signaling may be influenced by its association with glycolipid-enriched microdomains (membrane rafts) in the plasma membrane, although it is unclear whether gpVI is constitutively associated with the rafts or is recruited. The gpVI/Fcγ-receptor complex leads to platelet activation through a pathway that has many aspects in common with signaling by immune receptors, such as the Fcγ receptor family (of which FcγRIIA is the lone family member found in platelets) and the B- and T-cell antigen receptors (Fig. 17.2). Much of what we know about gpVI signaling has been based on earlier work related to immune-receptor signaling.
Immunoreceptors such as the FcRs and the FcRγ chain all have the ITAM in common. Tyrosine phosphorylation of the ITAM by Lyn and Fyn of the Src family of tyrosine kinases takes place after activation of gpVI. The phosphorylated Src kinase, in turn, leads to activation of the tyrosine kinase Syk after its autophosphorylation. Syk then initiates a downstream signaling cascade involving the LAT and SLP-76 adapter proteins, which leads to formation of a signaling complex by virtue of its multiple phosphorylation sites that also act as docking sites, leading to recruitment of additional proteins to the plasma membrane. Transport to the signaling complex and activation of the cytosolic second messenger-producing enzymes PI3K and PLCγ2 is also facilitated by tyrosine phosphorylated LAT. PI3K leads to the generation of PI3,4P3 and PI3,4,5P3 (PIP3), and this, in turn, supports recruitment of proteins to the membrane signalosome complex with specific plekstrin homology (PH) domains including a member of the Tec kinase family, Btk.
along with PlCγ2. Syk is critical for collagen-mediated platelet activation through the gpVI/FcRγ-chain complex, and knockout mouse studies have shown that absence of this enzyme leads to loss of phosphorylation of LAT, the adapter SLP-76, and PlCγ2.

Adapters such as LAT are modular proteins without enzyme activity that support protein-protein interaction. Many adapter proteins appear to participate in the regulation of PlCγ2. These proteins appear to come together in T lymphocytes along with PlCγ1 to form a LAT/SLP-76 signalosome that is essential for activation of PlCγ2. SLP-76 is thought to be especially important among adapters in the regulation of PlCγ2, because its loss results in reduced phosphorylation of PlCγ2.

Along with the adapter proteins noted above, PI3K and its associated second messenger pathway also play a very important role in the regulation of PlCγ2 through activation of other signaling proteins such as protein kinase B (PKB) (also known as Akt). One of the two PKB isoforms, PKBβ (Akt2), is important for normal platelet function and thrombus formation and leads to impaired alpha and dense granule secretion along with impaired αIIbβ3 activation when absent. Integrin-linked kinase (ILK) is another PI3K downstream effector that interacts with β1 and β3 integrin subunit cytoplasmic tails and is considered important in the bidirectional signaling of αβ1 and αβ3. It may also be playing a role in regulating PKB. Using PI3K inhibitors such as wortmannin and LY294002, studies have demonstrated significantly reduced PlCγ2 activation through gpVI, and these inhibitors have also been shown to block platelet activation through the FcRIIA immunoreceptor, and this demonstrates an additional similarity between signaling pathways of this receptor and the FcR chain.

PlCγ2 is known to play a critical role in aggregation and secretion responses to collagen, as demonstrated in PlCγ2 knockout mice and in other studies. The major role of PlC isoforms is concerned with the generation of the second messengers inositol 1,4,5-trisphosphate and 1,2-diacylglycerol (DAG), which participate in intracellular calcium homeostasis and activation of many isoforms of PKC. The former process culminates in a robust calcium signal that promotes efficient platelet activation. The PKC isoforms make possible the regulatory serine/threonine phosphorylation events needed for activation of αβ1 as well as αIIbβ3, and interaction of these two integrins with their ligands facilitates a second round of signaling that includes some of the same molecules downstream of gpVI, such as Syk, SLP-76, and PlCγ2.

Recent research has led to increased knowledge about αβ1 receptor signaling. The use of αβ1-selective ligands has demonstrated calcium-dependent spreading and tyrosine phosphorylation of several proteins when interaction with platelets takes place, including Src, Syk, SLP-76, PlCγ2, p38 MAP kinase, ILK, Rac, and PAK. It appears likely that only GPVI and GPib/V/IX are able to bind collagen and vWF, respectively, without prior platelet activation. Once activation starts, αβ1 and αIIbβ3 are able to bind their respective ligands as well.

Other Platelet Adhesion Receptors

Other adhesive proteins present in the extracellular matrix and involved in the interaction between platelets and the subendothelium include fibronectin, thrombospondin, laminin, and vitronectin. Fibronectin is stored in platelet α granules and secreted upon thrombin-mediated platelet activation. Thrombospondin is also stored in platelet α granules. It interacts with fibroinogen, fibrin, fibronectin, and collagen on the platelet membrane and its release during platelet activation might relate to its capability to overcome the antithrombotic activity of physiologic nitric oxide (NO). Laminin is a large glycoprotein and can amplify platelet activation through GPVI binding. Recent data suggest that laminin may also interact with vWF and the GPib/V/IX complex thereby supporting platelet adhesion under high-shear flow conditions. The extracellular adhesive protein vitronectin can bind to platelet receptor αIIbβ3 or the integrin αβ3 and appears to be functionally similar to fibronectin.

Physiologic Inhibition of Platelet Adhesion

Negative regulation of platelets is essential to set the stimulus threshold for thrombus formation, determine final clot size and stability, and prevent uncontrolled thrombosis. The mechanisms behind the negative regulation of platelet activation are described later in the chapter, and in this respect, roles of players such as NO and prostacyclin have been well characterized. Platelet activation and aggregation can also be inhibited by signaling through the platelet endothelial cell adhesion molecule (PECAM)-1 (CD31). This molecule is expressed on a number of blood cells and endothelial cells and has a wide array of regulatory functions in processes such as apoptosis and cell activation. It becomes tyrosine phosphorylated following platelet stimulation by a diverse set of agonists, which suggests that it has a negative feedback role in this setting. Its main ligand is itself, so it has been proposed that interactions between platelet and endothelial PECAM-1 might serve to restrict thrombus growth through the signaling mechanisms below; this is supported by studies involving PECAM-1-knockout mice.
Following homophilic interactions and/or clustering, PECAM-1 is tyrosine phosphorylated in its cytoplasmic tail ITIM domain (immunoreceptor tyrosine-based inhibition motif) by Src family kinases, and this engenders recruitment of tyrosine, serine/threonine, or lipid phosphatases with resultant kinase-dependent signaling inhibition. The net result is reduced total platelet tyrosine phosphorylation, calcium mobilization, and signaling through PI3K. ITIM-mediated signaling inhibition through the ITAM domain is not the only mechanism by which PECAM-1 dampens platelet adhesion, because low-density lipoprotein and thrombin-dependent signaling pathways also appear to be downregulated by PECAM-1. Negative effects have also been documented with gpIb signaling and platelet FcγRIIA-mediated responses.

Von Willebrand factor multimer size and thus also vWF activity is mainly regulated by the metalloprotease ADAMTS13 and recently other factors have been found to cleave vWF including plasmin and leukocyte proteases. ADAMTS13 cleaves released large vWF multimers into smaller fragments. Different circumstances can induce vWF unfolding thereby exposing the ADAMTS13 cleavage site. These include high-shear flow conditions, denaturing agents such as urea, and mutations seen in von Willebrand disease type 2A. In contrast, reduced ADAMTS13 activity may lead to insufficient vWF processing causing a prothrombotic state such as thrombotic thrombocytopenic purpura (see Chapter 48).

Platelet Thrombin (Protease-activated) Receptors and Signaling

PARs are G-protein-coupled receptors that use a unique mechanism to convert an extracellular protein cleavage event into an intracellular activation signal. In this case, the ligand is already part of the receptor per se, by virtue of the fact that it is represented by the amino acid sequence SFLLRN (residues 42 through 47) and is unmasked as a new amino terminus after thrombin cleaves the peptide bond between Arg 41 and Ser 42. This “tethered ligand” then proceeds to dock irreversibly with the body of its own receptor to effect transmembrane signaling, as shown in Figure 17.3.

Thrombin signaling in platelets is mediated, at least in part, by four members of a family of G-protein-coupled PARs (PAR-1, -2, -3, and -4; see previous section for a discussion of the gpIb complex as a thrombin receptor). Human platelets express PAR-1 and PAR-4, and activation of either is sufficient to trigger platelet aggregation. Mouse platelets express PAR-3 and PAR-4. PAR-1, -3, and -4 can be activated by thrombin, whereas PAR-2 can be activated by trypsin, tryptase, and coagulation factors Vlla and Xa but not thrombin. Presumably, other proteases are capable of recognizing the active sites of these receptors and can thus also trigger PAR signaling.

PAR-1 is the prototype family member and was the first to be cloned and characterized in the human and hamster. A synthetic peptide that mimics the PAR-1-tethered ligand (SFLLRN) is capable of functioning as an agonist by activating the receptor independent of cleavage of the 41-residue N-terminal exodomain.

The mechanism by which G-protein-coupled receptors, such as PAR-1, signal through the G proteins is shown in Figure 17.4. PAR-1 is capable of coupling to members of the G12/13, Gq, and Gz families and thus is connected to a significant number of intracellular signaling pathways. The α subunits of G12 and G13 are believed to be involved in mediating rearrangement of the actin cytoskeleton and platelet shape change, and downstream signaling mediators include Rho family members, among others. The α subunit of Ga is needed for platelet secretion and aggregation and participates in activation of PLCβ that leads to calcium mobilization and PKC activation. The α subunit of Gz is a Gz family member that has been speculated to play an epinephrinelike role in human platelets through inhibition of adenylate cyclase.
FIGURE 17.3. Structure and features of PAR-1. Cleavage of PAR-1 by thrombin between arginine 41 and serine 42 exposes a new N terminus that serves as a tethered ligand. Activation of PAR-1 is followed by a rapid burst of signaling before the receptor is desensitized and, in some cases, cleared from the cell surface. From Brass LF. Thrombin and platelet activation. Chest 2003;124:185-255, with permission.

The β-γ subunit counterparts of G proteins involved in PAR-1 signaling are involved in a plethora of activities, including activation of protein kinases, channels, and lipid-modifying enzymes, such as PI3K, which provides attachment for multiple signaling protein complexes close to the inner leaflet of the cell membrane.\textsuperscript{147,148} and \textsuperscript{149} Thus, this vast network of signaling pathways mediated through several G-protein families is in keeping with the pleiotropic roles that thrombin has been shown to exhibit in cellular homeostasis, which extends beyond platelet activation to include endothelial cells, leukocytes, smooth muscle cells, and T lymphocytes, along with physiologic processes such as tissue injury, inflammation, angiogenesis, and embryonic development.\textsuperscript{45}

Once activated, PAR-1 is rapidly uncoupled from signaling and internalized into the cell.\textsuperscript{150,151} and \textsuperscript{152} It is then transported to lysosomes and degraded.\textsuperscript{151,153,154} and \textsuperscript{155} Platelets presumably have no need for a thrombin-receptor recycling
mechanism, because once activated, they are irreversibly incorporated into blood clots. Conversely, in cell lines with characteristics similar to megakaryocytes (MKs), new protein synthesis is needed for recovery of PAR-1 signaling and, in endothelial cells, sensitivity to thrombin is maintained by delivery of naive PAR-1 to the cell surface from a preformed intracellular pool.

Physiologic differences exist between PAR-1 and PAR-4 on human platelets. When antibodies to the thrombin interaction site of PAR-1 are used, platelet activation is blocked at low, as opposed to high, thrombin concentrations. Antibodies that blocked PAR-4 alone had no effect on thrombin-mediated platelet activation. If both receptors were blocked, platelet activation was blocked at both low and high thrombin concentrations and so PAR-1 appears to be most efficient at mediating platelet activation at low concentrations of thrombin, whereas PAR-4 functions in the absence of PAR-1 but only at high thrombin concentrations. Because PAR-1 is capable of mediating platelet activation at low thrombin concentrations, the exact role of PAR-4 in human platelet function remains speculative. It has been shown that the rate of platelet activation through PAR-4 is significantly slower and more sustained than that through PAR-1. Given the importance of this system with respect to normal hemostasis, PAR-4 may serve as a redundant backup receptor to PAR-1, or it may serve as an important receptor for one or more proteases other than thrombin.

Initial studies addressing the role of thrombin in promoting platelet thrombus formation employing ex vivo perfusion systems pointed toward its importance at low- to intermediate-shear rates (100 to 650 s⁻¹), but not at higher shear rates (>2,600 s⁻¹). Subsequent studies employing PAR3 and PAR4 knockout mice have also demonstrated defective thrombus formation under high-shear conditions in vivo, although suggesting the possible existence of shear-based functional differences between PARs.

Platelet ADP (Purinergic) Receptors and Signaling

Evidence that ADP plays an important role in both formation of the platelet plug and the pathogenesis of arterial thrombosis has been accumulating since its initial characterization in 1960 as a factor derived from red blood cells that influences platelet adhesion. ADP is present in high (molar) concentrations in platelet-dense granules and is released when platelet stimulation takes place with other agonists, such as collagen; thus, ADP serves to amplify further the biochemical and physiologic changes associated with platelet activation and aggregation. Inhibitors of this ADP-associated aggregation include commonly used clinical agents such as clopidogrel that have proven to be very effective antithrombotic drugs.

---

The text above discusses the role of thrombin in platelet activation, focusing on PAR-1 and PAR-4 and their interactions with thrombin. It also highlights the role of ADP in platelet aggregation and its inhibition through clinical agents like clopidogrel.
mobilization of calcium stores, and the P2Y₁₂ receptor is coupled to inhibition of adenylate cyclase and is essential for a full aggregation response to ADP with stabilization of the platelet plug. P2X₁ is a third ADP receptor present in platelets and has been shown to contribute to aggregation in response to collagen. Both the P2Y₁₂ and P2X₁ receptors have been shown to play key roles in platelet activation and aggregation under flow conditions characterized by high-shear stress.¹⁶⁶,¹⁶⁷

The P2Y₁ receptor was first cloned in 1993 from a chick brain complementary DNA library.¹⁶⁸,¹⁶⁹ Messenger RNA was later found in MK-like cell lines, such as HEL and K562, along with human platelets.¹⁷⁰ It was also established that the purported agonist effects of purified triphosphate nucleotides were, in fact, due to their transformation into diphosphate IX analogs by the ectonucleotidases present at the cell surface of the platelets and brain capillary endothelial cells being studied.¹⁷¹,¹⁷² The P2Y₁ receptor has 373 amino acid residues and the prototype structure of a G-protein-coupled receptor. It is distributed in various tissues such as heart, blood vessels, testis, and ovary.¹⁷³

After the characterization of P2Y₁, it became clear that a second platelet ADP receptor had to exist which was responsible for the inhibition of cAMP production by ADP that, in turn, was unaffected by blocking P2Y₁.¹⁷³,¹⁷⁴,¹⁷⁵,¹⁷⁶,¹⁷⁷ and ¹⁷⁸ The P2Y₁₂ receptor was cloned in 2001 from human and rat platelet complementary DNA libraries using Xenopus oocytes.¹⁷⁹ The receptor indeed showed the ability to display ADP-mediated inhibition of platelet cyclic AMP (cAMP) formation that was not blocked by P2Y₁ antagonists. The receptor has been localized to certain regions of the brain, such as the substantia nigra and thalamus, in addition to platelets.¹⁸⁰

Platelet P2Y₁ and P2Y₁₂ Receptor Roles in ADP-Mediated Activation

Even at high concentrations ADP is a weak activator of PIC. Thus its role in platelet activation is based more on its ability to activate other pathways. Inhibition of either of the P2Y₁ or P2Y₁₂ receptors is sufficient to block ADP-mediated platelet aggregation, and co-activation of both receptors is therefore necessary, through the G proteins G₃ and Gᵢ, respectively, for ADP to activate and aggregate the platelet (Fig. 17.5).¹⁸⁰ A series of studies involving the use of selective P2Y₁ and P2Y₁₂ receptor antagonists, a cAMP inhibitor, gene targeting, and G₁₅ and Gᵢ₅ protein agonists that would theoretically activate the two main G-protein pathways associated with ADP stimulation (see below) has led to the conclusion that a signaling event downstream from Gᵢ₅ is required for the conformational change and subsequent aggregation associated with the α₁β₃ receptor.¹⁷⁶,¹⁷⁸,¹⁸⁰,¹⁸¹,¹⁸²,¹⁸³,¹⁸⁴,¹⁸⁵ and ¹⁸⁶

Studies done with platelets from patients who manifest defective P2Y₁₂, along with experiments involving the study of P2Y₁ receptor function in platelet-rich plasma that has high fibrinogen concentrations, have demonstrated that the P2Y₁ receptor has roles in activation and aggregation in addition to shape change, and that it is fully capable of mounting an aggregation response which is nonetheless transient in nature.¹⁸⁷,¹⁸⁸ The P2Y₁ receptor is an absolute requirement for ADP-mediated aggregation based on knockout mouse studies, the demonstration that platelets can become refractory to ADP due to desensitization of the P2Y₁ receptor, and the observation that adrenaline (which activates the G protein Gᵢ₇ that mediates inhibition of adenylate cyclase) does not restore aggregation in the presence of P2Y₁ selective antagonists.¹⁸³,¹⁸⁴,¹⁸⁵,¹⁸⁶,¹⁸⁷ and ¹⁸⁸ Platelet shape change is dependent on two separate G signaling pathways, a G₁₅-linked release of calcium from internal stores, and a G₁₅/G₁₇ link to activation of Rho kinases and Rho guanine nucleotide exchange factors that activate small G proteins.¹⁸⁴,¹⁸⁵ The primary role of the P2Y₁₂ receptor in platelet activation and aggregation is to amplify and complete the aggregation response to ADP as well as to other agonists.¹⁸⁴,¹⁸⁵,¹⁸⁷ and ¹⁸⁸ In the presence of a high ADP concentration, the receptor is also capable of mediating partial platelet aggregation on its own in P2Y₁ and Gᵢ₅ knockout mice, thus proving that α₁β₃ conformational change followed by aggregation can actually take place in the absence of calcium mobilization and PKC activation.¹⁸⁴,¹⁸⁵ In general terms, it appears that P2Y₁₂ is responsible for acting as an ADP co-stimulus receptor in the presence of low concentrations of other agonists, such as collagen, thrombin, chemokines, or IgG, whereas the P2Y₁ receptor has a specific role early in platelet activation.¹⁸⁹,¹⁹¹ and ¹⁹² Another role for the P2Y₁₂ receptor is the potentiation of platelet secretion.¹⁹³ Because of its central role in the formation and stabilization of thrombi, the P2Y₁₂ receptor is a well-established target of antithrombotic drugs such as clopidogrel.¹⁹⁴,¹⁹⁵

Platelets from P2Y₁₂-deficient mice aggregate poorly or not at all in response to ADP display a shift in the dose-response curves for collagen and thrombin and lack ADP-induced repression of cAMP levels.¹⁹⁶ The bleeding time of homozygous knockouts was markedly prolonged compared with near-normal results in heterozygotes.¹⁹⁷

FIGURE 17.5. Current view of the interplay between the platelet P2 receptors. Two G-protein-coupled receptors are involved in adenosine diphosphate (ADP)-induced platelet aggregation, P2Y1 and P2Y12. The former is responsible for intracellular calcium mobilization, shape change, and transient aggregation, whereas the latter is coupled to adenylate cyclase (AC) inhibition and is responsible for amplification of platelet aggregation and potentiation of platelet secretion. Both receptors are required for normal platelet response to ADP. A P2X receptor is also present on platelets and is responsible for rapid calcium influx. It therefore synergizes with the P2Y1 receptor. Both the P2Y12 and P2X1 receptors have been shown to play key roles in platelet activation and aggregation under high-shear stress conditions. ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; MLC, myosin light chain; P, phosphorylated; PLC, phospholipase C; Y, phosphotyrosine. Modified from Gachet C. ADP receptors of platelets and their inhibition. Thromb Haemost 2001;86:227, with permission.

P2X1 Receptor

P2X1 was first discovered in platelets using polymerase chain reaction of transcripts from platelets and MK-like cell lines.199,200,201 and 202 This third platelet P2 receptor is an ATP-gated ion channel (as are all other P2X receptors thus far discovered) and is known to mediate rapid and selective permeability to cations. On platelets, the P2X1 receptor has been shown to mediate fast calcium entry stimulated by ADP.203 P2X1 is a 399-amino acid protein composed of two transmembrane domains, intracellular N and C termini, and an extracellular loop with 10 conserved cysteine residues.165 At least three P2X subunits are required to constitute a membrane pore, and these receptors are typically expressed on excitable cells, such as neurons.

Despite the fact that activation of the P2X1 receptor alone cannot induce platelet aggregation, it contributes to aggregation in response to collagen.204,205 The role of P2X1 in platelet function seems to be particularly relevant under flow conditions characterized by high-shear stress.205,206 and 207 A study of P2X1-deficient (P2X1−/−) mice has further indicated that this receptor contributes to the thrombosis of small arteries. P2X1−/− mice display resistance to the localized arterial thrombosis of mesenteric arterioles triggered by laser-induced vessel wall injury and to the acute systemic thromboembolism induced by infusion of a mixture of collagen and adrenaline.205 Conversely, increased systemic thrombosis has been reported in mice overexpressing the human P2X1 receptor.208

ADP Receptor Signaling

ADP is considered a weak agonist compared with collagen or thrombin, for example. Aggregation is typically reversible when platelets are stimulated by ADP alone. In addition, low concentrations of ADP serve to amplify the effects of both strong and weaker agonists, the latter including serotonin and adrenaline, among others.136,137 As noted in the preceding paragraphs, ADP signal transduction downstream from the P2Y1 receptor leads to a transient rise in free cytoplasmic calcium as a result of mobilization from internal stores, and this is followed by secondary-store-mediated influx, whereas a
concomitant inhibition of adenylate cyclase is initiated by ADP stimulation of the P2Y<sub>12</sub> receptor (Fig. 17.5). The G-protein family member responsible for signaling through P2Y<sub>12</sub> to PI(3)C is G<sub>i</sub>, whereas the member responsible for signaling through P2Y<sub>12</sub> to inhibit adenylate cyclase is G<sub>i</sub>. The G<sub>i</sub> family member associated with P2Y<sub>12</sub> appears to be primarily G<sub>i3</sub>, inasmuch as G<sub>i3</sub> knockout mice have an impaired response to ADP and those lacking G<sub>i3</sub> and G<sub>i14</sub> do not. ADP also induces a rapid influx of calcium from the external media through ligand-gated calcium channels.<sup>212,213</sup> Although partial platelet aggregation without shape change can be seen in P2Y<sub>12</sub> and G<sub>i3</sub> knockout mice in the presence of high ADP concentrations, the fact that aggregation is not seen at lower concentrations suggests that the G<sub>i</sub>-dependent PI(3)C pathway leading to phosphoinositide hydrolysis and PKC activation is necessary to mobilize calcium after ADP stimulation and is essential for full platelet aggregation to take place in response to ADP.<sup>144,184,214,215</sup>

Although ADP-mediated platelet activation via the P2Y<sub>12</sub> receptor incorporates the G<sub>i</sub>-dependent PI(3)-β second messenger pathway, the P2Y<sub>12</sub> receptor mediates its post-occupancy signaling through G<sub>i</sub>-dependent PI(3) kinase activation and subsequent repression of cAMP levels. In addition to the PI3K role, several groups have reported a role for Rap1B in P2Y<sub>12</sub> signal transduction. Rap1B is a small GTPase that is highly expressed in platelets, and its ADP-stimulated increased activation is abolished by P2Y<sub>12</sub> antagonists and G<sub>i3</sub> knockout mice.<sup>216,217</sup> and Rap1B activation through other receptors such as FcγRIIA and gpVI also appears to have a P2Y<sub>12</sub> component.<sup>217,218</sup> Evidence suggests that ADP-induced Rap1B activation lies downstream of PI3K, because PI3K inhibitors have been shown to inhibit Rap1B activation, although evidence differs as to which isofrom is involved.<sup>216,218</sup>

The same G<sub>i</sub>-protein-associated signaling pathway used by platelet ADP receptors has been found to act in a synergistic fashion when it is triggered either through other platelet receptors, or through key downstream players triggered by other receptors, such as PICF<sub>γ</sub>.<sup>219,220</sup> It has been suggested that concomitant signaling through the G proteins and tyrosine kinases of other receptor pathways may potentially be seen as a general mechanism in which ADP contributes to efficient platelet activation and aggregation.<sup>191,221</sup> For example, ADP in platelets has been proposed to be an important co-factor of PI3 kinase activation that is stimulated through the PAR-1 thrombin receptor.<sup>222</sup> It is interesting that there is a difference in the ability of ADP to potentiate aggregation through the two platelet thrombin receptors (PAR-1 and PAR-4), in that PAR-1 is more dependent on secreted ADP acting through P2Y<sub>12</sub> than PAR-4.<sup>223,224</sup> Collagen-induced platelet aggregation is similarly facilitated by P2Y<sub>12</sub>.<sup>225,226</sup> ADP has been implicated as an important co-factor of platelet activation seen in the settings of experimental cross-linking of the FcγRIIA immunoreceptor and in patients with heparin-induced thrombocytopenia.<sup>225</sup> The latter is a disorder in which platelet activation and often serious thrombotic sequelae take place as a consequence of administration of the anticoagulant heparin or low-molecular-weight heparin. In susceptible patients, an autoantibody is generated by the immune system that is directed to a complex on the platelet membrane formed by the heparin molecule and platelet factor 4. The Fc portion of the autoantibody is then capable of activating the platelet through its interaction with the FcγRIIA receptor. Activation of PI3K has been shown to be a central player in these two settings.

P2Y<sub>12</sub> activation has been found to play an important role in activation of α<sub>ix</sub>β<sub>3</sub>. Using P2Y<sub>12</sub> knockout mice, Andre et al. noted that platelets activated with PAR-4 or ADP were defective in binding soluble fibrinogen relative to wild-type mice.<sup>201</sup> Similarly, in humans it has been observed that P2Y<sub>12</sub> antagonists such as clopidogrel inhibit P-selectin expression and platelet-leukocyte conjugate formation, whereas aspirin does not.<sup>229</sup> Platelet Activation by Soluble Agonists

α<sub>1</sub> Adrenergic Receptors and Epinephrine

Epinephrine is unique among platelet agonists because it is considered to be capable of stimulating secretion and aggregation, but not cytoskeletal reorganization responsible for shape change. Furthermore, generation of the key signaling enzyme PIC through epinephrine stimulation appears to be dependent on TxA<sub>2</sub> and can thus be blocked with aspirin.<sup>230</sup> It is interesting, however, that epinephrine stimulation in the presence of aspirin is still capable of leading to the conformational change in the α<sub>ix</sub>β<sub>3</sub> receptor that precedes fibrinogen binding and platelet aggregation.<sup>231,232</sup> Similarly, the thrombin inhibitor hirudin has been found to block epinephrine-associated aggregation of washed platelets in one study, suggesting that an element of thrombin co-stimulation of platelets may be necessary to enhance the effects of epinephrine.<sup>233</sup> In low doses epinephrine is thought to prime platelets for activation with other agonists and the resulting stimulation is stronger than with either agonist alone.
Platelet responses to epinephrine are mediated through α2-adrenergic receptors, and these responses have been found to vary among individuals, with some donors with otherwise normal platelets manifesting delayed or absent responses. Potentiation is typically attributed to cAMP formation inhibition.

**Arachidonic Acid, Thromboxane A₂, and Thromboxane Receptors**

After platelet stimulation by a number of agonists, arachidonic acid is generated directly by phospholipase A from its membrane phospholipid precursors (PC, PS, and PI) and indirectly by PIC generation of DAG followed by DAG lipase action. Most platelet agonists are believed to activate this pathway. Three known eicosanoid subsets of biochemical compounds are known to be derived from the formation of arachidonic acid: the prostanoids, leukotrienes, and epoxides. The prostanoids are formed by the cyclo-oxygenase pathway and include endoperoxides and thromboxanes along with prostaglandins. The leukotrienes are formed by the lipoxygenase pathway and the epoxides by the cytochrome P450 epoxygenase pathway. Although all three of these pathways are present in platelets, most arachidonic acid ends up being metabolized to TxA₂.

TxA₂ is produced in platelets from arachidonic acid through the generation of PGH₂ by the enzyme cyclo-oxygenase, which is irreversibly inhibited by aspirin through acetylation of a serine residue near its C terminus. PGH₂ is the parent compound for both biologically active prostaglandins, such as PGE₂ and PGI₂, and TxA₂. The former two compounds act to inhibit platelet activation by generating intracellular cAMP, whereas TxA₂ activates platelets. Although prostaglandin and thromboxane pathways can be present in the same cell, platelets primarily synthesize thromboxane, and endothelial cells mainly synthesize prostaglandins such as PGI₂, which acts as a local vasodilator and thus indirectly opposes platelet activation and vasoconstriction.

Like ADP and epinephrine, TxA₂ is also capable of activating nearby platelets after its release into plasma. It has a very short half-life of 30 seconds before its conversion to the inactive metabolite thromboxane B₂ prevents widespread platelet activation beyond the vicinity of thrombus formation. Both arachidonic acid and analogs of TxA₂ have been found to activate and aggregate platelets by mediating shape change and phosphorylation of signaling enzymes, such as PICβ, PKC, and so forth. Signaling events associated with stimulation of the TxA₂ receptor (TxR) farther downstream from PICβ and PKC include activation of p38 mitogen-activated protein kinase and the small heat-shock protein hsp27.

The TxR is a member of the seven-transmembrane G-proteincoupled receptor family and has been localized to the plasma membrane. The receptor is coupled to the α subunits of the G₉ and G₁₂/G₁₃ members of the G-protein family, and one isoform of the receptor has been cloned from placenta (TxRα) and the other from endothelium (TxRβ). Both are found in platelets, and platelet activation through the G₉ pathway has been found to activate PICβ and G₁₂/G₁₃ regulates myosin light-chain phosphorylation through activation of Rho kinase. In addition, the α receptor is associated with activation of adenylyl cyclase that leads to generation of cAMP, known to inhibit platelet activation, whereas the β receptor inhibits adenylyl cyclase activation after its stimulation. Because TxA₂ is a net agonist, the effects of PICβ activation must somehow outweigh those of adenylyl cyclase activation, or MK and platelet TxRβ receptor expression levels may outweigh those of TxRα receptor expression levels. TxR knockout mice have a prolonged bleeding time, do not aggregate in response to TxA₂ agonists, and show delayed aggregation with collagen.

**Coordination between Platelet Adhesion Events and Soluble Agonist Stimulation in Thrombus Growth**

The mechanism by which soluble agonists coordinate their actions with platelet adhesion-related processes is an important consideration in the context of the steps required to facilitate thrombus growth. The constraint imposed by blood flow on these prothrombotic processes represents the primary means by which platelet adhesion and activation are negatively regulated. These arterial high-shear forces have complex effects on platelet-vWF matrix interactions that are both pro- and antithrombotic in nature. Rapid blood flow also has complex and poorly characterized effects on the formation and clearance of soluble agonists such as TxA₂.

One model to explain these relationships incorporates intraand intercellular calcium signaling phenomena as a central unifying process. In this model the initial platelet/vessel wall interaction is characterized by contact between platelet gpⅠb and matrix vWF with subsequent early platelet αⅡbβ₃ conformational change, all leading to weak platelet activation. Co-stimulation of platelets by these adhesion events and soluble agonist receptors is then needed to potentiate and sustain activation signals initiated by the early gpⅠb/vWF/αⅡbβ₃ interactions, and this co-stimulation leads to deceleration and arrest of platelet movement as the nidus of the thrombus develops. Platelet intracellular calcium is proposed to be the primary second messenger mediating these events, based on evidence...
sustaining an inverse correlation between calcium flux and platelet translocation behavior under flow conditions. 251 Inter cellular calcium-related signaling between platelets is then thought to lead to ADP release at the site of contact between platelets, which in turn sustains these \( \alpha_{IIb}\beta_3 \)-derived calcium signals by a P2Y\(_{12} \)-linked signaling mechanism. 252

Physiologic Inhibition of Platelet Activation

One of the many remarkable features of platelets is their ability to remain in a physiologic resting state and resist becoming activated while navigating the heart, arterial, and venous circulations, and splenic microcirculation for an average of 10 days. Over this time, platelets can be expected to remain in a quiescent state while they encounter high-shear forces, what must be frequent collisions with other circulating cells as well as normal endothelium, and relatively profound turbulence associated with arterial branch points and diseased yet physically intact arteries and arterioles. Indeed, the pathologic consequences associated with widespread inappropriate platelet activation are life- and limb-threatening when associated with well-characterized clinical disorders such as thrombotic thrombocytopenic purpura and heparin-induced thrombocytopenia. The mechanisms responsible for maintaining the fine balance of keeping platelets in a resting state until they encounter a genuine need to undergo adhesion, activation, and aggregation at the site of vascular injury are almost as diverse as those responsible for mediating these physiologic phenomena.

Some general mechanisms involved in physiologic inhibition of platelet activation include phenomena such as (a) generation of negative-regulating molecules by the platelet (e.g., cAMP, endothelin (e.g., PGI\(_2\), NO, heparan sulfate), and at distant sites (e.g., antithrombin); (b) direct contact of circulating platelets with collagen prevented by a barrier of endothelial cells; (c) generation of an ecto-ADPase (CD39) by endothelial cells that will metabolize ADP secreted from activated platelets and thus is intended to limit further activation; (d) tendency for blood flow to wash away unbound thrombin from the site of platelet plug formation and hence limit the extent of clot formation; (e) brief half-life of certain key platelet activators such as TxA\(_2\); (f) ability to alter the conformation of a receptor such that it is then able to interact with a specific proaggregatory ligand, as happens with \( \alpha_{IIb}\beta_3 \) and plasma fibrinogen; and (g) the ability to inactivate switched-on receptors associated with activation through biochemical modification such as phosphorylation or their removal from the platelet surface.

Biochemical modification leads to receptor desensitization and occurs with G-protein-coupled receptors present on the surface of platelets, with the notable exception of PAR-1 because thrombin requires an intact N terminus to activate the receptor. 253 Desensitization of G-protein-coupled receptors is normally mediated through phosphorylation of serine and threonine residues associated with the cytoplasmic side of the receptor by G-protein-coupled receptor kinases. 254 The role of phosphorylation of these residues is to uncouple them from their G proteins and then lay the groundwork for internalization of the receptor through the binding of arrestin proteins. 255,256 Some of the physiologic and biochemical phenomena related to inhibition of platelet activation are described in the following.

Inhibitory Prostaglandins

PGE\(_2\) and PGI\(_2\), along with PGE\(_1\), are examples of prostaglandins generated through the arachidonic acid pathway that inhibit platelet activation and aggregation, which are processes mediated in part by other prostaglandins and thromboxanes derived from the same pathway. The inhibitors carry this out through G-protein-coupled receptors that regulate adenylate-cyclase-mediated generation of cAMP, which in turn activates PKA (or A kinases). PKA then goes on to inhibit other proteins that mediate platelet reactivity through phosphorylation.

The receptors of prostaglandins believed to increase cAMP levels in platelets such as PGI\(_2\) have been described as being coupled to the \( \alpha \) subunits of Gs. Conversely, most platelet agonists suppress cAMP formation by inhibiting adenylate cyclase via one or more of the Gi family members that are expressed in platelets. 257 In addition to these considerations, cAMP levels in platelets are also governed by the activity of phosphodiesterase, the enzyme responsible for cAMP metabolism. This enzyme activity is inhibited by drugs such as the weak antiplatelet agent dipyridamole, the bronchodilator theophylline, and sildenafil, used to treat erectile dysfunction in men.

Raising cAMP levels causes a number of specific changes in platelet function. These include limitation of phosphoinositide hydrolysis, which is believed to occur through blockade of the inositol 1,4,5-triphosphate receptor and inhibition of the resynthesis of the phosphatidylinositol 4,5-biphosphate precursor of DAG formation. There is also a smaller increase in the cytosolic free Ca\(^{2+} \) concentration in response to agonists and an accelerated uptake of Ca\(^{2+} \) into the dense tubular system. 258,259,260 and 261 The targets through which cAMP and PKA reduce platelet reactivity are incompletely understood. They include ABP (filamin), myosin light chain, VASP, and Rap1B. Another PKA substrate is the \( \beta \) subunit of the gpIIb complex, and this phosphorylation may in turn reduce platelet activation through its increased interaction with the 14-3-3\( \epsilon \) protein. 51,52 The 14-3-3 family of proteins exists as homodimers and modulates effector pathways in diverse cell types through interaction with key signaling enzymes. 48
Plektin and Protein Kinase C Inhibition

PKC is an important serine-threonine kinase with protean effector manifestations in platelet signaling. PKC is the receptor for the lipid second messenger DAG, and is a key enzyme in the signaling events that follow activation of receptors coupled to PIC. PKC isoforms phosphorylate multiple cellular proteins at serine and threonine residues. PKC is actually a family of structurally related molecules, and platelets contain at least the α, β, δ, ε, θ, and perhaps ξ and λ isoforms. Once activated, PKC appears to mediate individual roles that, in some respects, may be considered contradictory in nature. These include positive effects such as mediating secretion and aggregation, as well as negative effects that can be observed when platelets are incubated with phorbol esters before agonist stimulation. Under these circumstances, the agonist effector-mediated responses are reduced or do not occur, particularly if they are mediated by effectors downstream from phosphoinositide hydrolysis, and this phenomenon may represent a form of negative feedback and. This is speculated as possibly being due to a shorter duration of signaling for calcium release.

Several platelet proteins are known PKC substrates, and these include plektin (P47), myosin light chain (P20), ABP, and the α subunits of the G proteins G, G12, and G13. The precise role of plektin in platelets is unknown, although its first and last 100 residues are homologous with domains in molecules with roles in signal transduction. These so-called plektin homology domains are speculated to play roles in protein-protein interactions, and so phosphorylated plektin may have a role in the negative regulation of PKC. One study suggests that phosphorylated plektin may be accomplishing negative regulation of PKC through inhibiting phosphoinositide hydrolysis and the activity of the lipid kinase, PI3K. Reduced activity of PI3K leads to reduced phosphorylation of PI-4,5-P2 to PI-3,4,5-P3, a molecule that, in turn, is involved in the activation of the PKC isoforms.

Other Inhibitory Processes of Platelet Activation

The αIβ3 receptor on the surface of activated and resting platelets along with the fibrinogen that binds to stimulated platelets expressing the activated form of αIβ3 have been observed to undergo rapid internalization into MK and platelet α-granules. It has been speculated that this may represent a mechanism by which platelets not involved in clot formation may be able to return to a resting state. The in vivo evidence supporting this unique platelet-inhibitory process is included in a paper describing the transfusion of plasma into an afibrinogenemic patient followed by the demonstration that platelet fibrinogen could be restored faster than new platelets could be produced in the bone marrow.

NO is generated by endothelial cells and platelets from l-arginine in response to shear stress forces and other platelet agonists, such as thrombin and ADP. This molecule works to inhibit platelet activation through the cyclic guanosine monophosphate second messenger generated by guanylate cyclase activation. Endothelial NO synthase activity is enhanced during platelet activation, presumably as an additional means for limiting platelet aggregation.

Platelet Secretion

The extent of secretion of α-, dense-, and lysosomal-granule contents is dependent on the strength of the agonist, occurs in association with platelet activation, and is one of the many downstream consequences mediated by the activation and transport to the internal leaflet of the plasma membrane of PKC. Granule contents that are involved in enhancing activation and aggregation of both their own and other platelets in the vicinity include ADP, vWF, fibrinogen, and calcium ions. Platelets contain three types of granules: dense granules contain agonists that amplify platelet activation, α granules contain proteins that enhance adhesion, and lysosomal granules contain glycosidases and proteases with largely unknown function.

The strongest response a platelet can mount to agonist stimulation includes activation, secretion, and aggregation. The granule secretory (release) phase is most readily documented in vitro by the “secondary wave” that denotes a second surge of aggregation activity of a fixed number of platelets in response to release of proaggregatory granule contents. These platelets are exposed to an agonist under the controlled in vitro conditions associated with platelet aggregation studies in which clinical defects in primary hemostasis due to platelet perturbations are further characterized. The secondary wave is typically seen best when the agonist is a weaker one, such as epinephrine, or is a relatively lower concentration of another relatively weak agonist, ADP. These two agonists require both cyclo-oxygenase activity and a primary wave of aggregation to induce secretion at low calcium concentrations.
Although platelets are anucleate, they contain mRNA and are capable of synthesizing a restricted group of proteins mainly related to inflammation and apoptosis. In addition to this, vesicles are secreted from the membranes of stimulated platelets referred to as platelet microparticles that are enriched with specific membrane proteins which make them significantly procoagulant in settings such as heparin-induced thrombocytopenia, peripheral artery disease, and MI.

Several studies suggest that the mechanism by which platelet granules (vesicles) fuse with the cell membrane to release their granule contents involves soluble N-ethylmaleimide-sensitive factor attachment protein (SNAP) receptor (SNARE) complexes that are formed between vesicle-associated membrane proteins (VAMPs; v-SNAREs) and proteins in the target membranes (different members of the syntaxin, SNAP-25, and VAMP gene families; t-SNAREs) in a lock-and-key form of docking. Many lines of evidence show that these SNARE complexes are crucial for membrane trafficking and fusion events such as secretion and exocytosis. There is evidence that suggests the specific isoforms VAMP-3 and VAMP-8 form SNARE complexes with platelet syntaxin 4 and that these specific complexes mediate platelet secretion.

Simultaneous with the exocytosis of platelet granules, it is apparent that there is also inward (centripetal) movement of other intracellular contents, and this may play a role in transporting proaggregatory proteins away from the membrane surface and thus serve as another counterbalancing mechanism for limiting the extent of thrombus formation. Examples of this phenomenon include the internalization of fibrinogen from the surface of activated platelets, along with gpIIb-IIIa receptors from the surface of resting and activated platelets, as noted earlier.

PLATELET AGGREGATION: αIIbβ3 RECEPTOR AND ITS SIGNALING MECHANISMS

Platelet aggregation is a complex phenomenon that is the end result of a series of adhesion- and activation-related processes. The molecular mechanisms involved in platelet aggregation continue to be an area of very active research that also periodically reminds us that there is still much to be characterized about this important aspect of platelet function. Essential components of this process include an agonist, calcium, and the adhesive proteins, fibrinogen and vWF. Divalent cations, such as calcium and magnesium, are required for platelet aggregation in trace amounts, and these alter the specificity of the integrin αIIbβ3 for its ligands. Fibrinogen and vWF play dominant roles in platelet aggregation through binding to αIIbβ3 and also by the ability of the former to generate polymerized fibrin as support for the platelets in a thrombus. The multivalent nature of fibrinogen and vWF allows them to cross-link platelets on binding to αIIbβ3 on stimulated platelets to initiate platelet aggregation.

The molecular basis of integrin signaling that occurs in platelet αIIbβ3 is an integral part of thrombus formation and is important in understanding this process. gpllb (αIIb) and gpIIa (β3) were identified as the abnormal proteins present in patients with Glanzmann thrombopethenia in the 1970s. They represent the most abundant receptor on the platelet surface. Like all integrin receptors, this complex is composed of noncovalently linked subunits. Each subunit is encoded by separate genes on the long arm of chromosome 17. Both subunits consist of a large extracellular domain and very short cytoplasmic domains, and together they form a heterodimer. Within their combined extracellular domains is the ligand-binding pocket, with surrounding subunit domains conferring specificity. Equally important are the short cytoplasmic domains critical for transmembrane signaling. These domains act to anchor the receptor to the cytoskeletal elements.

The signaling pathways of gpllbαIIbβ3 are complex and have been extensively studied. Despite this, the terminal effector molecules affecting activation remain unknown. Central concepts of the signaling pathway include inside-out signaling, which involves the processes termed affinity and avidity modulation, and outside-in signaling in which messages are transmitted to the inside of the platelet via the events occurring outside the membrane through αIIbβ3 activation. Regarding the former, a major knowledge gap exists with respect to how second messengers effect functional changes in αIIbβ3. As examples, PKC, PI3-kinase, and Rap 1b have been implicated as intermediates in inside-out signaling, but identity of the effector molecules remains to be determined. Current knowledge regarding these complex pathways has been recently reviewed and is summarized in Figures 17.6 and 17.7.
Integrin activation is bidirectional and reciprocal. The $\alpha_{IIb}\beta_3$ complex equilibrates between resting and activated states, the resting state predominating in unstimulated platelets and the activated state in stimulated platelets. Conversion from resting to activated does not imply a single abrupt change but rather a series of coordinated and linked conformational transitions. A: Inside-out signaling. Agonist-dependent intracellular signals stimulate the interaction of key regulatory ligands (such as talin) with integrin cytoplasmic tails (in this case the $\beta_3$ tail). This leads to conformational changes in the extracellular domain that result in increased affinity for adhesive ligands such as fibrinogen, von Willebrand factor (vWF), and fibronectin. Plasma fibrinogen and vWF support platelet aggregation at low and high shear rates, respectively, by bridging $\alpha_{IIb}\beta_3$ receptors on adjacent platelets. Studies in mice deficient in fibrinogen and vWF indicate that plasma fibronectin can also promote thrombus initiation, growth, and stability at high shear rates. B: Outside-in signaling. Extracellular ligand binding, initially reversible, becomes progressively irreversible and promotes integrin clustering and further conformational changes that are transmitted to the cytoplasmic tails. This results in the recruitment and/or activation of enzymes, adaptors, and effectors to form integrin-based signaling complexes. From Shattil SJ, Newman PJ. Integrins: dynamic scaffolds for adhesion and signaling in platelets. Blood 2004;104:1606-1615, with permission.
Normally, undisturbed endothelium possesses nonthrombogenic properties that can inactivate activated coagulation factors, increase blood flow, inhibit platelet aggregation, and modulate fibrinolysis. Substances that inhibit platelet activation released by the endothelium include PGI₂, NO, and ADPase. In addition, platelets release PGE₂ that acts to prevent its own activation. These molecules act via the Gs protein pathway that stimulates protein kinases to modulate various enzymes involved in platelet receptor αIIbβ₃ activation (see later). They may also act to phosphorylate and inactivate various protein receptor agonists.

Primary platelet agonists such as ADP, thrombin, and matrix proteins collagen and vWF affect platelet aggregation through a process known as inside-out signaling. This term denotes an integrin property that involves the binding action of agonists and extracellular matrix ligands to their receptors, leading to activation of numerous platelet functions, including the conformational change of αIIbβ₃ to a high-affinity state, referred to as affinity modulation. The relative contribution of
soluble and extracellular matrix stimuli to inside-out signaling likely varies with flow conditions and other factors related to vascular perturbation. For example, gpib/VIIX function is most relevant under high-shear stress conditions such as those associated with arterioles and capillaries and in stenotic arteries. Ligand binding is initially reversible and later becomes irreversible in nature.\textsuperscript{295} Therefore, one of the effects of inside-out signaling on α\textsubscript{IIb}β\textsubscript{3} is exposure of the fibrinogen-binding site through signal transduction involving the cytoplasmic domains (Fig. 17.6).\textsuperscript{293,296} Various regulatory intracellular or transmembrane proteins participate

P.423

in this process. Overall, the data provide strong evidence that association between subunit cytoplasmic tails and possibly also between integrin subunit transmembrane domains works to maintain the α\textsubscript{IIb}β\textsubscript{3} complex in a resting nonadhesive conformation, and disruption of this state causes separation of the tails with consequent changes in the extracellular domains to increase α\textsubscript{IIb}β\textsubscript{3} affinity.\textsuperscript{297,298} Evidence currently suggests that any role for extracellular or transmembrane molecules in affinity modulation is secondary to α\textsubscript{IIb}β\textsubscript{3} regulation by intracellular proteins, in particular a 270-kDa dimer named talin that interacts with the integrin cytoplasmic tails.\textsuperscript{199} The complexity of the mechanisms by which inside-out signaling trigger α\textsubscript{IIb}β\textsubscript{3} activation is significant.\textsuperscript{200,201}

Talin is a large protein that has been implicated as a trigger of integrin activation and binds to two sites in the β\textsubscript{3} cytoplasmic tail: the NPLY sequence in the midsegment of the cytoplasmic tail and a sequence in the membrane proximal region.\textsuperscript{302} Its binding to the latter region may follow the former and may trigger separation of β\textsubscript{3} from the α\textsubscript{IIb} cytoplasmic tail resulting in activation. Other proteins bind to the NPLY sequence and whether these function as coactivators or suppressors remains to be determined (Chapter 115, ref 303,304). Talin must also be activated to accomplish this and multiple activation pathways have been described.

Avidity modulation, the less dominant action, acts to cluster the α\textsubscript{IIb}β\textsubscript{3} heterodimers into oligomers through lateral diffusion.\textsuperscript{305,306} These conversions are critical in allowing α\textsubscript{IIb}β\textsubscript{3} to engage soluble adhesive ligands. These ligands contain the classical integrin-recognition sequence RGD, Arg-Gly-Asp, which acts as a bridge between adjacent platelets allowing aggregation to proceed.\textsuperscript{307} In addition, more α\textsubscript{IIb}β\textsubscript{3} translocates to the platelet surface membrane from the degranulating α-granule pool, where additional receptor is stored. These changes facilitate irreversible binding to fibrinogen. An important role for tyrosine kinase- and phosphatase-associated phosphorylation-dephosphorylation in integrin activation exists as assessed by the blockade of fibrinogen binding and platelet aggregation by enzyme inhibitors.\textsuperscript{308,309}

After ligand binding occurs, a multitude of intracellular signals are generated that are collectively referred to as outside-in signaling. This “contact-dependent signaling” determines the extent to which platelets will spread on a vascular matrix and how resistant to detachment they are.\textsuperscript{310,311} Outside-in signaling occurs in a discrete pattern in which ligand binding initiates integrin clustering and assembly of a “nascent” signaling complex proximal to the α\textsubscript{IIb}β\textsubscript{3} cytoplasmic tails, and this is followed by the growth of a larger “actin-based” signaling complex. It can be envisioned that the nascent complex is characterized temporally by (a) activation of Src kinases bound to the β\textsubscript{3} cytoplasmic tail by fibrinogen engaging and facilitating integrin clustering, then (b) recruitment and activation of Syk by Src, then (c) Src and/or Syk phosphorylation of various substrates including adaptor proteins SLP-76 and c-Cbl along with the Rac GTPase Vav, and these substrates in turn act by participating in signaling to the actin cytoskeleton.\textsuperscript{292} As the nascent complex assembles, many additional proteins are recruited that can influence actin reorganization, including Rac, the adaptor Nck, PAK, PI3-kinase, and VASP, an actin-bundling protein.\textsuperscript{292} All these signaling events during platelet aggregation are further supported by release of granules induced by the binding of adhesive proteins to the extracellular domain of β\textsubscript{3}. This complex series of events serves as a determinant of the final clot size.

Activation of α\textsubscript{IIb}β\textsubscript{3} by agonists is very rapid and the platelet can become fully competent to bind fibrinogen/vWF via the receptor within seconds after its initial encounter with agonist. Once full spreading and aggregation of platelets occurs, usually within several minutes, focal adhesion kinase is phosphorylated.\textsuperscript{311,313} and \textsuperscript{314} The PI3K system is activated once α\textsubscript{IIb}β\textsubscript{3} is engaged, leading to generation of D3 phosphoinositides.\textsuperscript{315} These proteins act to prevent the depolymerization of the actin cytoskeleton, with the result that the platelet aggregate is stabilized.\textsuperscript{316} The end result of this outside-in signaling is a stable platelet clot.

In addition to outside-in signaling, following binding of fibrinogen to α\textsubscript{IIb}β\textsubscript{3} one or more of a number of other events can be postulated to occur that facilitate platelet aggregation. These include the formation of a dimeric fibrinogen bridge between α\textsubscript{IIb}β\textsubscript{3} receptors on adjacent platelets, conformational changes in bound fibrinogen and/or occupied α\textsubscript{IIb}β\textsubscript{3}, and additional interactions of bound receptor with cytoskeletal elements.\textsuperscript{317,318,319} and \textsuperscript{320}
Although fibrinogen is the dominant ligand, other RGD-containing peptides also bind to α₃β₃ including vWF, collagen, fibronectin, and vitronectin. Because vWF binds to GPIb/VI/IX it is close to α₃β₃ which may facilitate their interaction. Thus α₃β₃ may also play a role in platelet adhesion particularly in stabilizing cell-matrix interactions.²²¹ Other platelet membrane proteins have also been shown to associate with α₃β₃ including CD9 and Gas6²²² and these may play a role in modulating α₃β₃ function.

Not only does the α₃β₃ receptor have important roles with respect to platelet function, it affects coagulation and the inflammatory process as well. It acts to promote the formation of the prothrombinase complex³³²³³³³³³³ and mediates the adhesion of leukocytes to the platelet membrane and endothelium (i.e., vascular inflammation).³²⁴³²⁵³²⁶ and³²⁷ This receptor may also have a role in cell proliferation. In this respect, antagonists to α₃β₃ or to both α₃β₃ and α₂β₁ significantly inhibited intimal hyperplasia after vascular injury in all but 1 of at least 12 animal studies.³²⁸

Platelet Aggregation and Arterial Shear Flow

Until relatively recently platelet aggregation was considered to be comparatively straightforward involving just α₃β₃ interacting with fibrinogen as described in the preceding paragraphs. With the recent ability to analyze in vivo platelet aggregate formation in realtime, though, it has become apparent that this process is much more complex than previously thought. Platelet aggregation now appears to represent a series of adhesion reactions involving multiple receptors and adhesive ligands such as vWF, fibrinogen, and fibronectin with the contribution of individual receptor-ligand interactions dependent on prevailing blood flow conditions. It has been postulated that at least three distinct mechanisms can initiate aggregation with each mechanism working over a specific arterial shear range in vivo.³²⁹ Under low-shear conditions (<1,000 s⁻¹) the predominant mechanism is thought to involve fibrinogen and α₃β₃ exclusively and this occurs independent of GPIb/vWF interaction.³³⁰ Subsequent stimulation by locally generated soluble agonists induces platelet shape change and an increase in α₃β₃ affinity for fibrinogen. At shear rates between 1,000 and 10,000 s⁻¹ platelet-platelet interactions become more vWF dependent with roles for both GPIb and α₃β₃ in promoting platelet aggregates. Now a third mechanism initiating platelet aggregation has been identified that occurs when shear rates are very high (>10,000 s⁻¹) and it is interesting that this mechanism does not require platelet activation or the adhesive function of α₃β₃ and is mediated by GPIb/vWF bonds.³²⁶³³¹ This finding that nonactivated platelets can form large aggregates under very high shear may have important implications behind the mechanism of pathologic thrombus formation in stenosed arteries.

Integrin α₃β₃ Antagonists

Antithrombotic agents that act against the α₃β₃ receptor are extensive and represent a targeted therapy against the most prevalent platelet surface receptor. They have had a significant impact on clinical outcomes of patients with acute coronary syndromes (ACSs) and those requiring percutaneous coronary interventions (PCIs).

Although many anti-α₃β₃ agents have been developed, only a small number are currently approved for clinical use. Examples

P.424

of approved parenteral agents with various mechanisms of action include the chimeric monoclonal antibody abciximab, the synthetic peptide eptifibatide, and the synthetic nonpeptide tirofiban.

Coller reported on the first mouse monoclonal antibody directed against the α₃β₃ receptor,³³² and abciximab was subsequently developed. Abciximab is thought to block access of large molecules to the receptor by steric hindrance and/or conformational effects rather than interacting directly with the arginine-glycine-aspartic acid-binding site of gpIIb/IIIa.³⁸⁵ Within minutes of receiving the standard bolus dose, ~90% of α₃β₃ receptors are bound.³³³ Abciximab then slowly dissociates for up to 4 hours, and platelet function can be abnormal for up to 7 days after infusion.³³⁴

Eptifibatide is a synthetic cyclic heptapeptide based on an RGD sequence that blocks all RGD-recognizing integrin receptors. It binds to the ligand-binding pocket of the α₃β₃ receptor such that it blocks its interaction with fibrinogen and vWF. It has a very rapid onset of action and a low affinity, leading to quick dissociation. It is approved for use in both the PCI and ACS settings.

Tirofiban is a synthetic nonpeptide tyrosine derivative that mimics the RGD recognition sequence.³³⁴ This agent also acts by blocking the ligand-binding region of the α₃β₃ receptor such that it competitively inhibits platelet aggregation. Within minutes, it inhibits platelet aggregation, and it dissociates from the receptor within seconds. It is approved for use in ACS.

Numerous trials have been conducted to evaluate the efficacy of parenteral α₃β₃ antagonists (Fig. 17.8).²⁸⁵³³⁶ These trials evaluated the drugs in terms of 30-day post-intervention or event episodes of death or nonfatal MIs after PCI or ACS. With
>100,000 patients being evaluated in placebo-controlled trials, the absolute and relative risk reductions in PCI with the use of αIIbβ3 inhibitors were 2.9% and 34.0%, respectively. The benefit of the αIIbβ3 inhibitors among ACS patients is maximized in those undergoing PCI. This might relate to the relatively short time period between vessel injury and initiation of therapy. Correspondingly, the risk reductions provided by these agents in the medical management of ACS is more modest and the risk/benefit profile of currently available αIIbβ3 agents is substantially uncertain for patients with ACS who are not routinely scheduled for early revascularization. Among this particular population, benefit has been found to be highest in those with diabetes mellitus and/or elevated serum troponin levels reflecting microvascular obstruction and myocardial necrosis. Clopidogrel and anticoagulants have essentially curtailed the application of these agents in the non-PCI ACS setting.

After longer-term follow-up of 1 year, the evaluation of Ilb/Ilia platelet inhibitor for stenting (EPISTENT) trial demonstrated a significant reduction in mortality after the use of abciximab in PCI. This effect has not been demonstrated with the other mentioned agents, although significantly fewer studies have been performed with them to date. A meta-analysis of the trials performed using tirofiban and eptifibatide in ACS showed no significant difference in mortality with these agents, but did show that there was a significant reduction in endpoints of death/MI, as well as death/MI/revascularization at 48- to 96-hour, 30-day, and 6-month followup periods.

Disappointing clinical trial results have been seen with the oral αIIbβ3 inhibitors, and this even includes an increased allcause mortality rate. This could be explained by possible subtherapeutic drug levels leading to platelet activation and/or inflammation. Another explanation is that these agents may leave the receptor activated as they dissociate away.

**ROLE OF THE CYTOSKELETON IN PLATELET FUNCTION**

(See additional cytoskeleton structure information in Chapter 16 on platelet structure.)

Once an agonist has interacted with its platelet membrane receptor and triggered second messenger formation, a key event in platelet activation and subsequent aggregation is the transition of the platelet's shape from the discoid appearance associated with its circulating resting state to the amorphous amoebalike appearance with multiple pseudopodial projections that denote its activation state and readiness to participate in platelet plug formation. The platelet cytoskeleton and its associated signaling proteins are responsible for mediating shape change associated with activation, spreading, secretion, and aggregation. This cytoskeleton is associated with at least 14 different structural proteins that function interdependently as a single unit but can be seen as consisting of three major functional units: (a) a cytoplasmic network consisting mainly of actin, (b) a meshwork of proteins immediately proximal to the cytoplasmic leaflet of the platelet membrane referred to as the membrane skeleton (because it contains surface-associated proteins.
such as the gpIb complex), and (c) the platelet marginal band, which consists of a single peripheral microtubule coil that encircles the platelet to contribute to its resting discoid state.

Transmembrane receptors such as gpIb participate in anchoring the platelets to extracellular matrix in the arterial subendothelium through their extracellular domains, whereas their cytoplasmic domains are almost simultaneously associating with membrane skeletal proteins in response. In doing so, these surface receptors are providing sites at which tension can be generated by intracellular contractile elements that subsequently lead to shape change and activation of signaling proteins.

The cytoplasmic network consists of actin filaments and their associated proteins, referred to as intermediate filaments. In resting platelets, approximately half of actin is structurally filamentous in nature (with the rest present as globular monomeric G-actin), and this fraction increases to approximately three fourths during platelet activation. During this process, the actin filaments are reorganized into longer filaments after their initial breakdown into smaller units and this is thought to be regulated in part by an increase in phosphatidylinositol-4,5-bisphosphate (PIP$_2$) that accompanies platelet activation. Simultaneously, myosin is phosphorylated by myosin light-chain kinase and then associates with F-actin, with the resultant filament then attaching itself to the α subunit of the gpIb complex through ABP. These filaments are also anchored at sites called focal adhesions, where the tyrosine kinase Fak becomes activated after platelet stimulation. Focal adhesions assemble around the α$_2$β$_3$ integrin on its conformational change (activation) and so play a very important role in signaling pathways associated with platelet activation by drawing together membrane receptors, the cytoskeleton, and signaling phosphoproteins such as members of the Src family, PI3K, and Syk into close physical proximity. Other platelet integrin receptors, such as α$_2$β$_1$, also organize focal adhesions after binding to their respective extracellular ligands.

The membrane skeleton consists of actin, ABP, talin, vinculin, spectrin, cortactin, α-actinin, and several membrane glycoproteins, as noted in Chapter 16. ABP is a 250-kDa elongated dimer that associates with the cytoplasmic domain of the gpIbα chain and acts to link the receptor to actin in the early stages of platelet activation, as noted in the previous paragraph. After platelet activation, calpain, the calcium-dependent protease, is activated in aggregating and spreading platelets and cleaves the link between ABP and gpIb. Thus, ABP may be considered a prototype of sorts of membrane skeleton proteins that provides a good example of their important role in terms of interaction with second messengers and other signaling molecules that either may become activated or may act on their substrates after platelet stimulation.

The marginal microtubule band maintains platelet discoid shape and appears to be an essential intermediate in the microtubule-driven process of proplatelet formation and platelet release. This single microtubule polymer is wound in 8 to 12 coils in the cytoplasmic periphery and is located just beneath the plasma membrane. About 90% of β-tubulin in the marginal band is of the divergent, MK/platelet-restricted β$_3$ isoform. β$_1$-tubulin-null mice show reduced proplatelet formation, thrombocytopenia, and platelet spheroctytosis.

PLATELET-CELL INTERACTIONS

Platelets and Endothelium

The mechanisms behind platelet interaction with vWF, collagen, and other subendothelial matrix molecules exposed as a result of damaged endothelium have been well studied and described in earlier sections of this chapter. In addition to these platelet-subendothelial interaction paradigms, evidence has emerged that circulating unactivated platelets have the capacity (as do neutrophils) to roll on intact activated endothelium in vivo and then reversibly adhere to it in a process that is dependent on endothelial cell expression of P-selectin. This sequence of molecular interactions is a well-controlled multistep process involving platelet tethering and interaction of platelet P-selectin glycoprotein ligand-1 (PSGL-1) or gpIbα with endothelial P-selectin (“rolling”), followed by subsequent “firm adhesion” to the vascular wall mediated through β$_3$ integrins. gpIbα and PSGL-1 have structural similarities including similar ligand-binding domains. P-selectin is also expressed on the surface of activated platelets and is an α-granule component in resting platelets. Endothelial P-selectin is rapidly expressed on the surface in response to inflammatory stimuli by translocating from membranes of storage granules (Weibel-Palade bodies) to the plasma membrane within seconds.

As noted in an earlier section, there are multiple general mechanisms at play in inhibition of platelet activation that involve intact endothelium. It is increasingly recognized that inflammatory stimuli facilitate sustained platelet-endothelial interaction by perturbing these antiadhesion and activation mechanisms and increasing surface expression of endothelial molecules. Adhesion of platelets to inflamed endothelium involves a similar coordinated multistep process as occurs in
hemostasis and thrombosis, including platelet tethering, surface translocation, and firm adhesion. In atherosclerosis accumulation of modified oxidized lipoprotein particles in the setting of hyperlipidemia leads to surface expression of endothelial P- and E-selectin as well as endothelial vWF. Along with endothelial P-selectin, it is not surprising that vWF expressed on activated venous endothelium has also been implicated in platelet adhesion and translocation. The precise nature of the relationships between these two endothelial cell molecules and the platelet gpIb complex, and the role different shear forces may play in determining which ligand gpIb may preferentially associate with, remain to be determined. As noted in the section on “Platelet Aggregation and Arterial Shear Flow”, aggregation is currently considered to consist of a series of adhesion reactions involving multiple receptors and adhesive ligands such as vWF, fibrinogen, and fibronectin with the contribution of individual receptor-ligand interactions dependent on prevailing blood flow conditions. Studies using intravital microscopy have confirmed that platelet-endothelium adhesion takes place even under high-shear stress in vivo Platelets rolling on activated endothelium can be inhibited by both anti-P-selectin and anti-gpIbα antibodies, and this suggests that platelet gpIb/V/IX mediates platelet adhesion to both the subendothelial matrix and the intact endothelium. PSGL-1 on platelets has also been shown to mediate platelet rolling on the endothelial cell monolayer under high-shear stress. Platelet firm adhesion to intact endothelial cells following rolling is a process dependent on αIβ3, bridging to endothelium that involves endothelial receptors such as αIβ3 and intercellular adhesion molecule (ICAM)-1 interacting with platelet-bound fibrinogen, fibronectin, and vWF. This firm adhesion induces platelet surface P-selectin expression, and whether this selectin plays any role in their interaction with endothelium is unknown. The fact that P-selectin knockout mice have been observed to display impaired hemostasis suggests a potential role in this respect.

Platelets and White Blood Cells

In addition to the participation of the gpIb complex, selectins, and the β3 integrin in the interaction between platelets and intact endothelium described above, these proteins along with the β3 integrin receptor Mac-1 (αIβ2, or CD11b/CD18) participate in interactions between platelets and leukocytes. Platelets contribute to leukocyte rolling and extravasation, which are two well-characterized steps involved in the translocation of the latter cell from the circulation to sites of infection. Normally, after interaction of endothelial cell P-selectin with leukocyte receptors such as PSGL-1, β3 integrin activation on the leukocyte mediates increased adhesion to endothelium, followed by extravasation. Neutrophils are also capable of tethering and rolling on adherent and activated platelets through interactions between its P-selectin glycoprotein 1 and P-selectin expressed on the platelet surface, and they will subsequently display extravasation mediated by activation of Mac-1 and lymphocyte function-associated antigen 1 (αIβ2) which are required to mediate stable leukocyte adhesion.

The α subunits of certain integrins, such as Mac-1, have been found to contain “insert” (I) domains, homologous to the A1 domain of vWF. This observation has taken on added interest since it has been shown that Mac-1 is capable of binding to the gpIb complex and that this interaction required the I domain of Mac-1 and the leucine-rich repeat region of gpIbα. Mac-1 knockout mouse neutrophils were incapable of binding to isolated polypeptide fragments corresponding to the extracellular domain of gpIbα (called glycocalcin). For this reason and others, the role of Mac-1-gpIb complex interaction could turn out to be important with respect to initiating and propagating inflammation associated with the progression of atherosclerotic, purely thrombotic, or atherothrombotic processes. Mac-1 has also been found to associate with other receptors of the platelet membrane, including the junctional adhesion molecule-3, ICAM-2, fibrinogen bound to αIIbβ3, and high-molecular-weight kininogen bound to gpIbα. These associations have been characterized individually, however, their downstream signaling partners along with any coordinated actions that may exist between the ligand-receptor pairs in vivo remain to be determined. During this adhesive process, the association of platelet membrane PSGL-1 and Mac-1 stimulates the release of inflammatory cytokines from platelets, which in turn induces inflammatory cascades in monocytes. This integrin, selectin, and cytokine-based set of coordinated reactions linking neutrophils, platelets, and monocytes leads to circulating activated platelets and platelet-white cell aggregates that promote formation of atherosclerotic lesions.

Role of Platelets in Inflammation

The growing list of pathophysiologic processes in which platelets have a proposed role is a reflection of the many different cell types with which they interact. These include endothelial cells, neutrophils, monocytes, dendritic cells, cytotoxic T lymphocytes, malaria-infected red cells, and various tumor cells. In addition to the mechanisms behind interaction of platelets with activated endothelium and white cells described in the last section, platelet activation induces a local
release of alpha granule contents containing various potent inflammatory substances that further enhance the inflammatory response and alter chemotactic, adhesive, and proteolytic properties of endothelial cells. These include chemokines CXCL4 (PF-4), CXCL7 (PBP, β-TG, CTAP-III, and NAP-2), and CCL5 (RANTES), platelet-derived growth factor, IL-1β, CD40 ligand, TxA2, leukotriene B4, and platelet-activating factor.

The interaction between platelets, leukocytes, and the vascular wall can occur in various sequences. Inhibition of COX-1 leads to reduced arterial growth, followed by thrombus associated with plaque instability (Fig. 17.8).

ROLE OF PLATELETS IN ATHEROGENESIS AND ATHEROTHROMBOSIS

Atherosclerosis is the major cause of vascular occlusive disorders such as coronary artery disease, stroke, and peripheral arterial disease. Every year, more than 4 million patients are admitted to hospitals worldwide with ACS, more than 1.5 million of them in the United States. Peripheral arterial disease affects up to 12% of the general population and 20% of those older than age 70 years. The instability associated with atherosclerotic plaque progression enhances vulnerability to disruption or ulceration, and this is associated with secondary deep vessel wall injury and thrombus formation. Based on extensive laboratory and clinical experience, it is clear that platelet activation and aggregation play an integral role on two fronts: (a) in the cytokine-driven local inflammatory changes associated with plaque formation and growth, followed by (b) thrombus associated with plaque instability (Fig. 17.8).

Platelets in Atherogenesis

The importance of the role of both arterial wall and systemic inflammation in atherogenesis and its later clinical manifestations, along with the molecular interface between inflammation and thrombosis, have been the subject of much recent attention in the literature. An increased number of links between thrombosis and inflammatory mediators have been observed, and new roles for platelets in inflammation are becoming apparent. Many of the molecular players mediating leukocyte-endothelium interactions have also been found to play important roles coordinating leukocyte attachment and transmigration across layers of platelets adherent to injured vascular intima. In addition, the binding of platelets to leukocytes influences important whitecell effector responses, such as cell activation, signaling associated with integrin activation, chemokine synthesis, and so forth. Thus, it has become clear that inflammation is capable of leading to local thrombosis, and thrombosis is capable of initiating and propagating inflammation.

As noted in the section, “Platelets and Endothelium,” platelet adhesion to intact endothelium (as opposed to exposed subendothelium following vascular injury) has been well characterized using intravital microscopy and atherosclerosis animal models, and in some cases, adhesion has been shown to occur even before detectable atherosclerotic lesions are manifested. Animal models have recently provided strong evidence linking platelets to early events of atherogenesis. An atherosclerosis mouse model lacking α<sub>IIb</sub>β<sub>3</sub> exhibited substantial reduction in atherosclerotic lesion formation. The importance of P-selectin in atherosclerosis lesion formation has been well described. Platelet adhesion has been found to activate endothelial cell nuclear factor-κB (NF-κB) and its regulated genes, many of which play key roles in platelet-leukocyte-endothelium-extracellular matrix molecular events that support inflammatory and proatherogenic phenotypes. This includes events that contribute to lesion maturation such as smooth muscle cell and fibroblast proliferation and promotion of collagen synthesis, among others. Inhibition of COX-1, an enzyme with expression restricted to platelets, in turn inhibited lesion formation in an atherosclerosis mouse model. Another atherosclerosis mouse model demonstrated that prolonged antibody blockade of gpIbα leads to reduced arterial leukocyte accumulation in carotid arterial intima and subsequent reduced atherosclerosis lesion
formation. This suggests that vWF may also have a role in atherogenesis.

In contrast to animal data, conclusions regarding the role of human platelets in atherogenesis are not nearly as extensive. Mouse data cannot be unequivocally applied to humans, because mouse platelets differ from human with respect to expression levels of certain surface receptors. Systemic platelet activation in humans has been described in a variety of atherosclerosis disease presentations. However, antiplatelet agents have not been found to influence disease progression when applied in the secondary disease-prevention setting in humans in which atherosclerosis is likely advanced, as opposed to the possibly preventable progression of early lesions that are present before an initial atherosclerosis clinical event. With respect to the role of NF-kB noted in the preceding paragraph, one study of patients revealed a marked elevation of NF-kB in those with unstable as compared to stable angina.

Platelets in Atherothrombosis

The interior of intact atherosclerotic plaques is rich in components that are highly thrombogenic (e.g., collagen types I and III, fibrinogen/fibrin, thrombospondin), and the luminal surface is relatively nonthrombogenic. In contrast to these observations, the thrombotic response to plaque disruption is dynamic. In this respect, thrombosis, repeat thrombosis, and thrombolysis along with embolization all occur simultaneously in many patients with ACS, and this is considered responsible for intermittent flow obstructions. The initial flow obstruction is acknowledged as being due to platelet aggregation, but subsequent fibrin stabilization is important to the longevity of the early and fragile platelet thrombus. As a result of reduced flow caused by the platelet thrombus at the plaque rupture site, an erythrocyte- and fibrinrich thrombus may form and propagate up and down the artery in both directions.

Normally blood flow is laminar with adjacent fluid layers traveling parallel to each other but at different velocities due to fluid drag exerted by the vessel wall and this leads to shear forces between adjacent fluid planes. However, at arterial branch points, curvatures, and areas of stenosis these flow profiles develop alterations leading to shear gradients, turbulence, flow separation, and eddy formation and these will influence atherogenesis. Progression of the lesion exacerbates these flow disturbances and so a dangerous cycle of shear-dependent atherosclerosis acceleration can occur. The rate of fluctuation in blood flow has been quoted as the major parameter altering endothelial function and as such cell function responds to flow changes through a variety of mechanotransduction mechanisms. These mechanosensory signaling mechanisms are very sensitive to changes in wall shear stress leading to alterations in cell morphology, gene expression profiles, and increased adhesiveness. Thus at high shear rates as occurs in stenosed atherosclerotic arteries (>5,000 s⁻¹), shear will directly induce platelet activation and aggregation as noted in the section on “Platelet Aggregation and Arterial Shear Flow,” and recent evidence suggests this can occur independently of ADP and TxA₂, which implies shear gradients that can promote platelet deposition and initial thrombus growth even in the presence of aspirin and a P2Y₁₃ inhibitor.

There is evidence that alteration of the endothelium such as may occur with early atherogenesis (particularly when under the influence of atherosclerosis risk factors) or plaque disruption may cause the endothelium to generate more mediators that enhance constriction, such as endothelin-1, and fewer mediators that enhance dilation, such as PGI₂ and NO. Coronary angioplasty data collected at the time of ACS have shown that transient vasoconstriction often accompanies plaque disruption or fissuring, and thrombosis. This vasoconstriction occurs with significant vessel wall damage and is dependent on both platelets and thrombin, with platelet dependence shown to be mediated by serotonin and TxA₂. ACCNOWLEDGMENTS

Chapter 18 Blood Coagulation and Fibrinolysis

The opposing forces of fibrin clot formation and dissolution maintain hemostasis and preserve vascular function and integrity. Procoagulant events (platelet adhesion/activation, α-thrombin generation, and cross-linked fibrin clot formation) protect the vasculature from perforating injury and excessive blood loss in a process tightly regulated by plasma and cellular inhibition systems. Subsequent activation of the fibrinolytic system removes the clot, restores blood flow, and initiates tissue repair and regeneration. Hemostasis thus refers to multiple discrete processes that collectively culminate in preservation of vascular integrity. Circulating and adherent cells collaborate with plasma and cell membrane-associated proteins to carry out key roles in both pathways. Hemostasis is not a passive but a continuously active process in maintaining vascular integrity. With vascular perforation, focal interactions initiate procoagulant and fibrinolytic events and initiate tissue repair. Each process must operate in a cooperative fashion, or the entire system is compromised. Thus, balance between the procoagulant, anticoagulant, fibrinolytic, and antifibrinolytic processes is required to prevent extra-vascular blood loss, or undesirable intravascular thrombosis.¹

Much of our knowledge of hemostasis has been gleaned and validated from observations of hemostatic and thrombotic pathology; however, much is still not well understood. Epidemiologic studies have expanded our knowledge about key factors that determine risk for venous and arterial thrombosis; however, vascular thrombosis is still the primary cause of death in the United States and Western Europe.² Thus, although the present information base is formidable, investigators continue to examine the processes that contribute to blood coagulation and fibrinolysis. The current concepts governing the roles of protein and cellular components, their structures, functions, and regulations are summarized in the following sections.

ESSENTIAL FEATURES OF COAGULATION

MacFarlane³ and Davie and Ratnoff⁴ provided the first integrated descriptions of the coagulation system. They proposed a “cascade” or “waterfall” sequence of events in which the reactions occur in a defined series leading to prothrombin activation and fibrin clot formation. Each reaction shares a similar mechanism in which an inactive zymogen is converted to an active enzyme. Although some facets of these initial descriptions are still valid, the emerging concept of coagulation and fibrinolysis centers on a complex network of highly interwoven collections of simultaneously occurring processes. Procoagulant, anticoagulant, and fibrinolytic processes occur with many positive and negative feedback loops regulating the processes. These overlapped reactions can be operationally described as five distinct phases: initiation of coagulation, propagation of α-thrombin formation, termination of the procoagulant response, elimination of the fibrin clot, and tissue repair and regeneration. The reactions involved in these five phases share several key features and the nomenclature used to describe the protein components of the reactions is similar.

The proteolytic enzymes and their zymogen precursors are mostly members of the serine protease family that includes chymotrypsin and trypsin with the zymogen and enzyme forms distinguished by an “α” to signify the active enzyme. For example, factor Xα is the active enzyme and factor X is the corresponding zymogen. Factor II, most commonly referred to as prothrombin, is the zymogen that upon activation becomes factor αlla or α-thrombin. The non-zymogen procofactors factors V and VIII also share this nomenclature, in which the proteolytically activated fully functional cofactor forms are designated factors Va and VIIIa; conversely, the inactivated forms are designated with an “i” subscript (factor Vai). The
protein cofactors that are cell associated, tissue factor and thrombomodulin, primarily exist in one form and designation. The mechanisms of the individual procoagulant reactions are likewise similar. In each case, a complex consisting of a serine protease, a cofactor protein and Ca$^{2+}$ is assembled on a membrane surface. Each complex enzyme cleaves a zymogen to an enzyme. The progression from complex to complex results in amplification of product formation. In blood, the membrane surface is provided by platelets and by other circulating cells and microparticles. The vessel wall also contributes cofactors and membrane to support complex formation. The common features of these membrane-cofactor-protease complexes include target recognition, reaction amplification, regulation, and localization. The response to injury is rapid and ordinarily modulated to ensure a sufficient but not excessive response to the injury.

The initiation of the antihemorrhagic response occurs when the vascular wall is perforated and the antithrombotic nature of the vessel wall is overcome to achieve a prothrombotic state. Membrane surface and subcellular elements, including tissue factor, are presented and initiate the subsequent phases of coagulation. The assembly of the multicomponent procoagulant complexes on membrane surfaces triggers propagation of the coagulation response. The net result of the activities of these complexes (the intrinsic and extrinsic tenase and prothrombinase complexes) is an explosive local expression of α-thrombin. The initial burst of α-thrombin sustains the procoagulant response by activating circulating platelets, the procofactors V and VIII, and the zymogen factors VII and XI, and Thrombin cleaves the fibrinopeptides from fibrinogen and activates factor XIII (to factor XIIIa), a protransglutaminase that, when activated, cross-links (to fibrin) and stabilizes the fibrin clot. Tight regulation by antithrombin (AT), tissue factor pathway inhibitor (TFPI), and the dynamic protein C system (thrombin-thrombomodulin) ensures that the response is appropriate to the stimulating injury. The thrombin-activatable fibrinolysis inhibitor (TAFI), a procarboxypeptidase zymogen, thrombin-activated as TAFIa, protects the fibrin clot by downregulating the fibrinolytic system. The propagation phase thus stems blood loss by producing a platelet-rich cross-linked fibrin clot. Ultimately, inhibition of the procoagulant enzyme complexes by direct inhibition of the serine proteases and proteolytic inactivation of the cofactor proteins restores homeostasis by limiting coagulation to the site of vascular damage and preventing excessive clot formation.

The plasma proenzyme plasminogen is activated to plasmin by proteases associated with the vascular endothelial cells. Plasmin cleaves the cross-linked fibrin matrix to produce soluble peptides including D-dimer. The mechanism by which plasmin is generated is complex and involves several proteins with key roles throughout the hemostatic response. The solubilization and removal of the fibrin scaffolding of the hemostatic plug is coordinated with the processes of tissue repair and regeneration in part triggered by products of the processes. The extracellular matrix is degraded to allow for cell migration into the damaged area. Vascular cells repopulate the site and recreate the elements necessary to restore the vessel to its (relatively) previously unperurbed state.

These steps occur rapidly and in a precise choreographed manner and must be localized to the site of injury. Localization presents challenges because the hemostatic response occurs under conditions of highly variable flow in vascular tubes of various diameters. Localization is controlled on several levels. Endothelial cells actively inhibit coagulation by constitutively synthesizing various anticoagulants and platelet activation inhibitors. Furthermore, the surfaces of inactivated, undamaged blood and vascular cells are not conducive to the assembly and function of the procoagulant protein complexes. Thus, surface availability for procoagulant complex assembly is ordinarily limited by vascular pathology. The activated cell/damaged membrane surfaces may also provide for rapid transfer of intermediate products between complexes; such two-dimensional transfer of intermediates between complexes would increase the rates of complex formation and provide protection from the abundant plasma inhibitors. The essential features of the hemostatic response (recognition, amplification, regulation and localization) ensure that the response is localized to the injury, amplified appropriately according to the severity of the injury, and attenuated to block a systemic reaction.

In contrast to hemostasis, thrombosis is invoked by the presentation of intravascular tissue factor either by damaged endothelium or by an inflammatory cell. The resulting coagulation process is invoked, but in this instance results in the pathology of thrombosis. Vascular thrombotic occlusions composed of platelets and fibrin are significantly influenced by vascular architecture, vascular cell biology, and flow biophysics. In arterial thrombosis, high shear rates make platelet-rich clots (white clots) more apparent, while in the low shear venous circulation, fibrin-rich clots (red clots) are observed. However, it is likely that in both vascular environments, events similar to those associated with the hemostatic process occur.

OVERVIEW OF PROCOAGULANT PATHWAYS: PRIMARY (EXTRINSIC) AND ACCESSORY (INTRINSIC) PATHWAYS
Two procoagulant pathways have been identified which converge at the “intrinsic” fXase (fXa•fVIIa) complex (Fig. 18.1). The contact or “intrinsic” pathway is activated by the interaction of blood with a foreign surface. This pathway is activated by the factor XIIa-high-molecular-weight kininogen (HMWK)-prekallikrein complex in association with foreign surfaces including glass, dextran sulfate, or kaolin. The complex catalyst activates factor XI leading to the factor Xa-HMWK complex which activates fIX to fXa. The “intrinsic” fXase rapidly cleaves fX to fXa.

Factor Xa is directly but less effectively produced by the “extrinsic” fXase, which is composed of plasma-derived fVIIa and tissue factor and expressed when the latter is exposed to blood. The “extrinsic” fXase also activates fIX to fIXa as the reaction progresses. The “extrinsic” fXase also activates fIX to fXa as the reaction progresses, with suppression of the quaternary complex occurring by TFPI. The “intrinsic” fXase complex is kinetically superior and ultimately produces the majority of fXa.

Since bleeding pathology is not ordinarily associated with defects of the initiation protein complexes of the contact pathway, most investigations conclude that the “extrinsic” pathway is not the primary provider for hemostasis. The “intrinsic” pathway, however, has been implicated in some forms of thrombosis. The primary (“extrinsic”) and accessory (“intrinsic”) pathways, initiated by independent routes, both lead to the activation of factor IX and converge at the “intrinsic” fXase complex (Fig. 18.1). Regardless of the path, the outcome is the formation of the prothrombinase complex and thrombin generation. Each reaction of the primary pathway of coagulation involves the vitamin K-dependent zymogens and serine proteases, cofactor proteins, and Ca²⁺ ions assembled on membranes. The complexes display reaction rates 10⁴ to 10⁵ times greater than the respective serine proteases alone. ⁵

Clinical laboratory tests differentiate between the pathways. The activated partial thromboplastin time (aPTT) initiates coagulation through the accessory pathway, whereas the prothrombin time (PT) assay initiates coagulation through the primary pathway. ⁶ ²⁶ ²⁷ ²⁸ The designations of primary and accessory pathways are based on clinical evidence of bleeding diseases. Deficiencies of proteins associated with the “intrinsic” or accessory pathway (factor XII, prekallikrein, and HMWK) exist but are not associated with abnormal bleeding events, even after surgical challenge. ²⁹ ³⁰ ³¹ However, deficiencies of the protein components of the “extrinsic” or primary pathway (prothrombin and factors V, VII, VIII, IX, and X) can lead to severe bleeding diatheses. ¹⁶ ³² ³³ ³⁴ ³⁵ Factor XI deficiency may also result in bleeding episodes subsequent to trauma or surgery. ³⁶ ³⁷ The role of the accessory pathway is therefore not clearly understood. Factor XI appears to play a role in coagulation, ²¹ ³⁷ most likely unrelated to its activity in the “intrinsic” pathway, with the contribution of factor XI to hemostasis thought to be due to its activation by α-thrombin. Factor XIa then functions in the propagation phase of α-thrombin generation in association with the primary pathway. ⁷ ²²

Factor XII, prekallikrein, and HMWK are required for activity of the contact or accessory pathway and deficiencies are reported by the aPTT. Factor XII and prekallikrein are zymogens that are activated to serine proteases, while HMWK is a cofactor. The accessory pathway factors are hypothesized to play a role in disseminated intravascular coagulation (DIC) associated with the systemic inflammatory response syndrome, ¹⁸ ³⁹ and may also be involved in the promotion of thrombus stability. ⁵ ²⁴ ⁴⁰ ⁴¹ The accessory pathway may also be important in cardiopulmonary bypass because of contact between blood components and synthetic surfaces. ³⁹

The importance of the membrane component in coagulation was initially identified by kinetic studies of the prothrombinase complex. In the absence of the membrane surface, the cofactor (factor Va)-enzyme (factor Xa) interaction is relatively weak, with a dissociation constant (Kₐ) of 800 nmol/L. ⁴² ⁴³ ⁴⁴ The factor Va-lipid interaction (Kₐ = 3 nmol/L) and factor Xa-lipid interaction (Kₐ = 110 nmol/L) ⁴₅ show higher affinity. However, all of the components must be present to generate the high-affinity factor Va-factor Xa-Ca²⁺ membrane complex, with a Kₐ of 1 nmol/L. ⁴₆ The fully assembled complex is stabilized through factor Va-factor Xa, factor Va-lipid, and factor Xa-lipid interactions. ¹⁴ ⁴⁷ ⁴⁸ Similar properties have been observed for the fIIa/fVIIa, TF/fVIIa, and Tm/fIIa complexes. ⁴²

The primary pathway of coagulation is initiated or triggered by the interaction of circulating factor VIIa with its cofactor tissue factor. ⁴⁹ ⁵⁰ ⁵¹ In general, the serine proteases associated with hemostasis circulate in their zymogen or inactive forms; however, low levels of circulating factor VIIa are present in blood. ⁵² This factor VIIa binds to tissue factor expressed by pathology and initiates the procoagulant response. Free factor VIIa is a poor enzyme with virtually no proteolytic activity, but as a consequence is protected from interacting with the circulating inhibitors in the absence of tissue factor. Tissue factor, an integral membrane protein not normally expressed on vascular cell surfaces, is constitutively expressed on extravascular cellular surfaces ⁴⁹ ⁵³ ⁵⁴ ⁵⁵ ⁵⁶ ⁵⁷ ⁵⁸ and thus becomes exposed upon damage to the endothelial cell layer. Tissue factor is also expressed on peripheral blood cells and endothelial cells stimulated by inflammatory cytokines ⁵⁹ ⁶⁰.

Upon interaction of plasma factor VIIa and the injury/pathology presented, tissue factor, the “extrinsic” fXase complex (factor VIIa-tissue factor) is formed and initiates coagulation by
activating factors IX and X. Factor IXa forms a complex with its cofactor, factor VIIIa, to generate the intrinsic “fXase” complex, and factor Xa combines with factor Va to form the prothrombinase complex. The factor VIIIa-factor IXa complex more efficiently activates factor X to factor Xa, providing a robust source of the enzyme component (factor Xa) of the prothrombinase complex.

FIGURE 18.1. Overview of hemostasis. There are two pathways to initiate coagulation: the primary extrinsic pathway (shown on right) and the intrinsic (also called the contact pathway) (shown on left). The components of these multistep processes are illustrated as follows: enzymes (pink circles), inhibitors (blue circles), zymogens (green boxes), or complexes (cream ovals). The intrinsic pathway has no known bleeding etiology associated with it; thus, this path is considered accessory to hemostasis. On injury to the vessel wall, tissue factor, a membrane-bound cofactor, is exposed to circulating factor VIIa, forming the extrinsic fXase, a vitamin K-dependent complex. Factor IX and factor X are converted to the serine proteases factor IXa (FIXa) and factor Xa (FXa), which are the enzymatic components of the intrinsic fXase and the prothrombinase complexes, respectively. The combined actions of the intrinsic and extrinsic fXase and the prothrombinase complexes lead to an explosive burst of the enzyme thrombin (FIIa). In addition to its multiple procoagulant roles, thrombin also acts in an anticoagulant capacity when combined with the cofactor thrombomodulin in the protein Case complex. The product of the protein C case reaction, activated protein C (APC), inactivates the cofactors factors Va and VIIIa. The cleaved species, factors Va (FVa) and VIIIa (FVIIIa), no longer support the respective procoagulant activities of the prothrombinase and intrinsic fXase complexes. Once thrombin is generated through procoagulant mechanisms, thrombin cleaves fibrinogen (releasing fibrinopeptides A and B [FPA and FPB, respectively]) and activates factor XIII to form a cross-linked fibrin clot. Thrombin-thrombomodulin also activates thrombin-activatable fibrinolysis inhibitor (TAFI) that slows down fibrin degradation by plasmin. The procoagulant response is downregulated by the stoichiometric inhibitors tissue factor pathway inhibitor (TFPI) and antithrombin (AT). TFPI serves to attenuate the activity of the extrinsic fXase, the trigger of coagulation. AT directly inhibits thrombin, FIIa and FVa. The intrinsic pathway provides an alternate route for the generation of factor IXa. Thrombin has also been shown to activate factor XI. The fibrin clot is eventually degraded by plasmin, yielding soluble fibrin peptides (see Fig. 18.17). HMW, high molecular weight.
Deficiencies of the “intrinsic” fXase components factor VIIIa (hemophilia A) and factor IXa (hemophilia B) illustrate the significance of the factor IX activation by the FVIIa/TF complex and the enhanced rate of factor X activation by the intrinsic fXase and the inhibition of the extrinsic fXase by TFPI. Hemophilia A and B are detected using the aPTT. From inspection of Figure 18.1, it would appear activation of factor X by the “extrinsic” fXase should compensate for the lack of factor X activation by the “intrinsic” fXase in hemophilias A and B. However, this compensatory mechanism only occurs during clinical administration of supraphysiologic concentrations of recombinant factor VIIa during replacement therapy for hemophilia with inhibitors. The natural physiologic levels of factor VIIa are not able to provide sufficient levels of factor X to support normal coagulation. Factor Xa generation is suppressed to approximately one-half the level observed when factor X is the only substrate presented.61,62

Factor IX, not factor X, appears to be the preferred substrate of the extrinsic fXase. In addition, factor IXα, the intermediate species in factor IX activation, is generated more rapidly in the presence of factor X. Factor IXα activation to the final product factor IXa occurs at a higher rate than factor IX activation, thereby providing a burst of factor IXa to form the intrinsic fXase complex. The low level of factor Xa generated by the tissue factor-factor VIIa complex most likely functions in the activation of factor IX. A model of extrinsic fXase behavior suggests

that factor IX is converted to factor IXα by the extrinsic fXase or factor Xα-phospholipid complex. Factor IXα is then rapidly converted to factor IXa by the extrinsic fXase.61,62 The factor VIIIa-factor IXα complex subsequently activates the major fraction of factor X to factor Xa and provides the enzyme component for the prothrombinase complex. Measurements of second-order rate constants for factor Xa generation by the intrinsic and extrinsic fXase complexes also support this model. The rate of factor Xa generation by the tissue factor-factor VIIa complex is 1/50th the rate of factor Xa generation by the factor VIIIa-factor IXα complex 61,62 and 63. Both complexes thus have distinct roles in the procoagulant response.

In summary, the procoagulant response is triggered upon the interaction of factor VIIa with tissue factor, when the latter is exposed and/or expressed as a result of vascular perturbation. The extrinsic fXase generates low levels of factors IXa and Xa during the initiation phase of coagulation. Factor Xα-phospholipid complexes also assist in the activation of factor IX. Factor IXα combines with factor VIIIa on the membrane surface, and the intrinsic fXase accelerates factor Xa generation 50-fold over the extrinsic fXase. The burst of factor Xa overcomes circulating levels of factor Xa inhibitors and initiates maximal levels of prothrombinase complex activity. Prothrombinase activity subsequently leads to a burst of α-thrombin generation and propagation of the procoagulant response.61,62

PROCOAGULANT PROTEINS: ACCESSORY PATHWAY FACTORS AND FACTOR XI

The procoagulant proteins that make up the intrinsic or accessory pathway consist of factor XII, plasma prekallikrein, HMWK, and factor XI. These proteins are responsible for the contact activation of blood coagulation. The physiologic role of the intrinsic pathway is not clearly understood, but does not appear to be essential for hemostasis because individuals deficient in factor XII, plasma prekallikrein, or HMWK do not manifest abnormal bleeding. Factor XI appears to play a more prominent role, unrelated to its activities in the intrinsic pathway, after activation by thrombin.7,37 Each of these proteins is described in terms of its gene structure and expression, biochemistry, activation, function, and regulation in regard to hemostasis.

Factor XII (Hageman Factor, Contact Factor) Factor XII, or Hageman factor (HF), is the zymogen precursor of the serine protease factor XIIa. Factor XII is also known as contact factor for its role in the initiation of coagulation on contact with substances such as glass or kaolin. The contact pathway is the basis for the activated partial thromboplastin time clotting assay. Factor XII circulates in plasma at an average concentration of 40 µg/ml (500 nmol/L)64,65 (Table 18.1). Increased levels of factor XII are seen in postmenopausal women using estrogen replacement therapy and during pregnancy. Animal studies also demonstrate enhanced expression of factor XII by estrogen and prolactin,66,67 and 68 Since a deficiency of factor XII is not associated with any bleeding abnormality, its precise role in hemostasis is at present unknown. Studies show that mice lacking factor XII are protected against arterial thrombosis and stroke.40,41,69,70 This suggests that the intrinsic pathway of coagulation is essential for thrombus stability. The components of the contact pathway are also believed to provide a link between coagulation and inflammation,71 with the multifunctional cellular protein GC1q-R/p33 postulated to play a central bridging role between these two processes.72 Misfolded protein aggregates have been implicated in activating factor XII.73

Gene Structure and Expression
Human factor XII is produced by a single gene located on chromosome 5 q33-qter\(^{24,75}\) (Table 18.2). The gene for factor XII spans approximately 12 kilobases (kb) and is composed of 13 introns and 14 exons.\(^{76}\) The intron/exon gene structure is similar to the gene structures of tissue plasminogen activator (t-PA) and urokinase-type plasminogen activator (u-PA).\(^{76}\) The promoter does not contain the CAAT or TATA sequences common in other genes, but it does contain two LF-A1 transcription elements characteristic of genes with liver-specific expression. The promoter also contains one estrogen-responsive element.\(^{76,77}\)

Biochemistry

Human factor XII is synthesized as a precursor protein with a 19-residue signal peptide. The mature factor XII molecule is a 596-amino acid single-chain \(\beta\)-globulin with a molecular weight of approximately 80 kDa.\(^{78,79,80,81,82}\) It circulates at a concentration of 40 \(\mu\)g/ml (500 nmol/L) with a half-life (\(t_{1/2}\)) of 2 to 3 days (Table 18.1). The factor XII molecule is composed of two domains: an NH\(_2\)-terminal heavy chain and a COOH-terminal light chain. The heavy chain contains several domain structures: fibronectin type I and type II domains, two epidermal growth factor (EGF)-like domains, a kringle domain, and a proline-rich region (residues 277 to 330) (Fig. 18.2). The light chain contains the serine protease catalytic domain, a region homologous to the B-chain of the enzyme plasmin. The mature factor XII molecule contains approximately 17% carbohydrate. Glycosylation consists of an O-linked fucose at Thr\(^{83}\) in the first EGF domain, N-linked carbohydrates at Asn\(^{84}\) and Asn\(^{85}\) in the kringle and catalytic domains, respectively; and six O-linked carbohydrates in the proline-rich region.\(^{84}\) The factor XII molecule also contains four zinc ion (Zn\(^{2+}\))-binding sites.\(^{85}\) Zn\(^{2+}\) binding to factor XII likely induces a conformation change that promotes activation of factor XII associated with negatively charged surfaces.\(^{86,87}\) and \(^{88}\)

Activation

Factor XII undergoes autoactivation on interaction with negatively charged surfaces such as glass, kaolin, dextran sulfate, ellagic acid, celite, or bismuth subgallate,\(^{89,90,91,92,93,94,95,96,97,98}\) and \(^{99}\) and on interaction with hydrophobic surfaces.\(^{100}\) This is likely only an in vitro event triggered by the artificial surfaces used in studies of the contact pathway, although research is ongoing. Although factor XII associates with many physiologically relevant anionic surfaces, including negatively charged phospholipids,\(^{101,102,103}\) and \(^{104,105,106,107,108,109,110,111,112}\) and \(^{113}\) the autoactivation of factor XII induced by these surfaces in vitro does not appear to represent the mechanism for factor XII activation in vivo.\(^{114}\) Instead, factor XII is most likely activated by a cell membrane-associated proteinase.\(^{115,116}\) When factor XII, prekallikrein, and HMWK form a complex on anionic phospholipids of the cell membrane, prekallikrein is cleaved, forming the enzyme kallikrein. Kallikrein then activates factor XII (plasmin activates factor XII as well) via a single cleavage at Arg\(^{353,117}\) to generate an 80-kDa two-chain enzyme, \(\alpha\)-factor XIIa (factor XIIa, \(\alpha\)-HFa, or HFa), composed of an NH\(_2\)-terminal heavy chain (relative molecular weight [\(M_\text{r}\)] = 52,000) and a COOH-terminal light chain (\(M_\text{r} = 28,000\)) held together by a disulfide bond (Cys\(^{467}\)=Cys\(^{467}\)) (Fig. 18.2). This cleavage is essential for exposure of the active site in factor XIIa.\(^{117}\) Factor XIIa can then bind negatively charged surfaces and activate factor XI and prekallikrein.\(^{118,119}\) Two secondary cleavages can also occur on factor XII: one outside the disulfide bond (Arg\(^{334}\)=Asp\(^{335}\)) and one inside the disulfide loop (Arg\(^{322}\)=Leu\(^{344}\)), generating \(\beta\)-factor XIIa (FXII\(_a\), HF\(_a\),\(^{120,121,122}\) and \(^{123}\) \(\beta\)-Factor XIIa has no surface-binding capabilities but is able to activate prekallikrein.\(^{99,124,125}\)

+, presence of phenotype; −, absence of phenotype; ±, some individuals present with the phenotype and others do not; H, hemorrhagic disease/hemophilia; T, thrombotic disease/thrombophilia.

*Clinical phenotype: the expression of either H or T phenotype in deficient individuals.*
Factor XIIa is a serine protease that activates factor XI and prekallikrein by mechanisms dependent on anionic surfaces and the cofactor HMWK\(^{118,126}\). Factor XIIa also activates the C1 component of the complement system\(^{127}\). In addition, factor XIIa downregulates the Fc receptor on monocytes and macrophages\(^{128}\), induces release of interleukin (IL)-1 and IL-6 from monocytes and macrophages\(^{129}\), and stimulates neutrophils\(^{130}\). Although these roles have no apparent impact on normal coagulation, factor XII/XIIa may be an important link between coagulation and inflammation\(^{131}\).

Factor XIIa also activates plasminogen to plasmin, linking the contact pathway to fibrinolysis\(^{132}\).

**Regulation**

C1 inhibitor is the major inhibitor of both factor XIIa and β-factor XIIa and irreversibly inhibits both enzymes\(^{133,134,135}\) and\(^{136}\). Antithrombin and plasminogen activator inhibitor (PAI)-1 also inhibit factor XIIa\(^{137,138}\) and\(^{139}\). Endothelial cells and eosinophils are reported to produce proteins that inhibit factor XII activation but not factor XIIa activity\(^{140,141}\) and\(^{142}\). Amyloid precursor protein likewise is reported to inhibit factor XII activation but not factor XIIa\(^{143}\).

**Plasma Prekallikrein (Fletcher Factor)**

Plasma prekallikrein, or Fletcher factor, is the zymogen form of the enzyme kallikrein. Prekallikrein circulates in plasma at an average concentration of 42 µg/ml (486 nmol/L)\(^{144,145}\) (Table 18.1). Approximately 75% circulates in a noncovalent complex with HMWK\(^{146,147}\) and the remaining 25% circulates as free prekallikrein. Like factor XII, prekallikrein is a component of the intrinsic or accessory pathway and serves as a link between coagulation and inflammation. Prekallikrein is also linked to fibrinolytic events. Plasma prekallikrein deficiency is rare and is not associated with hemostatic defects except perhaps in deficient individuals with other cardiovascular risk factors\(^{148,149}\).

Gene Structure and Expression

The human prekallikrein gene is located on chromosome 4q34-35, close to the factor XI gene\(^\text{150}\) (Table 18.2). The human plasma prekallikrein gene spans 30 kb and contains 15 exons and 14 introns.\(^\text{151}\) A total of 12 allelic variants have been identified in the 5′ proximal promoter and in 7 of the exons. A common polymorphism (30% of the population) leads to an Asn124Ser replacement in the heavy chain of the apple 2 domain of prekallikrein. Two other polymorphisms in the coding region of the protein, His189Pro in the apple 3 domain of the heavy chain and His183Gln, were identified.\(^\text{151}\) Prekallikrein and factor XI are highly homologous, and both human and rat factor XI prekallikrein genes are located on chromosome 4, suggesting a gene duplication event from a common ancestor.\(^\text{152}\) Prekallikrein mRNA has been detected in human kidney, adrenal gland, placenta, and brain, but the liver is considered to be the major site of synthesis.\(^\text{153,154,155}\)

Biochemistry

Human plasma prekallikrein is synthesized as a precursor with a 19-amino acid signal peptide. The mature form of the protein, appearing as a doublet of 85 and 88 kDa when analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), is a single-chain fast γ-globulin of 619 amino acids (Table 18.1).\(^\text{132,156,157}\) Prekallikrein contains 15% carbohydrate with five N-linked sugar moieties.\(^\text{153}\) Structurally, prekallikrein contains four tandem repeats, called apple domains, in the NH2-terminal portion of the molecule (Fig. 18.2). Each apple domain consists of 90 to 91 amino acid residues including six to eight cysteines that are disulfide bonded to form the distinct domain structure.\(^\text{153,158}\) The apple 1 and apple 4 domains mediate the binding of prekallikrein to HMWK.\(^\text{159,160}\) The apple domains of prekallikrein are highly homologous to the apple domains of factor XI. Apple domains have been found only in these two proteins, lending support to a gene duplication event from a common ancestor.\(^\text{150,159}\) The COOH-terminal region of prekallikrein contains the catalytic site.

\(^{a}\) http://www.uniprot.org.
FIGURE 18.2. Schematic representation of the intrinsic pathway (contact) proteins. Factor XII (FXII), prekallikrein (PK), high-molecular-weight (HMW) kininogen, low-molecular-weight (LMW) kininogen, and factor XI (FXI) are shown with their various domains depicted as blocks. Activating proteases are placed in a box above the cleavage sites with the specific amino acid residues of the site shown directly underneath. Key interchain disulfide bonds (S-S) are included. For the kininogens, horizontal arrows indicate the amino acid residues defining heavy and light chain regions of the activated forms of the cofactors. Factor XI is illustrated as a monomer. EGF, epidermal growth factor.

Activation

Prekallikrein is activated by factor XIIa in complex with the cofactor HMWK on an anionic surface (Fig. 18.2). Prekallikrein is also activated by β-factor XII in the absence of a surface. The factor XIIa-HMWK complex or β-factor XII catalyzes the cleavage of the Arg371-Ile372 bond in prekallikrein. This cleavage is also reported to occur in the absence of factor XIIa when prekallikrein is bound to HMWK on the endothelial cell surface. The enzyme kallikrein is a two-chain molecule composed of an NH2-terminal heavy chain (M, 53,000) containing the four apple domains and a COOH-terminal light chain (M, 36,000 or 33,000) containing the active site.

Function

Kallikrein is a member of the trypsin family of serine proteases. In the presence of an appropriate anionic surface and the cofactor HMWK, kallikrein activates factor XII to factor XIIa and proteolyzes factor XIIa to β-factor XIIa. Kallikrein also undergoes autodigestion at Lys140-Ala141 to yield β-kallikrein. Enzyme activity is significantly reduced on conversion of kallikrein to β-kallikrein. Kallikrein cleaves HMWK at two sites to generate the vasoactive nonapeptide bradykinin. Bradykinin is a potent vasodilator and stimulates endothelial cell prostacyclin synthesis, resulting in hypotension. Kallikrein is also an activator of fibrinolytic zymogens and converts both plasminogen to plasmin and pro-u-PA to u-PA. In addition, kallikrein has been reported to activate neutrophils and stimulate elastase release as part of the hemostatic and inflammatory responses.

Regulation
C1 inhibitor and α₂-macroglobulin are the major inhibitors of kallikrein. C1 inhibitor forms a 1:1 stoichiometric complex with kallikrein and abolishes its proteolytic and amidolytic activities. α₂-Macroglobulin inhibits the ability of kallikrein to generate bradykinin and partially inhibits amidolytic activity. C1 inhibitor and α₂-macroglobulin each inhibit equivalent amounts of kallikrein in plasma, but C1 inhibitor acts much more rapidly and plays the major role in reducing kallikrein activity.

Antithrombin and antithrombin-heparin are slow inhibitors of kallikrein although the antithrombin-heparin-HMWK complex is an effective inhibitor.

Protein C inhibitor also inhibits kallikrein.

High-Molecular-Weight Kininogen (Fitzgerald Factor, Williams Factor)

HMWK, also known as Fitzgerald factor or Williams factor, circulates in plasma at an average concentration of 80 μg/ml (670 nmol/L) (Table 18.1). HMWK acts as a cofactor for the activation of factor XII and prekallikrein and is the precursor of the vasoactive peptide bradykinin. A second form of kininogen, low-molecular-weight kininogen (LMWK), is also found in plasma. LMWK can be cleaved to yield bradykinin but has no procoagulant activity. LMWK circulates at an average concentration of 90 μg/ml (1,300 nmol/L). Deficiencies of HMWKs and LMWKs are rare and are not associated...
with bleeding diatheses. The major established function of the kininogens is to serve as a source of bradykinin and thereby to contribute to a number of vascular events regulated by bradykinin. 

Gene Structure and Expression

The two forms of kininogen, HMWK and LMWK, are the products of a single gene located on chromosome 3q26-qter (Table 18.2). The kininogen gene consists of 10 introns and 11 exons and spans 27 kb. The gene produces messenger RNAs (mRNAs) for the two different forms of kininogen by alternative splicing. HMWK and LMWK share the coding region of the first nine exons and the portion of exon 10 containing the bradykinin sequence and the first 12 amino acids following the COOH-terminal of bradykinin. Exon 10 also codes for a 56-kDa light chain unique to HMWK, whereas exon 11 codes for a 4-kDa light chain unique to LMWK. Human liver contains mRNAs for both HMWK and LMWK; only HMWK is expressed and secreted by human umbilical vein endothelial cells. Estrogen administration and pregnancy increase HMWK levels. Conversely, progesterone treatment reduces kininogen gene expression and plasma kininogen levels.

Biochemistry

Human HMWKs and LMWKs are synthesized as precursor proteins containing 18 amino acid signal peptides. The mature form of HMWK is a 120-kDa single-chain α-globulin of 626 residues, whereas the LMWK form is a 66-kDa single-chain β-globulin composed of 409 residues. Glycosylation at a number of shared sites (Asn, Asn, Asn, and Asn) and sites unique to HMWK (Thr, Thr, Thr, Thr, Thr, and Thr) presumably accounts for the substantial increase over the masses predicted from the amino acid compositions (70,000 for HMWK and 46,000 for LMWK). The NH2-terminal heavy chains (residues 1 to 362) of the two forms are identical and consist of three consecutive regions designated domains 1, 2, and 3 (D1, D2, and D3). Domain 1 has a low-affinity Ca2+-binding site. Domains 2 and 3 share homology with cysteine protease inhibitors. Both HMWK and LMWK are potent inhibitors of cysteine proteases such as calpain.

Activation

Kallikrein, factor XIIa, and factor Xa cleave HMWK to release bradykinin (residues 363 to 371) (Fig. 18.2). Kallikrein also cleaves LMWK to release bradykinin. Bradykinin release from HMWK yields a two-chain protein composed of the heavy-chain (D1, D2, and D3) disulfide linked (Cys-Cys) to the light chain (D5, D6). This molecule retains procoagulant activity, binding to prekallikrein, factor XI, and anionic surfaces via light-chain interactions and induces apoptosis in endothelial cells.

Function

The major role proposed for the kininogens is as a source of bradykinin. Bradykinin release provides a key vasoactive agent with a variety of roles and directly links the contact pathway to vascular repair processes. HMWK also functions as a nonenzymatic cofactor in the contact pathway of coagulation. HMWK binds anionic surfaces, prekallikrein, and factor XI, thus enhancing their activation by surface-associated factor XIIa. Although most studies of contact activation make use of artificial surfaces, cell membranes may provide appropriate sites for contact activation in vivo. Many cells contain kininogens and express kininogen-binding sites. There is some evidence to support cell membrane-associated contact activation. Prekallikrein bound to HMWK on platelets or endothelial cells can result in the generation of kallikrein by a factor XIIa-dependent or -independent mechanism. However, factor XI bound to HMWK on the surface of platelets is not activated to factor Xa. HMWK and its cleaved form exert anticoagulant effects via their inhibitory action on platelet adhesion and aggregation.

Factor XI (Plasma Thromboplastin Antecedent)
Factor XI, also known as plasma thromboplastin antecedent, circulates as a homodimer at an average concentration of 5 μg/ml (30 nmol/L) in complex with HMWK (Table 18.1). Factor XI is also found in human platelets, and the platelet form accounts for approximately 0.5% of the factor XI antigen in blood. Factor XI is the zymogen precursor of the enzyme factor Xa. Unlike the other members of the accessory or contact pathway, factor XIa has an established role in coagulation as part of a positive feedback loop enhancing α-thrombin generation. Although rare in the general population (~1 in 100,000 individuals), factor XI deficiency is common in the Ashkenazi (European) Jewish population, with approximately 1 in 200 individuals affected by factor XI deficiency. Factor XI deficiency can be associated with severe bleeding tendencies after injury or surgical trauma. Spontaneous hemorrhage is not common. Factor XI deficiency is unusual in that bleeding abnormalities vary considerably and range from a complete absence of symptoms to life-threatening hemorrhage. The severity of the bleeding complications is also not related to the severity of factor XI deficiency. Individuals with mild deficiency may experience severe hemorrhagic events, whereas individuals with severe deficiency may have no abnormal bleeding.

Gene Structure and Expression

The gene for human factor XI is located on chromosome 4q35 and spans 23 kb (Table 18.2). The gene contains 14 introns and 15 exons. Although mRNA for human plasma factor XI has been found in liver, pancreas, and kidney, evidence suggests that the primary site of synthesis is the liver: Plasma factor XI levels decrease in liver disease, and a patient with no history of factor XI deficiency developed a deficiency subsequent to a liver transplant from a factor XI-deficient donor. Platelet factor XI is exclusively synthesized in the megakaryocyte. Human platelet factor XI lacks exon 5 and may be an alternative splicing product of the plasma factor XI gene or a product of a gene specific to megakaryocytes.

There are three major types of genetic mutations associated with factor XI deficiency: (a) intronic point mutations that interrupt exon splicing; (b) exonic point mutations that lead to mutations in specific amino acids and result in premature polypeptide termination, disruption of dimerization, or reduced protein secretion; and (c) nucleotide deletions that lead to decreased protein synthesis. Two specific exonic point mutations account for the majority of the cases of factor XI deficiency in the Ashkenazi Jewish population. An E117X mutation in exon 5 (type II mutation) introduces a stop codon and results in premature polypeptide termination. The type II mutation accounts for approximately 52% of the cases of factor XI deficiency in the Ashkenazi Jewish population. An F283L mutation in exon 9 (type III mutation) that accounts for 36% of the cases is believed to prevent intracellular dimer formation and protein secretion. These mutations are less frequent in the general population. Approximately 150 mutations have been identified in the factor XI gene with four exhibiting founder effects in specific populations.

Biochemistry

Human factor XI is found in plasma and in platelets. The two forms of the protein are somewhat different and may have different functions as well. Plasma factor XI accounts for most of the factor XI antigen in the human system and is a disulfide-linked homodimer (M, = 160,000), with approximately 5% of its mass made up by carbohydrate (Table 18.1). Each of the two identical polypeptide chains is synthesized with an 18-amino acid signal peptide. The mature polypeptide chain (M, = 80,000) consists of 607 amino acid residues and has five potential glycosylation sites, although only Asn, Asn, Asn, and Asn are glycosylated. Exons 3 to 10 of the plasma factor XI gene encode four NH2-terminal tandem sequences termed apple domains (apple 1 to apple 4, Fig. 18.2). The apple domains are homologous to the apple domains in human plasma prekallikrein. Exons 11 to 15 encode the COOH-terminal catalytic domain. Human platelet factor XI lacks exon 5 and amino acids Ala-Ag in the NH2-terminus of the apple 2 domain. The mature platelet polypeptide chain (M, = 55,000) may form a disulfide-linked tetramer of identical subunits (M, = 220,000) or may be disulfide linked to a platelet plasma membrane protein. Plasma factor XI circulates in complex with HMWK. Formation of this complex, mediated by the apple 1 domain of factor XI, is required for factor XI to associate with anionic surfaces. The apple 1 domain also contains binding sites for α-thrombin and prothrombin. The apple 2, apple 3, or both domains mediate the binding of factor IX, the substrate of factor XIa. In addition to potentially mediating the factor Xa-factor IX interaction, the apple 3 domain contains binding sites for platelets and heparin. The apple 4 domain contains the site involved in the dimerization process. Dimerization is required for efficient intracellular processing and protein secretion. Factor Xa associates with a region of the apple 4 domain as well. Polyphosphates have also been proposed as a natural cofactor for factor XI activation in plasma.

Activation
Plasma factor XI is cleaved at an internal Arg \( ^{306} \)-Ile \( ^{370} \) bond to yield a disulfide-linked two-chain activated serine protease (Fig. 18.2). The factor XI homodimer yields two disulfide-linked heavy chains containing the apple domains and two light chains containing the active sites. \( ^{275,276} \) and \( ^{277} \) Activation of factor XI can be accomplished by factor XIIa and α-thrombin and by autoactivation by factor XIa itself. Activation of factor XI by factor XIIa requires HMWK and an anionic surface. However, deficiencies of factor XII and HMWK do not result in bleeding diatheses, whereas factor XI deficiency is associated with hemorrhage. This suggests that factor XIa-dependent activation of factor XI, a part of the contact pathway, is not likely to be the primary route of factor XIa generation in hemostasis. The physiologically relevant pathway for factor XI activation in coagulation is believed to involve α-thrombin. \( ^{7,16,278} \) Factor XI in complex with HMWK binds to the platelet surface via the apple 3 domain. \( ^{269} \) The rate of α-thrombin activation of factor XI on the platelet surface is greater than the rates of platelet-supported factor XIIa activation and factor XIa autoactivation. \( ^{279} \) Although platelets appear to play a key role in providing the surface for factor XI activation, the precise mechanism of activation of platelet factor XI and its function remain unclear. \( ^{280} \)

Function

Subsequent to activation, factor XIa remains bound to the surface. Factor XIa is a trypsin-like serine protease that cleaves and activates factor IX in a Ca\(^{2+}\)-dependent fashion. \( ^{281,282} \) and \( ^{283} \) Factor IXa is the enzyme component of the intrinsic tenase complex that provides the burst of factor Xa necessary for normal coagulation. As part of a positive feedback loop, α-thrombin activates factor XI. In turn, factor XIa generates factor IXa, contributing to the high levels of factor Xa that ensure efficient α-thrombin generation. \( ^{7} \) Factor XI as an antithrombotic target is being explored. \( ^{284,285} \)

Regulation

Factor XIa is regulated by four serine protease inhibitors or serpins: antithrombin, α1-protease inhibitor, C1 inhibitor, and α2-antiplasmin. \( ^{131,276,286,287,288,289,290,291,292,293,294,295} \) and \( ^{296} \) Factor XIa is also reported to be inhibited by PAI-1 and protein C inhibitor. \( ^{139,297} \) In addition, platelets secrete several factor XIa inhibitors, \( ^{298,299,300,301,302} \) including protease nexin-2 (PN2). PN2 is a truncated form of the Alzheimer’s β-amyloid protein precursor and contains a Kunitztype serine protease inhibitor domain. Platelet-bound factor XIa is protected from inactivation by PN2 \( ^{281} \); however, heparin enhances PN2 inactivation of factor XIa. Factor XIa bound to the surface of endothelial cells that secrete heparan sulfate glycosaminoglycans (GAGs) may be readily inactivated by PN2. \( ^{303} \)

PROCOAGULANT PROTEINS: VITAMIN K-DEPENDENT PROTEIN FAMILY

The first identification/description of vitamin K-dependent pro-teins was introduced by Henrik Dam et al. at the University of Copenhagen in the late 1920s. \( ^{304,305} \) and \( ^{306} \) They demonstrated that chickens fed a lipid-free diet exhibited a hemorrhagic condition. The addition of alfalfa meal or a lipid extract of alfalfa prevented this condition. The active compound, 2-methyl-3-phytol-1, 4-naphthoquinone (phylloquinone), was subsequently isolated from green plants. Further work performed by Doisy et al. \( ^{307} \) in the 1930s showed that vitamin K activity in bacteria is also present as a series of menaquinones, 2-methyl-1,4-naphthoquinones substituted at the 3 position with an unsaturated polyisoprenoid chain. The Nobel Prize was awarded to Dam and Doisy in 1941 for their discovery of the fat-soluble vitamin K.

Simultaneously with the discovery of the vitamin, a naturally occurring antagonist,bishydroxycoumarin (dicumarol), was described. This naturally occurring vitamin K antagonist was identified as a toxic agent in spoiled sweet clover causing hemorrhage in cattle. The increase in clotting time was later identified as a function of decreased prothrombin time. \( ^{308} \) This led to the synthesis of several oral anticoagulant analogs and coumarin derivatives, including warfarin.

Vitamin K is essential in the biosynthesis of functional clotting factors. It is the required cofactor for the enzyme catalyzing the conversion of 9 to 13 NH₂-terminal glutamic acid residues to γ-carboxy glutamic acid residues (Gla). The enzyme required for this conversion uses a reduced form of vitamin K.

This specific posttranslational modification allows the vitamin K-dependent proteins to interact with Ca\(^{2+}\) and a membrane surface to exert their effect. The modification was initially identified and characterized in bovine prothrombin. \( ^{309,310,311} \) and \( ^{312} \) Gla residues were missing or present in decreased amounts in prothrombin isolated from cattle treated with coumarin derivatives. The vitamin K-dependent proteins present in plasma after treatment with anticoagulants lacked biologic activity due to decreased Ca\(^{2+}\)-dependent phospholipid binding. Therefore, preventing the formation of Gla residues became a basis for anticoagulant therapy.

Recently, two cDNAs were identified that encode proteins with NH₂-terminal Gla domains. \( ^{313} \) Both appear to be integral membrane proteins but bear no other similarity to the vitamin K-dependent proteins beyond the Gla domain. Mineralized tissues

P.438
contain two proteins with Gla residues. Gla has also been found as a component of the toxin peptides from the marine snail Conus. The biologic activity of the toxins has been found to depend on the Gla residue(s). The identification of Gla in invertebrates suggests that vitamin K has a much wider range of biologic functions than previously thought. Gas 6 is a novel member of the vitamin K-dependent family of proteins, and when bound to the receptor tyrosine kinase Axl has been shown to mediate cell survival. γ-Carboxylation of Gas 6 is necessary for its function.

The vitamin K-dependent proteins can be divided into two classes: procoagulant (factors II, VII, IX, and X; Fig. 18.3A) and anticoagulant (protein C, protein S, and protein Z; Fig. 18.3B). The vitamin K-dependent proteins are part of a family of serine proteinases (except for protein S and protein Z) related to the trypsin/chymotrypsin superfamily. Sequence homology exists between the proteins at both the gene and the protein level, possibly due to a common ancestral gene. Congenital deficiencies of factors II, VII, IX, and X are associated with bleeding tendencies, whereas protein C and protein S deficiencies are associated with thrombotic tendencies. These proteins are composed of separate domains, each of which is characterized by highly conserved regions that fold, independently from the rest of the molecule, into a characteristic three-dimensional shape. The domains of the vitamin K-dependent proteins are illustrated in Figure 18.3. NH2-terminal Gla domains (containing from 9 to 13 Gla residues) are followed by either a kringle domain in factor II or an EGF-like domain (EGF) in factor VII, factor IX, protein C, protein S, and protein Z. Protein S contains a thrombin-sensitive region before the EGF domain. The active site is contained within the serine protease domain for factor II, factor VII, factor IX, protein C and becomes functional on specific peptide bond cleavages. Protein S is not a serine protease precursor and instead contains a sex hormone-binding globulin-like domain in the COOH-terminus. Protein Z contains a “pseudo-catalytic domain” in the COOH-terminus and does not function as a serine protease enzyme.
FIGURE 18.3. Schematic representation of the vitamin K-dependent proteins. The building blocks for these proteins include an NH$_2$-terminal Gla domain with 9 to 13 Gla residues followed by either an epidermal growth factor (EGF)-like domain in factor VII (FVII), factor IX (FIX), factor X (FX), protein C, protein S, and protein Z, or a kringle domain in prothrombin. Protein S contains a thrombin-sensitive region (TSR) before the EGF domain. Active sites are contained within the serine protease domain. Cleavage sites for the conversion of zymogens to their active forms are designated by arrows; activating proteases are placed in boxes above the arrows. Factor IX, factor X, and protein C are activated by proteolytic removal of an activation peptide (AP). Protein S is not a serine protease precursor and instead contains a sex hormone-binding globulin-like domain (SHGB) in the COOH-terminus. Protein Z also contains a “pseudo-catalytic domain” in the COOH-terminus and does not function as a serine protease. For reference, the molecular weight for each zymogen is listed, and disulfide bonds (-S-S-) critical to the integrity of the two-chain zymogens or active forms are presented. A: Panel illustrates the procoagulant vitamin K-dependent proteins factor VII, factor IX, factor X, and prothrombin. B: Panel illustrates the anticoagulant proteins, protein C, protein S, and protein Z. C: Structural ribbon diagram of factor IXa (PDB-ID: 1PFX). FSAP, factor VII-activating protease; TF, tissue factor; mIIa, meizothrombin.

P.439
FIGURE 18.3. (Continued)
The synthesis of these proteins occurs primarily in the liver followed by secretion into circulation. However, recently, a functional prothrombin gene product has been found to be synthesized by human kidney cells. The concentration of circulating zymogens in plasma varies 200-fold from 100 µg/ml for prothrombin to 0.5 µg/ml for factor VII (Table 18.1). Levels present in plasma can be affected by polymorphisms in the promoter or coding region and aberrant levels are considered a risk factor for ischemic heart disease. Cholesterol and triglyceride levels have also been correlated with plasma concentrations of the vitamin K-dependent proteins. Liver function in the synthesis of the clotting factors, dietary intake/adsorption of vitamin K, and drug interactions can affect individuals on anticoagulant therapy.
Clearance \((t_{1/2})\) of the vitamin K-dependent proteins varies from approximately 6 hours for factor VII to 2.5 days for prothrombin (Table 18.1). Once the zymogen is activated to its serine protease form, it is then inactivated by inhibitors and the complex cleared from the blood.

These activated forms of the vitamin K-dependent proteins are key components in the formation of the vitamin K-dependent coagulation complexes: the extrinsic tenase (factor Vlla-tissue factor); the intrinsic tenase (factor IXa-factor
VIIIa); prothrombinase (factor Xa-factor Va); and protein Case (thrombin-thrombomodulin) (Fig. 18.4). When all the components for each complex are assembled on the appropriate membrane surfaces (e.g., activated platelets, monocytes, blood cells, or endothelium), the specific reactions occur with rates enhanced by $10^4$ to $10^9$-fold over enzyme-substrate alone⁵ (Table 18.3). A simple calculation can illustrate the importance of the rate enhancements achieved through complex assembly (vitamin K-dependent serine protease cofactor-membrane-Ca²⁺): If a normal person takes 4 minutes for his or her blood to clot, then in the absence of membrane and cofactor, blood clot formation would take approximately 3.8 years.

Gene Structure and Expression

The family of vitamin K-dependent proteins is mainly synthesized in the liver by hepatocytes. Decreased levels of the vitamin K-dependent proteins are indicators of liver dysfunction.³³³,³³⁴ Liver transplantation has been shown either to treat vitamin K deficiency³³⁵ or to bring about vitamin K deficiency.³³⁶ The genes encoding all of the vitamin K-dependent coagulation proteins have been sequenced and are seen in Table 18.2. The difference between the vitamin K-dependent protein genes and most other eukaryotic genes is that the 5'-flanking regions lack TATA boxes. Binding sites for liver-enriched or liver-specific (or both) transcription factors, which are important for hepatic expression of these proteins, are contained within the regulatory region of these genes. A common pentanucleotide motif that occurs in a similar location in the regulatory region of the genes encoding factor VII, factor IX, and factor X may be important in their possible coordinate expression.
FIGURE 18.4. Vitamin K-dependent complexes. A: Three procoagulant complexes (extrinsic tenase, intrinsic tenase, and prothrombinase) and one anticoagulant complex (protein Case) are illustrated. Each membrane complex consists of a vitamin K-dependent serine protease (factor VIIa [VIIa], factor IXa [IXa], factor Xa [Xa], or thrombin [IIa]) and a soluble or cell surface-associated cofactor (factor VIIIa [heavy and light chain VIIIH and IIIL], factor Va [heavy and light chain VH and
V_l], tissue factor [TF], or thrombomodulin [TM]. Each serine protease is shown in association with the appropriate cofactor protein and zymogen substrate(s) on the membrane surface. The membrane serves as a scaffold for the coagulation reactants, enhancing the reaction rates by $10^7$- to $10^9$-fold. When vascular damage or inflammatory cytokine activation occurs, TF becomes exposed to flowing blood carrying low levels of factor VIIa. The formed extrinsic tenase complex activates the circulating serine protease zymogens factors IX and X. Factor IXa becomes the serine protease for the intrinsic tenase complex, which, with its cofactor factor VIIIa, activates factor X to its active protease form factor Xa. Factor Xa formed primarily from the intrinsic tenase combines with its cofactor factor Va to activate II to IIa on the prothrombinase complex. Cofactor regulation occurs when IIa released from the prothrombinase complex binds to endothelial cell surface protein TM to form the protein Case anticoagulant complex. This complex generates activated protein C, which then proteolytically inactivates factors Va and VIIIa. (From Mann KG. Coagulation explosion. Vermont Bus Graph 1997, with permission.)

**B:** Structural models of extrinsic tenase and prothrombinase.

### Posttranslational Processing

The vitamin K-dependent proteins are synthesized in the liver as preprozymogens in a process that requires a dietary intake of vitamin K. They are modified posttranslationally at glutamic acid ($\gamma$-carboxylation to form $\gamma$-carboxy glutamic acid) and at aspartic acid and asparagine ($\beta$-hydroxylation to form erythro-$\beta$-hydroxy aspartic acid [Hya] and erythro-$\beta$-hydroxy asparagine [Hyn]), they are also modified by sulfation at tyrosine residues as well as the addition of sugar moieties (glycosylation). This high degree of posttranslational processing is necessary for the biologic activity of the mature vitamin K-dependent proteins.

a Complexes are assembled on membranes composed of PC and PS (3:1 molar ratio PC/PS).

b Rate enhancement is derived from the ratio of catalytic efficiency [number of catalytic events per unit time/Michaelis constant ($k_{cat}/K_m$)] for the complex to the catalytic efficiency of the free serine protease for a given substrate.

c No measurable activation of FIXa by FVIIa without TF and the membrane. The catalytic efficiency of the extrinsic tenase toward FIX is reduced relative to FX.

**Proteolytic Maturation**

The vitamin K-dependent proteins are synthesized in the liver as a single-chain precursor that contains a prepro sequence followed by the polypeptide region. The hydrophobic signal peptide (prepeptide) gets the protein to the endoplasmic reticulum, the first compartment in the secretory pathway. For the vitamin K-dependent proteins to become mature, the polypeptide is translocated out of the first compartment in the endoplasmic reticulum across the lipid bilayer into the lumen of the endoplasmic reticulum. The signal peptide is then removed by a signal peptidase. The propeptide, which plays a role in docking vitamin K-dependent carboxylase, is removed by an endoproteinase. The release of the propeptide coincides with $\gamma$-carboxylation (Gla formation) (Fig. 18.5a). Removal of an internal di- or tripeptide in singlechain factor X and protein C occurs, which converts them to their mature two-chain zymogen form. Several studies
describe the endoproteinase that cleaves the propeptide and the internal bonds as furin/paired basic amino acid cleaving enzyme.\textsuperscript{341,342} and \textsuperscript{343}

**Carboxylation and Vitamin K-dependent Carboxylase**

The $\gamma$-carboxylation reaction is catalyzed by the enzyme $\gamma$-glutamyl carboxylase. This enzyme is located in the rough endoplasmic reticulum and requires the reduced form of vitamin K, oxygen, and carbon dioxide.\textsuperscript{311} The carboxylation mechanism involves proton abstraction of the $\gamma$-hydrogen of the glutamate residues near the NH$_2$-terminus of the nascent prepro protein (Fig. 18.5B). The generated carbanion at each glutamic acid residue then reacts with free CO$_2$, forming $\gamma$-carboxy glutamic acid. It is this Gla region that mediates the Ca$^{2+}$-dependent binding of the protein to anionic phospholipid surfaces, thereby ensuring close proximity and interaction with other components of the coagulation sequence and with cell receptors for vitamin K-dependent ligands. Without vitamin K, the coagulation protein precursors continue to be synthesized but are not $\gamma$-carboxylated. In this form, they are still secreted into plasma but are nonfunctional.

The cDNA for the human $\gamma$-carboxylase gene was cloned and sequenced by Wu et al.\textsuperscript{344} The open reading frame predicts a molecular weight of approximately 87.5 kDa. Glycosylation of the carboxylase probably accounts for its decreased mobility on SDS-PAGE (94 kDa). Vitamin K-dependent carboxylase has been identified in many cell types.\textsuperscript{345} This supports the notion that vitamin K has a wide range of biologic functions.

The presence of vitamin K is essential to maintain the $\gamma$-carboxylation reaction. Vitamin K$_1$ (phyloquinone) is primarily found in leafy green vegetables and vegetable oils. Additional K activity may be provided by vitamin K$_2$ (menaquinones) synthesized by intestinal Gram-negative bacteria. Synthetic vitamin K$_3$ (menadione) has no intrinsic activity until it undergoes in vivo transformation to the active menaquinone form. These K vitamins are 2-methyl-1,4-naphthoquinones with repeating fivecarbon prenyl units at position 3. In vivo, vitamin K is recycled in a mitochondrial oxidation-reduction system for continued use in the $\gamma$-carboxylation reaction. To perform the $\gamma$-carboxylation reaction, vitamin K has to be present in its reduced hydroquinone form. As the precursor proteins are carboxylated, vitamin K is oxidized to the epoxide.\textsuperscript{346} The epoxide in the presence of 2, 3-epoxide reductase, using thiols as the reducing agent, yields the quinone form of vitamin K.\textsuperscript{347} A subsequent nicotinamide adenine dinucleotide phosphate- or nicotinamide adenine dinucleotidedependent quinone reductase reaction resynthesizes the hydroquinone form. The cycle can thus begin again.

One important target for anticoagulant therapy is the process required for the regeneration of reduced hydroquinone vitamin K. Anticoagulants that effectively block this reaction include warfarin (Coumadin), dicumarol, and phenprocoumon (Fig. 18.5B). These oral anticoagulants are structurally similar to the quinone form of vitamin K, thereby targeting the reductase enzyme and inhibiting the reduction to the requisite hydroquinone form. The affinity of the anticoagulants for the reductase enzymes determines the efficacy of the drug.\textsuperscript{12,348} In the United States, the most widely used oral anticoagulant warfarin (Coumadin) is also used as rat poison. It acts as a competitive inhibitor of oxidized vitamin K and interferes with its reduction. Without the regeneration of the reduced form of vitamin K, the vitamin K-dependent protein carboxylase is unable to convert glutamate to $\gamma$-carboxy glutamate. Thus, these drugs indirectly affect carboxylation and can be overcome with excess vitamin K. The level of competitive inhibition achieved in Coumadin therapy among individuals taking the same dose regimen is variable. Factors affecting the efficacy of treatment include liver function in the synthesis of the clotting factors, enhancement of effect from other medications, and dietary intake/adsorption of vitamin K.\textsuperscript{349} Therefore, proper monitoring of oral anticoagulant therapy is essential with frequently measured PT and corrected assay sensitivity using the international normalized ratio.\textsuperscript{350,351} Several lines of evidence indicate that vitamin K antagonists inhibit not only posttranslational modification on coagulation factors, but also the synthesis of functional extra hepatic vitamin K-dependent proteins potentially resulting in vascular calcification.\textsuperscript{352,353}

**Hydroxylation**

Hydroxylation in the context of vitamin K-dependent proteins refers to the addition of a hydroxyl group (-OH) to aspartic acid and asparagine residues present in the EGF-like domains. The EGF-1 domains of human factors IX and X, protein C, and protein S contain a homologous aspartic acid residue that is hydroxylated to form erythro-\(\beta\)-hydroxy aspartic acid (HyA).\textsuperscript{79,354,355} Protein S also contains asparagine residues in EGF-2 and EGF-4 domains that are hydroxylated to form erythro-\(\beta\)-hydroxy asparagine residues (HyN).\textsuperscript{356} This posttranslational modification to HyA and HyN occurs by a \(\beta\)-hydroxylase enzyme, a 2-oxo-glutarate-dependent dioxygenase.\textsuperscript{338,357} The mechanism of action involves the recognition of a consensus sequence Cys-X-Asp/Asn-X-X-X-X-Tyr/Phe-X-Cys-X-Cys.\textsuperscript{356} The reason for this modification to HyA and HyN is unclear. No effect has been found on the overall fold of the EGF-1 domain, its affinity, or specificity for calcium.\textsuperscript{358} These modifications also appear to have no relevance to the biologic activity or macromolecular interactions of the vitamin K-dependent proteins.\textsuperscript{359,360}
FIGURE 18.5. Vitamin K-dependent processes. A: Schematic representation of the synthesis and posttranslational carboxylation pathway of vitamin K-dependent proteins in the endoplasmic reticulum. (From Bovill EG, Malhotra OP, Mann KG. Mechanisms of vitamin K antagonism. Baillieres Clin Haematol 1990;3:555-581, with permission.) B: The mechanism of γ-carboxy glutamate (Gla) generation by a vitamin K-dependent reaction cycle is illustrated. The regeneration of vitamin K hydroquinone by the vitamin K-dependent reductases is inhibited by anticoagulants, as illustrated by Coumadin.

P.444
Glycosylation

The addition of a carbohydrate moiety as a posttranslational modification to proteins is referred to as glycosylation. The vitamin K-dependent proteins contain significant amounts of carbohydrate (Tables 18.1 and 18.4). Carbohydrate adducts on Asn, Ser, and Thr residues are found in key domains of these proteins, including the activation peptide of factor IX and factor X; the EGF domains in factor VII, factor IX, and protein Z; and the kringle domain in prothrombin. In most cases, the purpose of these modifications remains unknown. However, differences in the properties of the carbohydrate variants of protein C have been noted.361,362

General Structure/Function Features

The vitamin K-dependent proteins, both procoagulant and anticoagulant, share a common protein domain structure. Each has a tripartite design: an NH2-terminal γ-carboxy glutamic acid (Gla) domain, a linker region (kringle domains, EGF-like domains [EGF], or a thrombin-sensitive finger region, or all three), and a COOH-terminal domain usually consisting of a serine protease domain (factors II, VII, IX, and X and protein C) (Fig. 18.3). The Gla domain is involved in the Ca2+ ion-dependent binding of vitamin K-dependent proteins to anionic phospholipid membranes. The number of domains in the linker region is variable, and, in general, they are involved in protein-protein interactions. The COOH-terminal catalytic domain seen in factors II, VII, IX, and X and protein C is homologous to the pancreatic serine proteases, trypsin, and chymotrypsin. The nonserine protease domain seen in protein S (a cofactor of activated protein C [APC]) is homologous to sex hormone-binding globulin.363 Protein Z is an enzymatically inactive homolog of factors VII, IX, and X and protein C.364 A separate review of the Gla, EGF, and serine protease domains is presented below.

</table>
The importance of each of the domains has been uncovered through studies from natural variants that occur in patients with either familial bleeding (i.e., factor IX deficiency/hemophilia B) or thrombotic disease (i.e., protein C deficiency). The situations that can cause a disease state are either deficiency in the level of protein present (cross-reactive material [CRM]-negative) or expressed protein that is present but nonfunctional (CRM+). Defects have diverse causes, including mutations that lead to amino acid substitutions in one or more domains, defects in posttranslational modifications, or mutations that introduce stop codons resulting in either no expression or expression of truncated proteins. In the case of combined vitamin K deficiency, a rare hereditary bleeding disorder, two studies have identified a missense mutation in the γ-carboxylase gene that results in a defective γ-glutamyl carboxylase and thus incomplete processing of the vitamin K-dependent proteins.367,368

When a hemostatic disorder characterized by a dysfunctional protein (CRM+) is identified, it is through the combination of techniques including protein isolation, in vitro studies, and DNA technology that the root of the defect is elucidated. The importance of domains as functional units and of specific amino acid interactions can be uncovered using recombinant DNA technology. Single amino acid substitutions can be introduced into domains or entire domains removed to determine where the intra- and interprotein interactions take place. Structural information through nuclear magnetic resonance spectroscopy and x-ray crystallography provides amino acid assignments and tertiary structure, thus allowing for precise approaches to site-directed mutagenesis studies. The combination of all these techniques results in a map of how the domains are aligned and interact. Further, using computational molecular dynamics, one can predict conformational changes associated with protein-protein, protein-ligand, and protein-surface interactions. Identifying residues directly involved in binding to membranes, metal ions, or small substrates can lead to new drug therapies.

The first x-ray crystal structure of a vitamin K-dependent protein was obtained by Tulinsky’s laboratory for prothrombin fragment 1 (factor II, residues 1 to 155) in the presence and absence of calcium. These results provided information regarding the entire Gla domain, the connector peptide, and kringle 1. In the absence of calcium, only the connector peptide and the kringle can be visualized in the resulting x-ray crystal analysis. Prothrombin is the only vitamin K-dependent protein with a kringle domain. It is likely that organization of the polypeptide chains of the Gla domain is similar for all vitamin K-dependent proteins. To date, several other vitamin K-dependent protein structures have been elucidated and (see Table 18.5). Many studies on the individual vitamin K-dependent proteins have been conducted and are detailed under each protein subsection.

All the vitamin K-dependent proteins contain an NH2-terminal Gla domain, and only factors II, VII, IX, and X and protein C contain a serine protease domain. Factors IX, X, and VII, protein C, and protein S contain EGF domains. Several recent reviews have been written on vitamin K-dependent proteins.383,384,385 and 386

Gla Domain

The Gla domain constitutes the first approximately 50 residues of the vitamin K-dependent proteins (Fig. 18.3). The negative charge elicited from the string of Gla residues (9 to 13) contributes to the binding to Ca\(^{2+} \) and the generation of the conformation required for binding to anionic phospholipid membranes. This surface in vivo is supplied by activated platelets or other blood cells in response to vascular damage through exposure of the internal face of their cell membranes where it is phosphatidylserine (PS)-rich. \(^{389,397} \) In vitro systems that attempt to mimic coagulation mainly use natural or synthetic preparations of PS and phosphatidylycholine, often at a 1:3 molar ratio. Studies have shown that PS exposure is crucial for cells to support the membrane-bound enzymatic reactions and that PS is more effective than other equally charged lipids. \(^{5,388,389} \) The striking degree of homology among the Gla domains of the vitamin K-dependent clotting factors suggests that the affinity of the calcium-Gla complexes for

\[ \mathrm{P.446} \]

phospholipids would also be very similar. However, this turns out not to be the case. The dissociation constants for binding to phosphatidylycholine and PS-containing vesicles vary, with \( K_d \) values in the range of 50 nmol/L for protein Z and protein S, \(^{390} \) 100 to 300 nmol/L for factor X and prothrombin, \(^{391} \) 15 nmol/L for protein C, \(^{390} \) and 17,000 nmol/L for factor VII. \(^{390,392} \) A systematic analysis of the sequence/structural basis for these divergent membrane-binding properties is available. \(^{382,390} \)

The mode of interaction between the Gla domain-containing coagulation factors and biologic membranes has been difficult to study and is still a subject for debate. Two models of binding have been presented. One involves the bridging of calcium between specific Gla residues and the negative anionic phospholipid membrane components. \(^{392,393} \) A second model involves a major hydrophobic contribution to the membrane binding. X-ray crystallographic \(^{370,394,395} \) and nuclear magnetic resonance studies \(^{396} \) have been conducted to elucidate the conformational changes, in the absence and presence of calcium, that occur on Gla domain binding to a lipid membrane. In the absence of calcium, the negatively charged Gla residues appear exposed to the solution, and the hydrophobic residues of the Gla domain are buried in its interior. \(^{397} \) On Ca\(^{2+} \) binding to the Gla domain, the conformation is altered to expose the hydrophobic residues, making possible their insertion into the lipid membrane. The hydrophobic patch in prothrombin fragment 1 surrounding the first pair of Gla residues was determined to be Phe\(^4 \), Leu\(^5 \), and Val\(^6 \). Site-directed mutagenesis studies of protein C determined these residues (Phe\(^4 \), Leu\(^5 \), and Leu\(^8 \) ) to be important in membrane interactions. \(^{398,399} \) and \(^{400} \) The actual mechanism of membrane binding is still under active investigation.

Epidermal Growth Factor Domain

The Gla domain is followed by two tandem EGF domains (EGF-1 and EGF-2) in factor VII, factor IX, factor X, and protein C and four EGF domains (EGF-1 to EGF-4) in protein S \(^{401} \) (Fig. 18.3). The first EGF domain (EGF-1) contains the posttranslationally modified amino acid \( \beta \)-hydroxy aspartic acid in the case of factors IX and X, and \( \beta \)-hydroxy asparagine in the case of protein S. \(^{337,354,356,402,403} \) An EGF-like domain consists of 40 to 50 amino acids, including six cysteine residues involved in disulfide bond formation. The EGF domains have been evaluated by nuclear magnetic resonance spectroscopy. \(^{386,405,406,407,408} \) and \(^{409} \) The EGF-2 domains of factor Xa, \(^{378} \) factor VIIa, \(^{380} \) activated protein C, \(^{382} \) and factor Ixa \(^{411} \) have been evaluated by x-ray crystallography. The EGF-like domains are found widely distributed in extracellular and membrane proteins. Proteins containing these domains are involved in blood coagulation, fibrinolysis, complement activation, and microfibril formation in connective tissue and in signal transduction. \(^{356,411,412} \) These domains are similar to the archetypal protein, EGF, which contains nine of these domains and is derived from a membrane-bound precursor.
The structure of the EGF-like domains is dominated by β sheets and β turns. Several point mutations in the EGF domain of factor IX have been identified that cause hemophilia B. Calcium-binding sites have been identified in the NH₂-terminal EGF-like domains isolated from factors VII, IX, and X and proteins C and Z, with Kₐ values ranging from 1 to 5 mm. This Ca²⁺-binding site is functionally important because vitamin K-dependent proteins that have missense mutations in EGF-1 that disrupt the Ca²⁺-binding site have reduced biologic activity. In these proteins, the second EGF domain does not appear to bind calcium. The NH₂-terminal EGF domain of protein S does not appear to bind Ca²⁺.

The function of the EGF domain is still unclear. One hypothesis is that it serves as a spacer. A consistent elongation of the molecules of factors VII, IX, and X and protein C and protein S has been noted. The distance between the membrane-binding Gla domain and the serine protease domain is crucial to the placement of the active site in an appropriate position relative to the target peptide bond in its substrate. Calcium binding serves a role in the function of these domains. For example, it has been proposed that for appropriate docking of factor VIIa to tissue factor, Ca²⁺ binding to the EGF domain is required. Calcium binding to the EGF domains in non-vitamin K-dependent proteins has been observed in the Notch protein and fibrillin.

Serine Protease Domain

The serine protease domain accounts for approximately one-half the mass of each protein. Peptide bond cleavage at specific sites converts the vitamin K-dependent zymogens to their active serine protease forms (Fig. 18.3). These enzymes are serine proteases in the same family as trypsin and chymotrypsin. The mechanism of proteolysis by chymotrypsin involves a catalytic triad, composed of Asp¹⁰², His⁵⁷, and Ser¹⁹⁵ (chymotrypsin numbering). The nucleophilic attack is carried out by the hydroxyl group of Ser¹⁹⁵ with the imidazole ring of His⁵⁷ taking up the liberated proton and the carboxylate ion of Asp¹⁰² stabilizing the developing charge. More extensive elements of structure (i.e., calcium-, membrane-, and cofactor-binding sites) are required for interactions of enzymes and substrates in the coagulation process.

The serine protease domains of all the Gla-containing factors show a high degree of sequence identity with each other and to trypsin and chymotrypsin, cleaving almost specifically at arginyl residues. However, unlike trypsin, which shows little specificity beyond the requirement for arginyl or lysyl residues at the cleavage site, the activated coagulation factors have extended substrate specificity pockets where only a small number of amino acid sequences are recognized by each activated factor. Despite a high degree of structural similarity between the protease domains of protein C and factors II, VII, IX, and X, each of these factors has a highly specific function in coagulation. Some of this discrimination may be mediated by surface loops and other domains away from the substrate-binding pocket that are not highly homologous.

Factor VII (Proconvertin, Convertin)

The vitamin K-dependent single-chain zymogen factor VII (Mᵦ = 50,000), also known as proconvertin, circulates in plasma at a concentration of 0.5 µg/ml, or 10 nmol/L (Table 18.1). It is synthesized primarily in the liver. The activated two-chain serine protease form, factor VIIa, circulates in plasma at approximately 1% the concentration of its precursor, or 0.1 nmol/L. The mechanism for the initial activation of this zymogen is unclear. One recently identified candidate is the factor VII-activating protease (FSAP; see section on factor VII-activating protease). The function of factor VIIa is to serve as an initiator of the extrinsic pathway of coagulation when bound to its membrane cofactor, tissue factor. Factor VII has the shortest t½ of all the clotting factor zymogens (3 to 6 hours). Its activated form factor VIIa has a t½ of 2.4 hours.

Factor VII deficiency is an autosomal recessive disorder with wide phenotypic and genotypic variability. Its incidence in the general population is approximately 1 in 500,000. In a large French-Canadian kindred, the incidence is approximately 1 in 335. Bleeding phenotypes can range from mild to severe and include bruising, epistaxis, postsurgical hemorrhage, and cerebral hemorrhage. Severe bleeding is most commonly associated with plasma factor VII levels that are < 1%. Patients have prolonged PTs, and the final diagnosis is established by plasma factor VII coagulant activity (VII:C) using factor VII-deficient plasma and animal thromboplastins, immunologic quantitation of factor VII antigen, or both. Treatment of these individuals includes the use of fresh frozen plasma, prothrombin complex concentrates, factor VII concentrates (plasma-derived or recombinant), and liver transplantation. Due to its short t½ (3 to 6 hours), therapy with factor VII concentrates is difficult. Recently, the use of recombinant factor VII as a safe and effective treatment for factor VII deficiency has been evaluated. During the last decade, supraphysiologic concentrations of recombinant factor VIIa have been used clinically for treatment of patients with hemophilia A or B (factor VIII or factor IX deficiency, respectively) and patients undergoing surgical procedures. Recombinant factor VIIa has been suggested for treatment
of almost all bleeding disorders.\textsuperscript{442} The mechanism of hemostasis by recombinant factor VIIa is not fully understood, although several hypotheses have been proposed.\textsuperscript{443,444,445,446}

Studies on the molecular basis for factor VII deficiency have led to the identification of several mutations in the factor VII gene. These mutations have been identified in the splice site,\textsuperscript{447} the promoter region,\textsuperscript{448} the EGF domain,\textsuperscript{449} and numerous single base pair (bp) mutations.\textsuperscript{450,451} For more detail, there is a factor VII mutation database available at euroim.csc.mrc.ac.uk.\textsuperscript{452} Factor VII deficiency in mice is not lethal at the embryonic stage, but factor VII\textsuperscript{−/−} neonates die from hemorrhage within the first days after birth.\textsuperscript{453,454}

**Gene Structure and Expression**

The factor VII gene is located on chromosome 13 band q34-qter, consists of nine exons, and spans 12.8 kb\textsuperscript{455,456,457} (Table 18.2). It is located approximately 2.8 kb upstream from the factor X gene. The mRNA encodes a 2.5-kb message.\textsuperscript{458} Alternative splicing of the factor VII gene yields two gene transcripts. One gene transcript contains eight segments as exons, and the second gene transcript contains nine segments as exons. The additional exon, which is unique among the vitamin K-dependent proteins, is in the prepro leader sequence. Factor VII mRNA expression is localized in the liver,\textsuperscript{459} where its expression is 6% of the factor X mRNA level.\textsuperscript{460} Extrahepatic synthesis of factor VII has been observed in human atherosclerotic vessels.\textsuperscript{461} The 5′-flanking region of the factor VII gene contains binding sites for the liver-enriched transcription factor hepatic nuclear factor (HNF)-4.\textsuperscript{462} Three potential activation peptide-1 binding sites are also contained in this region. Both genetic and epigenetic modifications in the promoter region of the factor VII gene have been shown to affect plasma factor VIIa levels.\textsuperscript{463}

**Biochemistry**

Factor VII circulates in plasma as a single-chain zymogen of a molecular weight of 50,000,\textsuperscript{418,456,464,465} its 406-amino acid structure consists of an NH\textsubscript{2}-terminal Gla domain containing ten γ-carboxy glutamate residues, β-hydroxy aspartic acid at position 63,\textsuperscript{455} an aromatic residue-rich α-helical domain, two EGF domains, and a serine protease domain (Fig. 18.3). The NH\textsubscript{2}-terminus, along with the serine protease domain, is involved in the metal binding properties of the protein and its interaction with its cofactor tissue factor.\textsuperscript{466,467} and\textsuperscript{468} The COOH-terminus of factor VII is important in its interactions with factor X.\textsuperscript{469} Structures of factors VII\textsuperscript{470} and VIIa\textsuperscript{471} and the extrinsic tenase\textsuperscript{472} have been determined and have been utilized in a variety of ways to enhance our understanding of this protein.

**Activation**

The single-chain zymogen factor VII is activated to its two-chain serine protease form, factor VIIa, through a single peptide bond cleavage between Arg\textsuperscript{152} -Ile\textsuperscript{153} (Fig. 18.3). The resulting protease consists of an NH\textsubscript{2}-terminal light chain (M\textsubscript{r} = 20,000) containing the membrane-binding Gla domain (ten Gla residues), linked by a single disulfide bond between Cys\textsuperscript{135} -Cys\textsuperscript{262} to a COOH-terminal heavy chain (M\textsubscript{r} = 30,000) that contains the catalytic domain. A small amount of activated factor VII (10 to 100 pmol/L) already circulates in the cleaved active two-chain form.\textsuperscript{473} This small portion of plasma factor VIIa has very poor catalytic efficiency in the absence of its cofactor, tissue factor.\textsuperscript{474,475} The cleavage of factor VII to factor VIIa is catalyzed by several proteases, including α-thrombin,\textsuperscript{8} factor IXa,\textsuperscript{476} factor Xa,\textsuperscript{8} autoactivation by factor VIIa,\textsuperscript{476} factor XIIa,\textsuperscript{477} and FSAP.\textsuperscript{478} The endothelial cell protein C receptor has been reported to bind factor VII and suppress its activation by factor Xa.\textsuperscript{479}

**Function**

Factor VII is a crucial zymogen in blood coagulation and can bind to tissue factor with a subnanomolar K\textsubscript{d} and become activated by a number of proteases. Once converted to its active serine protease form and bound to its cofactor, the integral membrane protein tissue factor, it forms the extrinsic tenase complex\textsuperscript{480,481} (Fig. 18.4). The enzyme complex is so named because it contains a protein, tissue factor, normally extrinsic to the plasma environment. The extrinsic tenase complex (factor VIIa-tissue factor-membrane surface-Ca\textsuperscript{2+}) activates a fraction of the circulating vitamin K-dependent zymogens, factors IX and X, to their serine protease forms.\textsuperscript{45,482,483,484} Thus, it serves to initiate the formation of the intrinsic tenase (factor IXa-factor VIIa-membrane-Ca\textsuperscript{2+}) and the prothrombinase complexes (factor Xa-factor Va-membrane-Ca\textsuperscript{2+}). In vitro studies have shown that the rate of activation by the extrinsic tenase complex is significantly greater (~100,000-fold) than the rate of substrate (factors IX and X) activation by the enzyme factor VIIa alone.\textsuperscript{485,486} Factor Xa bound to a membrane surface can activate additional factor VII in a positive feedback loop.\textsuperscript{8,487}

**Regulation**

Free factor VIIa, unlike other serine proteases of the coagulation cascade,\textsuperscript{474} is not readily inhibited by circulating protease inhibitors, including the antithrombin-heparin complex.\textsuperscript{488,489} This is most likely because of its poor catalytic efficiency when not bound to its cofactor tissue factor. However, when factor VIIa is bound to tissue factor, antithrombin-heparin
exhibits significant inhibition of factor VIIa. Thus, regulation of tissue factor expression is the primary means to control factor VIIa activity. Paradoxically, in normal hemostasis, factor VII (10 nmol/L) is an effective competitor of factor VIIa (0.1 nmol/L) for binding to tissue factor. This competition downregulates the level of enzymatically active complex (factor VIIa-tissue factor), thus suppressing initiation of the clotting cascade. Once the extrinsic tenase complex (factor VIIatissue factor-Ca\(^{2+}\)-membrane) activates factor X to factor Xa, tissue factor pathway inhibitor (TFPI) can form a quaternary complex (factor VIIa-tissue factor-factor Xa-TFPI) with no enzymatic activity (Fig. 18.6).

**Factor IX (Plasma Thromboplastin Component, Christmas Factor, Hemophilia B Factor)**

The zymogen factor IX is a single-chain vitamin K-dependent procoagulant glycoprotein synthesized in the liver, which has also been referred to as plasma thromboplastin component, Christmas factor, or hemophilia B factor. It circulates in plasma (t\(_{1/2}\) = 24 hours) at a mean concentration of 5 µg/ml, or 90 nmol/L, with a relative molecular weight of 55,000 (Table 18.1). In addition, there may be a pool of noncirculating factor IX, which is readily available to the intravascular space, systemically distributed and sequestered either to the endothelial surface or subendothelial components, specifically collagen IV. High levels of factor IX have been correlated with an increased risk of venous thrombosis. Deficiency of this glycoprotein, known as hemophilia B, is considered one of the most common inherited coagulation disorders. The factor IX gene, found on the X chromosome, is a sex-linked recessive bleeding disorder that is found in males. The frequency of this disorder in the general population is approximately 1 in 30,000 males. It rarely affects females, but several cases have been identified involving a mutation on the factor IX gene. Acquired hemophilia can also occur due to the generation of autoantibodies. Many mutations, including large deletions, small deletions, point mutations, and missense mutations, have been identified in factor IX that appear to reduce activity in the presence of normal antigen levels (CRM\(^+\)) or impair synthesis resulting in reduction of both activity and antigen (CRM\(^-\)). Several specific cases and studies are noted: X translocation, \(^5\) links to factor V\(_{\text{Leiden}}\) population studies, and factor IX Denver. The point mutation called factor IX Denver results in a 100-fold decrease in the binding affinity of factor IXa Denver for factor VIIIa (K\(_d\) = 9.9 nmol/L) compared to normal factor IXa. Mutations in the EGF-1-like domain of factor IX, specifically at Gly\(^{48}\), have also been identified in CRM\(^+\) individuals with hemophilia B. Molecular insights into hemophilia B, as well as hemophilia A, have been formatted in reviews with references to accession numbers and locus identification.
FIGURE 18.6. Regulation of the procoagulant response. Four vitamin K-dependent complexes are illustrated: the extrinsic tenase, the intrinsic tenase, prothrombinase, and protein C. The procoagulant response is regulated by the stoichiometric inhibitors antithrombin (AT) and tissue factor pathway inhibitor (TFPI). AT inhibits thrombin, factor Xa, and factor IXa that are free in solution. TFPI inhibits both factor Xa and the factor VIIa-tissue factor (TF)-factor Xa complex. Activated protein C (APC) generated from the protein C complex [thrombomodulin (TM)-thrombin (IIa)] inactivates FVa and FVIIIa by proteolysis of their heavy chains. PC, protein C. Panel A: initiation phase; Panel B: Propagation; Panel C: Termination. (Adapted from Mann KG. Coagulation explosion. Vermont Bus Graph 1997, with permission.)

Hemophiliacs experience prolonged bleeding episodes that can be life threatening and lead to chronic disabilities. The clinical presentation or phenotype is not homogeneous. Severe disease is associated with < 1% functional factor IX, moderate disease with 1% to 5%, and mild disease with 5% to 25%. Female carriers usually have approximately 20% to 50% functional factor IX. Traditionally, treatment for hemophilia B involves plasma-derived or recombinant factor IX. One problem with this therapy is the development of inhibitory antibodies. There is a North American Immune Tolerance Registry to study immune tolerance in hemophiliacs. An alternative treatment in the last decade has been the use of recombinant factor VIIa at supraphysiologic concentrations (~90 µg/kg). These therapies eliminate the immediate danger of bleeding but do not constitute a cure for the patients. The potential for gene-based therapy for the treatment of hemophilia has become a new avenue for investigation.

Gene Structure and Expression
The gene for factor IX is located on the X chromosome at position q26.3-27.1, near the factor VIII gene. The gene contains eight exons and seven introns and has an overall size of 33 kb. Five cis-acting elements have been identified in the promoter region of the factor IX gene. These include binding sites for transcription factor C/EBP, an HNF-1 binding site, an HNF-4 binding site, and a site for the D-box binding protein. Two essential age-regulatory elements, AE5′ and AE3′, have been identified in the 5′ upstream region of the gene encoding factor IX in transgenic mice. Together, these elements identify the advancing age-associated increase in factor IX gene expression.

Single point mutations in the factor IX promoter region have been correlated with a rare form of hemophilia B termed hemophilia B Leyden.

Hemophilia B Leyden is characterized by an altered developmental expression of blood
coagulation factor IX. These individuals have increasing levels of factor IX after puberty, or after administration of testosterone, resulting in decreased bleeding instances. Studies in mice support the role of androgen receptor binding to the factor IX promoter in regulating the developmental expression of factor IX.

Biochemistry

The structure of human factor IX consists of 415 amino acids that are separated into a Gla domain (12 Gla residues), two tandem EGF domains (EGF-1 [residues 46 to 84] and EGF-2 [residues 85 to 127]), an activation peptide region, and a serine protease domain. Glycosylation in the form of O-linked and N-linked oligosaccharides makes up 17% by weight of the factor IX protein—specifically, O-linked oligosaccharides at Ser and Ser in the EGF-1 domain and O-linked and N-linked oligosaccharides at Asn, Thr, and Thr in the activation peptide region. The Gla domains are crucial for binding to anionic lipid membranes through Ca²⁺ interactions. The x-ray crystal structure of human factor IX with Ca²⁺ has shown that EGF-1 binds a single Ca²⁺ with residues Asp, Gly, Gln, Asp, and Asp functioning as the ligands. Hydrophobic interactions and a salt bridge (Glu-Arg) between the carboxy end of EGF-1 and EGF-2 have also been identified. Ca²⁺ binding and hydrophobic interactions lock the domains in a manner that ensures biologic activity. Several point mutations in the EGF domain give rise to hemophilia B.

Activation

Factor IX activation to its serine protease form, factor IXa, is a two-stage process requiring sequential cleavages at Arg and Arg, releasing a 35-residue activation peptide with an approximate molecular weight of 11,000 (Fig. 18.3). Physiologic activators of factor IX are either tissue factor-factor VIIa (extrinsic tenase complex) or factor XIa. The first step in activation is the cleavage by its physiologic activators at the Arg-Ala bond, resulting in factor IXa. This cleavage has been shown to be important in its affinity for its cofactor factor VIIIa and has been identified as a molecular defect in factor IXa. The second step is cleavage at the Arg-Val bond, resulting in factor IXa, the active form, also known as factor IXa. Both cleavages are required for full biologic activity of factor IXa. In vitro, factor IX has also been shown to be cleaved by factor Xa at Arg on phospholipid membrane surfaces, producing the inactive precursor factor IXa and increasing the overall rate of factor IXa production by tissue factor-factor VIIa. Both cleavage sites, Arg and Arg, have been identified as single point mutations in hemophilia B. The x-ray crystal structure of porcine factor IXa has also been solved.
FIGURE 18.7. Profiles of thrombin and factor Xa generation. A: Empirical time course (x-axis: 0 to 20 minutes) of thrombin-antithrombin formation (y-axis: nmol/L thrombin-antithrombin complex) during whole blood coagulation initiated with 5 pmol/L tissue factor. Data represent means plus or minus standard error of the means for 35 individuals; thrombin-antithrombin levels reach maximum levels of 900 nmol/L (blue diamonds) in this group of normal individuals. Clot time (CT) is shown below with the symbols for each curve. Thrombin generation is divided into two phases: an initiation phase and a propagation phase. When two hemophilia A patients were studied (green squares, red circles), CT was delayed, and the propagation phase of thrombin generation was not present. By not having factor VIIIa present, the intrinsic tenase complex is unable to generate the additional factor Xa that is required for the burst or propagation phase of thrombin generation. B: Computer simulation of the time course of factor Xa generation on activation of the factor VIIa-tissue factor pathway. Concentrations are expressed as the relative percentage of factor Xa produced by each catalyst at each time point. The factor Xa that is initially produced is via the extrinsic tenase complex. After CT, the majority of factor Xa generated is via the intrinsic Xase. The clot time represents the time point in the computer simulation at which
calculated thrombin levels are comparable to thrombin levels (~10 nmol/L) measured in clotting whole blood (see Fig. 18.11).

The active serine protease \((M_r = 45,000)\) structure is composed of a heavy chain \((M_r = 28,000)\) and a light chain \((M_r = 17,000)\) covalently associated through a disulfide bond. Factor IXa forms the intrinsic tenase complex with its cofactor factor VIIIa, \(\mathrm{Ca}^{2+}\), and a membrane surface primarily supplied by platelets (Fig. 18.4). On formation of this complex, factor X is activated to its serine protease form, factor Xa. Factor IXa (the enzyme) alone without its cofactor (factor VIIIa) has poor amidolytic and proteolytic activity (10³-fold less activity).

Function

The main role for factor IXa in blood coagulation is to form the intrinsic tenase complex, which efficiently activates factor X to factor Xa. The complex is so named because the components, including the cofactor, are intrinsic to circulating blood, unlike tissue factor, the cofactor for the extrinsic tenase complex. Both complexes activate factor X to factor Xa. The extrinsic tenase complex (factor VIIa-tissue factor-\(\mathrm{Ca}^{2+}\)-membrane) catalyzes the initial formation (picomolar amounts) of factor Xa, which ultimately participates in prothrombinase complex assembly and the resulting conversion of prothrombin to thrombin, allowing clot formation to occur. The intrinsic tenase complex (factor IXa-factor VIIIa-\(\mathrm{Ca}^{2+}\)-membrane) generates the second burst of factor Xa that results in the propagation phase of the activation of prothrombin to thrombin (Fig. 18.7). The intrinsic tenase complex is kinetically more efficient than the extrinsic tenase complex in generating factor Xa. Factor Xa generation by tissue factor-factor VIIIa occurs at

only 1/50th the rate of factor X activation by the factor IXa-factor VIIIa complex.\(^{51,62}\) Without the intrinsic complex being formed, as occurs in situations like hemophilia A or B, factor Xa is not generated in levels sufficient to produce the propagation phase of thrombin generation (Fig. 18.7). \(^{446,568,569}\)

When the competitive substrates factors IX and X are simultaneously presented to the extrinsic tenase complex, factor IXa generation is increased, whereas factor Xa generation is suppressed.\(^{61,62}\) This occurs because the factor Xa initially produced cleaves factor IX at Arg\(^{145}\), producing factor IXα. Factor IXa is a better substrate for factor VIIa-tissue factor than factor IX; the intermediate is converted to factor IXαβ (factor IXa) by cleavage at Arg\(^{180}\) by factor VIIa-tissue factor. This cooperative enzymatic action results in factor IX being an improved substrate for the extrinsic tenase complex, whereas factor X activation is suppressed.

Regulation

Plasma factor IXa is primarily inhibited by antithrombin \(^{570}\) (Fig. 18.6). In vitro experiments conducted on phospholipid vesicles and cell membranes showed that PN2/amyloid β-protein precursor (PN-2/APP) can also inhibit factor IXa.\(^{571}\) Interestingly, an insect salivary protein, Prolixin-S, has been shown to inhibit factor IXa generation and the intrinsic tenase complex formation.\(^{572}\)

One strategy to improve existing antithrombotic therapies has been to develop factor IXa inhibitors—\(^{573}\)—including the use of monoclonal antibodies that target factor IX/factor IXa \(^{574,575}\) or aptamers targeting factor IXa.\(^{576,577}\) Currently, problems exist in using direct thrombin inhibitors to regulate thrombin activity. Targeting the end product of an amplifying cascade results in a narrow window of therapeutic dose, which is difficult to achieve in clinical practice.\(^{578,579}\) and \(^{580}\) The advantages of regulating events upstream (factor IX/factor IXa; the intrinsic tenase complex) as an approach to antithrombotic therapy would be to potentially produce a partial reduction in the magnitude of thrombin formation.\(^{581,582}\)

Factor X (Stuart Factor)

The zymogen factor X, or Stuart factor, is a vitamin K-dependent glycoprotein that is synthesized in the liver.\(^{560,583}\) It circulates in plasma at a mean concentration of 10 µg/ml or 170 nmol/L, and has a \(t_{1/2}\) of approximately 1.5 days (Table 18.1). In the Leiden Thrombophilia study, a population-based case control study on venous thrombosis, high levels of factor X alone predicted the risk of thrombosis but were not a risk factor for venous thrombosis when the levels of other vitamin K-dependent proteins were taken into account.\(^{586}\)

Factor X deficiency is a rare autosomal recessive disorder with varied phenotype and genotype. Homozygous factor X deficiency has an incidence of 1 in 1 million in the general population.\(^{587,588}\) Whereas heterozygotes are often clinically asymptomatic, the most severely affected homozygous individuals exhibit extensive bleeding early in life. Multiple factor X deficiency cases have been identified, and the gene defects have been elucidated in individuals with bleeding tendencies\(^{589,590,591,592}\) and \(^{593,594,595}\) and in an individual without a bleeding tendency,\(^{596}\) although mutations within the
catalytic domain are not always consistent with the phenotype of the individual.\textsuperscript{597} As with most deficiencies, the level of factor X expression is indicative of the bleeding response. When factor X levels are approximately 1%, bleeding can include hemarthrosis, soft tissue hemorrhage, and menorrhagia. With functional levels above 15%, bleeding is infrequent and usually mild. Acquired factor X deficiency is rare and is usually associated with light chain amyloidosis.\textsuperscript{598,599} and \textsuperscript{600} In amyloidosis, factor X is thought to be adsorbed onto extracellular amyloid fibrils, thereby decreasing the circulating factor X level and increasing bleeding. In these cases, replacement with factor X products is not as effective a therapy for deficiency because it is continually removed from plasma. Treatment of bleeding from factor X deficiency can involve the administration of fresh frozen plasma or prothrombin complex concentrates. No sure venous or arterial thrombotic event has ever been reported in congenital factor X deficiency.\textsuperscript{601}

The importance of factor X generation is illustrated by transgenic mice with a total deficiency of factor X. Homozygous deficiency (\textsuperscript{-/-}) results in partial embryonic lethality with signs of massive bleeding.\textsuperscript{453,603} Those mice that survive to term die within 5 to 20 days from fatal neonatal bleeding. The lethality of factor X knockout genotype in mice supports the significance of factor X function in hemostasis.

Gene Structure and Expression

The gene for factor X spans 27 kb, is located on chromosome 13 bands q34-qter, and yields a 1.5-kb mRNA\textsuperscript{455,603,604} and \textsuperscript{605} (Table 18.2). The gene for factor X is located near the gene for factor VII. Studies to elucidate the liver-specific expression of factor X have included the characterization of the human\textsuperscript{606} and murine factor X promoter.\textsuperscript{607} Using a hepatoma cell line that expresses factor X, the first 279 bp of the 5'-flanking sequence upstream from the first AUG proved to be sufficient to confer maximal promoter activity.\textsuperscript{606} From mutagenesis studies, two protein-binding sites within the 279-bp fragment were identified that are critical for promoter activity: CCAAT (at -120 to -116) and ACTTTG (at -56 to -51).\textsuperscript{606} Factor X also lacks a typical TATA box. In the human factor X promoter, the binding proteins HNF-4 (at -123),\textsuperscript{608} nuclear factor-Y (at -128),\textsuperscript{609} GATA-4 (GATA element at -96),\textsuperscript{609} and the Sp family of transcription factors I footprinted sites (at -165 and -195)\textsuperscript{609} have been identified as playing crucial roles in modulating the activity of the proximal promoter of factor X.

Biochemistry

Human factor X is a vitamin K-dependent glycoprotein of molecular weight 59,000 that circulates in plasma (10 µg/ml or 170 nmol/L) as a two-chain molecule composed of a disulfide-linked light chain \((M_r = 16,500)\) and heavy chain \((M_r = 42,000)\) \textsuperscript{606,611} (Table 18.1). Its structure contains an \(\text{NH}_2\)-terminal light chain consisting of a Gla domain \((11 \text{ Gla residues})\), with a single \(\beta\)-hydroxy aspartic acid residue, and two EGF-like domains \((\text{EGF-1 and EGF-2})\) \textsuperscript{Fig. 18.3}. The COOH-terminal heavy chain consists of an activation peptide region and a catalytic \((\text{serine protease})\) domain. Most of the carbohydrate moieties (\(\sim 15\%\)) are located within the heavy chain \textsuperscript{584} in the activation peptide domain.\textsuperscript{584} \(\text{Ca}^{2+}\) binding in the first EGF domain has been proposed to enhance the structural rigidity of the factor X molecule.\textsuperscript{408} Numerous structures of factor Xa (des Gla)\textsuperscript{618} have been deposited in the Protein Data Bank, the majority of which are bound to inhibitors and have provided insight into specificity and function.\textsuperscript{613}

Activation

Factor X is activated to its serine protease form factor Xa through a cleavage of the activation peptide at \(\text{Arg}^{194}\text{-ile}^{195}\) \((\text{Arg}^{52}\text{-ile}^{53} \text{ of the heavy chain})\) \textsuperscript{Fig. 18.3}. A 52-amino acid activation peptide is released with a relative molecular mass of 12,000. The resulting catalytic serine protease, factor Xa, has a molecular weight of 48,000 and is composed of a light chain \((M_r = 18,000)\) and a disulfide-linked heavy chain \((M_r = 30,000)\). The activation of factor X is catalyzed by factor VIIa-tissue factor \((\text{the extrinsic tenase complex})\)\textsuperscript{485} and factor IXa-factor VIIIa \((\text{the intrinsic tenase complex})\).\textsuperscript{614} In vitro studies have determined that factor Xa has to be bound to the membrane before activation.\textsuperscript{45,615}

Function

The main function of factor Xa is to form the prothrombinase complex \((\text{factor Xa-factor Va-membrane-Ca}^{2+})\) \textsuperscript{Fig. 18.4}. Factor Xa

P.452

is the serine protease enzyme in the prothrombinase complex that catalytically activates prothrombin to thrombin, the key enzyme in blood coagulation. The prothrombinase complex activates prothrombin to thrombin 10\(^5\)-fold faster than factor Xa alone.\textsuperscript{42} Factor Xa is a unique regulatory enzyme in that it is formed through both the extrinsic tenase and intrinsic tenase complexes (as mentioned in the section on Factor IX). During the initial stages of the hemostatic event, low levels of both factor Xa and factor IXa are generated. Once generated, the limited amounts of factor Xa produced by extrinsic tenase bind to available membrane sites and convert picomolar amounts of prothrombin to thrombin.\textsuperscript{37,616,617}
commonly identified genetic risk factors for thrombosis. An additional polymorphism, A19911G, in the prothrombin gene associated with elevated prothrombin levels and an increased risk for venous thrombosis. One common polymorphism is the G20210A transition in the 3′-untranslated region of the promoter. This mutation has been linked to familial thrombosis. The G20210A polymorphism of the prothrombin gene has been associated with elevated prothrombin levels and an increased risk for venous thrombosis. It is one of the most commonly identified genetic risk factors for thrombosis. An additional polymorphism, A19911G, in the prothrombin gene...
has been identified that can modulate the risk of the G20210A polymorphism in developing deep vein thrombosis. Several reviews have been written on the influence of genetic polymorphisms (including the prothrombin G20210A) and the laboratory diagnosis of thrombophilia.

Biochemistry

Initial observations about the structure/function relationship of the prothrombin molecule came about from the partial primary structures of bovine and human prothrombins. Subsequently, the complete primary structure of human prethrombin 2 (residues 272 to 579), which is the precursor of thrombin, was determined. Finally, the primary structure for bovine prothrombin and human prothrombin were deduced from isolated cDNAs. The elucidated structure of human prothrombin is characterized by an NH2-terminal Gla domain (residues 1 to 40 with 10 Gla residues), followed by two kringle domains (kringle 1, residues 65 to 143; kringle 2, residues 170 to 248) and the serine protease precursor domain (residues 272 to 579). Human prothrombin has three N-linked sugar chains—one in the first kringle domain and one in the catalytic domain.

The first x-ray crystal structure of a blood coagulation protein fragment, bovine prothrombin kringle 1, was determined in Tulinsky’s laboratory in 1986. Kringles have been identified as common motifs in many plasma proteins, including prothrombin. The kringle 1 domain contains four cysteine residues participating in two disulfide bonds. The role of the kringle 1 domain of prothrombin is still unclear, but it has been suggested that it is involved with the interaction of prothrombin and factor Va in the prothrombinase complex. The NH2-terminal Gla domain and the first kringle domain together are referred to as prothrombin fragment 1. The kringle 2 domain of human prothrombin, located in prothrombin fragment 2 (residues 156 to 271), is similar in sequence and presumably in structure. The kringle 2 domain also binds Ca2+ and appears to be the primary region in prothrombin that mediates the interaction of the prothrombin molecule with factor Va in the prothrombinase complex. This latter interaction has been suggested to initiate conformational changes that make reaction sites accessible for enzymatic cleavage of prothrombin. The sequence of the enzyme α-thrombin is contained within prethrombin 2 (residues 272 to 579).

Activation

Prothrombin is activated to the procoagulant α-thrombin by two cleavages: one at Arg271-Thr272 and another at Arg320-Ile321 by the prothrombinase complex (factor Xa-factor Va-phospholipid membrane-Ca2+). Membrane-bound factor Va serves as the receptor for factor Xa, the catalytic serine protease. The rate of α-thrombin generation by prothrombinase is 3 x 105-fold faster than the rate for factor Xa alone at potential physiologic concentrations of the proteins. Recent studies have indicated that the order of these two cleavages differs depending on the cell surface upon which prothrombinase is assembled.

On synthetic phospholipid vesicles, the activation of prothrombin by prothrombinase proceeds through an initial cleavage of prothrombin at Arg320-Ile321, giving rise to meizothrombin, a twochain disulfide-linked molecule (Fig. 18.8; pathway A, cleavage at 1). The probable mechanism involves meizothrombin dissociating from prothrombinase with a subsequent rebinding step and conversion to α-thrombin. Meizothrombin expresses some of the activities of α-thrombin. However, meizothrombin has impaired fibrinogen clotting ability compared to α-thrombin. Meizothrombin is subsequently cleaved at Arg271-Thr272 (Fig. 18.8; pathway A, cleavage at 2), yielding the NH2-terminal half of the molecule, consisting of the Gla domain and two kringle domains (prothrombin fragment 1.2: residues 1 to 271) and α-thrombin. α-Thrombin consists of an NH2-terminal 49-residue A-chain (residues 272 to 320) disulfide-linked to a COOH-terminal 259-residue B-chain (residues 321 to 579) containing the catalytic triad.
FIGURE 18.8. Schematic representation of the pathways for prothrombin activation. The generation of α-thrombin from its zymogen precursor prothrombin by factor Xa involves the cleavage of two peptide bonds. The reaction begins either via step 1 (cleavage at R$^{320}$-I$^{321}$) or step 2 (cleavage at R$^{271}$-T$^{272}$). Cleavage at 1 (R$^{320}$), pathway A, produces meizothrombin. Meizothrombin is composed of a prothrombin fragment consisting of fragment 1 (F1, residues 1 to 155: Gla domain + kringles 1), fragment 2 (F2, residues 156 to 271: kringles 2), and residues 272 to 320 (A-chain) linked by a disulfide bond to the catalytic domain (B-chain). Subsequent cleavage at R$^{271}$ (cleavage at 2, pathway A) generates prothrombin fragment 1.2 (F1 and F2) and the disulfide-linked heterodimer α-thrombin (A- and B-chains). In pathway B cleavage occurs first at 2 (R$^{271}$), generating prothrombin fragment 1.2 (F1 and F2) and prethrombin-2. Subsequent cleavage at R$^{320}$ produces the A- and B-chains of α-thrombin.

An alternative cleavage pathway occurs when factor Xa alone acts on prothrombin or when prothrombinase is assembled on washed platelets. In the presence of factor Xa, Ca$^{2+}$, and an appropriate membrane surface, the initial cleavage occurs at Arg$^{271}$-Thr$^{272}$ and gives rise to prothrombin fragment 1.2 and prethrombin-2 (Fig. 18.8; pathway B, cleavage at 2). Cleavage at Arg$^{320}$ in prethrombin-2 (Fig. 18.8; pathway B, cleavage at 2) yields α-thrombin. In contrast to the meizothrombin pathway, the prethrombin 2 intermediate appears not to dissociate from prothrombinase. Prothrombin fragment 1.2 remains noncovalently associated with α-thrombin. In vitro, α-thrombin is associated (Kd = 10 nmol/L) with prothrombin fragment 2, or the latter's precursor prothrombin fragment 1.2, or both. In contrast to other vitamin K-dependent proteins, the phospholipid-binding region is no longer covalently attached to the serine protease domain after prothrombin conversion to thrombin.

Thrombin and meizothrombin catalyze cleavage at Arg$^{155}$ of prothrombin, yielding a truncated molecule called prethrombin 1 (residues 156 to 579) that lacks the Gla domain. Thrombin can also cleave at Arg$^{284}$, yielding a truncated α-thrombin species (residues 284 to 579), which is the form of thrombin found in commercial preparations.

The membrane surface that supports the prothrombinase complex in vivo has traditionally been assumed to be primarily provided by platelets, but can also be provided by other circulating blood cells, such as monocytes and lymphocytes, and by vascular endothelial cells. Since prothrombin activation on platelets proceeds through the prothrombin 2 pathway.
and meizothrombin formation has been observed in clotting blood,\textsuperscript{671,679} it appears that prothrombin activation in blood involve both pathways. Prothrombin activation through the meizothrombin pathway has been reported to occur on the subpopulation of red blood cells that express phosphatidylserine on their surface.\textsuperscript{671}

P.454

Function

\(\alpha\)-Thrombin can be considered the central enzyme in blood coagulation in that it contributes to reactions at all levels, allowing for the overall maintenance of vascular fidelity. Its main role is in stemming blood loss through fibrin clot formation.\textsuperscript{680} The series of events that leads up to and occurs after fibrin formation also involves protein activation by \(\alpha\)-thrombin. This includes activation of platelets,\textsuperscript{681} factor VII,\textsuperscript{6} factor V,\textsuperscript{682} factor VIII,\textsuperscript{683} factor XI,\textsuperscript{7} and factor XIII.\textsuperscript{17} \(\alpha\)-Thrombin activity also extends from the procoagulant process to anticoagulation and suppression of fibrinolytic reactions. For example, \(\alpha\)-thrombin-thrombomodulin activates the anticoagulant protein, protein C\textsuperscript{684} and the antifibrinolytic protein, TAFI.\textsuperscript{36}

Relatively minute concentrations of thrombin are generated during the initiation phase of blood coagulation, primarily due to the factor Xa generated from the extrinsic tenase complex (Fig. 18.7). These levels of thrombin, in the range of 0.5 to 2.0 nmol/L, have been shown to be sufficient for the initiation of rapid activation of platelets, factor XIII and factor V, and fibrin formation in an ex vivo whole blood model.\textsuperscript{569} All of these processes occur before the major burst of thrombin generation during the propagation phase of the reaction.

\(\alpha\)-Thrombin’s role continues into the tissue repair and remodeling phase that is necessary to regenerate damaged vascular tissue. \(\alpha\)-Thrombin is a potent mitogen\textsuperscript{685,686} and stimulates cell division in macrophages,\textsuperscript{687} smooth muscle cells,\textsuperscript{688} and endothelial cells.\textsuperscript{689} \(\alpha\)-Thrombin also appears to be involved in the growth and metastasis of tumors by promoting angiogenesis,\textsuperscript{690,691} possibly through vascular endothelial growth factor.\textsuperscript{692} The roles that thrombin plays in coagulation and beyond are outlined in a recent review.\textsuperscript{693}

Regulation

In vivo, the activity of the prothrombinase complex has to be tightly regulated to ensure that adequate but limited levels of \(\alpha\)-thrombin are generated. If too much \(\alpha\)-thrombin is continuously generated, localized clot formation can lead to occlusion or systemic thrombosis. Equally, if too little \(\alpha\)-thrombin is generated, hemorrhagic conditions result. Two reaction systems, one covalent and one proteolytic, regulate \(\alpha\)-thrombin generation. Antithrombin-heparin (or heparan sulfate) is a potent inhibitor of blood coagulation and inhibits both \(\alpha\)-thrombin and factor Xa via covalent interactions.\textsuperscript{594,695} \(\alpha\)-Thrombin also participates in its own downregulation by binding to thrombomodulin on the vascular cell surface and converting protein C to APC. This anticoagulant serine protease then cleaves factors Va and Vila. These cofactors for the vitamin K-dependent complexes are no longer available for ongoing reactions, thereby eliminating \(\alpha\)-thrombin generation. In ex vivo models of blood coagulation, prothrombin levels and antithrombin appear to have the most significant impact on \(\alpha\)-thrombin generation.\textsuperscript{696} Increased levels of antithrombin reduce \(\alpha\)-thrombin generation by inhibiting \(\alpha\)-thrombin activity and preventing positive feedback.\textsuperscript{696} Decreased levels of antithrombin allow for higher levels of prothrombin activation and prolongation of \(\alpha\)-thrombin generation.\textsuperscript{696}

PROCOAGULANT PROTEINS: PROCOAGULANT COFACTOR PROTEINS

There are two categories of cofactor proteins: the plasma-derived soluble procoagulant procofactors factors V and VIII (and their circulating carrier von Willebrand factor [vWF]), and the cell-associated coagulation cofactor, tissue factor. Factors V and VIII are highly homologous (40% identity), sharing many structural and functional similarities. Tissue factor is a single-chain transmembrane protein that is composed of extracellular, transmembrane, and cytoplasmic domains.

Tissue Factor (Tissue Thromboplastin, CD142, Coagulation Factor III)

Tissue factor, also known as tissue thromboplastin, CD142, and coagulation factor III, is a transmembrane protein that functions as a nonenzymatic cofactor for factor VIIa in the extrinsic tenase complex. In the absence of injury or stimulus, tissue factor is not ordinarily expressed on cellular surfaces in direct contact with circulating blood. Presentation of tissue factor to the circulation is the event that triggers the procoagulant primary pathway of coagulation (Fig. 18.1). There are no known mutations or deficiencies of human tissue factor, leading to the speculation that tissue factor is essential for life. In mice, inactivation of the tissue factor gene to create homozygous tissue factor-null mice proves to be lethal during embryonic development.\textsuperscript{697,698,699,700}
Gene Structure and Expression

The tissue factor gene is located on chromosome 1p21-22\textsuperscript{701,702} and spans 12.4 kb (Table 18.2). The gene contains five introns and six exons.\textsuperscript{703} Tissue factor expression can be induced in a number of cultured cell types. Fibroblasts express tissue factor on exposure to serum or mitogenic cytokines,\textsuperscript{704,705} as do vascular smooth muscle cells and keratinocytes.\textsuperscript{706,707} Monocytes and monocytes isolated from peripheral blood also express tissue factor when stimulated by bacterial endotoxin or other proinflammatory agents.\textsuperscript{706,707} The presence of these cells may be associated with DIC.\textsuperscript{708} In vitro, certain leukemic cell lines constitutively express low levels of tissue factor.\textsuperscript{709,710} and 711 Tissue factor expression by circulating and nonvascular cells plays key roles in cancer, sepsis, and perhaps atherosclerotic plaque formation.\textsuperscript{56,712,713,714,715} and 716 However, tissue factor in the subendothelial cell layer is proposed to trigger coagulation on exposure to the circulation. Cultured vascular endothelial cells express tissue factor on stimulation by IL-1, tumor necrosis factor (TNF)-\textalpha, and bacterial endotoxin.\textsuperscript{706,707} In vivo, there is little or no detectable tissue factor expression on unstimulated endothelial cells. Certain conditions such as sepsis, placental villitis and graft rejection induce tissue factor expression on endothelial cells in vivo.\textsuperscript{708,717,718} and 719 The mechanism governing tissue factor expression under nonpathologic conditions is presently unknown. Studies of transcriptional control of tissue factor expression in various cell lines have demonstrated that Sp1 sites are important in basal transcription of the tissue factor gene. EGR-1, activation peptide-1, and NF-\kappa\textbeta sites mediate tissue factor expression in response to pathologic stimulation.\textsuperscript{699,720,721,722,723} and 724

Biochemistry

Tissue factor is a single-chain glycoprotein (M\textsubscript{r} = 44,000)\textsuperscript{725} of 261 or 263 amino acids (Table 18.1). It is synthesized with a signal peptide of 32 amino acids. The variability in protein size is due to heterogeneity at the NH\textsubscript{2}-terminus.\textsuperscript{701,726,727} Tissue factor is a member of the class 2 cytokine receptor superfamily\textsuperscript{728} and a type I integral membrane protein. The type I designation refers to the location of the NH\textsubscript{2}- and COOH-terminus. The NH\textsubscript{2}-terminus of tissue factor (residues 1 to 219) is extracellular, whereas the COOH-terminus of the protein is intracellular (residues 243 to 263). Tissue factor also contains a hydrophobic membrane-spanning domain (residues 220 to 242) (Fig. 18.9). This domain appears to function solely to anchor tissue factor in the membrane.\textsuperscript{729} The NH\textsubscript{2}-terminal domain of tissue factor is composed of two fibronectin type III domains and is glycosylated at Asn\textsuperscript{11}, Asn\textsuperscript{124}, and Asn\textsuperscript{137,730} X-ray crystal structures of tissue factor show that the two fibronectin type III domains are joined at an angle of approximately 120\degree.\textsuperscript{731,732,733,734,735} and 736 There are also two disulfide bonds (Cys\textsuperscript{49}-Cys\textsuperscript{57}) in the NH\textsubscript{2}-terminal extracellular region.\textsuperscript{737} At least one of the disulfide bonds is required for tissue factor activity. Early studies suggested that glycosylation does not appear to play a key role in determining protein function\textsuperscript{730,738,739}; however, more recent work indicates that glycosylation\textsuperscript{740} and other posttranslational modifications\textsuperscript{741,742} play important roles in modulating tissue factor biological activities. The COOH-terminal cytoplasmic domain is quite short and contains a single cysteine residue (Cys\textsuperscript{245}) that is linked to a palmitate or stearate fatty acyl chain via a thioester bond.\textsuperscript{737} The COOH-terminus also contains a serine that may be phosphorylated.\textsuperscript{743} The function of the COOH-terminus and the importance of these two modifications are not clear, as deletion of this domain has no significant effect on tissue factor procoagulant activity.\textsuperscript{729}

P.456

and Cys\textsuperscript{186}-Cys\textsuperscript{209} in the NH\textsubscript{2}-terminal extracellular region.\textsuperscript{737} At least one of the disulfide bonds is required for tissue factor activity. Early studies suggested that glycosylation does not appear to play a key role in determining protein function\textsuperscript{730,738,739}; however, more recent work indicates that glycosylation\textsuperscript{740} and other posttranslational modifications\textsuperscript{741,742} play important roles in modulating tissue factor biological activities. The COOH-terminal cytoplasmic domain is quite short and contains a single cysteine residue (Cys\textsuperscript{245}) that is linked to a palmitate or stearate fatty acyl chain via a thioester bond.\textsuperscript{737} The COOH-terminus also contains a serine that may be phosphorylated.\textsuperscript{743} The function of the COOH-terminus and the importance of these two modifications are not clear, as deletion of this domain has no significant effect on tissue factor procoagulant activity.\textsuperscript{729}
FIGURE 18.9. Transmembrane cofactors. A: Schematics of tissue factor and thrombomodulin. Tissue factor is composed of an extracellular domain (residues 1 to 219), a transmembrane domain (residues 220 to 242), and a cytoplasmic domain (residues 243 to 263). Two disulfide bonds (S-S) and the sites of the three carbohydrate moieties (CHO) are identified by amino acid residue. One cysteine (C<sup>245</sup>) contains a thiol ester linkage to a fatty acid. Tissue factor is the cofactor for factor VIIa in the extrinsic tenase complex and is exposed on the subendothelial surface after injury. Thrombomodulin is an endothelial cell surface glycoprotein composed of five distinct domains. The domain structures include a lectinlike domain (residues 6 to 149), a domain containing six epidermal growth factor (EGF)-like regions (residues 227 to 462), a small
extracellular domain rich in threonine and serine residues (two residues, S⁴⁷² and S⁴⁷⁴, have been identified as sites of chondroitin sulfate adducts), a membrane-spanning region (residues 499 to 521), and a cytoplasmic tail (residues 522 to 557). There are nine known glycosylation sites (CHO) on the thrombomodulin molecule. Thrombomodulin functions as the cofactor in the protein Case complex and assists in the generation of activated protein C. B: Structural ribbon diagram of tissue factor (blue) (PDB-ID: 2HFT)³³³ and tissue factor and factor VIIa (green) (PDB-ID: 1DAN).⁴⁷¹ The tissue factor carbohydrate side chains have been added to the structure.⁷⁴⁰

Function

The nonenzymatic cofactor tissue factor can bind either factor VII or factor VIIa in a Ca²⁺-dependent manner and form a highaffinity 1:1 complex. Once bound to tissue factor, the zymogen factor VII is rapidly converted to an active enzyme via limited proteolysis.⁷⁴⁵ The tissue factor-factor VIIa, or extrinsic tenase complex, activates factors IX and X. When tissue factor is exposed or expressed, or both, subsequent to vascular perturbation, low levels of circulating factor VIIa bind to tissue factor, and the extrinsic tenase triggers the procoagulant cascade. Factor VII bound to tissue factor is converted to factor VIIa, augmenting factors IXa and Xa generation. The primary role of the complex is to provide factor IXa and low levels of factor Xa, which serve to promote factor IXa production⁶¹,⁶² and ⁶³,⁴⁸⁷ and to directly catalyze the conversion of trace amounts of prothrombin to thrombin.

In the absence of tissue factor, factor VIIa is relatively inert. Once bound to tissue factor, the catalytic activity of factor VIIa is increased 20- to 100-fold with low-molecular-weight substrates⁷⁴⁶,⁷⁴⁵,⁷⁴⁶ and ⁷⁴⁷ and approximately 10⁸-fold with its macromolecular substrates factors X and IX.⁷⁴⁵,⁷⁴⁷,⁷⁴⁸ Tissue factor alters the active site of factor VIIa, thus functioning as an allosteric activator of the enzyme.

Although the cofactor is necessary for enzymatic activity, complex formation between tissue factor and factor VIIa does not share the same requirements for an anionic phospholipid membrane surface as the other procoagulant complexes. The membrane dependency of the extrinsic tenase complex arises from membrane-mediated substrate delivery. Both factors X and IX bind to anionic membrane surfaces for efficient two-dimensional transfer to the extrinsic tenase. An additional role for tissue factor-factor VIIa beyond its activation of the coagulation cascade involves triggering signaling through the G-protein-coupled, protease-activated receptor 2, which is relevant to inflammation and angiogenesis.⁷⁴⁹,⁷⁵⁰

Regulation

Tissue factor activity is regulated by controlling its presentation. The common accepted source of functional tissue factor is through exposure of the subendothelium on vascular damage. However, there is controversy regarding the source and presentation of active tissue factor and whether functional tissue factor circulates in blood in healthy individuals or only in those with pathologies.⁵⁷⁵,⁷⁵³,⁷⁵⁴ Tissue factor function has been reported to be under the control of an allosteric disulfide bond.⁷⁵⁰,⁷⁵⁵,⁷⁵⁶ Once the tissue factor-factor VIIa complex is formed in the vicinity of an injury, the extrinsic tenase activity is then modulated by TFPI and antithrombin reduction of enzymatic activity.

Factor VIII (Antihemophilic Factor, Factor VIII:Antigen, Factor VIII:Coagulant)

Factor VIII, or antihemophilic factor, is a nonenzymatic procofactor that circulates in plasma in complex with the large multimeric protein vWF. Initially, factor VIII and vWF were thought to be a single entity, and early reports on factor VIII were actually measuring facets of vWF structure and function. The factor VIII protein is designated as factor VIII:Ag (antigen; VIII:Ag is vWF), and its procoagulant function is designated factor VIII:C (coagulant).⁷⁵⁷ Factor VIII circulates at an average concentration of 0.2 µg/ml (0.7 nmol/L; Table 18.1). The ratio of factor VIII to vWF is fairly constant and in the range of 1 molecule of factor VIII to 50 to 100 molecules of vWF monomeric units.⁷⁵⁸,⁷⁵⁹ vWF acts to regulate the plasma concentration of factor VIII. 1-Deamino-8-d-arginine vasopressin administration elicits an increase in the plasma concentration of vWF and, in turn, increases the plasma level of factor VIII.⁷⁶⁰ vWF also stabilizes factor VIII in plasma. Factor VIII in complex with vWF has a plasma t½ of approximately 12 hours, whereas factor VIII alone undergoes rapid clearance and has a t½ of approximately 2 hours.⁷⁶¹,⁷⁶²,⁷⁶³ and ⁷⁶⁴ Deficiency of factor VIII, or hemophilia A, is a well-characterized bleeding disorder linked to the X chromosome. Hemophilia A, therefore, occurs almost exclusively in males and occurs at a frequency of 1:5,000 to 1:10,000 males. Females with one abnormal factor VIII gene are unaffected carriers. The severity of bleeding in hemophilia A patients is correlated with the level of functional factor VIII in plasma.⁷⁶⁵,⁷⁶⁶ Approximately 50% to 60% of hemophilia A cases are severe, with factor VIII coagulant activity < 1% of normal. Severe hemophilia A is manifested in frequent episodes of spontaneous bleeding into joints, muscles, and internal organs. Factor VIII coagulant activity in the range of 1% to 5% of normal (25% to 30% of patients) results in moderate hemophilia A. In the moderate form, abnormal bleeding is generally linked to any trauma, including minor injury. The remaining patients have 6% to 30% of normal factor VIII activity and exhibit mild hemophilia A. In the mild form, factor VIII deficiency results in bleeding events only subsequent to significant trauma or surgery.⁷⁶⁷
Gene Structure and Expression

The factor VIII gene has been mapped to the long arm of the X chromosome in band q28. The factor VIII gene is 186 kb in length and contains 25 introns and 26 exons. The liver and spleen are thought to be the primary sites of factor VIII biosynthesis, although factor VIII mRNA has been detected in other cell types as well.

Biochemistry

Human factor VIII has a relative molecular weight in the range of 280,000 (Table 18.1). The heterogeneity in molecular weight is due to proteolysis of the protein in circulation or processing, or both. It is a glycoprotein of 2,351 amino acids that is synthesized as a precursor molecule with a 19-amino acid signal peptide. The sequence of factor VIII is highly homologous to factor V. The procofactors factors VIII and V are organized into discrete structural domains. The NH₂-terminal heavy chains of both proteins contain the A1 and A2 domains (Fig. 18.10). The COOH-terminal light chains contain the A3, C1, and C2 domains. The heavy and light chains are separated by the B domain. The three A domains of factor VIII are homologous to each other and to the A domains of factor V and ceruloplasmin. The C domains of factor VIII are homologous to each other and to the C domains of factor V. The C domains are also homologous to milk fat globule protein and the A-, C-, and D-chains of discoidin. The B domain of factor VIII is not homologous to the factor V B domain, nor do the B domains of either protein share homology with any known proteins.

The factor VIII molecule is secreted as a two-chain heterodimer as a result of intracellular proteolysis at the B-A3 junction (Arg1649). Additional cleavages within the B-chain yield A1-A2-B fragments that are variable in length. The B domain (residues 741 to 1,649) contains 18 of the 25 potential N-linked glycosylation sites in factor VIII and is highly glycosylated. The murine factor VIII B-chain is also heavily glycosylated, suggesting that glycosylation of the B-chain may be important for protein expression or function, or both. The B domains of factors VIII and V are excised during activation of the proteins to generate the cofactor molecules factors VIIIa and Va.
FIGURE 18.10. Soluble cofactors. A: Domain structures of the soluble cofactors factor VIII and factor V. The disulfide loop structures of factor VIII and factor V defining the α, β, and γ loops are illustrated as bubbles. α-Thrombin (IIa), activated protein C (APC), factor Xa, and Russell viper venom (RVV) cleavage sites are shown with vertical arrows. The linear domain structures (A1-A2-A3-C1-C2) are illustrated with horizontal arrows bracketed by the beginning and ending amino acid number. The B regions (factor V, residues 710 to 1,545; factor VIII, residues 741 to 1,649) are represented by the crosshatched regions. Phosphorylation sites are illustrated by a P inscribed in a circle and the phosphoamino acid, serine (S) or threonine (T), illustrated above or below it. Free cysteine thiols are represented by SH and identified by residue number. B: Crystal structures. Bovine factor Va des-A2 (PDB-ID: 1SDD)865 and human factor VIIIa (PDB-ID: 2R7E).
Factor VIII shares homology with the copper ion (Cu\(^{+}\))-binding protein ceruloplasmin and contains a Cu\(^{+}\)-binding site in the A1 domain.\(^{790,792}\) This site is important for protein function. A similar Cu\(^{+}\)-binding site in the A3 domain does not appear to play a role in protein function.

Factor VIII also contains binding sites for vWF, anionic phospholipids, factor IXa, and, potentially, factor X. Factor VIII interaction with vWF requires the NH\(_2\)- and COOH-termini of the factor VIII light chain (A3, C1, and C2 domains), although a specific vWF-binding site has been identified at residues 1,673 to 1,684 on the light chain.\(^{792,793,794}\) The vWF-binding site is removed from the factor VIII protein by \(\alpha\)-thrombin cleavage at Arg\(^{1689}\). A phospholipid-binding domain is located on the factor VIII C2 domain at residues 2,303 to 2,332.\(^{795}\) High-affinity factor IXa binding is mediated by the light chain of the factor VIII molecule. The A3 domain contains a high-affinity site for factor IXa localized at residues Glu\(^{1811}\) to Lys\(^{1818}\).\(^{796,797}\) Residues 552 to 565 in the A2 domain of the factor VIII heavy chain may also play a role in factor VIII interaction with factor IXa.\(^{798,799}\) Mutations within this region have been documented in the hemophilia A mutation database.\(^{800}\) Specifically, Ser558Phe, Val559Ala, Asp560Ala, and Gln565Arg have been described as CRM\(^*\) with defective activity resulting in mild hemophilia A. These residues have been shown to be essential for the catalytic efficiency of the factor VIIIa-factor IXa complex while not affecting the binding affinity between the two species.\(^{802}\) A model of factor VIII based on the x-ray crystal structure of ceruloplasmin has been used to examine structure/function relationships in the factor VIII molecule.\(^{803}\) This approach has recently been expanded upon by using the x-ray structure of the C2 domain to generate 10 hypothetical models of the intrinsic tenase complex.\(^{804}\) Based on homology between factor VIII and ceruloplasmin, the factor IXa binding sites in the A2 and A3 domains are likely located in close proximity on the same side of the factor VIII molecule. A factor X binding site may exist on the COOH-terminus of the factor VIII A1 domain.\(^{806,807}\)

Factor VIII also contains several tyrosine residues modified by the addition of sulfate.\(^{808}\) The tyrosine sulfate residues enhance \(\alpha\)-thrombin cleavage of the procofactor.\(^{809}\) In addition, factor VIII contains biantennary complex-type sugar chains with blood group A or H, or both, determinants.\(^{810}\)

**Function**

The procofactor factor VIII is activated by \(\alpha\)-thrombin to generate the cofactor factor VIIIa. Activation by \(\alpha\)-thrombin involves cleavages at Arg\(^{372}\) (the A1-A2 junction), Arg\(^{760}\) (the A2-B junction), and Arg\(^{1689}\) in the light chain (Fig. 18.10). The resulting molecule contains three separate polypeptide chains: A light-chain region (A3-C1-C2) bound to the NH\(_2\) region of the heavy chain (A1) in a Ca\(^{2+}\)-dependent manner and the noncovalently associated A2 region of the heavy chain. Once
formed, the cofactor factor VIIIa binds its serine protease enzyme factor IXa to form the Ca$$^{2+}$$- and membrane-dependent complex, the intrinsic tenase (Fig. 18.4). This complex is homologous to the prothrombinase complex. The intrinsic tenase complex catalyzes factor X conversion to factor Xa at a rate several orders of magnitude greater than the enzyme factor IXa alone.\textsuperscript{811,812} Factor Xa generated via the intrinsic tenase complex (factor IXa-factor VIIIa-Ca$$^{2+}$$-membrane) yields the propagation phase of α-thrombin generation by raising the factor Xa concentration approximately 100-fold over that achieved by the extrinsic tenase complex (Fig. 18.7B).\textsuperscript{567} Without formation of the intrinsic complex, as occurs in a situation like that of hemophilia A or B, factor Xa is not generated at a level sufficient to produce the propagation phase of α-thrombin generation (Fig. 18.7A).

Like the prothrombinase complex, the cofactor (factor VIIIa) interaction with the enzyme (factor IXa) in the presence of divalent cations and an anionic phospholipid surface is a high-affinity interaction with a $$K_d$$ of 2 nmol/L. The interaction of factor IXa with phospholipid in the absence of its cofactor is of approximately 100-fold lower affinity.\textsuperscript{812,813}

### Regulation

Factor VIIIa function is primarily regulated by dissociation of a fragment (residues 373 to 740) containing the A2 subunit from the heterotrimer. Once the A2 subunit is displaced, factor VIIIa loses all cofactor function. Dissociation is spontaneous and occurs rapidly under physiologic conditions. Factor IXa stabilizes factor VIIIa, delaying dissociation of the heterotrimer and prolonging the transient activity of factor VIIIa.\textsuperscript{814,815} Factor VIIIa is also regulated by limited proteolysis. Factor IXa cleaves the factor VIIIa A1 subunit at Arg\textsuperscript{336} and eliminates factor VIIIa function.\textsuperscript{815,816} In addition to factor IXa, the A1 subunit of factor VIIIa is cleaved by factor Xa and α-thrombin.\textsuperscript{11,808,815,818} APC is a key anticoagulant enzyme that likewise cleaves the A1 subunit at Arg\textsuperscript{336}. APC also cleaves the factor VIIIa A2 subunit at Arg\textsuperscript{562,11,819} The APC cleavages occur sequentially with the A1 cleavage first and the A2 cleavage second.\textsuperscript{820} Factor IXa protects factor VIIIa from APC cleavage at Arg\textsuperscript{562}; however, protein S blocks the protective effect.\textsuperscript{821}

Although factor VIIIa is proteolytically inactivated by a number of enzymes, spontaneous dissociation is the key regulator of cofactor function.

### Factor V (Labile Factor)

Factor V was first recognized as an unstable plasma component necessary for the generation of α-thrombin.\textsuperscript{27} Factor V is a large single-chain glycoprotein that circulates in plasma at an average concentration of 6.6 µg/ml (20 nmol/L) (Table 18.1). Factor V is also contained in the α-granules of human platelets, with approximately 18% to 25% of the total factor V present in platelets.\textsuperscript{822} The identification, role in coagulation, and overall importance of factor V in hemostasis has been discussed in recent reviews.\textsuperscript{823,824} and 825

Congenital factor V deficiency, or parahemophilia, is an extremely rare disorder inherited in an autosomal recessive manner. Patients can exhibit severe bleeding diatheses. Although complete lack of factor V in humans does not appear to be lethal, factor V-deficient mice experience fatal hemorrhage in utero.\textsuperscript{826} Combined deficiencies of factors V and VIII have also been observed. Interestingly, combined cofactor deficiencies occur more commonly than factor V deficiency alone.\textsuperscript{827,828} Recently, the gene for ERGIC-53, a calcium-dependent lectin that serves as a glycoprotein-sorting receptor between the endoplasmic reticulum and the Golgi complex, has been linked to combined factors V and VIII deficiency.\textsuperscript{829,830} Mutations in this gene in patients with combined hemophilia have been described. Factor V deficiency becomes even more complex when platelet factor V is taken into consideration. Patients have been identified with normal functional levels of plasma factor V, but deficiencies of platelet factor V that result in bleeding disorders.\textsuperscript{822,831,832} and 833 Lack of platelet α-granules and their contents in storage pool disorders leads to deficiency of platelet factor V.\textsuperscript{831,832} Factor V$$^{\text{defunct}}$$ is an autosomal dominant bleeding disorder characterized by mild thrombocytopenia, normal levels of plasma factor V, and degraded platelet factor V with very low activity.\textsuperscript{822,833} A database on factor V mutation\textsuperscript{834} has been compiled by Dr. Hans L. Vos (Hemostasis and Thrombosis Research Center, Leiden University Medical Center, Leiden, The Netherlands; e-mail: h.l.vos@lumc.nl) and is available upon request.

### Gene Structure and Expression

The human factor V gene is located on chromosome 1 bands q21-q25\textsuperscript{835} (Table 18.2). The gene spans approximately 80 kb and consists of 24 introns and 25 exons. Transcription and processing yield an mRNA species of 6.8 kb. The intron-exon structure of the factors V and VIII genes are quite similar, and the genes likely evolved from a common ancestor. The liver appears to be the primary site of factor V biosynthesis.\textsuperscript{782,836,837} While human megakaryocytes express factor V,\textsuperscript{838,839} and platelet factor V is likely derived from circulating liver-derived plasma factor V\textsuperscript{841,842,843} and 844; however, the source of
platelet factor V has not been definitively determined. Bovine aortic endothelial cells and vascular smooth muscle cells also have been reported to express factor V.

Biochemistry

Human factor V (M_r = 330,000) and is a single-chain glycoprotein of 2,196 amino acids derived from a precursor molecule with a signal peptide (Table 18.1 and Fig. 18.10). Factor V consists of an NH_2-terminal heavy chain (residues 1 to 709: A1-A2 domains), a central B domain (residues 710 to 1,545), and a COOH-terminal light chain (residues 1,546 to 2,196: A3-C1-C2 domains). The A domains are homologous to those found in factor VIII and plasma ceruloplasmin; the C domains are homologous to the slime mold protein discoidin. Like factor VIII and ceruloplasmin, factor V is also a copper-binding protein.

Factor V undergoes extensive posttranslational modification, including phosphorylation, sulfation, glycosylation, and formation of mixed disulfides between its five free cysteine residues and circulating thiols like cysteine and homocysteine. Phosphorylation occurs at sites in the heavy chain, B region, and light chain. Phosphorylation at Ser affects the rate of inactivation of factor Va by APC. Factor V is sulfated at a number of sites in the heavy chain (Tyr, Tyr, and Tyr), the B region (Tyr, Tyr, and Tyr) and the light chain (Tyr). The sulfation status of factor V has been related to its function. Carbohydrate accounts for 13% to 25% of the mass of factor V. The heavy chain has nine potential N-linked glycosylation sites. In the B region, 25 asparagine residues are candidates for modification with carbohydrate; carbohydrate accounts for approximately 50% of the mass of the B region. The light chain of factor V has three N-linked glycosylation sites. Differential glycosylation of Asn in the C2 domain is reported to be responsible for the factor V1 and factor V2 variants observed in plasma. The two variants have slightly different molecular masses and charges. Factors Va1 and Va2 are distinguished by functional differences as well. Factor Va1 does not appear to bind to anionic phospholipids as efficiently as factor Va2 and is not as competent a cofactor in the prothrombinase complex as factor Va2. The presence of an oligosaccharide at Asn apparently reduces the affinity of factor Va1 for the phospholipid surface and interferes with prothrombinase complex assembly and function. The COOH-terminal fragment of the factor Va light chain (residues 1,753 to 2,183) that contains the Asn glycosylation site is one of the two regions that mediate membrane association.

Several models of fragments of factor Va have been generated. The crystal structure of APC-inactivated bovine factor Va (factor Vai), which includes the A1 domain from the heavy chain and the entire light chain, showed a domain organization quite different from previous models of either factor V or factor VIII. Most notably, the structure places the C1 and C2 domains in a “side-by-side” orientation, in which both C domains can interact with the phospholipid surface. This model has been supported by biochemical experiments. Recently, homology models have been generated for the prothrombinase complex.

Activation

The procofactor factor V does not bind factor Xa and is essentially completely inactive. Limited proteolysis of the factor V molecule yields the active cofactor factor Va. Factor Va functions as both a factor Xa receptor and a positive modulator of factor Xa catalytic potential in the prothrombinase complex. Rate enhancements of 300,000-fold derive from the participation of factor Va in the process of factor Xa activation of prothrombin.

The crystal structure of the factor Va complex with factor Xa reveals a heterodimer consisting of an NH_2-terminal heavy chain (M_r = 105,000 [A1-A2 domains]) linked noncovalently to a COOH-terminal light chain (M_r = 73,000 [A3-C1-C2 domains]). The association of the heavy and light chains of factor Va shows a divalent cation dependence. The B domain is excised during proteolysis.

Factor Xa cleaves factor V at Arg, Arg, and Arg, producing a factor Va molecule similar to the factor Va produced by a-thrombin cleavage. Factor Xa cleavage of factor V is less efficient than a-thrombin cleavage, although factor V released from stimulated platelets is partially activated and is more efficiently cleaved by factor Xa than plasma factor V.

Other enzymes may also activate or partially activate factor V. Platelet calpain, cathepsin G, and human neutrophil elastase partially activate factor V. The fibrinolytic enzyme plasmin both activates and inactivates factor V.
Plasmin cleavage and inactivation of factor V are hypothesized to play a role in hemorrhage subsequent to thrombolytic therapy by decreasing the level of factor Va cofactor activity.

Function

Activation of the procofactor factor V yields the functional form factor Va. Factor Va acts as a cofactor for the serine protease factor Xa in the prothrombinase complex. Factor Va forms at least part of the receptor for factor Xa on platelets and serves to anchor factor Xa to the membrane surface. Factor Va stabilizes the prothrombinase complex and enhances prothrombin activation.

Factor Va Regulation and Factor V\textsuperscript{Leiden}

Factor Va is regulated by proteolytic inactivation by APC. An anionic membrane surface is required for complete cleavage and full inactivation of the cofactor; in the absence of phospholipid, factor Va cleavage is not complete, and the cofactor retains some activity. Protein S, a suggested cofactor for APC, only functions in the presence of a phospholipid bilayer as well. In the presence of a membrane surface, APC cleaves factor Va sequentially at three sites: Arg\textsuperscript{506}, Arg\textsuperscript{536}, and Arg\textsuperscript{679}. Factor Va is initially cleaved at Arg\textsuperscript{506}. Subsequently, the membrane-dependent cleavage at Arg\textsuperscript{536} results in complete loss of factor Va cofactor activity. An additional APC-mediated cleavage of factor Va fragments occurs at Arg\textsuperscript{679}. Loss of cofactor activity coincides with dissociation of the A2 domain of APC-cleaved factor Va in a process similar to the spontaneous dissociation of factor VIIIa.

The importance of this regulatory mechanism is demonstrated by the “APC resistance” syndrome associated with factor V\textsuperscript{Leiden}. Individuals with factor V\textsuperscript{Leiden} have a G to A substitution at nucleotide 1,691 in the factor V gene that results in an Arg\textsuperscript{506} →Gln mutation at the protein level. Factor Va\textsuperscript{Leiden} has normal cofactor activity as part of the prothrombinase complex. However, unlike normal factor Va, factor Va\textsuperscript{Leiden} is not readily inactivated by APC. The Arg\textsuperscript{506} →Gln mutation hinders the first step in the sequential series of inactivating cleavages by APC. Factor Va\textsuperscript{Leiden} retains cofactor activity and continues to promote α-thrombin generation for an extended period of time. Inactivation of factor Va\textsuperscript{Leiden} by cleavage of the Arg\textsuperscript{506} bond occurs eventually but is markedly slower than normal factor Va. The prevalence of the factor V\textsuperscript{Leiden} mutation is approximately 5% in whites.

Individuals heterozygous for factor V\textsuperscript{Leiden} have a sevenfold greater risk of thrombosis than normal individuals, whereas individuals homozygous for factor V\textsuperscript{Leiden} have an 80-fold greater risk of thrombosis. The risk of thrombosis in individuals with factor V\textsuperscript{Leiden} is also exacerbated by other genetic and acquired risk factors such as protein C or protein S deficiency, or both, and use of oral contraceptives. The effects of factor V\textsuperscript{Leiden} are of considerable interest, as factor V\textsuperscript{Leiden} is the most common prothrombotic risk factor yet identified.

von Willebrand Factor (von Willebrand Factor: Antigen, Ristocetin Cofactor, von Willebrand Factor: Ristocetin: Cofactor)

vWF is a multifunctional protein with several key roles in coagulation. vWF circulates in plasma at an average concentration of 10 µg/ml (Table 18.1) and is also contained in the α-granules of human platelets. ABO blood type has a significant influence on vWF levels, with individuals of types A, B, or AB blood having much higher levels of vWF than individuals with type O blood. vWF is known for its role in ristocetin-induced platelet aggregation which is the basis of clinical assays. vWF was first recognized as the missing or defective factor in a severe autosomal dominant bleeding disorder. von Willebrand disease is fairly common and is estimated to occur in 1% to 2% of the general population. vWF is also an acute phase reactant; levels are elevated as a result of stress, pregnancy, or surgical trauma, and is a key player in hemostasis.

Gene Structure and Expression

The vWF gene is located on chromosome 12 band 12p-12pter and is 178 kb long with 51 introns and 52 exons (Table 18.2). A pseudogene with approximately 98% homology to the vWF gene has been mapped to chromosome 22. vWF is expressed only by endothelial cells and megakaryocytes. vWF is stored in Weibel-Palade bodies in endothelial cells and in α-granules in platelets. There are several regulatory elements that control vWF expression including GATA-binding consensus sequences in the promoter region. Endothelial cellspecific expression appears to be regulated by NF1 and Oct-1 binding sites. vWF expression is also regulated by complex signaling pathways that are directed by specific cellular environments. In addition, vWF plasma levels can be regulated through release of vWF from endothelial cell and platelet storage compartments. Platelet activation results in the release of vWF, and endothelial cell vWF release is induced by histamine and 1-deamino-8-d-arginine vasopressin. Biochemistry
vWF is a large adhesive glycoprotein that circulates in plasma as a heterogeneous mixture of disulfide-linked multimers. The biocycle of vWF comprises a series of steps ranging from regulated expression of the vWF gene in endothelial cells and megakaryocytes to its clearance from the blood.\(^{930}\) vWF is synthesized as a prepro molecule containing a 22-amino acid signal peptide, a propeptide of 741 amino acids, and the mature vWF protein of 2,050 amino acids.\(^{931,932,933,934,935}\) The prepro vWF molecule is comprised of internally repeated A, B, C, and D domains arranged in the sequence D1-D2-D’-D3-A1-A2-A3-D4-B-C1-C2. The A repeats share homology with complement factor B, collagen type IV, chicken cartilage matrix protein, and the I domain of the integrin α-subunit.\(^{937,938}\) Portions of the C domains are homologous to sequences in procollagen and thrombospondin.\(^{939}\) Prepro vWF undergoes extensive posttranslational modification to yield the mature vWF protein lacking the D1 and D2 domains. The large vWF propolypeptide copurifies with factor VIII and vWF and is designated vWF antigen-II. The mature vWF monomer has a molecular weight of approximately 255,000 based on protein sequence and carbohydrate content.\(^{931,932,935,936,940}\) The disulfide-linked multimers range in size from dimers (\(M_r = 600,000\)) to extremely large multimers of 20 million D. vWF has binding sites for factor VIII, heparin, collagen, platelet glycoprotein (gp) Ib, and platelet gpIIb-IIIa.\(^{941,942,943,944,945,946,947,948,949,950,951,952,953}\) and \(^{954}\)

### Function

vWF has multiple functions in hemostasis. vWF stabilizes factor VIII and protects it from inactivation by APC,\(^{185,955}\) thus significantly prolonging factor VIII half-life in circulation.\(^{761,763,764}\) vWF is a structural protein and is part of the subendothelial matrix. vWF also acts as a bridge between platelets and promotes platelet aggregation. The primary platelet-binding site for vWF is the gpIIb-IX-V receptor complex. gpIIb-IX-V is an active receptor on unstimulated platelets and serves to promote platelet aggregation and adhesion to vWF in the absence of platelet activation.\(^{400}\) This is likely a key element in the procoagulant response serving to recruit and localize platelets to the site of damage before the events that induce platelet activation.\(^{956}\) Subsequent platelet activation also induces expression of another receptor complex, gpIIb-IIIa. The gpIIb-IIIa complex recognizes a number of adhesive proteins including vWF. gpIIb-IIIa receptor binding of these adhesive proteins creates a strong network of platelets, other cells and matrix components.

Endothelial cells secrete vWF multimers, which are larger than those found circulating in plasma.\(^{957}\) The function of these large multimeric forms of vWF is to bind to and agglutinate blood platelets under high shear rates. These large multimers of vWF are degraded by a specific metalloprotease called a disintegrinlike and metalloprotease domain with thrombospondin in type I motifs (ADAMTS)-13.\(^{958,959,960}\) In familial and acquired thrombotic thrombocytopenic purpura, ultra-large vWF multimers are correlated to defective ADAMTS-13 activity.\(^{961}\)

### PROCOAGULANT PROTEINS: THROMBIN (FACTOR IIa)

The enzyme α-thrombin, or factor IIa, is the central enzyme in blood coagulation and plays myriad roles in hemostasis\(^{23}\) as well as roles in tissue repair, development, and pathogenic processes.\(^{649,687,962,963}\) and \(^{964}\) α-Thrombin is the most potent activator of circulating platelets, thus providing the requisite surface for procoagulant activities. α-Thrombin cleaves fibrinogen to generate the fibrin clot,\(^{680,965,966}\) and \(^{967}\) converts factor XIII to factor XIIIa to crosslink and stabilize the clot,\(^{37,968}\) and, in association with thrombomodulin, activates TAFI, which delays dissolution of the fibrin clot.\(^{36,969}\) α-Thrombin also acts directly and indirectly to amplify its own production. The procofactors V and VIII are activated by α-thrombin\(^{682,683,781,970}\) as are factor XI\(^7\) and, potentially, factor VII.\(^8\) In an analysis of a whole blood model of coagulation, a time course of α-thrombin generation and of the protein products of its catalytic activities illustrates that most procoagulant responses to α-thrombin occur during the initiation phase before fibrin formation (Fig. 18.11).\(^{569}\) Less than 0.2% of the final α-thrombin produced is required to achieve the activation of its primary substrates in blood. After fibrin clot formation, during the propagation phase, the bulk of α-thrombin is formed (\(^{‘95\%}.\))
FIGURE 18.11. Initiation, propagation, and termination of thrombin generation and the procoagulant response. A: Low levels of thrombin are required to initiate clot formation (initiation phase) and trigger the coagulation cascade response (propagation phase). The enzymes, cofactors, and inhibitors act together to generate a hemostatic response that can be divided into an initiation phase and a propagation/termination phase. During the initiation phase, factors X and IX are converted to their respective serine proteases factor Xa and factor IXa; low levels of thrombin are subsequently generated by factor Xa. This thrombin then can activate platelets and the procofactors factors V and VIII, which stimulate further thrombin generation during the propagation phase. Thrombin generation is attenuated by shutting down the initiation phase by means of the stoichiometric inhibitor of the extrinsic tenase complex, tissue factor pathway inhibitor (TFPI), followed by antithrombin (AT), which directly inhibits thrombin and factors Xa and IXa. B: Time course of early thrombin-antithrombin (TAT) complex formation from whole blood coagulation of 35 individuals is presented: y-axis, TAT (solid line [green diamonds]) and free thrombin [dashed line (blue squares)] concentrations (nmol/L) are shown on a log scale; x-axis, time in minutes. Arrows indicate the time and TAT concentration at which each of the indicated events (osteonecst [OSN] release, a marker of platelet activation, factor XIII activation [fXIIa], fibrinopeptide A [FPA] release, fibrinopeptide B [FPB] release, and prothrombin activation) has entered a phase of rapid activation. The percent of total TAT present at the point of activation is shown in parentheses. APC, activated protein C; CT, clot time; PC, protein C; TF, tissue factor. (From Brummel KE, Paradis SG, Butenas S, Mann KG. Thrombin functions during tissue factor induced blood coagulation. Blood 2002;100:148-152, with permission.)

In addition, α-thrombin also acts as a mitogen in a variety of cell types and vasoactive compounds, and induces the release of cytokines, and vasoactive compounds, and chemoattractants, and thrombin possesses catalytic activity and cleave a variety of substrates. Although meizothrombin is a short-lived intermediate in the activation process, it appears to play several important roles in coagulation. Meizothrombin is a potent vasoactive agent and acts on the adrenergic receptor to induce

Roles in Coagulation

The initiation, propagation, and termination of thrombin generation are essential in the coagulation cascade. Thrombin acts as a procoagulant enzyme, promoting clot formation, and simultaneously, it plays a critical role in regulating the coagulation process. Thrombin is involved in activating platelets, which are essential for clot formation, and it also promotes the activation of other coagulation factors, such as factor Xa and factor IXa. Thrombin generation is tightly controlled to prevent uncontrolled clot formation.

Tissue factor, a key component of the extrinsic coagulation pathway, is activated by various stimuli, leading to the formation of factor Xa and subsequently thrombin. Thrombin is a potent activator of platelets, leading to the release of platelet granule contents and fibrinogen. It also activates other coagulation factors, such as factor IX, which converts to factor IXa, forming the intrinsic tenase complex.

The coagulation process is a complex interplay between activation and inhibition. Thrombin is inhibited by antithrombin (AT) and activated protein C (APC), which are crucial for controlling thrombin activity. Thrombin also inhibits its own generation through the protein C anticoagulation pathway, a dynamic inhibitory system. This regulation is vital to prevent uncontrolled thrombin generation and thrombosis.

The propagation phase involves the activation of coagulation factors, leading to the formation of clotting factors, such as factor Xa and factor IXa. The binding of thrombin to the endothelial cell membrane protein thrombomodulin leads to the activation of protein C, which in turn inactivates factors Va and VIIIa, thereby inhibiting further thrombin generation. This feedback mechanism is essential for preventing uncontrolled clot formation.

The termination phase involves the inactivation of thrombin and the control of clot formation. Thrombin is inactivated by antithrombin (AT) in the circulation, whereas in the local microenvironment, thrombin is inactivated by tissue factor pathway inhibitor (TFPI). These mechanisms ensure that thrombin activity is tightly regulated, preventing the development of thrombosis.

Thrombin also plays a role in the inflammatory response, as it can stimulate the release of cytokines, chemokines, and adhesion molecules from endothelial cells and leukocytes. This enhances the inflammatory response and contributes to the resolution of tissue damage. Thrombin also acts as a mitogen in various cell types, such as monocytes and fibroblasts, promoting tissue repair.

In summary, the regulation of thrombin generation is crucial for maintaining hemostasis and preventing thrombosis. The complex interplay between activation and inhibition ensures a delicate balance, allowing for efficient clot formation while preventing uncontrolled clot formation.
vascular constriction. The vasoactive potency of meizothrombin is five to seven times greater than that of \( \alpha \)-thrombin.\(^{999,1000}\) However, the ability of meizothrombin to activate platelets and cleave fibrinogen is greatly reduced compared to that of \( \alpha \)-thrombin.\(^{673,1001}\) These are major roles for \( \alpha \)-thrombin in promoting an efficient and effective procoagulant response. \( \alpha \)-Thrombin has long been recognized as the most potent platelet agonist.\(^{681}\) \( \alpha \)-Thrombin induces release of platelet \( \alpha \)-granule contents, including a number of procoagulant and adhesive proteins,\(^{187,893,1002,1003,1004,1005,1006,1007,1008,1009}\) and \(^{1010}\) and of adenosine diphosphate from the platelet-dense granules. \( \alpha \)-Thrombin also triggers the translocation of anionic phospholipid to the outer leaflet of the platelet membrane. \( \alpha \)-Thrombin thus provides a cross-linked platelet mesh and an anionic surface appropriate for procoagulant complex assembly and function.

In addition, \( \alpha \)-thrombin generates and stabilizes the fibrin clot. \( \alpha \)-Thrombin cleaves the Arg\(^{16} \)-Gly\(^{17} \) bond in the A\( \alpha \)-chain and the Arg\(^{34} \)-Gly\(^{35} \) bond in the B\( \beta \)-chain of fibrinogen, releasing fibrinopeptide A (FPA) and fibrinopeptide B (FPB), respectively.\(^{680}\) FPA and FPB release allow formation of overlapping fibrin strands.\(^{965,966}\) and \(^{967}\) \( \alpha \)-Thrombin cleavage of the 37-residue NH\(_2\)-terminal activation peptide of factor XIII generates the transglutaminase factor XIIIa.\(^{17,968}\) Factor XIIIa cross-links and stabilizes the fibrin clot by catalyzing the formation of intermolecular \( \varepsilon \)-lysyl isopeptide bonds between fibrin molecules.\(^{37}\) TAFI, also known as plasma carboxypeptidase B or carboxypeptidase U, is likewise activated in an \( \alpha \)-thrombin-dependent manner to provide activated TAFI (TAFIa).\(^{36,960}\) TAFIa has carboxypeptidase B-like activity and is a key link between the coagulation and fibrinolytic cascades. TAFIa prevents premature clot lysis by cleaving COOH-terminal lysine and arginine residues on fibrin, rendering it a less suitable cofactor in t-PA-dependent plasminogen activation.\(^{1011}\) At elevated concentrations, TAFIa also directly inhibits plasmin and therefore clot lysis.\(^{1011}\) In addition, TAFI is a substrate for factor XIIIa and is cross-linked to fibrin and incorporated into the fibrin clot.\(^{1012}\) The \( \alpha \)-thrombin-dependent processes involved in clot formation and stabilization likely occur simultaneously to generate a mature clot that effectively reduces blood loss.\(^{1013}\)

\( \alpha \)-Thrombin has other key roles in procoagulant events as well. \( \alpha \)-Thrombin activates factor XI,\(^{7,617}\) and the procofactors factor V, factor VIII,\(^{682,683,782,970}\) and potentially factor VII.\(^{8}\) Meizothrombin likewise is an efficient activator of factor XI\(^{1014}\) and possibly factor V.\(^{1015}\) Meizothrombin is thought to function to enhance \( \alpha \)-thrombin generation by activating factor XI before its final processing to form \( \alpha \)-thrombin.

**Roles in Anticoagulation**

Although \( \alpha \)-thrombin is the central enzyme in the procoagulant response, it is also a key mediator of anticoagulant events as well.\(^{1016}\) When \( \alpha \)-thrombin binds to the cell membrane-associated cofactor thrombomodulin, the reactivity of \( \alpha \)-thrombin is altered. Instead, \( \alpha \)-Thrombin bound to thrombomodulin no longer cleaves fibrinogen or acts as a procoagulant enzyme.\(^{999,992}\) Instead, the \( \alpha \)-thrombin-thrombomodulin complex, or protein Case, cleaves protein C to generate the enzyme APC. APC is a potent anticoagulant and inactivates the cofactors factor Va and factor VIIIa.\(^{991,1013}\) \( \alpha \)-Thrombin activation of platelets also induces the release of anticoagulant and inhibitory proteins from the \( \alpha \)-granules.\(^{299,1018,1019}\) and \(^{1020}\)

**Roles in Tissue Repair and Regeneration**

Tissue repair and regeneration is the final phase of the hemostatic response to injury. Subsequent to lysis of the fibrin clot, multiple cell types choreograph the restructuring of the damaged vasculature. Vascular permeability is increased, and inflammatory cells accumulate at the site of injury. Smooth muscle cells, fibroblasts, and endothelial cells migrate to the site and proliferate. Cellular differentiation, as well as production and remodeling of the extracellular matrix, restores the vascular tissue. \( \alpha \)-Thrombin contributes to these processes through a variety of interactions with different cell types. \( \alpha \)-Thrombin is a potent mitogen and stimulates proliferation of smooth muscle cells,\(^{685,686,971,972,973}\) macrophages,\(^ {1014}\) and endothelial cells.\(^ {687,689}\) The mitogenic effects of \( \alpha \)-thrombin are due to direct activation of cellular proliferation or \( \alpha \)-thrombin-induced secretion of a variety of growth factors, or both. Platelet activation, an early event in the procoagulant response, results in the release of a plethora of \( \alpha \)-granule proteins that regulate cell growth, vascular permeability, and chemotaxis.\(^ {310,1021,1022,1023,1024,1025,1026,1027}\) \( \alpha \)-Thrombin thus mediates multiple aspects of the hemostatic response to vascular injury from the formation and stabilization of the initial fibrin plug to the final stages of tissue repair and regeneration.

**Thrombin Receptors**

Many of the effects of \( \alpha \)-thrombin on platelets and cells are elicited through \( \alpha \)-thrombin interaction with receptor molecules in which \( \alpha \)-thrombin binds to a receptor and initiates a signal transduction mechanism. The interaction between \( \alpha \)-thrombin and the human platelet thrombin receptor, protease-activated receptor (PAR)-1, however, is characterized by a more unusual mechanism in which the receptor is also a substrate for \( \alpha \)-thrombin.\(^ {989,1029,1030}\) PAR-1 is a
425-amino acid transmembrane protein with a large NH₂-terminal extracellular domain. α-Thrombin cleaves the extracellular region of the receptor at Arg⁴¹, producing a “tethered ligand.” The new NH₂-terminus binds back to and activates the receptor. PAR-1 is also found on T lymphocytes, monocytes, and endothelial cells and mediates the α-thrombin-induced responses of these cells as well.

Two additional α-thrombin receptors homologous to PAR-1 have also been identified: PAR-3 and PAR-4. PAR-3 is expressed on human platelets and endothelial cells, although at much lower levels than PAR-1. PAR-3 is required for normal α-thrombin-dependent platelet activation in mice, but in the human system, the role of PAR-3 appears to be primarily in cellular development. PAR-3 is expressed at high levels on human megakaryocytes, the precursor cells of platelets. PAR-4, however, is believed to act in combination with PAR-1 as a dual mechanism to elicit the multiple effects of α-thrombin on human platelets.

Structure/Function Relationships

In vivo, α-thrombin is derived from proteolytic cleavage of prothrombin by the prothrombinase complex (Figs 18.3 and 18.8). Cleavage of the Arg¹²₀-Ile¹²¹ bond in prothrombin yields meizothrombin. Subsequent cleavage of the Arg²⁷¹-Thr²⁷² bond gives rise to fragment 1.2 and α-thrombin. Human α-thrombin cleaves its own NH₂-terminus at Arg²⁸⁴-Thr²⁸⁵ to generate a stable α-thrombin molecule. The initial form of human α-thrombin has an NH₂-terminal A-chain of 49 residues, whereas the autocatalytically generated stable protein has an A-chain of 36 residues. The COOH-terminal B-chain of α-thrombin has 259 amino acid residues including the catalytic triad residues His¹⁸⁴, Asp⁴¹⁹, and Ser⁵₂⁵.

α-Thrombin is subject to further degradation resulting in stable, degraded thrombin molecules with reduced reactivity. These degraded forms are designated β- and γ-thrombin. The degradation of α-thrombin may be autocatalytic or may be due to proteolysis by enzymes other than α-thrombin. Human β-thrombin is generated by cleavage at Arg³⁸² and Arg³⁹³, which deletes a segment of the α-thrombin B-chain. Cleavage of β-thrombin at Arg⁴⁴³ and Lys⁷⁴⁷ deletes an additional segment of the B-chain and results in formation of γ-thrombin. β- and γ-thrombin retain some activity toward small peptide substrates, factor XIII, antithrombin, prothrombin, and factor XI. However, both β- and γ-thrombin have no significant ability to cleave fibrinogen or protein C. These proteolyzed forms of α-thrombin have been identified as products of the blood clotting reaction in vivo, but their mechanism of production and function is unknown.

The stable form of human α-thrombin possesses at least five distinct binding sites for substrates, inhibitors, cofactors, apolar molecules, and sodium ions (Na⁺). The apolar binding site is located near the catalytic center of α-thrombin. The Na⁺ binding site is in the B-chain, in a cavity formed by three antiparallel β sheets, and appears to play a role in determining whether α-thrombin acts as a procoagulant or an anticoagulant. In the presence of Na⁺, α-thrombin recognizes fibrinogen as a substrate and acts as a procoagulant. In the absence of Na⁺, α-thrombin has increased specificity for protein C and functions in an anticoagulant capacity. The binding of Na⁺ therefore appears to mediate the dual nature of α-thrombin as both a procoagulant and an anticoagulant.

Exosite I, the fibrinogen-binding site, is an anion-binding, electrropositive site distinct from, but acting in concert with, the active site of the α-thrombin molecule. In addition to fibrinogen, exosite I also recognizes the COOH-terminal domain of hirudin, the hirudin-like region of PAR-1, and the fifth and sixth EGF-like domains of thrombomodulin. Detailed information about exosite I is available from the x-ray crystal structure of the α-thrombin-hirudin complex. In solution, the COOH-terminal domain of hirudin is disordered. However, in the α-thrombin-hirudin complex, the COOH-terminus of hirudin inserts into the large groove in the α-thrombin molecule to interact with exosite I. Hirudin also inserts into the active site of α-thrombin. The high-affinity interaction (Kₐ = 2 × 10⁻¹⁴ mol/L) between α-thrombin and the inhibitor hirudin is thus stabilized by electrostatic, polar, and hydrophobic interactions.

Exosite II is a second electrropositive, anion-binding site located on the opposite side of the α-thrombin molecule compared to exosite I. Exosite II recognizes the COOH-terminal region of the B-chain of thrombin and sulfated polysaccharides such as heparin and the chondroitin sulfate moiety of thrombomodulin. The active site of α-thrombin is responsible for mediating interactions with substrate molecules including fibrinogen, protein C, and antithrombin. The active site of α-thrombin is similar to the active sites of trypsin and chymotrypsin. However, unlike the relatively nonspecific pancreatic enzymes, α-thrombin also has secondary binding sites, exosites I and
II, that confer specificity to α-thrombin. For substrates such as fibrinogen, there may be multiple secondary binding sites.

Regulation

α-Thrombin regulates its own production through complex formation with thrombomodulin and activation of protein C (Fig. 18.6). α-Thrombin enzymatic activity is mediated mainly by antithrombin-III. The inhibitory activity of antithrombin is potentiated in vivo by cell-expressed heparan sulfate GAGs or by pharmaceutical heparins.594,695 Antithrombin inhibits α-thrombin through formation of a covalent complex with the active site of α-thrombin.1053 α-Thrombin-antithrombin (TAT) complexes are rapidly cleared from the circulation by the liver.1054

α-Thrombin is also inhibited by α2-macroglobulin, a broad specificity proteinase inhibitor. α2-Macroglobulin does not appear to be a primary inhibitor of α-thrombin, but rather functions as a secondary inhibitor.1000 Unlike antithrombin, α2-macroglobulin does not complex with the active site of its target enzymes. Enzymes in complex with α2-macroglobulin retain the ability to cleave small peptidyl substrates, although they are unable to cleave large substrates.1055 α-Thrombin interaction with α2-macroglobulin involves limited proteolysis of α2-macroglobulin. Subsequent to cleavage, α2-macroglobulin undergoes a conformation change that traps the enzyme inside the α2-macroglobulin molecule.1056,1057 The α2-macroglobulin-enzyme complexes are rapidly cleared from circulation.1058,1059

ANTICOAGULANT PROTEINS: DYNAMIC INHIBITORY SYSTEM

The protein C pathway provides a dynamic inhibitory system to regulate α-thrombin production.1056,1060,1061 The activity of this anticoagulant pathway is directly dependent on the level of α-thrombin production. The protein C activating complex, or protein Case, is a membrane-dependent multiprotein complex similar to the membrane-dependent procoagulant complexes (Figs. 18.4 and 18.6). The key proteins in the protein C pathway are α-thrombin, thrombomodulin, protein C, and protein S.

Protein C

Protein C, first identified as a thrombin inhibitory activity or autoprotrombin II-A,1063 is the zymogen form of the enzyme APC. Protein C circulates at a concentration of 4 μg/ml (65 nmol/L) with a t1/2 of 8 to 10 hours1064,1065 and 1066 (Table 18.4). The t1/2 of protein C is markedly shorter than most other members of the vitamin K-dependent protein family and is the likely basis of the transient hypercoagulable state subsequent to administration of coumarin-based anticoagulants.1067,1068,1069,1070 and 1071 Homozygous protein C deficiency is associated with severe thrombotic tendencies and can result in fatal neonatal thrombotic events.1072 Heterozygous protein C deficiency is associated with increased risk of thrombosis.1073,1074 and 1075 The mutation in factor V Leiden, which blocks a key APC cleavage site in factor Va Leiden, is another defect leading to an alteration in the protein C anticoagulant pathway and predisposition to thrombosis.

Gene Structure and Expression

The protein C gene is located on chromosome 2 bands q14-q21 and spans 11 kb with eight introns and nine exons1076,1077 (Table 18.6). The promoter region contains HNF-1, HNF-3, and Sp1 binding sites that promote gene expression.1078,1079 HNF-3 is a liver-specific transcription factor.

Biochemistry

Protein C is synthesized in the liver as a single-chain polypeptide with a prepro sequence of 42 amino acids. The prepro protein is subsequently processed to remove the leader sequence and the dipeptide Lys156-Arg157. Thus, in plasma, most protein C circulates as a heterodimer consisting of a disulfide-linked (Cys141-Cys171) heavy and light chain, and 1081. However, approximately 5% to 10% of circulating protein C is the single-chain form.361 The twochain form of human protein C (M, = 62,000) is a 419-amino acid glycoprotein with approximately 23% carbohydrate (Table 18.4 and Fig. 18.3B). The NH2-terminal light chain (residues 1 to 155; M, = 21,000) contains the Gla domain (residues 6 to 29; nine Gla residues) and a hydrophobic region that connects the Gla domain to two EGF domains (residues 55 to 90 and 94 to 134). The COOH-terminal heavy chain (residues 158 to 419; M, = 41,000) contains the serine protease domain. Residues 158 to 169 constitute the activation peptide domain. A β-hydroxy aspartate residue (Asp21) in the first EGF domain is required for Ca2+-dependent alterations in protein C. Ca2+ binding is mediated by the first EGF domain as well as the Gla domain and the serine protease domain.

P.464

There are several glycosylation variants (Asn97, Asn248, Asn113, and Asn299) with two to four N-linked carbohydrate
The major forms, α-protein C and β-protein C, have four and three carbohydrate moieties, respectively. All the protein C carbohydrate variants can be activated, but appear to have different anticoagulant properties and rates of activation. An x-ray crystal structure has been determined for Gla-domainless activated protein C.

### Activation

Protein C is the zymogen form of the enzyme APC. Protein C is cleaved at the Arg<sup>169</sup>-Leu<sup>170</sup> bond, releasing its activation peptide from the heavy chain to generate the active enzyme. The α-thrombin-thrombomodulin complex is likely the major physiologic activator of protein C. There are other activators as well. Plasmin activates and then inactivates protein C. Meizothrombin also binds thrombomodulin and can efficiently activate protein C. Factor Xa has likewise been reported to bind to thrombomodulin and activate protein C, however, this mechanism has not been confirmed in subsequent studies. More recently, glycosaminoglycans have been shown to potentiate factor Xa-mediated protein C activation. Copperhead snake venom also contains a protein C activator.

### Function

APC is a serine protease with key anticoagulant functions. The most important anticoagulant role for the protein C pathway is the proteolytic inactivation of factor Va. APC inactivates factor Va via a series of proteolytic cleavages, thus inhibiting the generation of α-thrombin. APC also cleaves and inactivates factor VIIIa, although the spontaneous dissociation of the factor VIIIa A2 domain is the probable physiologic regulator of factor Xa generation. Full inactivation of factor Va by APC requires an anionic phospholipid surface, and the rates of APC inactivation of factors Va and VIIIa are enhanced by protein S.

APC also has a profibrinolytic effect. This effect is due to TAFI. TAFI is activated by the α-thrombin-thrombomodulin complex and acts to prolong clot lysis. APC cleavage of factor Va inhibits α-thrombin generation, thus reducing α-thrombin-thrombomodulin-mediated TAFI activation. The prolongation of clot lysis by TAFI likely contributes to the prothrombotic tendencies associated with factor V<sub>Leiden</sub>.

The endothelial cell protein C receptor provides cell-specific binding sites for both protein C and APC. However, two other coagulation proteases, factors VIIa and Xa, have been shown to bind to this receptor. Endothelial cell protein C receptor is downregulated by TNF-α. Monocytes appear to express specific binding sites for APC that are distinct from endothelial cell protein C receptor. The cell-expressed binding sites may be important in the antiinflammatory
properties of APC.\textsuperscript{1111} APC blocks the septic shock response in animal models\textsuperscript{1112,1113} and has shown clinical success in severe sepsis patients.\textsuperscript{1114,1115} APC reduces the levels of inflammatory cytokines such as TNF-\(\alpha\).\textsuperscript{1113,1116} The antiinflammatory properties of APC are also due to inhibition of \(\alpha\)-thrombin generation and, therefore, inhibition of the proinflammatory properties of \(\alpha\)-thrombin.

Regulation

Protein C activation and APC activity are controlled on several levels. Inflammatory agents such as endotoxin, IL-1\(\beta\), transforming growth factor-\(\beta\) (TGF-\(\beta\)), and TNF-\(\alpha\) regulate protein C activation on endothelial cells.\textsuperscript{1117,1118,1119,1120,1121,1122,1123,1124,1125} and \textsuperscript{1126} TNF-\(\alpha\) is responsible for downregulation of thrombomodulin on the endothelial cell surface.\textsuperscript{1120,1123,1124,1125} and \textsuperscript{1126} There are multiple other factors that downregulate thrombomodulin as well. APC activity is regulated mainly by the protein C inhibitor or PAI-3.\textsuperscript{1127,1128} and \textsuperscript{1129}

Protein S

Protein S is a vitamin K-dependent protein that is not a serine protease precursor. Protein S circulates at a plasma concentration of 20 \(\mu\)g/ml (300 nmol/L)\textsuperscript{1130,1131} (Table 18.4). Approximately 40% of protein S circulates in the free form, and the remaining 60% circulates as a 1:1 complex with C4b-binding protein (C4bBP), a regulatory protein of the complement system.\textsuperscript{1132} Protein S is thought to function as a cofactor for APC in the inactivation of factors Va and VIIIa.\textsuperscript{1133,1134,1135,1136} and \textsuperscript{1137} Heterozygous deficiency of protein S increases the risk for developing thrombosis; however, the diagnosis is complicated.\textsuperscript{1138} The protein S cofactor effect is minimal, however, and does not correlate with the thrombotic pathways manifested in protein S-deficient patients.\textsuperscript{1139,1140,1141,1142,1143,1144} and \textsuperscript{1145} Protein S has also been reported to inhibit prothrombin activation through several mechanisms.\textsuperscript{1146,1147,1148} Although the precise function of protein S is not clear, protein S is important in anticoagulation.

Gene Structure and Expression

The gene for protein S is located on chromosome 3 and spans at least 80 kb \textsuperscript{1149,1150} (Table 18.6). The gene contains 15 exons and 14 introns.\textsuperscript{1149,1151,1152} A second copy of the protein S gene has also been identified; however, this second gene is likely a pseudogene.\textsuperscript{1153,1154} The pseudogene spans approximately 55 kb and differs from the protein S gene in that it lacks exon 1 and has multiple nucleotide substitutions. Protein S is synthesized in the liver\textsuperscript{1155,1156} and by a variety of other cell types including endothelial cells,\textsuperscript{1157,1158} and \textsuperscript{1159} osteoclasts,\textsuperscript{1160} and lymphoid cells.\textsuperscript{1161} Protein S is also found in the \(\alpha\)-granules of platelets.\textsuperscript{1162}

Biochemistry

Protein S (M\(_r\) = 69,000) is a single-chain glycoprotein with approximately 8% carbohydrate and 11 Gla residues\textsuperscript{584,1162} (Table 18.4 and Fig. 18.3B). Protein S is synthesized with a signal sequence and propeptide region of 41 amino acids.\textsuperscript{1151,1152,1156,1163} The mature form of the protein has 635 amino acids and is organized into eight domains: An NH\(_2\)-terminal Gla domain (residues 1 to 45), an aromatic stack, a 29-residue thrombin-sensitive domain (residues 46 to 75), four EGF domains (residues 76 to 242), and a COOH-terminal domain homologous to the sex hormone-binding globulin and androgen-binding protein.\textsuperscript{1164,1165} The Gla domain and EGF domains mediate Ca\(^{2+}\) binding.\textsuperscript{1166} The Gla domain is also involved in interactions with phospholipid membranes.\textsuperscript{1167} C4bBP binds to the COOH-terminal sex hormone-binding globulin domain.\textsuperscript{1168,1169} Protein S reversibly self-associates in the absence of Ca\(^{2+}\).\textsuperscript{1170}

Function

The precise function of protein S in the protein C inhibitory pathway is not clearly defined. Protein S enhances APC inactivation of factors Va and VIIIa in a phospholipid-dependent fashion.\textsuperscript{185,1132,1133,1134,1135,1136} and \textsuperscript{1137} The interaction between protein S and APC alters the structure of APC and moves the APC active site closer to the membrane surface.\textsuperscript{1171} Protein S may also serve directly in an anticoagulant capacity. Protein S has been reported to bind to factor Xa,\textsuperscript{1147} factor VIII,\textsuperscript{1172} and factor Va\textsuperscript{1146} to compete for prothrombinase-binding sites on the membrane surface\textsuperscript{696,1148} and to stimulate the inhibition of factor Xa by TFPI.\textsuperscript{1173,1174} These interactions serve to inhibit prothrombin activation in vitro.\textsuperscript{1175} The C4bBP-protein S complex may inhibit factor X activation as well.\textsuperscript{1176} Protein S also has additional potential roles outside of anticoagulation. Protein S interaction with T cells promotes T cell aggregation and proliferation and may serve to regulate inflammatory processes.\textsuperscript{1177}
α-Thrombin cleavage of protein S at Arg⁴⁹, Arg⁶⁰, or Arg⁷⁰ in the thrombin-sensitive domain inhibits the ability of protein S to act as a cofactor for APC. Protein S activity is also regulated by interaction with C4bBP. The 1:1 complex between protein S and C4bBP neutralizes the anticoagulant capacity of protein S. Approximately 60% of plasma protein S circulates bound to C4bBP.

Protein Z

Protein Z, a vitamin K-dependent glycoprotein, is an enzymatically inactive homolog of factors VII, IX, and X, and protein C. Protein Z was first identified in bovine plasma by Prowse and Esnouf in 1977, and later in human plasma by Broze and Miletich in 1984. The name protein Z came about from its being the last of the vitamin K-dependent proteins to elute during anion exchange chromatography. Protein Z circulates in plasma in a complex with protein Z-dependent protease inhibitor (ZPI). This inhibitor, ZPI, has been identified as a 72-kDa member of the serpin superfamily. Reports suggest that protein Z behaves as a negative acute phase reactant. Protein Z levels have been found to be low in newborn infants and in individuals with DIC, liver disease, and amyloidosis. High plasma levels have been found in individuals on chronic hemodialysis and with idiopathic thrombocytopenic purpura. Protein Z levels also appear to be more susceptible to warfarin therapy than other vitamin K-dependent proteins.

Gene Structure and Expression

The gene for protein Z is located on chromosome 13 at band q34 (Table 18.6). It spans approximately 14 kb and consists of nine exons, including one alternative exon. The gene organization is similar to that of the other vitamin K-dependent proteins, factors VII, IX, and X, and protein C.

Homozygous and heterozygous protein Z-deficient mice showed no abnormalities in growth and development. Protein Z deficiency has been reported to be prothrombotic in nature in factor V Leiden mice. In general, evidence supports the anticoagulant role of the complex between protein Z and the serpin protein Z-dependent protease inhibitor (ZPI) and the thrombotic consequences of its deficiency. Protein Z-deficient mice crossed with factor V Leiden mice did not have viable progeny. Several clinical studies identified diminished levels of plasma protein Z in patients with unidentified bleeding disorders. Protein Z has also been identified in liver disease and atherosclerosis.

Biochemistry

Protein Z has a molecular weight of 62,000 and circulates in plasma at a mean concentration of 2.9 ± 1.0 μg/ml (Table 18.4). The plasma t₁/₂ of protein Z is 2.5 days. Structurally, protein Z is similar to factors VII, IX, and X, and protein C, containing a Gla domain (13 residues) and two EGF domains at its NH₂-terminus. (Fig. 18.3B). However, like protein S, protein Z does not function as a protease. The COOH-terminus contains a region homologous to the catalytic domains present in the serine protease zymogens. The catalytic triad is not present in protein Z, except for the conserved Asp residue.

Function

Protein Z is a vitamin K-dependent protein that does not function as a serine protease enzyme. Protein Z circulates in plasma in complex with ZPI. The function of protein Z in vivo is still unclear to date. It has been reported that protein Z inactivates factor Xa by forming a Ca²⁺-dependent complex with factor Xa bound to phospholipid with the help of ZPI. Factor IXa has also been reported to be a target for the protein Z/ZPI system. The overall importance of these protein Z/ZPI activities is unclear. In vitro, protein Z has also been shown to have a weak interaction (K₅ = 8.9 μmol/L) with thrombin that facilitates the binding of thrombin to phospholipid surfaces. It is also consumed, like all other coagulation factors and inhibitors, during the course of DIC.

P.466

Thrombomodulin

Thrombomodulin is a type 1 transmembrane protein constitutively expressed on the surface of vascular endothelial cells (Fig. 18.9). It is an essential that displays a range of antiinflammatory, anticoagulant, and antifibrinolytic properties. Thrombomodulin is a high-affinity receptor for α-thrombin and acts as a cofactor for the α-thrombin-dependent activation of protein C and TAFI. Thrombomodulin activity on the surface of endothelial cells is decreased by inflammatory cytokines and may contribute to the hypercoagulation characteristic of inflammatory states. Thrombomodulin is expressed widely during fetal development. Homozygous thrombomodulin-deficient mice die in utero before the formation of the cardiovascular system, suggesting a potential role for thrombomodulin in mammalian development.
Gene Structure and Expression

The human thrombomodulin gene is located on chromosome 20 band p-12cen and spans 3.7 kb. Thrombomodulin expression has been reported in a variety of cell types, including vascular endothelial cells, neutrophils, monocytes, platelets, synovial cells, and squamous epithelial cells. Vascular expression is limited to endothelial cells. Thrombomodulin activity on the surface of endothelial cells is decreased by homocysteine, lipopolysaccharide, IL-1β and TNF-α. Many of these same inflammatory agents that downregulate thrombomodulin also upregulate tissue factor, contributing to the hypercoagulation associated with inflammation. Hypoxia also downregulates thrombomodulin expression. Likewise, thrombomodulin expression is decreased by glucose-modified albumin, which may provide a link to diabetic thrombotic complications. Conversely, dibutyl cyclic adenosine monophosphate, retinoic acid, shear stress, and increased temperature (42°C) upregulate thrombomodulin activity on endothelial cells. Upregulation of thrombomodulin expression by TNF-α may involve a consensus sequence of a cyclic adenosine monophosphate response element in the 3′-untranslated region of the thrombomodulin gene. Increased thrombomodulin expression due to elevated temperature is mediated by consensus sequence recognition sites for a heat shock element in the S′-promoter region. Upregulation of thrombomodulin expression in response to elevated temperature may be a protective mechanism to compensate for the procoagulant effects of the inflammatory mechanism.

Biochemistry

Thrombomodulin is synthesized with an 18-amino acid signal sequence followed by a 557-residue polypeptide chain of the mature protein. Thrombomodulin has five different domain structures: An NH2-terminal domain having weak homology to lectins (residues 6 to 149) such as the asialoglycoprotein receptor, six EGF-like domains (residues 227 to 462), a 34-residue region rich in serine and threonine corresponding to potential O-linked glycosylation sites (residues 463 to 497), a 23-residue hydrophobic transmembrane region (residues 499 to 521), and a COOH-terminal domain (residues 522 to 557) containing several potential phosphorylation sites and one free cysteine residue (Cys436). The fifth and sixth EGF domains support α-thrombin association. The region required for efficient protein C activation extends from the linker region between EGF domains 3 and 4 through EGF-6 and Ser1232 and Ser1241 in the serine- and threonine-rich region are potential sites for chondroitin sulfate addition. The presence of chondroitin sulfate increases the affinity for α-thrombin more than 10-fold, thus increasing the ability of thrombomodulin to block fibrinogen cleavage and platelet activation by α-thrombin. The chondroitin sulfate moiety also enhances inactivation of α-thrombin by antithrombin and modulates the Ca2+ dependence of protein C activation. The O-linked sugar domain of thrombomodulin is required for APC generation on cellular surfaces. This domain is extended and rigid and rises approximately perpendicular to the membrane surface. The O-linked sugar domain likely functions to elevate α-thrombin from the membrane surface. The active site of α-thrombin bound to thrombomodulin is located approximately 65 Å from the membrane surface.

Although no consensus sequence for internalization via coated pit-mediated endocytosis is found in thrombomodulin, coated and noncoated pit-mediated endocytosis has been observed. Internalization appears to be mediated by the NH2-terminal lectin-like domain.

Function

Thrombomodulin functions as a cofactor for α-thrombin in the activation of protein C and TAFI. Production of APC by the α-thrombin-thrombomodulin complex is approximately 1,000 times faster than by equivalent concentrations of protein C and thrombin. Once bound to thrombomodulin, α-thrombin’s procoagulant activities are neutralized. The high-affinity α-thrombin-thrombomodulin interaction is mediated mainly by exosite I on the α-thrombin molecule. Exosite I also binds fibrinogen, and the interaction of α-thrombin with thrombomodulin therefore blocks fibrinogen binding and cleavage. In addition, thrombomodulin induces conformational changes in α-thrombin, and overall, the changes that occur on α-thrombin interaction with thrombomodulin reduce the ability of α-thrombin to generate fibrin, and to activate factor V and platelets, while increasing the rate of inactivation of α-thrombin by antithrombin. α-Thrombin-thrombomodulin, or protein Case, functions solely in an anticoagulant and antifibrinolytic capacity.

Regulation

There are several potential mechanisms of thrombomodulin regulation on the cell surface. Thrombomodulin expression is downregulated by endotoxin and inflammatory cytokines. Shear stress, homocysteine, and hypoxia likewise downregulate thrombomodulin expression. α-Thrombin may also regulate thrombomodulin activity, although evidence is somewhat controversial. Thrombomodulin-dependent α-thrombin internalization has been
However, the α-thrombin-thrombomodulin complex appears to be stable under some conditions. In addition, thrombomodulin activity can be regulated proteolytically, mainly by neutrophil elastase. Neutrophils decrease thrombomodulin activity via oxidation as well.

**ANTICOAGULANT PROTEINS: PROTEASE INHIBITORS**

Proteinases, enzymes that hydrolyze peptide bonds, are found in a wide array of biologic systems, including the blood coagulation process (clot formation and fibrinolysis), digestive system, apoptotic cascades, and the immune system. To keep these systems in balance between activation and inhibition, a complex system of proteinase inhibitors has evolved. In blood, proteinase inhibitors constitute a significant percentage of circulating proteins. In general, proteinases that activate the coagulation and fibrinolytic cascades have highly defined substrate specificities. Coagulation is kept in check through the action of several specific and broad-spectrum proteinase inhibitors. Specific clot formation inhibitors are antithrombin and TFPI. Fibrinolysis-specific inhibitors are PAI-1 and α2-antiplasmin. Together, specific and broad-spectrum inhibitors function to localize, limit, and control hemostasis.

**α2-Macroglobulin**

α2-Macroglobulin is a nonspecific proteinase inhibitor that targets a broad spectrum of protease substrates. It is present in human plasma at concentrations ranging from 2 to 4 μmol/L (2 to 3 mg/ml) (Table 18.4). α2-Macroglobulin can also be found at higher concentrations in extravascular fluids. This protease inhibitor can be produced in a variety of cells including hepatocytes, fibroblasts, and macrophages. α2-Macroglobulin is also found in several species including the horseshoe crab.

Reduced levels of serum α2-macroglobulin in humans have been observed in individuals with chronic obstructive lung disease and cancer metastasis. In humans, no absolute deficiency has been reported to date, leading to the suggestion that such a congenital deficiency is incompatible with survival. The inactivation of the mouse α2-macroglobulin gene results in viable mice that produce normal-sized litters but are more resistant to endotoxin challenge. In a later study, it was suggested that this phenotype in mice functions as a neutralizer of transforming growth factor-β and as an inducer of nitric oxide synthesis.

**Gene Structure and Expression**

The gene encoding human α2-macroglobulin spans approximately 48 kb and consists of 36 exons and 35 introns. It is located on chromosome 12p12.3-13.3. The α2-macroglobulin gene is a single copy gene in the human genome. α2-Macroglobulin is synthesized in the liver as a pro-α2-macroglobulin, which contains a 23-residue signal peptide. Three transcription initiation sites, including a TATA box, a TATA-like structure (ATAAA), and a potential HP-1 binding site, have been identified in the liver.

**Biochemistry**

Human α2-macroglobulin circulates in plasma as a tetramer with four identical single-chain subunits with an individual relative molecular weight of 180,000 and a total relative molecular weight of 735,000. An unusual feature of this protein is that multiple forms may be found in various species and may appear only during acute-phase reactions. A dimeric form termed pregnancy zone protein has been found in human plasma at peak levels during the last trimester. Therefore, this protein may be found in human plasma composed of either two or four identical subunits.

α2-Macroglobulin has a unique mechanism by which it achieves broad specificity. The initial step involves the “bait region” of α2-macroglobulin. This region consists of a 25-amino acid sequence that has sequence motifs appropriate for many proteases. After proteolysis in this bait region, α2-macroglobulin undergoes conformational changes that trap the proteinase inside the molecule. The crystal structure of human α2-macroglobulin displays a large central cavity capable of containing one or two average-sized proteases. These conformational changes have been referred to as a slow to fast transition. The active site of the substrate proteinase is not found in complex with the inhibitor. Studies have shown that the entrapped proteinase is no longer able to interact with macromolecular substrates, inhibitors, and antibodies, but still appears to retain its ability to react with small substrates and inhibitors. These complexes are rapidly cleared from the circulation by the endocytic α2-macroglobulin receptor also known as the lowdensity lipoprotein.
receptor-related protein (LRP). This receptor is found on most mast cells and tissues. The proteinase inhibitor complex has an approximate t_{1/2} of 2 to 5 minutes.\textsuperscript{1058}

Another important feature of α₂-macroglobulin is the presence of a β-cysteinyl-y-glutamyl thiol ester.\textsuperscript{1289,1290} Studies have shown that these thiol esters may directly react with small nucleophiles, such as ammonia or methylamine; induce a conformational change; and prevent proteinase binding.\textsuperscript{1291} The conformational changes associated with proteolysis of the bait region generate a thiol ester more susceptible to nucleophilic attack, with the result that surface Lys residues of the trapped proteinase can react with it and become covalently linked to α₂-macroglobulin. Binding studies in vitro have identified specific high affinity receptors for α₂-macroglobulin-proteinase complexes on many cell types, including fibroblasts, macrophages, and hepatocytes.\textsuperscript{1059}

Function

One role for α₂-macroglobulin is to inhibit a broad range of proteinases. It is distinctive in its capacity to inhibit members from each of four mechanistic classes of proteinases (serine, cysteine, and aspartic proteinases, and metalloproteinases), α₂-Macroglobulin functions as a secondary inhibitor to serine proteinases in plasma by inhibiting thrombin, kallikrein, and plasmin.\textsuperscript{1292,1293} It may also be important in preventing thromboembolic events when there is a congenital deficiency of antithrombin or sepsis.\textsuperscript{1294,1295} α₂-Macroglobulin also inhibits various growth factors and cytokines, including TGF-β,\textsuperscript{1296} IL-1β,\textsuperscript{1197} IL-6,\textsuperscript{1198} acidic fibroblast growth factor,\textsuperscript{1299} basic fibroblast growth factor,\textsuperscript{1299} TNF-α,\textsuperscript{1300} and IL-2.\textsuperscript{1300} Polymorphisms identified in α₂-macroglobulin have been thought to play a role in Alzheimer disease.\textsuperscript{1302,1303} and 1304 Overall, the biologic role of α₂-macroglobulin in vivo is still being elucidated.

Tissue Factor Pathway Inhibitor

TFPI, formerly called extrinsic pathway inhibitor or lipoprotein-associated coagulation inhibitor, is a multivalent, Kunitz-type plasma proteinase inhibitor. TFPI modulates tissue factor-dependent coagulation in vivo by rapidly inhibiting the extrinsic tenase complex (factor VIIa-tissue factor) as soon as it is formed\textsuperscript{1305,1306} and \textsuperscript{1307} (Fig. 18.6). It circulates in plasma at approximately 0.1 μg/ml\textsuperscript{1308} as a heterogeneous collection of partially proteolyzed forms \textsuperscript{1315,1320,1310} and \textsuperscript{1311} (Table 18.4). Ninety percent of circulating TFPI is found associated with lipoproteins, primarily low-density lipoprotein.\textsuperscript{1310,1312,1313} Parenteral TFPI is cleared from the circulation primarily by the liver and has an unusually short t_{1/2} (minutes) compared to other proteinase inhibitors.

Many reviews of TFPI have been published.\textsuperscript{1314,1315,1316,1317} and 1318 The importance of TFPI in blood coagulation has been best illustrated through transgenic mice that have a complete deficiency (-/-) of TFPI. This deficiency is incompatible with birth and survival.\textsuperscript{1319} However, this lethality in mice can be rescued by heterozygous or homozygous factor VII deficiency.\textsuperscript{1320} This implies that diminishing the level of factor VII lessens the need for TFPI-mediated inhibition of the factor VIIa-tissue factor coagulation pathway during embryogenesis.\textsuperscript{1320} When mice are generated that have a combined heterozygous TFPI deficiency and homozygous apolipoprotein E deficiency, they exhibit a greater atherosclerotic burden.\textsuperscript{1321} These observations suggest a role for TFPI in protection from atherosclerosis and as a potential regulator of thrombosis.

To date, there are no known human TFPI-deficient individuals described, which suggests that human embryos with TFPI/- genotype fail to develop. A role for TFPI in preventing thrombosis and other cardiovascular diseases is currently under intensive clinical and in vitro investigation.\textsuperscript{1322} One application for recombinant TFPI is in the area of sepsis in which patients frequently have reduced TFPI levels.\textsuperscript{1323,1324}

Gene Structure and Expression

The human TFPI gene has been localized to chromosome 2 bands q31-q32.1\textsuperscript{1325,1326} and \textsuperscript{1327} (Table 18.6). It spans 85 kb, over half of which

P.468

consists of the 5′ noncoding region. The coding region is distributed over nine exons; mature TFPI contains three Kunitz domains that are encoded on separate exons. The gene specifies a protein of 304 amino acids; the first 28 residues comprise a signal peptide. Two variants of TFPI (isoforms α and β) arising from alternative splicing have been identified; the variable region involves residues 210 to 251 of the primary gene product, spanning a large portion of the third Kunitz domain. TFPI is expressed constitutively by cultured endothelial cells, and its level of synthesis is hardly affected by endotoxin or inflammatory cytokines.\textsuperscript{1311,1329} TFPI is not expressed by hepatocytes. TFPI is found bound to low- and high-density lipoproteins located within platelets or noncovalently associated with endothelial cell heparin sulfate
proteoglycans.\textsuperscript{1308} TFPI is catabolized in the liver and kidney by uptake/degradation via the low-density LRP or its homologs.\textsuperscript{1330}

Biochemistry

TFPI (M, = 40,000) is a single-chain glycoprotein of the Kunitz proteinase inhibitor family.\textsuperscript{1331,1332} As isolated, the COOH-terminus of TFPI displays some degradation. Structurally, mature full-length TFPI (276 amino acids in the α isoform) consists of an acidic NH₂-terminal region, three tandem Kunitz-like serine protease inhibitor domains (K1 to K3), and a positively charged COOH-terminal region\textsuperscript{1330,1331} (Fig. 18.12). The tandem Kunitz domains are essential for the function of TFPI.\textsuperscript{1308} The Kunitz 1 inhibitor domain (residues 26 to 76) binds factor VIIa-tissue factor. The second Kunitz domain (residues 97 to 147) of TFPI binds the factor Xa active site. The Kunitz 3 domain (residues 189 to 239) of TFPIα binds protein S, and the protein S mediated potentiation of factor Xa inhibition by TFPIα involves protein S-Kunitz 3 interaction.\textsuperscript{1333} Heparin binds at two heparin-binding sites: a high-affinity site in the COOH-terminal basic region and a low-affinity site between Gly\textsuperscript{212} and Phe\textsuperscript{243} in the third Kunitz domain.\textsuperscript{627,628,1334}

![Tissue factor pathway inhibitor (TFPI): 40 kDa](image)

![Antithrombin (AT): 58 kDa](image)

FIGURE 18.12. Soluble stoichiometric inhibitors. Tissue factor pathway inhibitor (TFPI) contains three Kunitz domains. TFPI inhibits the serine protease factor Xa (FXa) directly and tissue factor-factor VIIa complex in a factor Xa-dependent mechanism, shutting down the extrinsic pathway of coagulation. Kunitz 1 domain binds factor VIIa, Kunitz 2 domain binds factor Xa, and Kunitz 3 binds protein S, with this interaction reported to enhance the activity of TFPI.\textsuperscript{1333} The COOH-terminus of TFPI contains a basic region, the cell-binding domain, which binds to heparin. Antithrombin (AT) contains two intrachain disulfide bonds (-S-S-) in its NH₂-terminal and one in its COOH-terminus with a carbohydrate-rich domain (CHO) in between. Asn\textsuperscript{135} is not glycosylated in the β form of AT. The region of interaction between the active sites of target proteases and AT is illustrated as a circle (reactive center loop) above the reactive site bond R\textsuperscript{393}-S\textsuperscript{394}. Heparin binding occurs in the NH₂-terminus, involving interactions with residues R\textsuperscript{27}, K\textsuperscript{114}, K\textsuperscript{125}, and R\textsuperscript{129}, and enhances the rate of inhibition of certain serine proteases.

TFPI contains three potential N-linked glycosylation sites (Asn\textsuperscript{117}, Asn\textsuperscript{167}, and Asn\textsuperscript{228}), with one or more of these oligosaccharides sulfated during expression by cultured endothelial cells.\textsuperscript{1335} Two O-linked glycosylation sites have also been identified (Ser\textsuperscript{200} and Thr\textsuperscript{201}). A significant proportion of TFPI molecules in the blood is truncated to variable extents at the COOH-terminal end (some lacking most of the third Kunitz domain) and has compromised inhibitory activity.\textsuperscript{1336}
contrast, TFPI released by heparin infusion is full length and more active than the truncated forms. The inhibitory activity of TFPI is enhanced by heparin.

P.469

The normal plasma concentration of TFPI is 0.1 μg/ml. TFPIα is found either associated with lipoproteins, such as low- and high-density lipoproteins or lipoprotein(a), complexed noncovalently to endothelial cell heparan sulfate proteoglycans; or associated with endothelial cell surfaces via a glycosyl-phosphatidylinositol (GPI) anchor. On heparin administration, TFPI is released from endothelial cells, primarily microvascular, causing a two- to 10-fold increase in circulating TFPI levels. TFPI release on heparin therapy is responsible for the observed elevation in PT and raises the possibility that a portion of the antithrombotic effect of the polysaccharide may be mediated by TFPI. GPI-anchored TFPIα is not released by heparin therapy and represents the largest in vivo pool of TFPI. A minor pool of TFPI (10% of total TFPI in blood) is located within platelets and is released after dual stimulation by collagen and thrombin. TFPIβ has Kunitz 1 and Kunitz 2 domains and a unique C-terminal region that contains a GPI-anchor sequence.

The qualitative and quantitative properties of TFPI can be altered both by the genotype of an individual and by environmental factors. This is illustrated by in vitro experiments in which factor V Leiden is combined with reduced levels of TFPI. Factor V Leiden, when combined with TFPI levels that are at the low end (50%) of the normal range, can produce an unregulated propagation phase of thrombin generation in a synthetic plasma system. In a control with normal factor V, the propagation phase of thrombin generation is attenuated substantially at the tissue factor concentrations used in this experiment (i.e., it is near threshold). With factor V Leiden and low normal TFPI, the propagation phase of thrombin generation is equivalent to a situation in which the protein C regulatory system is totally dysfunctional. This observation suggests the risk of thrombotic pathology. An in vivo parallel to this in vitro experiment has been reported by Eitzman et al., who showed that factor V Leiden (+/+) mice with reduced levels of TFPI (+/-) died of thrombosis.

Function

TFPI is the principal stoichiometric inhibitor of the extrinsic pathway (factor VIIa-tissue factor) of coagulation (Fig. 18.6). The extrinsic pathway generates low levels of the serine proteases, factor IXa (~1 pmol/L), and factor Xa (~10 pmol/L). As soon as the proteases are formed, factor Xa can activate prothrombin to generate thrombin, and factor IXa can combine with its cofactor factor VIIIa and form the intrinsic tenase complex to generate more factor Xa. This is followed by the formation of the prothrombinase complex (factor Xa-factor Va), which converts prothrombin to thrombin. The TFPI mechanism allows the factor VIIa-tissue factor complex to initiate factor Xa formation but then suppresses high levels of factor Xa product formation by this complex. TFPI is the principal regulator of the initiation phase of thrombin generation (Fig. 18.11).

The actual mechanism involves a rapid interaction between the second Kunitz domain of TFPI with the factor Xa active site; localization of the complex to the membrane surface is mediated by the Gla domain of factor Xa. Once surface bound, the factor Xa-TFPI complex rapidly inactivates tissue factor-factor VIIa. This complex formation depends on the binding of the first Kunitz domain of TFPI to the factor VIIa active site. These interactions together form a stable quaternary complex, tissue factor-factor VIIa-TFPI-factor Xa. Ethylenediaminetetraacetic acid (EDTA) can readily dissociate this inhibited quaternary complex. Protein S enhances TFPIα inhibition of factor Xa; although whether this affects TFPIα suppression of the factor VIIa-tissue factor complex is controversial.

Inhibition of factor VIIa-tissue factor by TFPI is not completely dependent on the presence of factor Xa because the factor IXa-TFPI complex can also bind to and inhibit factor VIIa-tissue factor. However, the binding affinity of TFPI for factor IXa is significantly less than for factor Xa. The physiologic relevance of this route of inhibition is thus debatable because high plasma concentrations of TFPI are required. At normal plasma concentrations, this multicomponent interaction of TFPI allows basal function of the factor VIIa-tissue factor complex but inhibits it after more extensive activation occurs.

When combined with the stoichiometric inhibitor antithrombin, a synergistic regulatory effect of blood coagulation occurs by inducing kinetic “thresholds” such that the initiating tissue factor stimulus must achieve a significant magnitude to propel thrombin generation. Tissue factor concentrations below the threshold concentration are ineffective in promoting robust thrombin generation because of the cooperative influence of the inhibitors; concentrations in excess of the threshold yield robust and almost equivalent thrombin generation. In a similar fashion, TFPI and the dynamic protein C-thrombomodulin-thrombin system cooperate to provide a threshold-limited, synergistic inhibition of thrombin production. In this instance, TFPI slows the initiation phase, whereas the APC system reduces the availability of the cofactors factors Va and VIIIa, thereby shutting down the propagation phase of thrombin generation (Fig. 18.11).
Regulation

TFPI administered intravenously to rats and mice is cleared rapidly from the circulation by liver hepatocytes, which recognize its COOH-terminal region (third Kunitz domain and basic COOH-terminus)\(^{1347,1348}\) and \(^{1349}\) TFPI is cleared by the promiscuous endocytic receptor, low-density LRP. Several lines of evidence suggest that TFPI binding to heparin-like sites on the cell surface may precede its catabolism by LRP. In addition, TFPI appears to be important for factor Xa catabolism. TFPI-factor Xa complexes are cleared by a liver receptor that is distinct from LRP.

**ANTICOAGULANT PROTEINS: SERINE PROTEASE INHIBITOR SUPERFAMILY (SERPIN)**

Inhibitory serpins are irreversible covalent suicide protease inhibitors. These inhibitors target serine proteases, a family of proteolytic enzymes sharing common active site architectures and common catalytic mechanisms. Key features of these enzymes include a nucleophilic serine hydroxyl moiety that attacks the carbonyl group of the targeted bond and the formation of a transient acyl-enzyme intermediate between the enzyme and the NH\(_2\)-terminal part of the substrate polypeptide. In vivo, when a serpin successfully reacts with a protease, catalysis of serpin proteolysis is arrested at the acyl-enzyme stage, and the serpin-enzyme complex is cleared from the circulation by specific receptor-mediated processes. Members of this multigene inhibitor family include antithrombin, heparin cofactor II, \(\alpha_1\)-proteinase inhibitor (also known as \(\alpha_1\)-antitrypsin), C1 esterase inhibitor, protein C inhibitor, PAI-1, \(\alpha_2\)-antiplasmin, protein Z-dependent protease inhibitor, and protease nexin-1. Plasminogen activator-1 and \(\alpha_2\)-antiplasmin are discussed in detail in the section on Inhibitors of the Fibrinolytic System, and protein Z-dependent protease inhibitor is discussed briefly in the section on Protein Z. Serpins function in diverse physiologic processes including blood coagulation, fibrinolysis, complement activation, angiogenesis, apoptosis, inflammation, neoplasia, and viral pathogenesis\(^{1350,1351,1352}\) (Table 18.7). When a member of the serpin family is either deficient or dysfunctional, several biologic disorders are evidenced, including thrombosis,\(^{1353,1354}\) emphysema,\(^{1355}\) lupus erythematosus,\(^{1356}\) liver disease,\(^{1357}\) and dementia.\(^{1358}\)

In the past two decades, advances have been made to further understand the mechanism of action of serpins.\(^{1053,1359,1360,1361,1362,1363,1364,1365,1366}\) and \(^{1367,1368,1369,1370}\) Serpins in uncleaved states

\(^{P.470}\)

\(^{1367,1371,1372}\) Achievement of the first crystal structure for a serpin-protease complex (\(\alpha_1\)-antitrypsin-trypsin)\(^{1371}\) has confirmed the physical displacement of the tethered protease: The conformation of \(\alpha_1\)-antitrypsin in the complex is superimposable with that of the isolated cleaved \(\alpha_1\)-antitrypsin. The crystal structure also revealed that the translocated, tethered protease has undergone an overall 37% loss of structure with its catalytic site radically disrupted.

Human antithrombin is a single-chain glycoprotein (M, = 58,000) that circulates in blood at a concentration of approximately 140 µg/ml (2.4 µmol/L). It circulates as two glycoforms, \( \alpha_2 \)-Antiplasmin and plasmin, and is involved in the regulation of coagulation and fibrinolysis. It is primarily expressed in the liver and kidney, and its gene expression is not well established. It is primarily expressed in the liver with low levels detected in the brain and kidney. Cis-acting elements and trans-acting factors have been identified that regulate constitutive expression of the human antithrombin gene.

Antithrombin

Antithrombin is a member of the serpin proteinase inhibitory family and circulates in blood as a single-chain glycoprotein (Table 18.4). Its \( t_{1/2} \) is approximately 61 to 72 hours. Other names for antithrombin include antithrombin-heparin cofactor and heparin cofactor. Despite its name, antithrombin inhibits not only thrombin, but also many of the other enzymes in the coagulation pathway. Congenital antithrombin deficiency exhibits an autosomal dominant pattern of inheritance, with an incidence of 1:2,000 to 1:5,000. The complete absence of antithrombin is lethal. Individuals with this deficiency have partial expression of antithrombin and are prone to thromboembolic disease. Inherited deficiency is categorized by either quantitative defect with a reduction in antigen and activity (type I) or qualitative with reduced antithrombin functional activity and normal antigen levels (type II). These defects are caused by a variety of mutations that include insertions, deletions, and missense mutations. Function can be compromised by mutations in the thrombin-binding domain or the heparin-binding domain. Unstable variants of antithrombin have been identified in families with severe episodic thrombotic disease. Acquired antithrombin deficiency occurs in patients with sepsis or severe traumatic shock. Therefore, studies are being conducted on the use of antithrombin as an agent for treating coagulation abnormalities associated with sepsis or other inflammation disorders.

Gene Structure and Expression

The gene encoding antithrombin is located on chromosome 1 in the q23-q25 region and spans 13.5 kb of genomic DNA (Table 18.6). The gene is composed of seven exons and six introns. The mechanisms underlying antithrombin gene expression are not well established. It is primarily expressed in the liver with low levels detected in the brain and kidney. Cis-acting elements and trans-acting factors have been identified that regulate constitutive expression of the human antithrombin gene.

The mechanisms underlying antithrombin gene expression are not well established. It is primarily expressed in the liver with low levels detected in the brain and kidney. Cis-acting elements and trans-acting factors have been identified that regulate constitutive expression of the human antithrombin gene.

Biochemistry

Human antithrombin is a single-chain glycoprotein (M, = 58,000) that circulates in blood at a concentration of approximately 140 µg/ml (2.4 µmol/L). It circulates as two glycoforms,
α and β variants, that contain identical polypeptide backbones but differ in carbohydrate content and heparin affinity.\(^\text{1401}\)

The antithrombin α variant is the predominant form (\(^\text{90%}\)).\(^\text{1402}\) The structure of antithrombin α consists of 432 amino acid residues, with three disulfide bonds and four sialylated oligosaccharides at Asn\(^\text{96}\), Asn\(^\text{135}\), Asn\(^\text{155}\), and Asn\(^\text{192}\) (Fig. 18.12). The carbohydrate residues account for 15% of the total mass.\(^\text{1402,1403,1404,1405}\) The antithrombin β variant is not glycosylated at Asn\(^\text{115}\). Antithrombin β binds heparin more tightly than does antithrombin α and is observed to preferentially accumulate on the vessel wall when heparan sulfate proteoglycans are exposed.\(^\text{1406}\) The reactive site peptide bond is Arg\(^\text{103}\)-Ser\(^\text{194}\).

The first x-ray crystal structure of antithrombin that was determined was a cleaved form that diffracted to 3.2 Å resolution.\(^\text{1407}\) Significant differences between structures of antithrombin and another serpin, α1-antitrypsin, were identified in the NH\(_2\)-terminal region that defines the heparin-binding site. Since then, several x-ray crystal structures of intact antithrombin have been solved to 2.6 to 3.0 Å.\(^\text{1408,1409}\) and \(^\text{1410}\)

Function

Antithrombin has a broad spectrum of inhibitory activity with most of its target proteases participating in the coagulation cascade. It is primarily an inhibitor of the serine protease thrombin as well as factor Xa, factor IXa, factor VIIa-tissue factor, factor Xla, factor XIIa, and plasma kallikrein.\(^\text{1411,1412}\) and \(^\text{1413}\) Antithrombin plays a key role in maintaining hemostasis. Antithrombin also displays antiproliferative and antiinflammatory properties that primarily derive from its ability to inhibit thrombin. In addition, latent or cleaved forms of antithrombin have antiangiogenic activities.\(^\text{1414}\) Heparins and heparan sulfates potentiate these reactions and are used in the treatment of thrombosis.\(^\text{1415}\) When antithrombin is complexed with heparin, its rate of inhibition of several coagulation proteases is accelerated by up to 10,000-fold.

In general, binding of heparins to antithrombin improves its reactivities with proteases in two ways: (1) By inducing conformational changes in antithrombin, including better presentation both of the reactive center loop and of exosites on antithrombin that interact with target enzymes; and (2) by enabling a template effect, whereby binding of enzyme and antithrombin to the same heparin molecule improves the likelihood of the interaction.

The mechanism of inhibition involves reaction of the active site of the enzyme with a peptide loop structure (reactive center loop, Fig. 18.12) of the serpin to form a tight, equimolar (1:1) complex. Inactivation is suspected to proceed through covalent bond formation between antithrombin and the protease, followed by inactivating structural rearrangements of both antithrombin and the protease. However, the exact mechanism of inhibition of serine proteases by antithrombin is uncertain. In the case of factor Xa inhibition, crystallographic data indicate that heparininduced conformational change in antithrombin permits contacts between antithrombin and the active site and two exosites of factor Xa.\(^\text{1416}\)

Heparin Cofactor II (Leuserpin 2)

Heparin cofactor II, also called leuserpin 2, is a member of the serpin family.\(^\text{1417}\) Like antithrombin, heparin cofactor II inhibits thrombin in a reaction that is accelerated more than 1,000-fold by heparin.\(^\text{1418}\) However, heparin cofactor II is unique in that it is also stimulated by the proteoglycan dermatan sulfate. The plasma concentration of heparin cofactor II is 0.5 to 1.4 μmol/L\(^\text{1419,1420}\) (Table 18.4). Its plasma t\(_{1/2}\) is approximately 2.5 days. The physiologic role of heparin cofactor II is uncertain at the present time. Low levels of thrombin-heparin cofactor II complexes are detected in normal plasma samples; elevated levels were detected in patients with DIC.\(^\text{1421}\) Although inherited deficiency of heparin cofactor II has been associated with thrombosis, this is not always the case.\(^\text{1422,1423}\) and \(^\text{1424}\) The incidence of heparin cofactor II deficiency in patients with thromboembolic disorders appears to be similar to that in the normal population.\(^\text{1425}\)

Gene Structure and Expression

The gene encoding human heparin cofactor II, consisting of five exons and four introns, spans approximately 14 kb on chromosome 22 in the q11 region proximal to the breakpoint cluster region.\(^\text{1426,1427}\) The human heparin cofactor II gene is expressed exclusively in the liver and by a hepatoma-derived cell line.\(^\text{1428,1429}\)

Biochemistry

Human heparin cofactor II (M, \(\approx 66,000\)) circulates as a single chain protein of 480 amino acid residues that contains 10% carbohydrate.\(^\text{1419,1427,1428}\) It is glycosylated at Asn\(^\text{30}\), Asn\(^\text{169}\), and Asn\(^\text{368}\) and is sulfated at Tyr\(^\text{60}\) and Tyr\(^\text{73}\). It has three cysteines with no identified disulfide bonds. A cationic region of the molecule encompassing residues 163 to 194 constitutes the GAG binding site; dermatan sulfate and heparin bind to heparin cofactor II at nonidentical but overlapping
sites in this region. Residues Lys173, Arg184, Lys185, Arg189, Arg192, and Arg193 have been specifically implicated in heparin binding. The NH2-terminal region of heparin cofactor II contains a cluster of acidic residues that are thought to interact with the positively charged GAG binding site. This “acidic” tail of heparin cofactor II contains two so-called hirudin domains—GlutAspAspTyrLeuAsp47 and GlutAspAspTyrIleAsp45; in each, the Tyr residue is sulfated. It has been proposed that the NH2-terminal “acidic” tail is constrained in the native structure through association with the highly cationic heparin-binding region. In the presence of GAG, the acidic region is displaced from the heparin-binding site, thus making it available for binding to the anion-binding exosite I of thrombin. However, crystallographic studies of heparin cofactor II indicate that the acidic tail of heparin cofactor II is flexible in the crystal and not associated with the heparin-binding site. Other functionally important regions of heparin cofactor II include a chemotactic peptide harbored between residues Asp56 and Tyr60 that is released by leukocyte proteases. Residues Phe606 to Ile666 constitute a pentapeptide recognition motif for the hepatic serpin enzyme complex receptor that may be involved in clearance of heparin cofactor II-enzyme complexes.

The domain of heparin cofactor II with homology to other serpins is at the COOH-terminus of the protein. It exhibits approximately 30% homology to antithrombin and other serpins. The reactive site peptide bond is Leu—Ser. This reactive center loop sequence is consistent for an inhibitor with specificity for proteases with a preference for nonpolar residues with relatively bulky side chains in the P1 position. Two such proteases, chymotrypsin and cathepsin G, do react with heparin cofactor II. Thrombin reactivity with heparin cofactor II is unusual because thrombin generally prefers substrates with arginine in the P1 position. Exosite binding interactions, such as that between the hirudin-like sequences of heparin cofactor II and exosite I of thrombin, compensate for the less than ideal structure of the P1 residue and allow thrombin to form a productive Michaelis complex with heparin cofactor II.

Function

The only coagulation enzyme inhibited by heparin cofactor II appears to be thrombin. However, the rate of thrombin inhibition by heparin cofactor II in the absence or presence of GAGs is significantly slower than by antithrombin under similar conditions. Considering that the plasma concentration of heparin P.472

cofactor II is 25% to 50% that of antithrombin and that low levels of heparin cofactor II are not strongly associated with thrombosis, the physiologic role of heparin cofactor II as a systemic thrombin inhibitor has been questioned. In vitro, heparin cofactor II inhibition of thrombin is stimulated by dermatan sulfate proteoglycans synthesized by fibroblasts and vascular smooth muscle cells. Thus, heparin cofactor II may be uniquely suited to regulate extravascular thrombin in areas of vascular endothelial disruption, in which heparin cofactor II would be exclusively stimulated by dermatan sulfate in the subendothelial layers. In addition, heparin cofactor II may participate in regulation of acute inflammation and wound healing by harboring a peptide chemotactic for neutrophils and monocytes that is released by leukocyte proteolysis.

Heparin cofactor II may also have a role in protection from thrombosis during pregnancy. Increased levels of dermatan sulfate in the maternal and fetal circulation along with increased levels of heparin cofactor II in pregnant women have been reported. Heparin cofactor II has also been reported to potentiate the activation of endothelial cells and promote angiogenesis.

α1-Proteinase Inhibitor (α1-Antitrypsin)

α1-Proteinase inhibitor is the most abundant circulating inhibitor of the serpin family. It is a single-chain glycoprotein that circulates in blood at a concentration of 1.5 to 3.5 mg/ml with a relative molecular weight of 53,000 (Table 18.4). It is synthesized predominantly in the liver and has a t1/2 of 6 days. α1-Proteinase inhibitor is considered an acute-phase reactant.

Deficiency in α1-proteinase inhibitor is a common autosomal recessive disorder (1:1,600 to 1:1,800) that can potentially be lethal. It is found associated with emphysema, liver cirrhosis, and hepatocellular carcinoma. Treatment for α1-proteinase inhibitor deficiency relies on infusions of human plasma-derived α1-proteinase inhibitor. Progress is under way to develop a therapy based on gene repair and or strategies to block aberrant conformational transitions.

Gene Structure and Expression

The gene for α1-proteinase inhibitor is located on chromosome 14 band q32.1, is approximately 5 kb long and contains seven exons and six introns (Table 18.6). Uniquely, α1-antichymotrypsin, corticosteroid-binding
Biochemistry

α1-Proteinase inhibitor is the most studied of the serpins, with high-resolution crystal structures achieved for the inhibitor by itself and in complex with a target protease. The 452-amino acid sequence for human α1-proteinase inhibitor shows two disulfide bridges and four glucosamine-based carbohydrate chains. The reactive site bond that is targeted by serine proteinases is between Met and Ser. Studies using nuclear magnetic resonance spectroscopy of the complex between human methionine-labeled α1-proteinase inhibitor and porcine pancreatic elastase have shown that a tetrahedral intermediate complex is formed during the serpin-protease interactions. The three-dimensional x-ray crystal structure of cleaved α1-proteinase inhibitor identified that for activity, α1-proteinase inhibitor requires the insertion of a single residue, Thr, into β sheet A. This was supported by the x-ray crystal structures of α1-proteinase inhibitor complexed with synthetic peptides that correspond to the unprimed NH2-terminal of the active site loop. The five-stranded β sheet A of α1-proteinase inhibitor undergoes conformational changes that facilitate and stabilize the insertion into sheet A of the reactive center loop after cleavage by its target serine proteases. The solution structure of α1-proteinase inhibitor has also been characterized by high-flux neutron scattering and by synchrotron x-ray scattering.

Function

α1-Proteinase inhibitor can inhibit a wide range of serine proteases. Its primary physiologic target is the inhibition of neutrophil elastase to protect the elastin fibers of the lung. The role of α1-proteinase inhibitor in blood coagulation is minimal. It has been shown to inhibit factor Xla in vivo to be an important inhibitor of factor Xa in purified and plasma systems. APC complexes with α1-proteinase inhibitor have also been detected by enzyme-linked immunosorbent assay in patients with DIC. Inhibition by α1-proteinase inhibitor is heparin independent.

C1 Esterase Inhibitor

C1 esterase inhibitor is a member of the serpin proteinase inhibitor family that is present at 170 µg/ml in blood (Table 18.4). It is predominantly synthesized in the liver. When complexed with a protease (e.g., factor Xla), it has a t1/2 of 95 to 104 minutes. Targets for C1 esterase inhibitor are found in the complement cascade and the coagulation cascade.

Deficiency in C1 esterase inhibitor can result in hereditary angioedema and has been identified in a patient with lupus erythematosus. Cases of acquired C1 esterase inhibitor deficiency have been reported associated with splenic lymphoma. C1 esterase inhibitor-deficient mice show no obvious phenotypic abnormality, although, in conjunction with a bradykinin type 2 receptor knockout, diminished vascular permeability was observed. The C1 esterase inhibitor is used in the treatment of hereditary angioedema and sepsis. Its potential use in reducing ischemia reperfusion injury is being investigated.

Gene Structure and Expression

The primary structure of human C1 esterase inhibitor was initially determined by peptide and DNA sequencing. The only proteolytic processing that occurs is that a 22-residue signal peptide required for secretion is cleaved. The C1 esterase inhibitor gene is located on chromosome 11, bands p11.2-q13 (Table 18.6). The C1 esterase inhibitor gene consists of eight exons and seven introns and is approximately 17 kb in length. In vivo, androgens enhance expression of C1 esterase inhibitor. In vitro studies show that C1 esterase inhibitor mRNA and protein levels increase after stimulation with γ- and α-interferon, TNF-α, IL-6, and monocyte colony-stimulating factor.

The molecular defects found associated with C1 esterase inhibitor deficiency include Alu repeat-mediated deletions, missense mutations, frame-shifts, stop codon mutations, promoter variants, splice site mutations, or deletions of a few amino acids. The clinical manifestation of this deficiency is predominantly angioedema.

Biochemistry

C1 esterase inhibitor is a single-chain glycoprotein containing 478 amino acid residues that circulates with an apparent molecular mass of 104,000 when analyzed by SDS-PAGE. The amino acids account for only 51% of the apparent molecular mass of the circulating protein, with 35% of the remaining mass accounted for by carbohydrate moieties. Neutron scattering, x-
ray crystal structure determinations, $^1$H nuclear magnetic resonance spectroscopy, and Fourier transform infrared spectroscopy have been used to study the structure of C1 esterase inhibitor, revealing a two-domain structure. $^{1489,1490}$ and $^{1491}$ The NH$_2$-terminus, containing 113 amino acids, is heavily glycosylated with three N-linked and seven O-linked oligosaccharides. The COOH-terminus contains 365 amino acids with three N-linked oligosaccharides. When C1 esterase reacts with target proteases, the serpin undergoes changes in its whole secondary structure—not only the reactive site loop.

Function

C1 esterase inhibitor is a member of the serpin inhibitor family. It plays an important role in the regulation of the classic complement pathway, specifically as the sole regulator of the activities of C1r and C1s. $^{1492}$ C1 esterase inhibitor’s role in coagulation is mainly targeted to the contact activation pathway through the regulation of kallikrein, $^{179,1493}$ factor XII, $^{134}$ factor XIa, $^{138}$ and factor Xa. $^{128,293,1426,1427,1484}$ Unlike other serpin inhibitors, such as antithrombin, protein C inhibitor, or PAI-1, the activity of C1 esterase inhibitor is not affected by heparin. $^{1495}$

Protein C Inhibitor (Plasminogen Activator Inhibitor-3)

Protein C inhibitor is a member of the serine proteinase inhibitor family. It is also known as PAI-3. Protein C inhibitor is considered nonspecific in that its targets range from procoagulant, anticoagulant, and fibrinolytic enzymes to plasma and tissue kallikreins, the sperm protease acrosin, and prostate-specific antigen. $^{1496,1497}$ It circulates in blood at a concentration of 5 µg/ml $^{1498,1499}$ (Table 18.4), and is cleared from the circulation with a t$_{1/2}$ of 1 day. When in complex with a target (e.g., APC), it is cleared from circulation with a t$_{1/2}$ of 20 minutes. $^{1500}$ Hereditary or acquired protein C inhibitor deficiency has not been documented to date. $^{1501}$ A case control study of thrombophilia showed that high levels of protein C inhibitor might constitute a mild risk factor for venous thrombosis. Protein C inhibitor-deficient mice (-/-) show impaired spermatogenesis and male infertility. $^{1502}$

Gene Structure and Expression

The gene for protein C inhibitor has been mapped to chromosome 14 band q32.1 (Table 18.6). It is 11.5 kb in length and consists of five exons separated by four introns. $^{1503,1504}$ The organization and location of this gene are similar to those of the genes for α2-antitrypsin and α1-antichymotrypsin, suggesting a common ancestor for these genes. $^{1503,1505,1506}$ Human protein C inhibitor is mainly synthesized in the liver, $^{1499}$ but has also been identified in platelets and megakaryocytes, $^{1507,1508}$ the kidney, $^{1509}$ and the testes, seminal vesicle, and prostate. $^{1509}$

Biochemistry

Human protein C inhibitor in blood has a relative molecular weight of 57,000. $^{1498,1505}$ The mature protein contains 387 amino acids; a 19-amino acid signal peptide is present before secretion. Five potential N-linked glycosylation sites were found in the mature protein, $^{1505}$ and their roles in protein C inhibitor activity have been studied by mutational analysis. $^{1510}$ The reactive site bond is located at Arg$^{345}$-Ser$^{355}$, and a stable 1:1 molar complex is formed between protein C inhibitor and its target proteases. Protein C inhibitor binds heparin, and its activity is accelerated when in complex with heparin $^{1511}$; unlike other related heparin-binding serpins such as antithrombin, heparin cofactor II, and protease nexin, the primary heparin-binding site of protein C inhibitor is in the H helix, not the D helix. $^{1512}$ A recent crystal structure of this inhibitor provides a structural basis for understanding its multiple functions. $^{1513}$

Function

Protein C inhibitor is a nonspecific inhibitor of serine proteinases and inhibits APC, thrombin, thrombin-thrombomodulin, factor Xa, u-PA, $^{1514,1515}$ and t-PA $^{1517,1518}$ The major target of protein C inhibitor, as its name suggests, is APC, $^{1500,1519,1520}$ although from a kinetic point of view, the reaction with thrombin-thrombomodulin is the most favorable. $^{1518}$ This is the physiologically most important inhibitor of APC. Protein C inhibitor has been shown to regulate TAFI activation by inhibiting the thrombin-thrombomodulin complex. $^{1514}$ Its importance as a dual regulator of coagulation and fibrinolysis remains unresolved. $^{1521}$ The importance of the regulation of APC by protein C inhibitor is evident by the use of this complex as a marker for detection of deep vein thrombosis. $^{1522}$ Other targets for protein C inhibitor include human kallikrein, $^{183}$ factor XIa, $^{183}$ Factor Xa, and thrombin. Because there are no documented patients with a deficiency to date, the actual function of protein C inhibitor in vivo is yet to be elucidated.

PROTEINS OF CLOT FORMATION

Early efforts to understand how blood clots form were directed at dissecting the vertebrate coagulation system and determining its components. This work revealed the central event in blood coagulation to be the conversion of soluble fibrinogen (factor I) to insoluble fibrin. Basically, this is accomplished when the coagulation enzyme thrombin (factor IIa)
removes small polar peptides (termed fibrinopeptides) from each fibrinogen molecule, forming fibrin. These fibrin molecules noncovalently interact with each other, forming a fibrin web. Fibrin stabilization is accomplished by the action of a second coagulation enzyme (factor XIIIa) that introduces numerous covalent cross-links between these fibrin molecules. The resulting fibrin web is able to capture platelets and red blood cells, effectively sealing the wound and stemming plasma loss.

Factor XIII (Fibrin Stabilizing Factor)

The first apparent suggestion of cross-linked fibrin by factor XIII came in 1923 from Barkan and Gaspar, who reported that fibrinogen preparations, when clotted in the presence of Ca²⁺, generated clots that were insoluble in weak bases. Later, in the 1940s, work by Robbins, Laki and Lorand, and Lorand confirmed the presence of a serum factor that caused the transition to an insoluble clot and termed it fibrin stabilizing factor. It was not until 1963 that the International Committee on Blood Clotting Factors acknowledged fibrin stabilizing factor as a clotting factor and termed it factor XIII. Recommended terms and abbreviations for factor XIII have been established.

Factor XIII functions as a transglutaminase that can form cross-linked amide bonds between specific glutamine and lysine residues on polypeptide chains. It plays an important role in hemostasis and thrombosis as well as participating in physiologic processes of cell proliferation and cell migration. Factor XIIIa has multiple substrates including fibrin(ogen), fibronectin, α₂-plasmin inhibitor, collagen, vitronectin, vWF, actin, myosin, factor V, and thrombospondin. Recent reviews discuss the role of factor XIII in blood clotting, angiogenesis, cellular function, inflammation, and cardiac and vascular diseases.

Gene Structure and Expression

Plasma factor XIII circulates as a heterotetramer composed of two A-chains and two B-chains. The genes are located on different chromosomes. The gene for the factor XIII A subunit is located on chromosome 6, bands p24-25, and spans approximately 160 kb (Table 18.2). The gene has 15 exons specifying a mature protein of 730 amino acids. The circulating product of the B subunit gene is a protein of 641 amino acids. The gene is located on chromosome 1, bands q31-32.1, spans approximately 28 kb, and has 12 exons (Table 18.2). Ten short homologous units, termed sushi or glycoprotein-1 domains, are coded for by exons 2 to 11 in the B subunit gene. Proteins associated with regulation of the complement system also contain sushi domains.

Factor XIII deficiency is autosomal recessive and is a rare bleeding disorder. It has a frequency in the general population of 1 in 2 million. The phenotype displays varying degrees of bleeding and is typically associated with the absence of cross-linking of fibrin monomers and impaired cross-linking of α₂-antiplasmin inhibitor to fibrin. Mutations have been identified in both the A and B subunits, with the latter being the least common. Reviews by Loewy et al. and Arians et al. describe the deficiency mutations and polymorphisms for both gene products that have been identified to date.

Five common polymorphisms in the A subunit have been identified. Three of these (Val34Leu, Pro564Leu, and Glu651Gln) have allele frequencies > 0.2. Adverse effects have not been associated with the Glu651Gln variation; however, young women with the Leu564/Leu564 genotype may be at increased risk of hemorrhagic stroke. The (Val34→Leu) polymorphism in the A subunit is found in approximately 25% of the population. This Val to Leu replacement takes place three amino acids away from the thrombin cleavage site at Arg-Gly. Due to its close proximity to the thrombin cleavage site, it has been postulated that this mutation might modulate factor XIII activation. Studies suggest that this polymorphism is a determining factor in arterial and venous thrombosis.

This polymorphism has been suggested to be associated with a protective effect against myocardial infarction. The Leu encoding allele occurs at a lower frequency in patients exhibiting myocardial infarction, deep vein thrombosis, and cerebral infarction. Studies also showed that the Leu³⁴ mutation accelerates factor XIII activation by thrombin and affects fibrin cross-linking. This acceleration has been proposed to account for the wide reference range reported for factor XIII activity. A study by Undas et al. demonstrated in a bleeding time blood model that aspirin has a more pronounced effect on factor XIII activation when individuals are carriers of the Leu³⁴ allele. The mechanism underlying the lower risk for myocardial infarction observed in the Leu³⁴ carriers, despite faster factor XIII activation, is still unclear.

Biochemistry

There are two pools of factor XIII—a plasma pool and an intracellular platelet pool. Plasma factor XIII circulates as a 320-kDa A₂B₂ heterotetramer composed of two identical A-chains (Mᵣ = 83.2 kDa) and two B-chains (Mᵣ = 79.7 kDa) (Table
18.1). The A- and B-chains associate noncovalently with an apparent binding constant of 0.4 µmol/L. Plasma concentration of factor XIII is approximately 30 µg/ml (94 nmol/L), with a reference interval in the population of 66% to 134%. The A subunit contains 730 residues, and the C-terminal portion of the A-chain contains three important functional sites: the catalytic site (Cys β1548-His β1573-Asp β1593), a calcium-binding site, and the activation peptide. The A subunit is arranged into five distinct structural domains: the activation peptide (residues 1 to 37); the β sandwich (residues 38 to 184); the catalytic core (residues 185 to 515); barrel 1 (residues 516 to 628); and barrel 2 (629 to 730). The activation peptide of one A subunit limits access to the active site cysteine of the other A subunit of the dimer. The B subunit contains 641 residues, is glycosylated, and contains 10 sushi domain repeats. Each sushi domain repeat contains approximately 60 amino acids and is stabilized by two disulfide bonds. By electron microscopy, the B domain appears as strands that are thin, flexible, and kinked. The B-chain has no enzymatic activity and has been thought to function as a carrier of the A subunit.

Several x-ray crystal structures of the zymogen factor XIII A2 subunit have been solved up to 2.0 Å. These studies revealed a catalytic triad of Cys β1548-His β1573-Asp β1593 similar in structure to that observed in cysteine proteases. Crystal structures of thrombin-activated factor XIII have been solved with and without Ca²⁺. The bone marrow is the primary site of synthesis for the plasma factor XIII A-chain, and intracellular factor XIII is present in platelets, megakaryocytes, and monocytes as the 160-kDa A2 homodimer. The intracellular A₂ dimer, located in the cell cytosol, does not contain a leader sequence or carbohydrate, and its amino terminus is acetylated. How the A₂ dimer is transferred out of the cell and which cell type is the primary source of plasma A₂ are not clearly understood. Secretion may be accomplished by the same pathway used by other nonclassically secreted proteins in blood, including fibroblast growth factor and the interleukins. Approximately 50% of the total potential factor XIII A-chain activity in human blood is found in platelets.

During fibrin formation, platelet A₂ can be expressed on the platelet surface and plays an important role in fibrin cross-linking. Plasma factor XIII A2-chains can also bind to thrombin-activated platelets. This binding is enhanced by thrombin cleavage of the A-chains as well as the thrombin-dependent activation of the platelet. The association of the factor XIIIa molecule with the activated platelet surface allows it to participate at the platelet-fibrin interface, thereby stabilizing hemostatic plugs. The factor XIIIa binding site on platelets can be degraded by plasmin, and the B subunit is solely synthesized in the hepatocyte and is secreted as a monomer. After being secreted, the A and B subunits associate, becoming an A₂B₂ tetrameric molecule in the blood.

Activation

Activation of the zymogen by thrombin occurs in the NH₂-terminus of the A-chains at Arg³⁷-Gly³⁸ and releases a 36-amino acid activation peptide from each of the A-chains (Fig. 18.13). Whether immediate dissociation of the activation peptide from the rest of the molecule is part of the activation process is not clear, because crystals of thrombin-activated FXIII showed no change in the location and conformation of the activation peptides. This was also seen in the ion-bound structures, and in which the active site residues remained inaccessible to solvent and substrate. These combined results suggest that exposure of the catalytic residues is likely to occur on substrate binding. Calcium is required for factor XIIIa to expose its active site cysteine and catalytic activity is expressed only after the A-chain dimer is dissociated from the B-chain through a Ca²⁺-dependent process after thrombin proteolysis. Fibrin and fibrinogen play important roles as cofactors in the dissociation of the B-chains from thrombin-cleaved factor XIII. The intracellular form of factor XIII only contains the A-chain; therefore, it does not require the dissociation of the B-chain, but it still requires a calcium-dependent thrombin proteolysis. The process of factor XIII activation in whole blood has been correlated with fibrin formation, while in hemophilia this coordination is disrupted. This creates a carefully regulated system that has cross-linked polymers occurring as soon as fibrin is being formed. The rate of thrombin cleavage of plasma factor XIII has been shown to be greatly accelerated by the presence of fibrin polymers. This positive feedback network between thrombin, fibrin(ogen), and factor XIII ensures that a stable clot can form rapidly to maintain hemostasis.

P.475
FIGURE 18.13. Activation of plasma factor XIII. The thrombin-catalyzed activation of plasma factor XIII (A2B2; 320,000 Da) occurs in two steps. In the first step, thrombin cleaves the (R37-G38) bond. This releases the activation peptides (residues 1 to 37) from the A-chains, producing the inactive intermediate a’A2B2. Fibrinogen interactions promote this event. In the second Ca2+-dependent step, the B-chains dissociate from the a’A2B2 intermediate, exposing the active site cysteine, Cys314, of the a’ subunits. These chains can re-associate in the presence of divalent cation chelators like ethylenediaminetetraacetic acid (EDTA). The enzyme a’A2 is now capable of catalyzing the formation of isopeptide bonds between glutamine residues and lysine residues of adjoining polypeptide chains. In this model, the a’-chains are oriented in such a way as to promote cross-linking of fibrin polymers in an antiparallel configuration.

Function
Activated factor XIII is essential for normal hemostasis and performs numerous functions in pathologic processes. Being a transglutaminase, activated factor XIII forms isopeptide bonds between the γ-carboxylamide and α-amino groups of glutamyl and lysyl residues, respectively. Factor XIIIa is the only enzyme in the blood coagulation cascade that uses a cysteine for catalysis. To date, no known endogenous inhibitor has been described to regulate this important enzyme. Substrates for factor XIII include fibrin(ogen), fibronectin, α2-plasmin inhibitor, collagen, vitronectin, vWF, actin, myosin, factor V, and thrombospondin.

Fibrin is the main physiologic substrate for factor XIIIa. The basic mechanism involves γ-chain dimerization and α-chain polymerization by creating isopeptide cross-links. The structural specificity for this reaction remains poorly defined. It
appears to reside within the primary amino acid sequence surrounding the surface-exposed glutamine residues.\textsuperscript{1605,1606}

How clot stabilization occurs in fibrin formation is covered in the section on Polymerization (Fibrin Formation).

### Fibrinogen (Factor I) and Fibrin

This section focuses on the gene structure, structure/function relationships, and regulation of fibrinogen and its insoluble counterpart fibrin. These topics, although extensively discussed within this section, have also been the subject of several comprehensive reviews.\textsuperscript{1607,1608,1609,1610} and \textsuperscript{1611} as well as a 2000 New York Academy of Sciences symposium.\textsuperscript{1612}

Fibrinogen is composed of six polypeptide chains (two A\textsubscript{α}-chains, two B\textsubscript{β}-chains, and two γ-chains); after posttranslational modification, the mature protein circulates in the blood with an average molecular weight of 340,000 Da (Table 18.1). The polypeptide chains are distributed into two symmetric halfmolecules, each containing one A\textsubscript{α}, one B\textsubscript{β}, and one γ-chain with the NH\textsubscript{2}- and COOH-termini oriented in the same direction. The half-molecules are linked by noncovalent and disulfide bonds at their amino termini, yielding a linear arrangement of three nodular structures. The outside two domains, formed by the carboxyl-terminal regions of the B\textsubscript{β}- and γ-chains of fibrinogen, are designated D, whereas the central domain that contains the amino termini of all the chains is designated E. Between 1.7 and 5.0 g of fibrinogen is synthesized per day by the liver,\textsuperscript{1613,1614} with approximately 75% of this fibrinogen secreted into the plasma and the remainder distributed between the lymph and interstitial fluids.\textsuperscript{1614} This translates into a mean plasma level of 2.5 mg/ml with a normal t\textsubscript{1/2} of 3 to 5 days.\textsuperscript{1615,1616} Fibrinogen is considered to be an acute-phase reactant, and as such, it is upregulated two to 10-fold in response to a variety of physiologic stresses including trauma, pregnancy, and tissue inflammation.\textsuperscript{1617}

Fibrinogen has been found in the blood plasma of all vertebrates, including the most primitive vertebrate, the lamprey. Early phylogenetic work on fibrinogen began with protein sequences obtained for various fibrinopeptides.\textsuperscript{1618,1619} It was immediately obvious that although these peptides were exceptionally variable, certain features were conserved; without exception, they all contained an arginyl-glycine bond required for thrombin cleavage.\textsuperscript{1620} Determination of the protein sequences for all three chains revealed that they were homologous and were evolved from a common ancestor.\textsuperscript{1621} The β- and γ-chains share the most identity (42%) in their COOH-terminal domains, although they share no homology with the C-terminal α-chain.\textsuperscript{1622,1623,1624} and \textsuperscript{1625} In fact, the C-terminal α-chain varies greatly between species (molecular weight ranges from 60 to 120 kDa).

Sequence data, especially the detailed work determining intron/exon junctures, support the hypothesis that all three fibrinogen genes evolved from a common ancestor through a series of duplications that began approximately 1 billion years ago.\textsuperscript{1626,1627,1628,1629} and \textsuperscript{1630} At this point, the ancestral gene duplicated to form both the Aα-chain and a β/γ-chain precursor gene. Then, sometime before the last time lampreys and mammals shared a common ancestor (450 million years ago), the β/γ gene duplicated, forming today's β- and γ-chains. There is now a growing collection of proteins that share more than 30% sequence identity with both the β- and γ-chains, including α\textsubscript{C} domains,\textsuperscript{1631,1632} and chicken cytotactin,\textsuperscript{1633} mouse T-cell protein,\textsuperscript{1634} sea cucumber,\textsuperscript{1635} and scabrous gene product from the fruit fly.\textsuperscript{1636}

### Gene Structure and Expression

The fibrinogen locus is composed of three closely linked genes (specifying the polypeptides A\textsubscript{α}, B\textsubscript{β}, and γ) found as single copies in a region of approximately 50 kb (bands q23 to q32) of chromosome 4\textsuperscript{1637,1638,1639,1640,1641} and \textsuperscript{1642} (Table 18.2).

Both the A\textsubscript{α}- and γ-chains are transcribed from the same DNA strand, whereas the B\textsubscript{β}-chain is transcribed from the opposing strand.\textsuperscript{1626} The Aα gene contains six exons, whereas the Bβ has eight and the γ-chain has 10.\textsuperscript{1643,1644} The expression of all three genes appears to share a common regulatory mechanism, potentially via their 5′-flanking regions.\textsuperscript{1646,1647} and \textsuperscript{1648} Therefore, expression for the three chains is coordinately controlled and, at least for the hepatocyte, results in almost equal levels of mRNA for each chain in the cell.\textsuperscript{1629,1641,1644,1649}

A single transcription initiation event at the promoter of each chain produces multiple mRNAs due to alternative polyadenylation site selection in all three chains, as well as alternative splicing for both A\textsubscript{α}- and γ-chains.\textsuperscript{1631,1650,1651} and \textsuperscript{1652} In the case of the γ-chain, normal processing results in a polypeptide chain ending at Val\textsuperscript{411} (human numbering); however, approximately 10% of the time during splicing, the last intron is retained as an exon, resulting in a new chain, γ′, which ends at Leu\textsuperscript{427} 1641,1653. Sometimes the α-chain also fails to remove the last intron, producing a translated protein product that is 27-kDa larger.\textsuperscript{1631,1632} and \textsuperscript{1633,1654} The resulting larger form of fibrinogen is called fibrinogen-420 (1% to 2% of circulating human molecules), and the α-chain extension is called
Interestingly, this new domain shares as much sequence identity (~40%) with the COOH-terminal domain of the β- and γ-chains as the two share with each other.\textsuperscript{1654}

Common polymorphisms of the fibrinogen genes are associated with plasma fibrinogen concentrations as well as susceptibility to, or severity of, atherothrombotic disease.\textsuperscript{1656} Epidemiologic studies have shown a strong association between two polymorphisms of the fibrinogen β-chain gene and fibrinogen plasma concentration.\textsuperscript{1657,1658} However, the majority of the studies did not find any relation with fibrinogen polymorphisms and cardiovascular disease.\textsuperscript{1657,1658} The effect of these polymorphisms and vascular disease still remains in question because environmental or intermediate conditions of the phenotype can influence the outcome. This supports the notion of individualized susceptibility to disease, which is determined by the genotype and environmental risk factors.

Afibrinogenemia

Inherited or congenital afibrinogenemia is an autosomal recessive disorder characterized by a total lack of fibrinogen in the plasma. This disorder, originally described in 1920, now affects more than 150 families, putting the estimated prevalence in the general population at approximately 1 in 1 million.\textsuperscript{1641,1659,1660} It is usually detected at birth with uncontrollable bleeding from the umbilical cord. The phenotype varies from mild to severe with some patients experiencing spontaneous intracranial hemorrhage and splenic rupture throughout life, as well as bleeding after minor trauma.\textsuperscript{1661,1662} It has been suggested that the presence of functional vWF, which allows platelet thrombus formation in the absence of fibrin, may be responsible for the phenotypic variation observed.\textsuperscript{1663,1664} Most patients respond well to replacement therapy.\textsuperscript{1665} To date, 86% of all afibrinogenemia results from a truncation mutation in the fibrinogen Aα gene.\textsuperscript{1659}

Investigation of the roles that both fibrinogen and fibrin play in vivo has been greatly enhanced by the creation of transgenic mice either lacking fibrinogen\textsuperscript{1666} or expressing a modified form of fibrinogen.\textsuperscript{1667} The fibrinogen-deficient mice (Fib Aα\textsuperscript{−/−}) were often able to survive to sexual maturity even though they had no immunologically detectable levels of any chain (Aα, Bβ, γ) in circulation.\textsuperscript{1666} As expected, plasma from these deficient mice was unable to clot in vitro even when combined with exogenous thrombin. In addition, the plasma did not support platelet aggregation in vitro. This is consistent with the view that fibrinogen bridges platelets via activated receptors (e.g., α\textsubscript{IIb}β\textsubscript{3}).\textsuperscript{1668} However, in vivo, these mice are able to form platelet thrombi and are often able to withstand spontaneous bleeding episodes.\textsuperscript{1664} The resilience of the Fib Aα\textsuperscript{−/−} mice is probably due to the fact that all factors required for thrombin generation and platelet activation are present and that platelets have alternative ligands for their activated receptors that are capable of supporting adhesion and thrombus formation.\textsuperscript{1660}

Breeding experiments crossing fibrinogen-deficient mice with other mice deficient in a hemostatic factor are providing insights into the roles fibrinogen and fibrin play in vivo. For example, mice with combined deficiency in both fibrinogen and vWF were found to form stable thrombi, although platelet deposition was found to be delayed and unstable.\textsuperscript{1664} However, crossbreeding plasminogen-deficient mice (Plg\textsuperscript{−/−}) with Aα\textsuperscript{−/−} mice eliminated many of the spontaneous pathologies\textsuperscript{1669,1670} (conjunctivitis, pulmonary lesions, terminal vessel thrombosis, ulceration, or prolapse of the rectum and wasting) normally associated with the Plg\textsuperscript{−/−} genotype, including death at 6 months. In addition, the delayed tissue repair observed in Plg\textsuperscript{−/−} mice after arterial challenge,\textsuperscript{1671} corneal damage,\textsuperscript{1672,1673} or skin incision were all corrected by the removal of fibrinogen. These data, in combination with other data not discussed here, support the concept that the physiologic role for the plasminogen activation system is fibrin lysis.\textsuperscript{1674}

Hereditary Dysfibrinogenemias

Like many of the other coagulation disorders, classic dysfibrinogenemias were frequently recognized by the mother when her child bled abnormally. These disorders are associated with prolonged thrombin times usually caused by a point mutation in one of the chains, but clinically, the patient presents with normal plasma fibrinogen concentrations. Hypofibrinogenemias, on the other hand, are associated with low plasma fibrinogen concentrations (< 1.5 mg/ml) due to a mutation(s) that can affect transcription, mRNA processing, translation, chain processing, and assembly, excretion, or stability of the mature protein.\textsuperscript{1675} Hypofibrinogenemias can be classified into four groups according to the effect of the mutation: (a) mutations that affect intracellular processing, (b) retention in the endoplasmic reticulum, (c) intracellular assembly, and (d) Aα-chain truncations.\textsuperscript{1661,1662,1675}

Dysfibrinogenemias can be divided into five groups based on their specific action: (a) mutations that impair or impede thrombin, (b) defects in the construction of protofibrils, (c) impaired lateral association of protofibrils, (d) defects in interactions with other substances, and (e) other unknown mechanisms.\textsuperscript{1675} Thus, most common mutations are those that impede conversion of fibrinogen to fibrin by thrombin, which catalyzes the hydrolysis of the bonds between Argα\textsuperscript{16}-Glyα\textsuperscript{17}
and Arg₁₁₄-Glyβ₁₅, releasing FPA and FPB, respectively. The active site of thrombin is highly specific for an Arg in the P₁ position as observed by the human variant replacement of Argα₁₆ by His, which leads to delayed release of FPA₁⁶⁷⁶ or Cys, resulting in no release of FPA. In the case of Argβ₁⁴, only a Cys variant (fibrinogen Christchurch¹⁶⁷⁹) has been observed.

The identification of these mutations, originally through protein chemistry methods and now using DNA technology, has provided unique insights into the structural/function relationships of fibrinogen and fibrin. These mutants were originally gathered and published in the Index of Variant Human Fibrinogen,¹⁶⁸⁰ but with the advent of the Web, the material has been converted to a dynamic database (http://www.geht.org).¹⁶⁸¹ As of January 2012 (Release 37), 617 molecular abnormalities were present in the database, with 356 found in the Aα-chain (99 were Argα₁₆ mutations), 82 in the Bβ-chain, and 176 in the γ-chain.

Biosynthesis

Pulse chase experiments in a human hepatic carcinoma line have shown that there is a large intercellular pool of both Aα- and γ-chains, but it is the Bβ-chain synthesis that limits assembly in the rough endoplasmic reticulum.¹⁶⁸²,¹⁶⁸³ However, in both chicken and rat hepatocytes, it seems to be the Aα-chain that limits fibrinogen assembly.¹⁶⁸³,¹⁶⁸⁴ Additionally, several extrahepatic sites of fibrinogen synthesis have been identified, including human cervical epithelial cells¹⁶⁸⁵ and lung alveolar epithelial cells.¹⁶⁸⁶ γ-Chain-only synthesis has been observed in vivo in the brain, lung, and bone marrow.¹⁶⁸⁷,¹⁶⁸⁸ A physiologic role remains to be determined.

A number of posttranslational modifications (Table 18.8) must occur after synthesis but before secretion. These include removal of the signal peptides from all three chains during or after passage across the membrane¹⁶⁸⁹; a biantennary carbohydrate (M, ∼ 2,500 Da) being added to Asnγ₅₂ on the γ-chain much earlier than the Asnβ₁⁶⁴ on the Bβ-chain¹⁶⁸⁷,¹⁶⁸⁹; and when synthesized, fibrinogen being fully phosphorylated (Serα1 and Serδα₄⁶)—but in its circulating form, only 20% to 30% of these sites remain phosphorylated.¹⁶⁹⁴ Additionally, the first residue on the Bβ-chain is also posttranslationally modified to form pyroglutamic acid, thus removing its free amino terminus.

Biochemistry and Activation

The fibrinogen molecule contains two copies of three separate polypeptide chains designated Aα, Bβ, and γ (Table 18.8). These

P.477

are arranged into two identical half-molecules in an elongated structure composed of three globules. In the central globule all six NH₂-termini of the polypeptides reside, and thus it has been referred to as the N-disulfide knot.¹⁶⁹⁵ There are 11 disulfide bonds in this region, three of which link the two half-molecules. Experiments in which one or more of the 29 intra- and interchain disulfides were removed or small deletions made have shown that for dimer formation both disulfide bonds and the noncovalent interactions of the amino termini are important.¹⁶⁹⁶,¹⁶⁹⁷,¹⁶⁹⁸,¹⁶⁹⁹ and 1700 The common form of the Aα-chain contains 610 amino acid residues with an M, of 66,500 D and two phosphorylation sites (Serα₁ and Serα₄⁶), and thrombin cleavage of the Argα₁⁶-Glyα₁³ bond releases FPA. The Aα-chain of fibrinogen has sites appropriate for factor Xlla-catalyzed formation of cross-links,¹⁷⁰¹ t-PA enhancement site (resides 148 to 160) found in fibrin,¹⁷⁰² as well as consensus integrin recognition sites (resides 95 to 98 and 572 to 575). The Bβ-chain is composed of 461 amino acids, displays an M, of 52,000 Da and has a single glycosylation site (Asnβ₁⁶⁴) and a Ca²⁺-binding site (resides 381 to 385). Thrombin cleavage of the Argβ₁⁴-Glyβ₁₅ bond releases FPB. The γ-chain of fibrinogen is made up of 411 amino acids with an M, of 46,500 D, is glycosylated at Asnγ₅₂, and has a Ca²⁺-binding site (resides 318 to 324), a t-PA enhancement site (resides 320 to 324) in fibrin, and both donor (Glyγ₁⁵) and acceptor (Lysγ₁⁵) sites for cross-link formation.

A comprehensive history of early fibrinogen and fibrin structure/function relationships can be found in an excellent review by Blomback.1612 In the first recorded structural experiment, Bailey et al.1703 placed both a concentrated solution of fibrinogen (which forms a viscous strand) and a fibrin thread in an x-ray beam. The resulting patterns were indistinguishable not only from each other, but also from the patterns of keratin and myosin. They all showed a characteristic 5.1 Å-repeat spacing that was later determined to be due to supercoiled α-helices.1704 Around this same time, a different physiochemical “picture” of fibrinogen was emerging. Techniques including electrophoresis, ultracentrifugation, viscosity measurements, and light scattering were coming into vogue and determined that fibrinogen was a prolate ellipsoid with a length between 500 and 700 Å, an axial ratio between 5 and 20 Å, and a molecular weight near 340 kDa.1607,1703,1705

Hall and Slayter1708 produced shadow-cast photographs of fibrinogen and observed three unconnected globules in a line. The center globule was the smallest, with a diameter of approximately 50 Å; the terminal globules were found to be of equivalent size, approximately 60 Å. The total molecule length was estimated to be 475 Å; thus, the connections between the globules were approximated to 150 Å, and Cohen1709 suggested that these globules could be linked by α-helices, which would explain the characteristic α-helix 5.1 Å-repeat spacing observed in the fiber diffraction. This trinodular structure has become known as the Hall and Slayter model of fibrinogen.

The reconstruction of fibrinogen from both enzymatic and chemical fragmentation products has allowed an exact picture of the structure and function of fibrinogen to emerge. Many fragments were subjected to protein sequencing, and the sequences reassembled until the whole structure was determined. These fragments also gave insights into the polymerization process as well as the shape of fibrinogen. Because plasmin is the natural protease for fibrin removal, it was the obvious choice for initial fragmentation. Nussenzweig et al.1710 characterized such a fibrinogen lysate that was chromatographed using a diethylaminoethyl cellulose column. The resulting peaks were denoted A through E, and it was determined that the pools D and E contained the bulk of the material, with an approximate mass ratio of 2:1. This coordinated well with the Hall and Slayter model in which pool E would represent the center globule and be called fragment E, and the terminal globules would be found in pool D and called fragment D.1711 Thus, fibrinogen is a symmetric molecule, with a dyad axis drawn through fragment E.

Much effort has been expended in trying to crystallize fibrinogen. The first view was an 18-Å structure of a modified bovine fibrinogen,1712 later refined to approximately 4 Å.1711 The modification was a partial proteolysis that predominantly removed the C-terminal α-chains. However, the density for the central domain was “poorly defined.” The first look at an unmodified fibrinogen was the 5.5-Å followed by 2.7-Å structures of chicken fibrinogen.1714,1715 Chicken fibrinogen was chosen as a target because it has the shortest α-chains that lack a series of repeated sequences found in most other species1633,1716,1717 (Fig. 18.14). This structure provided the first atomic resolution view of the central domain of fibrinogen, although the α domains were too disordered to allow the chain to be traced. A 35-kDa digestion product of fragment E (FEγ) was solved at 1.4 Å,1712 which correlates well with the observed fragment E region in the 2.7-Å chicken fibrinogen structure.

The first atomic resolution structure in the fibrinogen field was for a human recombinant γ-chain.1720 As predicted, the fold of the γ-chain was unique and not represented in any of the structural databases.1625 The next advance came with the 2.9-Å structure of human fragment D,1721 displaying the two globular β and γ domains forming the furrow. As expected, the β and γ COOH-terminal domains share the same fold1720,1722 and are oriented approximately 130° apart. These observations have been confirmed in a structure of lamprey fragment D1723 and a recombinant human fragment D.1724,1725 To date, a crystal structure of intact human fibrinogen has not been solved.
FIGURE 18.14. A schematic and crystal structure of human fibrinogen (PDB-ID: 3GHG). All six NH$_2$-termini are gathered together in the central or E domain. Three chains [α-, β-, and γ-] extend out from this domain through coiled-coils in either direction forming the terminal or D domains. Thrombin (IIa) cleavage sites at the N-termini of the Aα and Bβ are indicated, with the new N-termini that associate with “holes” in the D domains to form fibrin depicted in the boxes. Pink spheres indicate the four Ca$^{2+}$ sites. Note that the carboxy termini of the α-chains are not visible in this structure.

Polymerization (Fibrin Formation)

The goal of a polymerization is to build a scaffold of sufficient mechanical strength to serve as a hemostatic plug. Interestingly, only 20% of a “clot” is actually protein—the remainder is solvent. In 1952, Ferry proposed a half-staggered overlap model to explain the polymerization process. This model can be expressed succinctly in terms of “knobs” and “holes”. When thrombin removes the fibrinopeptides, it creates new amino termini on the α- and β-chains called knobs. Because the knobs are located in the central globule (fragment E) of the Hall and Slayter model, the holes for them to fit into must be present on the terminal domains (fragment D). To accommodate the half-staggered overlap model, the knobs on one molecule interact with holes in two different molecules. Reciprocally, a knob from each of these molecules fits into the holes on the first molecule's fragment D. The binding sites of the α and β knobs were localized to the γ- and β-chains, respectively, using fragment D digested to different extents. To identify the polymerization hole in the γ-chain, recombinant γ-chain crystals were soaked in a solution containing a peptide mimic of the knob. As was expected, the hole was preformed and contained a strong electronegative potential that was neutralized on the binding of the doubly positively charged peptide. The binding interaction was noncovalent and composed of only ionic and hydrogen bonds. Using laser tweezers, the strength of this interaction has been measured between 125 and 130 pN, which is the majority of the force holding fibrin polymer together at this early stage.

The existence of a β-chain hole and that this hole binds the β-chain knob were confirmed with a double-D x-ray crystal structure in which peptide knobs for the α- and β-chains were present. As would be expected, the β-chain knob also binds with a combination of ionic and hydrogen bonds to the β-chain hole, though it contributes only 15 to 20 pN to the interaction. In another study using combinations of peptide knobs, it was determined that the β hole is not fully formed until the knob is present and is much less discriminating in peptide acceptance. This conformational change may be the basis for the acceleration of fibrin formation observed in the presence of the peptide ligand GHRP. No evidence has been found for an analogous mechanism with the γ hole; rather, the γ hole seems always ready to accept an α knob, though in the absence of an α knob, the β knob readily binds to both holes. A single example of an α knob peptide (GPRVVE) has been observed occupying a β hole, but recent experiments using laser tweezers have demonstrated that this interaction is not physiologically relevant.

The conversion of fibrinogen to fibrin can be separated into three congruent processes: (a) removal of the fibrinopeptides, (b) assembly, and (c) covalent stabilization. We examine each in depth in the following sections.

Fibrinopeptide Release
Many early investigators tried to determine the differences between fibrinogen and fibrin. Their molecular weights were identical, and fibrinogen was the more electronegative of the two. In the conversion of fibrinogen to fibrin, thrombin catalyzes the hydrolysis of Arg-Gly bonds, removing small, polar amino terminal pieces (fibrinopeptides) from the α- and β-chains. Cleavage of Argα16 by thrombin releases FPA and forms fibrin I. The release of two FPA peptides exposes a site in fragment E that aligns with a complementary site in fragment D to form overlapping fibrils. Subsequent cleavage by thrombin at Argβ14 releases FPB and leads to the formation of fibrin II, presumably increasing lateral aggregation of the protofibrils. FPA and FPB vary in length (between 13 and 21 amino acids in various mammals) and constitute < 2% of the total mass.

Early studies in citrated plasmas or purified fibrinogen found that FPA and FPB are released at very different rates, with FPA being released first. A sequential model for release has been postulated in which thrombin binds equally to both chains, but the presence of FPA hinders the release of FPB because thrombin is unable to undergo a required conformation change. As the polymerization process proceeds, the FPB release rate continues to increase, suggesting that a polymerization-induced structure change facilitates its release. When the fibrinogen to fibrin conversion is studied in a nonanticoagulated whole blood system, the pattern of fibrin formation based on fibrinopeptide release is different from that seen in citrated plasma or purified fibrinogen.

Bettelheim and Bailey first hypothesized that on FPA and FPB release these newly exposed amino termini (knobs) must be the principal contact sites during polymerization. In human fibrinogen, the α-chain knob, after FPA release, begins with the sequence GPRVV; whereas the β-chain, after FPB release, starts with GHRPL. Synthetic peptide GPR derivatives based on the β knob were found to bind to both fibrinogen and fragment D and inhibit fibrin monomer polymerization. Peptides based on the β knob also bound to both fibrinogen and fragment D but were unable to inhibit fibrin monomer polymerization. In analogous studies, venoms can be used to selectively remove only FPA without activating factor XIII, and fibrin will still form. Although it appears morphologically the same, this type of fibrin lacks the normal strength of fibrin. Removal of only FPB (without FPA release) results in fibrin formation in lampreys, but human fibrinogen clots only if the temperature is maintained below 15°C.
FIGURE 18.15. Schematic representation of whole blood fibrin formation. Thrombin at the beginning of clot formation simultaneously acts on fibrinogen (D-E-D) and factor XIII (fXIII). A portion (~40%) of fibrinopeptide A (FPA) is released from fibrinogen, and an initial clot is formed from the complementary overlap of the exposed sites between the E and D domains of adjacent molecules. Activated factor XIII (fXIIIa) simultaneously cross-links adjacent D domains (D=D). Thus, the initial soluble fibrin clot is composed of fibrinogen, fibrin, and γ-γ dimers (double yellow lines) with fibrinopeptide B (FPB) still attached. The initial clot is continuously acted on by thrombin, releasing the remaining FPA and some of the FPB to yield a final clot with the majority of FPB still attached. The released FPB is selectively acted on by a carboxypeptidase B-like enzyme (CPB) cleaving the carboxyl terminal arginine to produce des-Arg FPB. The significance of this cleavage is still unclear. (From Brummel KE, Butenas S, Mann KG. An integrated study of fibrinogen during blood coagulation. J Biol Chem 1999;274:22862-22870, with permission.)

Fibrin Assembly

The release of the FPAs from fibrinogen results in the formation of an intermediate termed fibrin monomer, which is all but indistinguishable from fibrinogen, and leads to the formation of the fibrin dimer through the noncovalent charge-charge (salt links) and hydrogen bonds between the knobs and the holes. As fibrin monomers continue to be generated, the dimer elongates from both ends as a two-stranded molecule until it reaches approximately 30 monomers, when it becomes a protofibril.

The second step in fibrin assembly is the lateral association of protofibrils into thicker fibrin fibers. These fibers are formed from the association of between 14 and 22 protofibrils. Because protofibrils, not dimers, are required for this step, it is believed that the forces involved in lateral association are weak and, therefore, only become “strong” in large numbers. Fragment D, specifically the β-chain, is likely responsible for this aspect of fiber growth. Clots are known to branch, although how this is accomplished is not clear. For example, perhaps a protofibril can attach and form a
link between two growing fibers, or perhaps this is the role for the C-terminal region of the α-chains. The presence or absence of carbohydrates also seems to affect branching.

The description of fibrinogen activation and fibrin assembly has been based on studies using citrated plasmas, purified proteins, or both. To understand the in vivo process of fibrin formation, a system with nonanticoagulated blood has been used; in this experimental model, the pattern of fibrin formation based on fibrinopeptide release is different from systems using citrated plasma or purified fibrinogen (Fig. 18.15). In this study, cleavage of FPA and subsequent clot formation occur just before the propagation phase of thrombin generation. At the point of visual clot formation, virtually all fibrinogen (and some product already cross-linked) disappears from the fluid phase of the reaction. Thus, the “clot” appears to be a mixture composed of fibrin I and fibrinogen. The insoluble material present in the fibrin clot is believed to be a mixture composed of fibrin I and fibrinogen. The insoluble material present in the fibrin clot is believed to be a mixture composed of fibrin I and fibrinogen.

Fibrin Cross-linking

To strengthen the “weak” (noncovalent) interactions holding the dimers and protofibrils together, factor XIII (a transglutaminase found circulating in the plasma) is activated to factor XIIIa by thrombin in the presence of Ca²⁺ to link the side chains of lysyl and glutamyl residues by isopeptide bonds. Thrombin activation of factor XIII has been shown to coincide with FPA release during the initiation phase of thrombin generation. The concentrations of thrombin (based on thrombin-antithrombin complex) needed for factor XIII activation, FPA release, and FPA release have been calculated to be 0.8 ± 0.3 nmol/L, 1.3 ± 0.4 nmol/L, and 1.7 ± 0.5 nmol/L, respectively.

It has been proposed that as many as six cross-links can form between a fibrin monomer and its neighbors and that the presence of these cross-links increases the strength, chemical resistance to urea, and lysis by plasmin. Early in fibrin assembly, factor XIIIa has been shown to link Glunγ and Lys γ in reciprocal cross-links between adjacent C-terminal γ-chains. Once the majority of γ-chain cross-links are inserted, then a much slower process begins to insert multiple cross-links between neighboring α-chains. Because each α-chain has two glutamyl acceptor sites and five potential lysine donor sites, a complex cross-linked network can result. The result is cross-linked fibrin, which is more resistant to clot lysis. Factor XIIIa also covalently attaches αγ-plasmin inhibitor (the principal fibrinolytic inhibitor) to α-chains in the clot, thereby increasing resistance to degradation.

Function

Fibrinogen functions in hemostasis to stem blood loss. It serves as a molecular bridge to support interplatelet aggregation, and it is the precursor of fibrin, which is the main component of the protein scaffolding of the forming hemostatic plug. Platelet aggregation critically depends on fibrinogen binding to activated platelets via the platelet fibrinogen receptor gpIIb-IIIa as well as fibrin adhesion. Fibrinogen/fibrin also regulates thrombin activity by interactions that include the proteolytic cleavage by thrombin of fibrinopeptides to form a fibrin clot and thrombin exosite binding to fibrin, which potentially limits the diffusion of thrombin and thereby regulates clot propagation. The structure, stability, and duration of the insoluble counterpart fibrin are controlled by an interplay between fibrin formation and fibrinolysis, which includes other molecular and cellular components. An important enzyme for the structure and stability of the fibrin clot is the transglutaminase factor XIIIa. Its function is to cross-link fibrin and other adhesive proteins including integrin receptors, providing a stable network. Once activated, the fibrinolysis inhibitor called TAFI functions to attenuate fibrinolysis by removing C-terminal lysines from fibrin. This appears to be critical in the stabilization of the fibrin clot by reducing the number of sites available for plasminogen binding, thus reducing the rate of plasmin generation with consequent prolongation of fibrin dissolution. TAFI has also been shown to play a role in the premature lysis of clots from hemophilic plasma.

Fibrinogen is primarily recognized for its role in hemostasis but is also required for competent inflammatory reactions. Fibrinogen is an acute-phase reactant, with levels increasing during inflammation. During these situations, fibrinogen functions as a bridging molecule in cell-cell interactions. Fibrin and fibrinogen constitute a matrix that can allow for the modulation of cellular responses through a variety of different cell types, including endothelial cells, epithelial cells, and macrophages. The matrix also provides a scaffold for the deposition of other proteins, including factor XIIIa.
leukocytes, platelets, and fibroblasts. Cellular receptors that can bind fibrinogen and fibrin include the integrins \(\alpha_{IIb}\beta_3\), \(\alpha_v\beta_3\), and \(\alpha_v\beta_1\), and the cellular adhesion molecules intercellular adhesion molecule-1 and vascular endothelial cadherin.

Although the function of fibrinogen and fibrin as a barrier to stemming blood loss through the dense fibrin network appears central to hemostasis, the findings from fibrinogen-deficient mice suggest that compensating mechanisms exist. Homozygous \(A\alpha\)-chain-deficient mice are born with normal appearance and without elevated fetal mortality.\(^{1666}\) These mice have no detectable levels of the \(A\alpha\), \(B\beta\), and \(\gamma\)-chains in their blood.\(^{1666}\) Therefore, the maintenance of hemostasis in these animals is most likely derived from normal thrombin generation and the support of platelet aggregation and adhesion by vWF.

Most clinical assays use fibrin formation as a means to assess hemostasis (PT and activated partial thromboplastin time). The formation of a visible fibrin clot occurs during the initiation phase of coagulation at very low levels of thrombin, approximately 3% to 5% of the total amount of thrombin produced.\(^{569,616}\) The majority of thrombin (\(^*\)95%) is generated after clot formation during the propagation phase, which is overlooked when a fibrin endpoint assay is used.\(^{569}\) In congenital hemophilia A and B, only a slight prolongation of clot time is observed; the major impairment is in thrombin generation during the propagation phase of the reaction (Fig. 18.7).\(^{882}\) Thus, most catalyst and thrombin formation is ignored using the current technology for evaluating clinical hemorrhagic risk or thrombosis. The survivability of the afibrinogenemic genotype in mice and male patients also supports this concept that critically important events are taking place beyond the endpoint of fibrin formation.

Regulation of Fibrin Lysis

The coagulation system prevents blood loss at the site of injury, filling one role in hemostasis. However, there must also exist mechanisms to limit the coagulation system and processes to remove a clot once it is no longer needed. This role is filled by the fibrinolytic system that uses elements from plasma, platelets, tissue, and other blood cells to regulate the degradation of fibrin. The main player is the zymogen plasminogen that on activation becomes plasmin, a serine protease, whose primary physiologic role is the degradation of the fibrin clot and extracellular matrix molecules. Even though the plasmin cleavage sites are similar for both fibrinogen and fibrin, we consider them separately for clarity.

Fibrinogenolysis

Marder\(^{1777,1778}\) proposed a scheme for fragmentation of fibrinogen based on his own detailed studies and the work of others.\(^{1779,1780}\) In the first step, fibrinogen is converted to fragment X (M, \(~247,000\)) by the removal of the C-terminal \(\alpha\)-chain as well as the first 42 amino acids of the \(\beta\)-chain\(^{1781,1782}\) (Fig. 18.16). Fragment X remains clottable before it is split asymmetrically, forming fragment Y (M, \(~150,000\)), fragment D (M, \(~88,000\)), and some small detritus relating to the coiled-coil region. Finally, fragment Y is further split into fragment D and fragment E (M, \(~50,000\)), and some more detritus is released.

P.481
FIGURE 18.16. Fibrinogenolysis and fibrinolysis. A: Fibrinogen is represented as a trinodular structure (D-E-D domains). Each E domain and D domain is separated by a coiled-coil domain. The Aα-chain tail is shown as a line. Plasmin digests fibrinogen, yielding various fragments, the largest of which is fragment X. Fragment X contains the two D domains, the E domain, and the α-helical coiled-coils, but lacks the C-termini of the Aα-chains and the peptide Bβ-chains. Fragment Y consists of the central E domain connected by the coiled-coil to one of the terminal D domains. Fragment Y can be further degraded by cleavage of the coiled-coil domain to release a second D domain and fragment E.

B: The domain composition of the monomer units of degraded fibrin is indicated by the circles containing a D or an E. Intermolecular cross-links between the γ-chains are shown as thicker lines connecting the D regions. The structures of the various-sized fragments of cross-linked fibrin monomers resulting from plasmin proteolysis of fibrin are presented.

Fibrinolysis

Differences observed in the degradation products between fibrinogen and fibrin are due to the presence of the cross-links, not a change in the specificity of plasmin, which predominantly attacks the coiled-coil region between fragment E and fragment D. Degradation of cross-linked fibrin is much slower than fibrinogen, in large part because of the inaccessibility of the plasmin cleavage sites. The first step in degrading cross-linked fibrin is the removal of the α-chains so that the coiled-coils are exposed. As the coiled-coils are cleaved, different-sized fragments are released. The smallest of these degradation products are double-D (Mw ~180,000), also known as D-dimer, a soluble fragment in which the two D fragments are linked by two isopeptide linkages, and a fragment with the stoichiometry D2E (termed DY; Mw ~235,000), a double-D and a fragment E held in place by strong, noncovalent bonding. A large number of intermediate-sized fibrin degradation products arising from cleavages between the fragment D and fragment E regions are also generated (Fig. 18.16). The largest of these fragments is the XXD (two fragment Xs and a fragment D) with a mass in the range of 595 kDa. Some of these complexes (e.g., D-dimer) have been identified in the blood of patients with various thrombotic or thrombolytic disorders.

PROTEINS OF THE FIBRINOLYTIC SYSTEM

Clot formation is integrated with clot dissolution to maintain hemostasis. The biochemical mechanisms of clot dissolution center on fibrin-specific activation of plasminogen to plasmin. The key proteins involved are plasminogen, plasminogen activators (t-PA and u-PA), PAI-1, α2-antiplasmin, and TAFI (Fig. 18.17).
Plasminogen

Plasminogen is the inactive precursor of the enzyme plasmin, which is the primary catalyst of fibrin degradation. Hereditary plasminogen deficiency has been described as either a deficiency of plasminogen antigen and activity (type I), or as a normal antigen level but reduced activity (type II, dysplasminogenemia). Thrombophilia and ligneous conjunctivitis are clinical manifestations associated with homozygous deficiency; the impact of heterozygous deficiency remains in dispute. Homozygous plasminogen-deficient mice are viable but exhibit severe thrombosis with systemic fibrin deposition, and die prematurely.\textsuperscript{1788,1790}
FIGURE 18.17. Schematic of the dynamic interaction between the proteins and inhibitors of fibrinolysis. Cross-linked fibrin formation is integrated with fibrin clot dissolution and degradation of its products. The enzymes (open circles), inhibitors (hatched circles), zymogens (open boxes), and complexes (large open ovals) are illustrated in a simplified form to show this multicomponent process. The key proteins involved are plasminogen, plasminogen activators (tissue-type plasminogen activator [tPA], single-chain urokinase-type plasminogen activator [scu-PA], and two-chain urokinase-type plasminogen activator [tcu-PA]), plasminogen activator inhibitor-1 (PAI-1), α2-antiplasmin (α2-AP), and thrombin-activatable fibrinolysis inhibitor (TAFI). t-PA and plasminogen both bind to the fibrin surface, where t-PA is an effective catalyst of plasminogen activation. Initially, plasmin proteolysis of fibrin generates new, higher affinity binding sites for plasminogen, setting up an amplifying loop of plasminogen activation. Reinforcing this process, generated plasmin can convert the single-chain form of urokinase, an ineffective catalyst, to its active form, thus increasing the concentration of available plasminogen activation. Opposing these events are antifibrinolytic mechanisms. α2-AP, both soluble and cross-linked to fibrin, forms complexes with plasmin, rendering it inactive. PAI-1 rapidly reacts with both t-PA and two-chain urokinase, reducing the concentration of plasminogen activators. Formation of activated TAFI (TAFIa) results in removal plasmin-generated COOH-terminal lysine residues, thus suppressing the rate of fibrin lysis. Fibrin degradation occurs by cleavage at the D-E-D domains of fibrin polymers by plasmin to yield a variety of polymers as illustrated (see Fig. 18.16).

Gene Structure and Expression

The plasminogen gene is located on the long arm of chromosome 6 at band q26-q27 (Table 18.9). It spans 52.5 kb of DNA with 19 exons. It is in close proximity to two genes for apolipoprotein A and for the plasminogen-related genes A and B. The first exon codes for the signal sequence; each of the five kringle domains is encoded by two exons, as is the activation peptide. Plasminogen expression is normally stable, with the regulation of the activit... of the plasminogen activators and their inhibitors. However, plasminogen is an acute-phase reactant protein. Two sequence elements common to acute-phase reactant genes have been located at positions 76 to 81 and -553 to -558. Other potential regulatory transcriptional elements... Heterogeneity in the primary sequence of plasminogen has also been observed, reflecting the presence of two high-incidence polymorphisms and a number of lowincidence polymorphisms in the human population. Functional differences between the two major carbohydrate forms have been reported. An additional glycosylation site at Ser... containing a trisaccharide has been identified. The primary structure of plasminogen contains 791 amino acids segregated into an NH2-terminal activation peptide domain (residues Glu-Lys), a region containing five kringles (K1-K5; residues Lys-Arg), and a catalytic domain (residues Val-Asn) (Fig. 18.18). As secreted into the blood, plasminogen has a glutamic acid at its NH2-terminal, referred to as Glu-plasminogen. Proteolysis by plasmin at one of several potential sites in the NH2-terminal region results in a degraded form of plasminogen; the most common product is Lys-plasmin. Removal of the NH2-terminal peptide region results in a major structural change in the plasminogen molecule, yielding a species of plasminogen that has a higher affinity than Glu-plasminogen for fibrin and is a better substrate for plasminogen activators. The primary site for Lys-plasminogen formation is at the fibrin clot; the t1/2 of Lys-plasminogen is shorter than the full-length molecule (t1/2 = 0.8 days). Each kringle domain contains 78 to 80 amino acids. The K1 and K4 kringle domains have been identified as containing sites that are responsible for regulating the binding of plasminogen to fibrin... α2-antiplasmin, histidine-rich glycoprotein, the kininogens, thrombospordin, and cell surface receptors. These sites on the plasminogen kringles (called lysine-binding sites) bind lysyl residues in the target molecules; COOH-terminal lysyl residues are bound more avidly. Lysine analogs (i.e., ε-aminocaproic acid and tranexamic acid) can compete with lysyl residues in proteins for binding to plasminogen and, hence, are useful inhibitors of fibrinolysis. The conformational change associated with the removal of the NH2-terminal activation peptide also occurs on binding of...
lysine or its analogs to the appropriate kringle domains of Glu-plasminogen.\textsuperscript{1818,1819} and \textsuperscript{1820} The shape of the Glu-plasminogen molecule changes from a prolate ellipsoid of axial ratio 2.6 to a more random coil-type structure of axial ratio > 5, similar in dimension to Lys-plasminogen.\textsuperscript{1821,1822} A fragment of plasminogen comprising K1-K4, also known as angiostatin, has been shown to inhibit angiogenesis.\textsuperscript{1823} The catalytic domain of plasminogen (Val\textsuperscript{562}-Asn\textsuperscript{791}) shows considerable homology to trypsin and other serine proteases and includes the catalytic triad (His\textsuperscript{603}, Asp\textsuperscript{646}, and Ser\textsuperscript{741}) typical of these proteases.\textsuperscript{1824}

Function
Plasminogen is a zymogen devoid of enzymatic activity until converted to the serine protease plasmin by cleavage of the Arg\textsuperscript{561}-Val\textsuperscript{562} peptide bond by plasminogen activators such as u-PA and t-PA (Fig. 18.19). In plasma or bound to fibrin in a blood clot, cleavage of this peptide bond by either t-PA or u-PA converts Glu-plasminogen into Glu-plasmin, a two-chain enzyme that can degrade fibrin, fibrinogen, and a number of other molecules.

Plasmin is composed of a heavy chain (kringle domains) and a light chain (catalytic domain) that are attached by two disulfide bonds. Glu-plasmin can autodigest by cleaving itself—most commonly at Lys\textsuperscript{77} to generate Lys-plasmin.\textsuperscript{1825,1826} Inhibition of plasmin by \(\alpha\)-2-antiplasmin is the primary route for regulation of plasmin's hemostatic function; suppression of plasmin activity beyond the locale of fibrin deposition is imperative if systemic fibrinogenolysis is to be prevented. Plasmin bound through its lysine-binding sites to fibrin reacts more slowly with \(\alpha\)-2-antiplasmin than when free in solution. This differential reactivity effectively localizes plasmin activity to the fibrin surface.

Plasminogen Activators
The process of plasminogen activation can occur through three distinct pathways: (a) the intrinsic activator system (analogous to the contact system of blood coagulation), (b) the extrinsic activators (t-PA and u-PA), and (c) an exogenous
activator system involving pharmacologic agents (thrombolytic drugs). The pathway used in vivo appears to be the extrinsic pathway. However, both the intrinsic and exogenous activator systems could play an important role in human disease.

$^b$ Estimated value calculated from difference of molecular weight determined by sodium dodecyl sulfate-polyacrylamide gel electrophoresis and weight of sum of amino acids derived from complementary DNA.

Intrinsic Activators

The body has evolved a mechanism to recognize invasion by foreign substances. Many of these foreign substances contain negatively charged surfaces that allow for the activation of the intrinsic (contact) pathway (factor XII, prekallikrein, HMWK, and factor XI). Plasminogen can interact with this intrinsic pathway of blood coagulation to generate plasmin. There is continued debate as to the extent to which the intrinsic pathway functions in regulating normal fibrinolysis. It has been estimated that this pathway contributes only approximately 15% of the total fibrinolytic activity in human plasma. $^{1827}$ Several studies have established that kallikrein and factors IXa and XIIa can directly activate plasminogen to plasmin. $^{1828,1829,1830}$ At this time, it is best to conclude that the physiologic significance and relevance of the contact system in fibrinolysis are not entirely clear. It has been suggested that individuals with factor XII deficiency as well as deficiencies in some of the other intrinsic coagulation factors may have a subtle, but potentially significant, defect in fibrinolysis under certain clinical conditions. Additional studies are needed to address this controversial subject.
FIGURE 18.18. Schematic of plasminogen. Plasminogen is the inactive precursor of the enzyme plasmin, which is the primary catalyst of fibrin degradation. Human plasminogen is a single-chain glycoprotein containing 2% carbohydrate (CHO). CHO variants are shown for plasminogens 1 and 2. The primary structure of plasminogen contains 791 amino acids segregated into an NH₂-terminal activation peptide domain (pan), a region containing five kringles, and a catalytic domain. Proteolysis by plasmin at one of several potential sites in this NH₂-terminal region results in a degraded form of plasminogen; the most common product is K78-plasminogen. Cleavage by plasminogen activators at R561-V562 results in plasmin.

Extrinsic Activator: Tissue Plasminogen Activator

There are two dominant extrinsic activator systems in the body: t-PA and u-PA. These activators have unique structures and properties that affect the specificity and rate of plasmin generation.

The t-PA molecule is predominantly a product of endothelial cells; it is also produced by vascular smooth muscle cells, neuronal cells, megakaryocytes, mast cells, monocytes, and fibroblasts. Factors that regulate its secretion and release from the endothelium are important mediators of blood clotting or inflammation. These include thrombin, histamine, acetylcholine, bradykinin, epinephrine, ILs, shear stress, and vaso-occlusion. t-PA antigen is present in normal plasma at approximately 5 µg/L (70 pmol/L; Table 18.10). Functional concentrations have been reported to be < 20 pmol/L with the remainder of the t-PA antigen found in complex with PAI-1. The t-PA molecule and the t-PA/PAI-1 complex are cleared from the plasma by two specific cell receptor systems in the liver as well as receptor-mediated clearance by endothelial cells (for review see 1778,1857,1858).

Gene Structure and Expression

The human gene for t-PA is found on chromosome 8, bands p12-q11.2, and spans 32.7 kb (Table 18.9). There are 14 exons with distinct structural motifs encoded by individual exons. The processed transcript codes for a protein product of 562 amino acids: residues 1 to 23 comprise the signal peptide, whereas residues 24 to 32 function as a propeptide region. Further processing removes residues 32 to 35 to yield the circulating protein product. The 5'-flanking region of the t-PA gene extends more than 9,500 bp with a functional retinoic acid response element identified at -7,300 bp and a multihormone responsive enhancer localized to the region -7,145 to -9,758 bp. A number of cisacting elements have been identified in the proximal promoter region. A transcription initiation site 209 bp upstream of
the translation start site was initially identified. A consensus TATA sequence was identified 22 bp upstream from this transcription start site.\textsuperscript{1861,1862} Subsequently, a TATA-independent transcript initiation site 99 bp upstream from the translation start site was identified as the primary site of transcription initiation in fibroblasts\textsuperscript{1867} and endothelial cells.\textsuperscript{1868} The significance of t-PA transcripts with different-length 5′-untranslated regions is not established; deletion of the entire 5′-untranslated region of t-PA was observed to increase the stability of the t-PA transcript.\textsuperscript{1869}

Translational control of t-PA gene expression has been observed in some cell types, implicating a regulatory role for the 3′-untranslated region of the t-PA transcript.\textsuperscript{1870,1871}

\includegraphics[width=\textwidth]{figure18.19.png}
\caption{Molecular forms of plasmin(ogen). Plasminogen in its native form has a glutamic acid at residue 1 and is referred to as glu-plasminogen. Glu-plasminogen has a molecular weight of 88,000 Da and contains 791 amino acids. Cleavage at R\textsuperscript{561}-V\textsuperscript{562} in glu-plasminogen by plasminogen activators (tissuetype plasminogen activator [t-PA] and urokinase-type plasminogen activator [u-PA]) yields glu-plasmin. Glu-plasmin consists of an NH\textsubscript{2}-terminal heavy chain linked by two disulfide bonds to a catalytic domain. At the localized clot level, plasmin that is formed can cleave glu-plasminogen at the NH\textsubscript{2}-terminal bond K\textsuperscript{77}-K\textsuperscript{78} to yield lys-plasminogen. Lys-plasminogen can be activated by plasminogen activators that hydrolyze the R\textsuperscript{561}-V\textsuperscript{562} bond to yield lys-plasmin.}
\end{figure}

A number of polymorphisms of the t-PA gene have been identified. A 311-bp Alu insertion/deletion polymorphism within the eighth intron of the t-PA gene has been extensively studied.\textsuperscript{1872,1873,1874,1875,1876} and \textsuperscript{1877} A similar polymorphism in the angiotensin-converting enzyme gene has been linked to plasma levels of this enzyme.\textsuperscript{1878} In contrast, no correlation of plasma t-PA levels with its Alu polymorphism has been observed.\textsuperscript{1874,1875} and \textsuperscript{1876} With one exception,\textsuperscript{1872} clinical studies have indicated no correlation between this polymorphism and the incidence of stroke or myocardial infarction.\textsuperscript{1874,1875} and \textsuperscript{1876} A single nucleotide polymorphism (-7351 C/T) in an Sp1-binding site in the far upstream enhancer element of the t-PA gene has been linked to the vascular release rate of t-PA in vivo\textsuperscript{1879} and to the frequency of occurrence of first myocardial infarction.\textsuperscript{1880}

No cases of congenital deficiency of t-PA have been reported. Transgenic mice lacking a functional t-PA gene developed normally and displayed a normal basal hemostatic phenotype.\textsuperscript{1881} Mice in which both the t-PA and u-PA genes were disabled had shortened lifespans and experienced severe, spontaneous thrombotic episodes.\textsuperscript{1881,1882}
Biochemistry

The t-PA molecule is a serine proteinase with a molecular weight of 70 kDa (Table 18.10 and Fig. 18.20). It was originally isolated as a single polypeptide chain of 527 amino acids with an NH₂-terminal serine residue; full-length t-PA has an NH₂-terminal extension of three amino acids (Gly-Ala-Arg) and Numbering in this chapter is based on Ser¹-t-PA, the most extensively studied form because of its availability as a recombinant product.

The single-chain t-PA molecule is an efficient plasminogen activator in the presence of fibrin and is converted into a somewhat more active two-chain molecule by cleavage of the peptide bond between Arg²⁷⁵ and Ile²⁷⁶. This cleavage is performed primarily by the action of plasmin during fibrinolysis; factor Xa and kallikrein can also catalyze this conversion. The t-PA molecule divides structurally and functionally into two major regions with the Arg²⁷⁵-Ile²⁷⁶ bond as the boundary: the 38-kDa NH₂-terminal portion (Ser¹-Arg²⁷⁵), called the heavy or A-chain in the two-chain molecule, contains structures involved in fibrin binding, fibrin-specific plasminogen activation, and plasma clearance mechanisms; and the 28-kDa catalytic region (Ile²⁷⁶-Pro⁵²⁷), called the light or B-chain, is homologous to the proteolytic domain of other serine proteases. Specifically, the A-chain contains a fibronectin fingerlike domain, an EGF-like domain, and two kringle domains. The finger domain extends from residues 4 to 50 and is involved in the binding of t-PA to fibrin. The binding of the finger region to fibrin is not blocked by ε-aminocaproic acid. The finger domain of t-PA has sequence homology and structural homology to similar structures found in fibronectin. Selected mutations in the finger or P.486 the EGF domain have been shown to result in prolonged half-lives in vivo for the modified t-PA molecules, indicating a role for these regions in uptake mechanisms. The kringle domains of t-PA span residues 87 to 176 (kringle 1) and residues 176 to 262 (kringle 2). The biologic role of kringle 1 remains undiscovered. The kringle 2 domain is involved in the binding of t-PA to fibrin. This binding interaction is blocked by lysine and its analogs such as ε-aminocaproic acid, indicating the presence of a plasminogen-like lysine-binding pocket. The overall crystal structure of t-PA kringle 2 resembles that of kringle 4 of plasminogen, although differences are observed in the arrangement of residues forming the lysine-binding sites. The light or B-chain of t-PA contains the active site catalytic triad of this serine protease (His⁵²¹, Asp⁷¹, and Ser⁴⁷⁸). Both the single- and two-chain forms of t-PA cleave plasminogen at Arg⁵⁶¹-Val⁵⁶² to yield the enzyme plasmin. The catalytic efficiency of single-chain t-PA toward plasminogen in solution and toward tripeptide paranitroanilide substrates is lower than the two-chain form. Both forms have been crystallized and exhibit enhanced and roughly equivalent rates of proteolysis of plasminogen when fibrin is present.
FIGURE 18.20. Fibrinolytic proteins tissue-type plasminogen activator (t-PA) and single-chain urokinase-type plasminogen activator (sc-uPA). The single-chain t-PA molecule is an efficient plasminogen activator in the presence of fibrin and is converted into a somewhat more active two-chain molecule by cleavage of the peptide bond between R\(^{275}\) and I\(^{276}\). This cleavage is performed primarily by the action of plasmin during fibrinolysis. Structurally t-PA contains a fibronectin type I domain, an epidermal growth factor (EGF)-like domain, and two kringle domains, as well as a serine protease-type catalytic domain. The kringle 2 domain and the fibronectin domain of t-PA are involved in the binding of t-PA to fibrin. sc-uPA is an ineffective catalyst. Plasmin or plasma kallikrein can hydrolyze the K\(^{158}\)I\(^{159}\) peptide bond, converting sc-uPA into the fully active two-chain form (two-chain urokinase-type plasminogen activator). u-PA is composed of an EGF domain (EGF), a single kringle domain, and the serine protease-type catalytic domain. One glycosylation site (CHO) is present in the serine protease domain.

The t-PA molecule has three potential N-linked glycosylation sites and one O-linked site. The O-linked site is found at Thr\(^{51}\) in the EGF domain. \(^{1910}\) The presence of a fucose at this site appears to facilitate the uptake of t-PA by hepatocytes. \(^{1911}\) Two major carbohydrate variants of t-PA have been identified. Type I is glycosylated at Asn\(^{117}\) (kringle 1), Asn\(^{184}\) (kringle 2), and Asn\(^{448}\) (catalytic domain), whereas type II is glycosylated only at Asn\(^{117}\) and Asn\(^{448}\). \(^{1912,1913}\) The presence of carbohydrate at Asn\(^{117}\) appears to downregulate the fibrinolytic activity of type I t-PA by interfering with the association between the lysine-binding site of its kringle 2 domain and fibrin.

Regulation

Regulation of t-PA activity in blood is accomplished by three primary mechanisms: Control of its catalytic potential via the fibrin dependence of plasminogen activation; control of systemic levels of functional t-PA by the concerted processes of rapid t-PA removal by hepatic clearance and of inhibition by the circulating serpin PAI-1; and control of t-PA activity levels at the site of injury by the competing processes of increased t-PA secretion by traumatized and recruited cells versus PAI-1 release by activated platelets. t-PA manifests its full fibrinolytic potential only when bound to fibrin. \(^{1914,1915}\) and \(^{1916}\) This binding interaction aligns t-PA and plasminogen on the fibrin surface so that the catalytic efficiency of t-PA is enhanced several hundredfold. This is vital to the localization of plasmin generation at the site of fibrin deposition. Systemic t-PA levels in blood are under highly dynamic control characterized by maintenance of relatively low levels of the protein (70 pmol/L) with a high clearance rate (\(t_{1/2} = 2.4\) minutes) and by maintenance of an extremely effective inhibitor, PAI-1 (second-order rate constant for complex formation = \(10^7\) to \(10^8\) M\(^{-1}\) second\(^{-1}\)), at a
circulating concentration severalfold higher than t-PA. The release of t-PA from the vessel wall is another important regulator of fibrinolysis.\textsuperscript{1957,1958} The rate at which clots lyse is dependent on how rapidly t-PA is secreted by the relevant cells in the vicinity of an injury.\textsuperscript{1959,1960} For example, activated platelets secrete serotonin that can induce endothelial cells to release t-PA; they also release PAI-1 from their α-granules. Although only a fraction of this PAI-1 is in the active form, it functions to downregulate plasminogen activation.\textsuperscript{1971,1972} and \textsuperscript{1973}

Extrinsic Activator: Urokinase Plasminogen Activator

The other major extrinsic activator in the blood is u-PA. This activator was first identified in the urine,\textsuperscript{1924,1925} and \textsuperscript{1926} where it is present at relatively high concentrations (40 to 80 μg/L).\textsuperscript{1926,1927} It was subsequently detected in the media of cultured human kidney cells, endothelial cells, malignant cell lines, and tumors; and in plasma.\textsuperscript{1928,1929,1930} and \textsuperscript{1931} u-PA is a serine protease and is synthesized as a single-chain molecule called prourokinase or single-chain u-PA (scu-PA). The plasma concentration of scu-PA ranges from 2 to 4 ng/ml (37 to 74 pmol/L; Table 18.10)\textsuperscript{1932}; the t\textsubscript{1/2} of scu-PA is quite short, approximately 5 minutes, and metabolism occurs in both the liver and the kidney. scu-PA has a very low level of proteolytic activity.\textsuperscript{1933} Plasmin can hydrolyze the Lys\textsuperscript{158} - Ile\textsuperscript{159} peptide bond, converting scu-PA into the two-chain form (tcu-PA).\textsuperscript{1924,1925,1935} and \textsuperscript{1936} The mechanism in blood by which scu-PA is converted into tcu-PA still remains poorly defined. It has been postulated that, within a thrombus, t-PA initially activates plasminogen bound to fibrin to form plasmin, and that it is this fibrinlocalized plasmin that then converts scu-PA into tcu-PA.\textsuperscript{1937,1938} and \textsuperscript{1939} This process results in an amplification of the rate of plasmin formation. The main site of urokinase-driven plasminogen activation appears to be extravascular, where it has an important role in promoting degradation of extracellular matrix by triggering the activation of plasminogen and, possibly, matrix metalloproteinases.\textsuperscript{1940} Regulation of urokinase is important to normal and pathologic processes including embryogenesis, wound healing, tumor cell invasion, and metastasis.\textsuperscript{1941,1942} and \textsuperscript{1943} Inhibitors of urokinase have been shown to suppress the growth of primary tumors and to interfere with metastasis of tumor cells.\textsuperscript{1944,1945,1946,1947,1948,1949,1950} and \textsuperscript{1951}

Gene Structure and Expression

The human u-PA gene spans 6.4 kb with 11 exons\textsuperscript{1952} and is located on chromosome 10, band q24\textsuperscript{1953} (Table 18.9). The overall intron-exon arrangement is similar to that of the t-PA gene. The primary amino acid sequence of the purified, intact two-chain molecule has been determined,\textsuperscript{1924,1925,1954} and the cDNA has been isolated and sequenced.\textsuperscript{1955} The gene specifies a protein of 431 amino acids, with the first 20 residues constituting a signal peptide.

The disruption of the urokinase gene (u-PA\textsuperscript{−/−}) in mice is not lethal.\textsuperscript{1881} These mice did not display spontaneous thrombi in their vasculature. The phenotype of u-PA\textsuperscript{−/−} mice included occasional minor fibrin deposits in the liver and intestine, excessive fibrin deposits in chronic nonhealing skin lesions, and increased susceptibility to bacterial infections.\textsuperscript{1881,1956,1957} and \textsuperscript{1958}

Biochemistry

u-PA is a single-chain glycoprotein containing 411 amino acids (M\textsubscript{r} = 54,000; Table 18.10; Fig. 18.20). It has 12 disulfide bonds with one (Cys\textsuperscript{148} - Cys\textsuperscript{275}) serving to link the catalytic domain (B-chain) to the NH\textsubscript{2}-terminal domain (A-chain). Posttranslational modifications include glycosylation at Asn\textsuperscript{302}, addition of a single fucose residue at Thr\textsuperscript{8}, and regulatory phosphorylation at Ser\textsuperscript{138}/Ser\textsuperscript{303}.\textsuperscript{1960} u-PA is composed of an EGF domain (residues 7 to 43), a single kringle domain (residues 50 to 131), a connecting peptide region (residues 132 to 157), and the serine protease-type catalytic domain (residues 159 to 411). The EGF domain contains the residues essential for urokinase binding to the urokinase receptor.\textsuperscript{1961} and appears to be the domain responsible for the ability of urokinase to induce cellular proliferation and differentiation.\textsuperscript{1962,1963} and \textsuperscript{1964} The function of the kringle domain of urokinase remains to be established. It displays no binding affinity for fibrin. Recent evidence indicates that the kringle domain may have a role in mediating the process by which urokinase stimulates smooth muscle migration.\textsuperscript{1965,1966} and \textsuperscript{1967} Residues His\textsuperscript{204}, Asp\textsuperscript{255}, and Ser\textsuperscript{356} form the catalytic triad of urokinase; unlike the single-chain form of t-PA, they are not properly positioned for efficient catalysis. scu-PA does not form complexes with PAI-1 or react with peptidyl chloromethylketones that inhibit the two-chain form; scu-PA-catalyzed hydrolysis of tripeptide paranitroanilide substrates proceeds with 0.1% to 0.4% the efficiency of tcu-PA,\textsuperscript{1968,1969} and plasminogen activation by scu-PA appears to be equally inefficient when compared to tcu-PA.\textsuperscript{1939,1970}

The urokinase molecule is asymmetric in shape with the growth factor, kringle, and catalytic domains arranged like differently configured beads on a string.\textsuperscript{1959,1971,1972} and \textsuperscript{1973} A crystal structure for the entire urokinase molecule has not been accomplished. However, a crystal structure at a resolution of 2.5 Å has been reported for the catalytic domain. The molecule used was a recombinant, nonglycosylated human u-PA (residues 159 to 411) with its active site histidine residue derivatized with a peptidyl chloromethylketone.\textsuperscript{1974} The catalytic domain of u-PA has the expected overall topography and
S1 specificity pocket of a trypsin-like protease, an S2 pocket of hydrophobic character, and a solvent-accessible S3 pocket suitable for binding a wide range of amino acid side chains. The crystal structure of a mutant urokinase catalytic domain (residues 159 to 404: C122A and N302Q) at a resolution of 1.5 Å has also been reported.

Activation

Conversion of single-chain urokinase to an active two-chain form occurs principally through hydrolysis of the Lys$^{158}$-Ile$^{159}$ bond. This molecular form, referred to as high-molecular-weight tcu-PA, is composed of NH$_2$-terminal heavy chain (residues 1 to 158) linked by one disulfide bond to the catalytic domain. In the blood, during fibrinolysis, plasmin is the primary catalyst of this conversion; in addition, both kallikrein and factor XIa, products of the intrinsic pathway of coagulation, hydrolyze this bond. A number of other proteases that cleave the Lys$^{158}$-Ile$^{159}$ bond have also been identified, including several cathepsins, mast cell tryptase, nerve growth factor-γ, human T-cell serine proteinase-1, and FSAP.

A second, catalytically active form of two-chain urokinase, known as low-molecular-weight tcu-PA, is found in plasma when fibrinolysis is stimulated. It is formed by an additional plasmin cleavage at Lys$^{155}$-Lys$^{156}$. This yields a truncated heavy chain containing most of the connecting peptide region (residues 136 to 158) linked to the catalytic domain by the Cys$^{148}$-Cys$^{149}$ disulfide bond. This cleavage produces a more efficient enzyme, and this lowmolecular-weight form is used clinically for thrombolytic therapy. Another low-molecular-weight form of scu-PA arises from cleavage of the Glu$^{143}$-Leu$^{144}$ bond by the matrix metalloproteinases Pump 1 and metalloproteinase 3.

This form appears to be a better clot-lysing agent than low-molecular-weight t-PA.

Neutrophil cathepsin G and elastase from granulocytes cleave scu-PA at the Ile$^{155}$-Ile$^{160}$ bond, yielding a two-chain molecule that is inactive. Thrombin, and, more efficiently, the thrombin-thrombomodulin complex cleave scu-PA at Arg$^{156}$-Phe$^{157}$, yielding an inactive two-chain urokinase species. The release of the dipeptide Phe$^{157}$-Lys$^{158}$ from the catalytic domain is catalyzed by cathepsin C and plasmin.

Function

t-PA appears to be the primary plasminogen activator in the vasculature, with fibrin-localized scu-PA conversion to tcu-PA acting as an amplifying rather than initiating mechanism for plasmin formation. Direct scu-PA activation of Glu-plasminogen bound to COOH-terminal lysine residues found in partially proteolyzed fibrin has been proposed as contributing to clot lysis. This catalytic role of scu-PA, although direct, still depends temporally on t-PA-derived plasmin to create the circumstance (plasmin proteolyzed fibrin) under which it can contribute to overall fibrinolysis.

Extrinsic Activator: Factor VII-Activating Protease

Recently, a novel serine protease in human plasma has been described that can support coagulation by activating factor VII. It was originally described as plasma hyaluronan-binding protein and was isolated by adsorption to immobilized hyaluronic acid as a disulfide-linked heterodimer. Independently, a thrombin-like amylodase activity was purified from commercial prothrombin complex concentrates. Sequencing data indicated that this protease and plasma hyaluronan-binding protein were the same proteins. Subsequently, the protease from prothrombin complex concentrates was shown to be a potent activator of factor VII and termed FSAP. The capacity of FSAP to activate factor VII has been challenged. This protease has also been shown to be an efficient activator of single-chain urokinase and appears to catalyze the inactivating proteolysis of TFPI. Its single-chain precursor has been purified from plasma.

Gene Structure and Expression

FSAP has been mapped to chromosome 10, bands q25-q26. It spans 35 kb and is composed of 13 exons (Table 18.10). Its transcript specifies a protein of 560 amino acids; the first 23 amino acids comprise the signal peptide sequence. Two single nucleotide polymorphisms have been identified. One, called FSAP Marburg I (SNP-1), yields a Gly511Glu substitution near the COOH-terminus of the protease resulting in impairment of its scu-PA-activating properties. The second polymorphism, Marburg II, contains a Glu370Gln mutation that does not appear to have an effect on the catalytic properties of FSAP.

Biochemistry and Activation

FSAP is a single-chain glycoprotein containing 537 amino acids with an M$_r$ of 64 kDa. It circulates at a concentration of approximately 12 µg/ml (190 nmol/L; Table 18.10). It is composed of 5% carbohydrate and is glycosylated at Asn$^{31}$ (NH$_2$-
The physiologic function of FSAP is still unclear. The ability of two-chain FSAP to convert factor VII to factor VIIa in the absence of tissue factor suggests that it could contribute to the maintenance of normal factor VIIa levels in blood or contribute to the localized production of factor VIIa at the site of vascular injury. In a system of synthetic hemophilia (factor VIII deficiency), two-chain FSAP has been shown to correct the hemostatic defect. Similar results have been found with the addition of exogenous factor VIIa to hemophilia blood. The two-chain form of FSAP appears to be an efficient activator of single-chain urokinase, comparing favorably with plasmin when heparin is present. It has been suggested that GAG-binding properties of FSAP may localize it to cell surfaces and extracellular matrix proteins, where it may play a role as an initiator of urokinase-dependent proteolytic cascades. The role of FSAP in inflammatory processes is under investigation.

INHIBITORS OF THE FIBRINOLYTIC SYSTEM

A wide variety of natural inhibitors of fibrinolysis exist in plasma, blood cells, tissues, and extracellular matrices. These natural inhibitors can act either to inhibit plasmin directly or to block the conversion of plasminogen to plasmin. The two-chain form of FSAP appears to be an efficient activator of single-chain urokinase, comparing favorably with plasmin when heparin is present. It has been suggested that GAG-binding properties of FSAP may localize it to cell surfaces and extracellular matrix proteins, where it may play a role as an initiator of urokinase-dependent proteolytic cascades. The role of FSAP in inflammatory processes is under investigation.

Thrombin-activatable Fibrinolysis Inhibitor

TAFI (E.C.3.4.17.20) (for reviews, see and ) is a plasma zymogen with homology to procarboxypeptidases A and B. Its plasma concentration is 75 nmol/L (4.5 μg/ml; Table 18.10). TAFI is synthesized in the liver and is thought to circulate in blood in complex with plasminogen. A small pool of TAFI (< 1% of plasma concentration) is found in platelets and has been found to enhance the attenuation of fibrinolysis in vitro. Activation of TAFI yields an exopeptidase (TAFIa) with carboxypeptidase B-like substrate specificity. It catalyzes the removal of basic amino acids (arginines, lysines) from the COOH-termini of polypeptides. Its primary physiologic activator appears to be the thrombin-thrombomodulin complex, thus defining TAFIa as a coagulation-dependent activity. COOH-terminal lysines that appear in fibrin as it degrades have been identified as the primary substrates for TAFIa (Fig. 18.21). The initial phase of plasmin proteolysis yields products that amplify plasminogen activation by t-PA. These fibrin degradation products thus constitute a positive feedback process, thereby accelerating clot lysis. COOH-terminal lysines that appear in fibrin as it is degraded by plasmin function as additional binding sites where efficient plasminogen activation can occur. Removal of these terminal lysine residues by TAFI reduces the number of plasminogen-binding sites, thus serving to downregulate the rate of plasmin generation and thereby the rate of clot lysis. Thus, TAFI/TAFIa functions as an antifibrinolytic factor by suppressing the positive feedback pathway of fibrinolysis. The importance of vivo in vivo evidence consistent with the proposed role of the TAFI/TAFIa system in regulating fibrinolysis. However, TAFI knockout mice develop normally and prove no more sensitive to a wide range of hemostatic challenges than their wild-
In humans, TAFI antigen concentration has been correlated with an increase in risk for deep vein thrombosis.

**FIGURE 18.21.** Mechanism of thrombin-activatable fibrinolysis inhibitor (TAFI) regulation of fibrinolysis. Thrombin-thrombomodulin (IIa-TM) cleaves TAFI to its active carboxypeptidase form TAFIa. TAFIa interferes with fibrinolysis by cleaving COOH-terminal Arg (R) or Lys (K) residues made available as a consequence of partial plasmin digestion of the fibrin clot. Removing these residues attenuates the self-amplifying mechanism of fibrin-based plasmin formation wherein partial plasmin proteolysis of fibrin increases the number of binding sites (COOH-terminal lysines) available for efficient plasminogen activation. (From Mann KG. Coagulation explosion. Vermont Bus Graph 1997, with permission.)

The nomenclature associated with carboxypeptidase B-type activity in serum reflects the history of its isolation and characterization. The presence of a carboxypeptidase B-type activity in serum that differed from that of carboxypeptidase N, a previously characterized enzyme found in plasma, was first reported by two groups: Hendriks et al. named the enzyme carboxypeptidase unstable because of its short $t_{1/2}$ compared to carboxypeptidase N; Campbell and Okada named their activity carboxypeptidase R because of its apparent preference for substrates with COOH-terminal arginine residues, again in contrast to carboxypeptidase N, which showed a selectivity for COOH-terminal lysines. Subsequently, Eaton et al. purified a novel plasminogen-binding protein from human plasma, which, based on sequence homology and enzymatic properties, proved to be a procarboxypeptidase. They named this protein plasma procarboxypeptidase B. Independently, Bajzar et al., using an assay designed to detect the factor responsible for thrombin-dependent inhibition of fibrinolysis, purified a protein from human plasma. Initial characterization of this protein indicated that it was a procarboxypeptidase B-type protein, which converted to an active carboxypeptidase on treatment with thrombin. This group named the protein TAFI. Further characterization established that TAFI is identical to protein plasma procarboxypeptidase B. Whether carboxypeptidase R and carboxypeptidase unstable are identical to TAFI has not been resolved because of differences in the reported molecular mass and subunit structure of these proteins.

**Gene Structure and Expression**

TAFI is a member of a multigene family that includes the pancreatic and mast cell carboxypeptidases but not other carboxypeptidases with a specificity for basic amino acids, such as carboxypeptidases N, M, H, and D. TAFI shares
34% to 40% amino acid identity with its family members, including exact conservation of cysteine residues and residues critical for catalysis, zinc binding, and substrate binding.

The human gene for TAFI maps to chromosome 13\(^{2035}\) and is composed of 11 exons within 48 kb of DNA\(^{2035}\) (Table 18.9). When the TAFI gene is compared with the genes from rat pancreatic carboxypeptidases A1, A2, and B and human mast cell carboxypeptidase A, the positions of intron/exon boundaries are conserved, whereas the intron lengths diverge significantly. The TAFI promoter lacks a consensus TATA sequence but does have a 70-bp sequence in the 5′-flanking region of the gene that is required for liver-specific transcription.\(^{2035}\) Transcription is initiated at multiple sites. Primer extension analysis of human liver Poly (A)\(^{+}\) RNA identified nine major transcription start sites with similar frequencies of usage.\(^{2035}\) The TAFI transcript is polyadenylated at three different sites.

The TAFI transcript encodes a gene product of 423 amino acids. The first 22 amino acids comprise a signal peptide that is absent in the circulating form of the protein. Three single nucleotide polymorphisms in the coding region of the human TAFI gene have been identified, resulting in two distinct isoforms of TAFI: a base change of C to T at base 678, resulting in a silent mutation; a base change of A to G at base 505, yielding a Thr to Ala substitution at amino acid position 147; and a base change of C to T at base 1,057, resulting in an Ile to Thr substitution at TAFI residue 325. No functional difference was observed between purified TAFIa (Ala\(^{147}\)) and TAFIa (Thr\(^{147}\)).\(^{2038}\) However, purified TAFIa (Ile\(^{325}\)) showed greater activity and stability than TAFIa (Thr\(^{325}\)).

The plasma concentration of TAFI antigen has been observed to vary approximately 10-fold in the human population. The origin of this variability appears to be primarily genetic.\(^{2039}\) Polymorphisms in the TAFI gene that have been shown to be strongly associated with plasma TAFI levels include a number in the 5′-flanking region,\(^{2029,2040}\) the 3′-untranslated region,\(^{2040}\) and the coding region.\(^{2041}\)

**Biochemistry**

The TAFI transcript specifies a preprotein of 423 amino acids composed of a signal peptide, an activation peptide domain, and a catalytic domain. Removal of the signal peptide yields the circulating zymogen of 401 amino acids (45 kDa); when analyzed by

P.490

SDS-PAGE, the apparent molecular weight of TAFI is 58 kDa (Fig. 18.22). The difference in mass derives from a high level of glycosylation involving all four of the potential sites (Asn\(^{22}\), Asn\(^{51}\), Asn\(^{63}\), and Asn\(^{86}\)) present in the activation peptide domain (residues 1 to 92). In addition to its structural role in suppressing the catalytic potential of TAFI, the activation peptide domain mediates the association in blood of TAFI with plasminogen.\(^{19}\) The sequence of the catalytic domain (residues 93 to 401; 35 kDa) displays exact conservation when compared to pancreatic and mast cell carboxypeptidases of cysteine residues and residues critical for catalysis, Zn\(^{2+}\) binding, and substrate binding.\(^{19,2035}\) The activated form of TAFI is a carboxypeptidase that catalyzes the removal of arginine or lysine residues from the COOH-termini of polypeptides. TAFIa is inhibited by agents that can chelate Zn\(^{2+}\), such as o-phenanthroline, and by 2-guanidinoethylmercaptosuccinic acid, a specific inhibitor of pancreatic and mast cell carboxypeptidases.\(^{19,36}\) TAFIa is an unstable enzyme at physiologic pH and temperature.\(^{18,19,36}\) At 37°C, TAFIa has a functional \(t_{1/2}\) of approximately 10 minutes; its loss of activity is coincident with a significant change in conformation.\(^{2042}\)

**Activation**

The activation of TAFI requires the cleavage of the zymogen at Arg\(^{92}\), yielding an activation peptide of approximately 15 kDa and an active carboxypeptidase of 35 kDa (Fig. 18.22). Trypsin,\(^{19}\) plasmin,\(^{19,2043}\) plasmin-anionic GAG complex,\(^{2043}\) thrombin,\(^{19,36}\) thrombin-thrombomodulin complex,\(^{969}\) and meizothrombin-thrombomodulin complex\(^{1087}\) all catalyze this reaction in vitro. A ranking of these catalysts in terms of relative catalytic efficiency shows the following order: thrombin-thrombomodulin (1.0) > meizothrombin-thrombin (0.1) = plasmin-anionic GAG (0.1) > plasmin (0.006) > thrombin (0.0008). The complement protease MASP-1 also has been shown to activate TAFI.\(^{2044}\) The relative contributions of thrombin and plasmin to TAFI generation in vivo may be regulated by the availability of their respective cofactors at the site of vascular injury: cell-associated thrombomodulin versus the extent of exposure of subendothelial extracellular matrix. Platelet factor 4 has been reported to inhibit activation of TAFI by the thrombin-thrombomodulin complex.\(^{2045}\)
FIGURE 18.22. Schematic of thrombin-activatable fibrinolysis inhibitor (TAFI). Activation of TAFI yields an exopeptidase (TAFIa) with carboxypeptidase B-like substrate specificity. It catalyzes the removal of basic amino acids (arginines, lysines) from the COOH-termini of polypeptides. TAFI contains four glycosylation sites in its activation peptide region. TAFIa is an unstable enzyme undergoing spontaneous conformational change resulting in a loss of catalytic activity ($t_{1/2} = 8-10$ min).

**Function**

Thrombin cleavage of fibrinogen yields insoluble fibrin polymers and soluble fibrinopeptides, all bearing COOH-terminal arginine residues. These COOH-terminal arginines are substrates for TAFIa, and the kinetics of their release in an in vitro clot lysis system $^{1011}$ and whole blood system where des-Arg FPB was detected $^{1013}$ have been reported. The significance of this removal of arginine residues from these sites is not known. The activation of many of the cofactors and zymogens of the coagulation and fibrinolytic cascades results in the generation of functional proteins with COOH-terminal arginines or lysines. Their status as TAFIa substrates is unknown. Bradykinin and several enkephalins have been shown in vitro to be good TAFIa substrates $^{2034}$; to date, only circumstantial evidence connects TAFIa and bradykinin in vivo. $^{2046}$

Extensive in vitro data $^{1011,1104,1775,1776,2042,2047,2048}$ attest to the ability of TAFIa to slow the rate of fibrin degradation by plasmin generated in situ. Proteolysis of insoluble fibrin by plasmin proceeds through repetitive cleavages at lysine residues terminating in the formation of soluble fibrin degradation products. Before solubilization, each cleavage shortens the fibrin molecule and generates a new COOH-terminal lysine residue. COOH-terminal lysines in partially degraded fibrin have been shown to function as potent cofactors for t-PA-catalyzed activation of Glu-plasminogen. $^{2049,2050,2051,2052}$ and $^{2053}$ Removal of the COOH-terminal lysines by TAFIa thus reduces the number of sites available for plasminogen binding, thereby reducing the rate of plasmin generation with consequent prolongation of fibrin dissolution $^{1011,1775,2054}$ (Fig. 18.21). TAFIa functions as an attenuator of fibrinolysis, $^{2055}$ and thus an adequate rate of TAFIa generation may be critical in the stabilization of the blood clot. For example, plasmas with specific deficiencies in the coagulation pathway showed reduced rates of thrombin production, decreased levels of TAFIa, and premature clot lysis. $^{1776,2026,2056}$

**Regulation**

TAFI circulates in plasma bound to plasminogen $^{19}$ and is a substrate for factor XIIIa, which catalyzes its covalent attachment to
fibrin. Whether these two mechanisms for concentrating TAFI at the site of fibrin formation contribute to the function of TAFI in vivo is not established. It has been proposed, because the thrombin-thrombomodulin complex has a $K_m$ 10 to 20 times the plasma concentration of TAFI, that rates of TAFI activation would vary directly with changes in TAFI concentration.

A plasma inhibitor of TAFIa has not been described. Carboxypeptidase inhibitors from potato and the leech active against TAFIa have been identified. TAFIa is an unstable enzyme under physiologic conditions. It undergoes a spontaneous conformational change with a $t_{1/2}$ of 10 minutes at 37°C. This appears to be the primary route of inactivation because proteolytic cleavage at Arg by thrombin or plasmin has now been identified as secondary to and dependent on the inactivating conformation change. TAFI plasma concentrations vary significantly in the human population. Although genetic factors appear to be the largest contributor to this variation, a growing number of stimuli have been shown to affect TAFI plasma concentration. Some of this variability stems from polymorphisms in the TAFI gene; however, a larger fraction of the variability appears to derive from the responsiveness of TAFI gene expression to a wide variety of physiologic effectors and conditions as well as pharmacologic agents. Higher levels of plasma TAFI-1 prolong fibrin removal by shortening the functional lifetime of plasminogen activators, thereby shifting hemostasis to a more thrombotic state. The $t_{1/2}$ of TAFI-1 in blood is < 10 minutes. Potential sites of constitutive TAFI-1 synthesis in humans include the liver, spleen, adipose tissue, and cells of the vasculature, including endothelial cells, smooth muscle cells, macrophages, and megakaryocytes. The relative contributions from these sources to plasma TAFI-1 levels in normal or specific pathologic conditions remain unresolved. The major fraction of TAFI-1 in blood is present in platelets, apparently synthesized and stored in the $\alpha$-granules during the maturation of megakaryocytes. Although 75% to 80% of platelet TAFI-1 is present in the latent form, there appears to be enough active TAFI-1 released from platelets at sites of thrombus formation to contribute to the suppression of fibrinolysis.

PAI-1 is the primary physiologic inhibitor of plasminogen activation in blood, targeting u-PA and t-PA. It also appears to have a role, independent of its antiproteolytic function, in tissue remodeling by interfering with vitronectin-dependent processes of cell adhesion and migration. Congenital deficiency of PAI-1 is rare, with homozygous individuals displaying abnormal bleeding in response to trauma. In a normal population, plasma PAI-1 concentration varies over a 15-fold range (6 to 80 ng/ml; Table 18.10) and exhibits a circadian variation. Some of this variability stems from polymorphisms in the PAI-1 gene; however, a larger fraction of the variability appears to derive from the responsiveness of PAI-1 gene expression to a wide variety of physiologic effectors and conditions as well as pharmacologic agents. Higher levels of plasma PAI-1 prolong fibrin removal by shortening the functional lifetime of plasminogen activators, thereby shifting hemostasis to a more thrombotic state. The $t_{1/2}$ of PAI-1 in blood is < 10 minutes. Potential sites of constitutive PAI-1 synthesis in humans include the liver, spleen, adipose tissue, and cells of the vasculature, including endothelial cells, smooth muscle cells, macrophages, and megakaryocytes. The relative contributions from these sources to plasma PAI-1 levels in normal or specific pathologic conditions remain unresolved. The major fraction of PAI-1 in blood is present in platelets, apparently synthesized and stored in the $\alpha$-granules during the maturation of megakaryocytes. Although 75% to 80% of platelet PAI-1 is present in the latent form, there appears to be enough active PAI-1 released from platelets at sites of thrombus formation to contribute to the suppression of fibrinolysis.

PAI-1 is a single-chain protein with an $M_\text{r}$ of 50,000 (13% carbohydrate; Table 18.10). It is a typical serpin with its reactive site bond, $\text{Arg}^{302}-\text{Met}^{347}$, positioned in an exposed loop region where it is available for complexation with its target proteases. However, this conformation, with the reactive site accessible to proteases, is unstable ($t_{1/2} < 90$ minutes), reverting spontaneously to a latent form of the inhibitor in which the reactive loop is buried in $\beta$ sheet A of the protein core. This positioning of the reactive loop is observed in PAI-1 and other serpins after cleavage of the reactive site bond. Plasma PAI-1 circulates in noncovalent association with vitronectin ($K_d < 0.05 \text{ nmol/L}$); in vitro, this association results in a twofold increase in its functional $t_{1/2}$ and, in the presence of heparin, increases PAI-1 reactivity with thrombin.

**Gene Structure and Expression**

PAI-1 is an inhibitory serpin with significant sequence homology to $\alpha_1$-antitrypsin, antithrombin, and $\alpha_1$-antichymotrypsin. It shares the fundamental structural plan of these serpins: three $\beta$ sheets, nine $\alpha$-helices, and a reactive site loop. PAI-1 is distinguished from the other inhibitory serpins in that it lacks cysteine residues.

The human gene for PAI-1 is located on chromosome 7 bands q21.3-q22 in close proximity to the loci for erythropoietin, paraoxonase, and cystic fibrosis (Table 18.9). It covers 12.2 kb of DNA with nine exons specifying the 23 amino acids of the signal peptide and 379 amino acids of the mature protein and. Introns, totaling approximately 9,000 bp, define boundaries of individual structural subdomains or are found in random coil regions of the protein. The transcription start site is located 25 bp downstream of a consensus TATA sequence. The 5′-flanking region of the PAI-1 gene shows an extensive region of nucleotide sequence identity with the 5′-flanking region of the gene encoding t-
PA. 2093,2094 The 3’ region of the human PAI-1 gene contains alternative polyadenylation sites resulting in two mRNA species of different lengths (2.4 and 3.2 kb). 2091

Normal plasma levels of PAI-1 antigen range between 6 and 80 ng/ml. Polymorphisms in the PAI-1 gene appear to correlate with different plasma levels of PAI-1; thus, genotype-specific regulation of PAI-1 accounts for some of the observed variation in the normal population. Nine polymorphisms have been described, with three of these the subject of human population studies. 2095 A polymorphism located 675 bp upstream of the transcription start site consists of a single guanine insertion/deletion variation (4G/5G) leading to a sequence of four or five guanine nucleotides in the promoter. 2096 Individuals homozygous for the 4G polymorphism have the highest levels of PAI-1; heterozygotes show intermediate levels; those homozygous for the 5G allele have the lowest levels. 2097,2098,2099,2100 and 2101 The basis of this differential expression of the PAI-1 gene appears to be the specificity of a transcriptional repressor protein that binds the 5G allele and not the 4G allele. 2101 The predictable relationship between the 4G/5G genotype, plasma PAI-1 level, and the risk of thrombosis is controversial. 2102,2103 and 2104 The two other polymorphisms investigated both in vitro and in human population studies include an eight-allele (CA)n repeat in intron 3 2105 and a two-allele Hind III restriction fragment length polymorphism of the 3′-flanking region. Individuals with one of the homozygous genotypes associated with the Hind III site exhibit higher plasma PAI-1 activity than the complementary homozygous individuals. 2105 In vitro studies of the Hind III polymorphism have shown genotype-specific regulation of PAI-1 synthesis by a number of effector molecules. 2106,2107,2108 and 2109

Congenital PAI-1 deficiency is a rare disorder, with homozygous PAI-1-deficient individuals showing abnormal bleeding after trauma or surgery. 2080,2089 A study of an extended family with 19 heterozygotes and 7 individuals homozygous for a null mutation in the PAI-1 gene found no significant developmental or other abnormalities in the homozygotes beyond abnormal bleeding episodes. 2079 Homozygous PAI-1-deficient mice display normal fertility, viability, and development, with no identified histologic abnormalities. 2110,2111 A mild hyperfibrinolytic state and greater resistance to venous thrombosis were reported. Mice with combined homozygous deficiency of PAI-1 and α2-antiplasmin show normal fertility and development while displaying a higher fibrinolytic capacity. 2111 However, this increase appears to depend on the α2-antiplasmin deficiency alone, suggesting a less critical role for PAI-1 in the regulation of fibrinolysis.

Biochemistry
PAI-1 is a single-chain glycoprotein of 379 amino acids that has no cysteine residues. It is an inhibitory serpin with a reactive

P.492

site bond, Arg 346-Met 347, positioned in a surface-exposed, disordered loop of 20 amino acids. 2079 Reaction with t-PA or u-PA involves rapid formation (second-order rate constant = 10⁷ to 10⁸ M⁻¹ second⁻¹) of a reversible complex; specific interactions between a negatively charged region (amino acids 350 to 355) of the PAI-1 molecule and positively charged regions in t-PA 2111 or in u-PA 2115 are important to this initial association. Cleavage of the reactive site Arg 346-Met 347 bond in PAI-1 by the protease triggers a large conformational change in both the inhibitor and the protease that renders the protease unable to efficiently hydrolyze the normally transient ester linkage between its active site serine residue and the carboxyl moiety of the targeted peptide bond. PAI-1 converts to an inactive (latent) form spontaneously; it can be returned to its active conformation by treatment with denaturants. 2116 The crystal structure of latent PAI-1 indicates that the reactive site loop is inserted into the β sheet A of the molecule, making it unavailable to proteases. 2117 The crystal structure of a mutant PAI-1 stabilized in the active conformation by substitutions at four sites (N150→H; K154→T; Q319→L; M354→I) shows the reactive site bond to be located at the apex of a flexible, exterior loop. 2079 The vitronectin binding site of PAI-1 involves five residues located on the exterior of the molecule. 2118 Extensive structural differences have been noted when this region is compared in active and latent conformations of PAI-1. 2079 Stabilization of the conformation of this region of PAI-1 by the PAI-1 vitronectin binding interaction presumably impedes the insertion of the reactive site loop into β sheet A of the molecule.

Function
PAI-1 is the central physiologic inhibitor of the plasminogen activator t-PA in blood. It reacts with both the secreted, singlechain form of t-PA and the two-chain form generated by plasmin during the process of fibrin dissolution. Both PAI-1 and t-PA are characterized by high turnover rates (t-PA, t½ = 3 to 4 minutes; PAI-1, t½ = 10 minutes) with functional PAI-1 circulating concentrations maintained at least at severalfold molar excess over the concentration of functional t-PA (14 pmol/L). From the circulating concentration of PAI-1 and the second-order rate constant for the association of PAI-1 with either form of t-PA (10⁷ to 10⁸ M⁻¹ second⁻¹), the predicted t½ of t-PA is < 1 minute. This is consistent with the observation
that approximately 80% of the t-PA antigen in plasma (70 pmol/L) is found complexed with PAI-1. PAI-1-t-PA complexes have a clearance $t_{1/2}$ of approximately 5 minutes.\(^{3544}\) Although other plasma proteins have been identified in vitro with inhibitory activity toward plasminogen activators (PAI-2, PAI-3, protease nexin), only PAI-1-plasminogen activator complexes have been detected in vivo.\(^{1127,2119}\)

PAI-1 is an important inhibitor of u-PA. Unlike t-PA, PAI-1 forms complexes only with the two-chain form of urokinase; it does not complex with the single-chain form of urokinase. The second-order rate constant for the association of PAI-1 and t-PA is in the range of $10^8$ M\(^{-1}\) second\(^{-1}\). Conversion of circulating scu-PA (37 to 74 pmol/L) to t-PA occurs at sites of fibrin lysis. Urokinase is also involved in physiologic and pathologic processes such as embryo development, wound healing, cell migration, inflammation, and metastasis of tumor cells. A large body of in vitro work supports a regulatory role for PAI-1 as a protease inhibitor in u-PA-mediated events outside the vasculature, and as a consequence, its dysregulation has been implicated in the pathogenesis of fibrosis in different organs.\(^{2120}\)

PAI-1 also appears to be involved in regulating cell adhesion and migration by a mechanism independent of its function as a protease inhibitor. Its high-affinity association with the somatomedin B domain of vitronectin makes it an effective competitor with other ligands such as urokinase-type plasminogen activator receptor (uPAR)\(^{2121,2122,2123}\) and\(^{2124}\) and integrins including $\alpha_6\beta_3$\(^{2125}\) that also bind to vitronectin at this site. The ability to interfere with the binding of such cell-associated ligands to matrix-associated vitronectin suggests a role for PAI-1 as a regulator of the interaction of cells with the extracellular matrix.

### Plasminogen Activator Inhibitor-2

PAI-2 is a member of the serpin subfamily designated the ovalbumin-related serpins.\(^{2126}\) It was initially identified in human placenta as an inhibitor of urokinase.\(^{2127}\) It has also been referred to as the placental-type PAI.\(^{2127,2128,2129,2130,2131}\) and\(^{2132}\) It is not normally detected in plasma, although it has been detected in human thrombi.\(^{2133}\) During pregnancy, PAI-2 is found in plasma at levels that may exceed those of PAI-1.\(^{2119}\) PAI-2 appears to have significant functions within the cytoplasm of certain cell types and in the extracellular region outside of the vasculature, where it may regulate urokinase-dependent events. However, its role in hemostasis remains problematic and a definitive intracellular role for PAI-2 is not established.\(^{2134}\) PAI-2 (–/–) null mice developed normally and did not display any phenotypic abnormalities.\(^{2135}\)

### Gene Structure and Expression

The gene for PAI-2 is located on chromosome 18, band q22.1, and spans 16.5 kb\(^{2136,2137,2138,2139,2140}\) and\(^{2141}\) (Table 18.9). Its transcript specifies a protein of 415 amino acids that lacks a cleavable NH\(_2\)-terminal signal sequence. PAI-2 is synthesized and secreted by human blood cells such as monocytes and macrophages, and cells of epithelial lineage such as keratinocytes and certain tumor cells.\(^{2142,2143,2144}\) and\(^{2145}\) A large number of agonists have been shown to affect transcription rates of the PAI-2 gene (reviewed in\(^{2126,2146,2147}\)). For example, the PAI-2 gene has been shown to respond dramatically to TNF\(^{2148}\) and to lipopolysaccharide.\(^{2149}\) In human monocytes, exposure to lipopolysaccharide induced approximately a 100-fold increase in PAI-2 mRNA levels.\(^{2150}\) Posttranscriptional regulation of PAI-2 mRNA levels has also been documented.\(^{2151,2152}\) Regulation of the stability of PAI-2 mRNA has been shown to derive in part from an AU-rich mRNA destabilizing determinant in the 3′-untranslated region\(^{2153}\) and from an mRNA instability element identified within exon 4 of the coding region.\(^{2153}\)

### Biochemistry and Function

There are two forms of PAI-2: an intracellular nonglycosylated form ($M_\text{n} = 47$ kDa) and a secreted glycosylated form ($M_\text{n} = 60$ kDa) (Table 18.10). However, the nonglycosylated form has been observed in the blood of pregnant women.\(^{2119}\) Glycosylation occurs at Asn\(^75\), Asn\(^115\), and Asn\(^339\). PAI-2 is structurally distinguished from other serpins by the presence of a unique 33-residue-long loop (CD loop: residues 66 to 98) positioned between helices C and D. This solvent-exposed loop region has two glutamine residues (Gln\(^83\) and Gln\(^86\) that have been shown to be sites for factor XIIIa-catalyzed cross-linking of PAI-2 to fibrinogen.\(^{2133,2134}\) PAI-2 cross-linked to fibrinogen remains functional after its fibrinogen carrier is converted to insoluble fibrin.\(^{2154}\) The CD loop has also been implicated in the association of intracellular PAI-2 with other cytoplasmic proteins.\(^{2155}\) The crystal structure of PAI-2 at 2-Å resolution has recently been reported using a PAI-2 mutant lacking the CD loop.\(^{2156}\) The reactive site bond (Arg\(^380\)-Thr\(^381\)) is located in a highly disordered reactive center loop extending from Thr\(^367\) to Pro\(^386\). PAI-2 is a serpin inhibitor that can inhibit plasminogen activators. The second-order rate constants defining its interactions with two-chain urokinase ($1 \times 10^8$ M\(^{-1}\) second\(^{-1}\)) and two-chain t-PA ($2 \times 10^7$ M\(^{-1}\) second\(^{-1}\)) are approximately 100-fold lower than those characterizing the reaction of PAI-1 with these proteases. Unlike PAI-1, PAI-2 reacts very slowly with the single-chain form of t-PA. Also unlike PAI-1, PAI-2-t-PA or PAI-2-u-PA complexes have not been detected in
plasma. Thus, it has been suggested that PAI-2 may not play an important role in regulating intravascular clot lysis. However, fibrin deposition at sites of chronic inflammation within blood vessels may represent an instance in which monocye-derived PAI-2 could end up cross-linked to fibrin, thereby exerting some effect in the vasculature. An extravascular role for PAI-2 in aspects of tissue remodeling and wound healing that depend on urokinase catalysis is consistent with the observed induction of PAI-2 production by inflammatory mediators in cell types such as keratinocytes and macrophages.

The nonglycosylated form of PAI-2 is found in the cytosol of a number of cell types. Data supporting a diverse set of roles for intracellular pools of PAI-2 include effects on cellular differentiation, cell proliferation, TNF-α-induced apoptosis, signal transduction, and, in monocytes, multiple roles in modulating adhesion, proliferation, and differentiation. α2-Antiplasmin (α2-Plasmin Inhibitor)

α2-Antiplasmin (or α2-plasmin inhibitor) is the primary plasmin inhibitor in human plasma and thus an important regulator of fibrinolysis. Congenital deficiency of α2-antiplasmin is rare, with homozygous individuals displaying a severe to moderate bleeding disorder. α2-Antiplasmin is a single-chain glycoprotein with a calculated mass of 58 kDa and a relative molecular weight of 70 kDa. It is present in plasma at a concentration of 70 mg/L (Table 18.10). The primary site of synthesis is the liver, although the kidney may be another contributing source, its in vivo t1/2 is 2.6 days. Two NH2-terminal variants of α2-antiplasmin are isolated from human plasma in roughly equivalent amounts: α2-antiplasmin Met1, the full-length protein secreted into the blood; and α2-antiplasmin Asn1, lacking the first 12 amino acids (Asn13 in α2-antiplasmin Met2). α2-Antiplasmin is a member of the serine protease inhibitor superfamily. It forms a stable 1:1 stoichiometric complex with plasmin that has no proteolytic or esterase activity. It is structurally distinct from related serpins in having a 55-amino acid extension at its COOH-terminus. This region mediates α2-antiplasmin binding to specific regions (lysine-binding sites) on the kringle domains of plasminogen and plasmin, and Approximately 30% of α2-antiplasmin in human plasma lacks part of this COOH-terminal region (resides 449 to 464). This truncated form appears to be functionally inert in plasma, although it has been shown, when purified, to slowly form complexes with plasmin.

The α2-antiplasmin molecule has three domains defining its role in fibrinolysis: the reactive site (Arg1466-Met1467), the plasminogen-binding site (both of which are critical to its reactivity with plasmin), and a cross-linking site mediating the attachment of α2-antiplasmin to the α-chain of fibrin during clotting. The binding of the plasminogen-binding domain of α2-antiplasmin to a lysine-binding site of plasmin has been shown to occur more rapidly than the association between the active site of plasmin and the reactive site of α2-antiplasmin. Thus, the rate of binding of α2-antiplasmin depends primarily on the availability of the lysine-binding site(s) of plasmin. This dependence of the rate of inhibition on an exosite interaction between the two molecules results in the differential reactivity of α2-antiplasmin with its primary targets in clotting blood: plasmin released into the circulating blood (t1/2 = 0.1 second) versus plasmin bound through its lysine-binding sites to fibrin or cellular sites at the site of vascular injury (t1/2 = 10 seconds).

Gene Structure and Expression

α2-Antiplasmin is a member of a multigene family of serine protease inhibitors that includes α1-antitrypsin, antithrombin, PAI-1, and α2-antichymotrypsin. These serpins interact with their target proteases at a reactive Arg-X peptide linking site positioned in a loop structure located 30 to 40 amino acids from the inhibitor COOH-terminus. The human gene for α2-antiplasmin is located on chromosome 17, band p13 and is composed of 10 exons distributed over 16 kb of DNA (Table 18.9). The 5′-untranslated region and leader sequence are interrupted by three introns; a TATA box sequence is found 17 nucleotides upstream from the transcription initiation site. Exons 4 through 10 code for the protein, with exon 10 specifying both the reactive site and the unique COOH-terminal plasminogen-binding site. One common polymorphism, RGW, has been mechanically linked to differences in the levels of α2-antiplasmin Met1 and α2-antiplasmin Asn1.

Congenital α2-antiplasmin deficiency has been described; the transmission is autosomal recessive. Bleeding problems vary from severe to moderate in homozygotes. The majority of heterozygotes have no bleeding problems, although exceptions have been described. One instance of congenital deficiency, α2-antiplasmin Enschede, is characterized by dysfunctional full-length α2-antiplasmin at normal plasma concentrations. All other cases involve quantitative defects with the four characterized instances showing mutations in the coding exons or an intron splicing donor site with consequent truncated, nonsecreted peptide products. Homozygous α2-antiplasmin-
deficient mice have been generated. They display normal fertility, viability, and development, and show no overt bleeding disorder.

Biochemistry

α₂-Antiplasmin is a single-chain glycoprotein of 464 amino acids with an M, of 70 kDa (13% carbohydrate; Table 18.10). Glycosylation occurs at Asn³⁻⁻, Asn⁶⁻⁻, Asn¹²⁻⁻, and Asn¹⁷⁻⁻. α₂-Antiplasmin contains four cysteine residues but only one S-S bridge. It is a member of the α₂-protease inhibitor class of the serine proteinase inhibitor superfamily.

α₂-Antiplasmin functions as the primary inhibitor of plasmin in blood. It is synthesized primarily in the liver with a signal peptide of 27 amino acids and circulates at a concentration of 1 μmol/L with a t½ of 2.6 days. Isolation from plasma yields both Metα₂-antiplasmin (464 amino acids) and a truncated form with an NH₂-terminal Asn (Asn¹⁻⁻-α₂-antiplasmin); the truncated form appears to be generated within circulating blood by a plasma protease. Plasma α₂-antiplasmin is also found to have two COOH-terminal forms: a slow-reacting, non-plasminogen-binding form (30%) that lacks the terminal 26 amino acids and the fully active molecule with an intact COOH-terminal extension. Conversion to the non-plasminogen-binding form occurs in the blood. α₂-Antiplasmin has three functionally important domains: a reactive site, a plasmin/plasminogen-binding site, and a cross-linking site. The reactive site of the inhibitor is the Arg³⁷⁶-Met³⁷⁷ peptide bond. α₂-Antiplasmin reacts with plasmin in a two-step process. First, a rapid (second-order rate constant = 2 to 4 × 10⁻³ M⁻¹ sec⁻¹) reversible interaction yields a 1:1 complex (K d = 10⁻⁸ M). Second, a slower first-order (t½ = 166 seconds) covalent bond forms between the active site seryl residue of plasmin and Arg³⁷⁶ of α₂-antiplasmin with subsequent release of a COOH-terminal fragment (residues 377 to 464) of α₂-antiplasmin. The plasmin/plasminogen-binding domain is located within residues 410 to 464, with Lys⁶⁴⁴ acting as the key residue. It complexes with lysine-binding site(s) located in the kringle structures of plasminogen and plasmin, exhibiting at least a 10-fold stronger binding to plasmin. Lysine-binding sites on kringle 1 and 4 have been identified as the points of interaction with α₂-antiplasmin, although their relative importance individually is not resolved. Maximum rates of α₂-antiplasmin inhibition of plasmin require the unimpeded interaction of both the plasminogen-binding domain and the reactive site of α₂-antiplasmin with their respective target domains in the plasmin molecule. Cross-linking of α₂-antiplasmin at Gln¹⁴ to the α-chain of fibrin is catalyzed by activated factor XIII. In vitro, Asnα₂-antiplasmin is more efficiently cross-linked to fibrin.

Function

α₂-Antiplasmin is the primary plasmin inhibitor in human plasma. Its effective concentration in plasma is in the range of 0.5 μmol/L. Approximately one-third of the circulating pool (1 μmol/L) is poorly reactive, and another fraction is bound to circulating plasminogen (K d = 4 μmol/L). α₂-Antiplasmin stabilizes the fibrin scaffolding of the developing blood clot by attenuating the rate of plasin-driven fibrinolysis and protects against systemic degradation of fibrinogen and other proteins by plasmin. Fibrin, as the key cofactor for efficient t-PA activation of plasminogen, localizes plasmin generation to the site of fibrin formation. Generated plasmin is partitioned: one fraction is surface associated through binding interactions between its lysine-binding sites and active site and insoluble fibrin; the other fraction mixes with the circulating blood. α₂-Antiplasmin rapidly inhibits solution phase plasmin (t½ ~ 0.1 second), preventing systemic fibrinogen degradation until more than 50% of its neutralizing capacity has been exhausted. The in vitro rate of inhibition of fibrin-bound plasmin by α₂-antiplasmin decreases by at least a factor of 100 (t½ ≥ 10 seconds). This decrease in reactivity reflects the dependence of the rate of inhibition on the availability of both the lysine-binding and active sites of plasmin. Offsetting this, α₂-antiplasmin is accumulated on fibrin through a factor XIIIa-catalyzed tethering of the NH₂-terminal of α₂-antiplasmin to the α-chain of fibrin. Approximately 20% of the available α₂-antiplasmin is rapidly bound to fibrin. This process has been shown to play a significant role in stabilizing the fibrin clot against lysis.

PHYSIOLOGIC REGULATION OF FIBRINOLYSIS

The physiologic regulation of fibrinolysis centers on controlling the rate and location of plasmin formation. Under quiescent conditions, there is little systemic plasmin formation. t-PA is a poor catalyst of the conversion of plasminogen to plasmin in the absence of fibrin. In addition, circulating levels of active t-PA are continually suppressed by reactions with PAI-1, thus further reducing the potential for solution phase plasminogen activation by t-PA. scu-PA has negligible activity toward plasminogen in solution. Further, there is no gradual accumulation of plasmin in the blood because the circulating concentration and efficacy of α₂-antiplasmin limit the t½ of plasmin formed away from a fibrin surface to 0.1 second. Thus, significant plasmin formation occurs only after the formation of fibrin. t-PA and plasminogen bind to fibrin as the...
clot forms, localizing plasmin generation to the clot. Initial plasmin degradation of fibrin actually increases the number of plasminogen-binding sites in the fibrin, thus amplifying plasmin formation rates. Plasmin also cleaves scu-PA to generate the active two-chain form of the catalyst, further enhancing rates of plasmin activation. In addition, fibrin-bound plasmin is protected from inactivation by circulating α₂-antiplasmin. These mechanisms ensure that plasmin formation is not premature, that plasmin formation is localized to the clot; the extent of plasmin formation is tied to the amount of fibrin present, thus allowing the process to efficiently dissolve thrombi of different sizes.

Regulation of fibrinolysis is achieved through a dynamic balance between profibrinolytic and antifibrinolytic processes maintained by complex interactions between circulating proteins, clot-based factors, and endothelial cells. Recruitment of the proteins key to fibrinolysis to the site of injury occurs simultaneously with the initiation of fibrin formation. The fibrin clot not only serves as a substrate, but also acts in a role similar to the phospholipid surface in coagulation, functioning as a surface for the activation and localization of fibrinolytic proteins. The association of plasminogen and t-PA with fibrin enhances the rate of plasminogen activation by t-PA. Plasmin bound to fibrin is protected from inhibition by α₂-antiplasmin. These mechanisms both enhance fibrinolysis and serve to limit proteolytic activity to the clot. However, profibrinolytic processes are balanced by antifibrinolytic responses. PAI-1 associates with fibrin and inactivates t-PA and u-PA within the meshwork of the clot. Factor Xllla crosslinks and stabilizes the fibrin clot and renders it less susceptible to plasmin proteolysis. Factor Xllla also cross-links α₂-antiplasmin to fibrin; this incorporation has been shown to play an important role in fibrin clot stabilization. TAFIa removes COOH-terminal lysines from partially proteolyzed fibrin, reducing the number of plasminogen-binding sites and attenuating the rate of plasmin formation. In addition, activated platelets release PAI-1 and α₂-antiplasmin at the fibrin surface, thus supplementing the ongoing downregulation of plasmin levels by the plasma pools of these serpins.

Cellular Regulation of Fibrinolysis

The fibrin clot and, thus, fibrinolysis are localized to the surface of the blood vessel at sites where the normally nonthrombogenic façade presented by the endothelium is either mechanically removed or altered in its molecular composition. The unperturbed endothelium secretes PAI-1 and is actively antifibrinolytic. Once the endothelial layer is disturbed, α-thrombin is generated, and fibrin formation proceeds at that site. Intact endothelial surfaces in the vicinity of the injury become “activated” via interaction with products of the coagulation cascade, shifting from an antifibrinolytic to a profibrinolytic state. “Activated” endothelial cells express t-PA and u-PA as well as specific receptors for the plasminogen activators. t-PA is likely the primary activator of plasminogen at the fibrin surface. u-PA has profibrinolytic activity but appears to be primarily associated with extracellular matrix degradation and initiation of tissue repair and remodeling.

In addition to receptors for plasminogen activators, receptors for plasminogen have been identified on a number of cell types including platelets, monocytes, fibroblasts, and endothelial cells, in which they appear to localize and accelerate plasmin formation. Plasmin generated at the cell surface is protected from serpin inhibitors by binding to specific cell receptors. Therefore, the cell surface can serve as a sanctuary for plasmin activity.

Urokinase-type Plasminogen Activator Receptor

uPAR is synthesized and expressed by normal and malignant cells including monocytes, neutrophils, fibroblasts, platelets, and endothelial cells. A primary function of uPAR is to localize u-PA-mediated plasmin generation to the cell surface; however, more generally, uPAR mediates cell migration and tissue remodeling during development and wound healing. Thus, uPAR function appears to be enmeshed with coagulation, fibrinolytic, and inflammatory processes. uPAR binds both single-chain u-PA and plasminogen via high-affinity interactions, forming a ternary complex that enhances plasminogen activation and initiates proteolysis of the extracellular matrix. The receptor is a heterogeneously glycosylated single-chain polypeptide (Mₙ = 50,000 to 60,000) of 313 amino acids. Although uPAR is an integral membrane protein, there is no defined transmembrane sequence. uPAR is instead anchored to the cellular membrane by a glycosyl-phosphatidylinositol moiety. The glycolipid is most likely attached to Gly, indicating that the mature protein consists of 283 amino acids. Because uPAR has no intracellular domain, uPAR mediated signaling presumably occurs through surface interactions with other components of the plasma membrane. At least 9 stable and 33 membrane-associated binding proteins have been identified. The neutrophils of individuals experiencing the hematopoietic stem cell disorder paroxysmal nocturnal hemoglobinuria, a disease in which these glycosyl-phosphatidylinositol moieties are lacking, show impaired transendothelial migration. The absence of the receptor
may play a role in the hypercoagulable state associated with this disorder. The crystal structure of uPAR has been reported in its ligand free form\textsuperscript{2240} and complexed with sc-UPA.\textsuperscript{2241}

Tissue-type Plasminogen Activator Receptors

Many structurally unrelated components that bind t-PA have been described. These receptors can be separated into two distinct functional groups: activation receptors and clearance receptors. Activation receptors are described as localizing t-PA onto a cell surface and enhancing the activation of plasminogen by t-PA.\textsuperscript{2242} Receptors in the activation category include annexin II (42 kDa),\textsuperscript{2243,2244} heparan sulfate and chondroitin sulfate-like proteoglycans,\textsuperscript{2245} cytokeatin 8 and 18,\textsuperscript{2246,2247} and tubulin.\textsuperscript{2248} In patients with promyelocytic leukemia, overexpression of the t-PA receptor annexin II has been associated with a hyperfibrinolytic state resulting in bleeding.\textsuperscript{2249} The t-PA receptor(s) on endothelial cells is poorly defined (for descriptions of these receptors, see Bachmann\textsuperscript{1788}).

Clearance receptors are responsible for clearing t-PA from the circulation and its subsequent degradation. These receptors control not only the plasma concentration of t-PA but also the levels of inactive t-PA/PAI-1 complexes. t-PA clearance occurs principally in the liver and involves two different receptors: the mannose receptor and the LRP/\alpha_2-macroglobulin receptor. The mannose receptor is a major t-PA receptor and binds t-PA with a high-affinity \( K_d \) of 1 to 4 nmol/L.\textsuperscript{2250,2251} and \textsuperscript{2252} Liver endothelial cells and Kupffer cells bind t-PA via the mannose receptor. The other major pathway for t-PA clearance is through the LRP/\alpha_2-macroglobulin receptor. This receptor has a relative molecular weight of 600 kDa.\textsuperscript{1789} This receptor mediates the clearance of t-PA, t-PA/PAI-1, and u-PA/PAI-1 complexes, toxins, cytokines, apolipoprotein E-enriched chylomicron remnants, and complexes of \alpha_2-macroglobulin.\textsuperscript{2253} Free and PAI-1-complexed t-PA have also been shown to be cleared from the circulation through a glycoprotein 330-kDa LRP receptor and a 130-kDa very-low-density lipoprotein receptor.\textsuperscript{2253,2254} and \textsuperscript{2255}

Role of Platelets in the Regulation of Fibrinolysis

Platelets are vital to procoagulant events and contribute to the fibrinolytic process as well. Platelets bind both t-PA and plasminogen and support plasmin generation.\textsuperscript{2256,2257} and \textsuperscript{2258} Plasmin bound to the platelet surface is also protected from inhibition by \alpha_2-antiplasmin.\textsuperscript{2259} Platelets likewise contribute to the antifibrinolytic mechanism. Activated platelets release PAI-1, \alpha_2-antiplasmin, C1-esterase inhibitor, and \alpha_2-macroglobulin, which function to inhibit plasminogen activators and plasmin. Therefore, platelets, when present at high concentrations, can promote thrombosis and inhibit fibrinolysis.

Several studies have shown that plasmin can directly modify the function of platelets.\textsuperscript{2259,2260,2261,2262,2263} and \textsuperscript{2264} When plasmin is present at a low concentration, it can inhibit platelet aggregation by arachidonic acid metabolism or by proteolysis of membrane glycoproteins. At a high plasmin concentration, a proteolytic modification of the platelets occurs that affects fibrinogen binding and platelet aggregation. Plasmin is also able to increase the number of plasminogen-binding sites on the surface of platelets, an alteration that may function as a positive feedback loop for t-PA-mediated plasmin production. Increasing the size of the pool of fibrin-localized, platelet-bound plasminogen would augment the other readily activatable pool (plasminogen bound to fibrin), thereby increasing the amount of plasminogen available for efficient t-PA activation. Plasmin has also been shown to degrade the platelet-binding site for factor XIIIa, decreasing the rate of clot stabilization.\textsuperscript{2233}

CONCLUSION

This chapter describes the process of blood coagulation by dividing it into sections based on procoagulant, anticoagulant, and fibrinolytic enzymes, cofactors, and inhibitors in the overall process of fibrin formation and fibrin dissolution. The role of each protein is described as either essential or accessory to hemostasis. The overall process of blood coagulation and fibrinolysis is better described when all the players are considered as contributing to a threshold-limited, complex, intertwined process that together promotes hemostasis.

Our understanding of the coagulation process has ancient historical roots; the accomplishments of numerous clinical and basic investigators have provided a relatively complete description of the inventory, connectivity, and dynamics of the overall process that occurs after vascular injury. Significant progress has been made in achieving a complete set of x-ray crystal structures for all the proteins involved in these processes (Table 18.5). The challenge for the future is the use of this knowledge in the development of new technology for the advancement of diagnosis, prophylaxis, and treatment of vascular disease.

ACKNOWLEDGMENTS

We, the authors, would like to thank Matthew Gissel and Stacia Rymarchyk for their assistance in the preparation of this chapter. This work was supported by an NIH grant (HL46703).

Chapter 19 Endothelium: Angiogenesis and the Regulation of Hemostasis

As outlined by Conway, Collen, and Carmeliet, physiologic angiogenesis is a well-organized stepwise process that involves dilation and increased permeability of the parent vessel, dissolution of the extracellular matrix, division and migration of EC, cord formation, and the development of lumina, and, finally, the maintenance of new vessel integrity. The entire process involves the complex and choreographed effects of multiple inducers and inhibitors (Table 19.1).

The first step in angiogenesis is vasodilation. This is mediated through the activation of the soluble guanylate cyclase by nitric oxide (NO). NO also up-regulates vascular endothelial growth factor (VEGF) production. By causing intercellular adhesion molecules to redistribute (platelet-EC adhesion molecule-1 and VE-cadherin, among others), VEGF induces an increase in vascular permeability. The VEGF-induced increase in vascular permeability is negatively controlled by angiopoietin-1 (Ang1) through its receptor, Tie2. The next key step to vascular development is the dissolution of the extracellular matrix, which is accomplished by proteases belonging to the matrix metalloproteinase family. These proteases also induce the liberation of EC growth factors from the extracellular matrix, including VEGF and basic fibroblast growth factor. The action of matrix metalloproteinases is negatively controlled by a family of protease inhibitors, including the tissue inhibitors of metalloproteinases.

Degradation of the extravascular matrix allows the development of the tissue inhibitors of metalloproteinases. 6,11,12,13,14,15,16 Angiopoietin-2 (Ang2) could have angiogenic effects in the presence of VEGF, whereas it is antiangiogenic in the absence of VEGF.14,15,16,17 The role of Ang2 was played by the endothelial NO synthase and NO has been the subject of controversy, with reports showing that NO has both pro- and antiangiogenic effects.18,19,20,21 Other factors that stimulate angiogenesis include basic fibroblast growth factor and platelet-derived growth! EC growth is negatively controlled by endogenous angiogenesis inhibitors that include angiostatin, endostatin, interferons, and antithrombin.22,26,28 ECs then migrate in large part through the action of integrins (αβ1 and αβ3).29 The end result of EC division and migration is sprouting and the formation of cords. This is followed by lumen formation, which is controlled by different VEGF isoforms, Ang1, and integrins.1,12 Thrombospordin-1 acts as an endogenous inhibitor of lumen development.

Once formed, new vessels survive for years. This prolonged survival is maintained by the interaction of VEGF with its receptor VEGFR-2, phosphoinositide 3-kinase, β-catenin, and VE-cadherin. The angiopoietins also play a role in maintaining vessel survival through their receptors Tie1 and Tie2. Ang1 stabilizes the vessel, whereas Ang2 has an opposite effect (see later). An essential element in the maintenance of the integrity of vessels is their “coating” with smooth muscle cells and pericytes. Evidence suggests that vascular smooth muscle cells and ECs have a common precursor.33 On stimulation with platelet-derived growth factor-BB, these precursor cells differentiate into smooth muscle cells, whereas VEGF stimulation drives them to differentiate into EC.33 Besides providing physical support for endothelial vessels, smooth muscle cells and pericytes are a source of factors that are important for the maintenance and control of
vascular integrity and function. The extracellular matrix plays a key role in that respect by being a dynamic storage site for growth factors and proenzymes that are important in vessel function and angiogenesis.

Vascular Endothelial Growth Factor and Its Receptors

VEGF is the pivotal factor controlling angiogenesis. As such, it is the best-studied angiogenic factor. Several proteins belong to the VEGF family and include VEGF (also known as VEGF-A), VEGF-B, VEGF-C, VEGF-D, and placental growth factor. Although VEGF-A is the main angiogenic factor discussed here, VEGF-B seems to play an important role in coronary vascular development. VEGF-C is essential for lymphangiogenesis by interacting with the VEGFR-3 receptor. The function of VEGF-D has yet to be determined.

Being the major regulator of angiogenesis, VEGF is a mitogen and survival factor for EC. As mentioned earlier, it is also a potent inducer of vascular permeability, an essential step in the angiogenic process. It has two well-characterized receptors, VEGFR-1 and VEGFR-2 (also known as Flt-1 and Flk-1/kinase domain receptor, respectively). They are both tyrosine kinases. VEGFR-2 is the main effector of a VEGF-induced chemotactic and mitogenic response in EC. VEGFR-2 also mediates the ECs' permeability effects. The role of VEGFR-1 in EC response to VEGF has not been totally elucidated. Indeed, mice that have been engineered not to express VEGFR-1 have evidence of excess and disorganized angiogenesis. In addition to its role in angiogenesis, VEGF has been shown to be trophic for nerve cells, lung epithelial cells, and cardiac muscle fibers.

Angiopoietins and Their Receptors

Angiopoietins and Tie receptors play an important role in angiogenesis. To date, four angiopoietins have been identified. However, only Ang1 and Ang2 have been fully characterized. They interact with the Tie tyrosine kinase receptors, mainly Tie2. Ang1 plays an important role in stabilizing the vasculature. Supportive cells express Ang1 and interact with EC through the Tie2 receptor. Genetically engineered mouse embryos that lack Ang1 develop a normal primary vasculature. However, they do not undergo further vascular remodeling. Transgenic mice that overexpress Ang1 have evidence of vascularization characterized by larger vessels rather than a greater number of vessels. Additionally, those vessels are resistant to leak, further supporting the role of Ang1 as a stabilizing factor.

Ang, angiopoietin; bFGF, b-fibroblast growth factor; EC, endothelial cells; ECM, extracellular matrix; IFN, interferon; IL, interleukin; Meth, metalloproteinase and thrombospondin; MMP, matrix metalloproteinase; NP, neuropilin; PlGF, placental growth factor; TGF, transforming growth factor; TSP, thrombospondin; VEGF, vascular endothelial growth factor; VEGFR, vascular endothelial growth factor receptor.

The function of Ang2 has been more difficult to characterize. It too binds with high affinity to the Tie2 receptor. Transgenic overexpression of Ang2 in mice is embryonically lethal and induces a phenotype that is similar to Ang1 or Tie2 knockout experiments. Thus, it has been suggested that Ang2, by acting as an antagonist of Tie2, negates the stabilizing effects of Ang1 on the vasculature. As such, Ang2 may be a destabilizing factor that helps initiate angiogenesis and vascular remodeling.
Carmeliet and Jain have proposed a model for vessel development whereby in the angiogenesis process, ECs can be divided into two categories, namely tip cells and stalk cells. Tip cells migrate and lead vessel development whereas stalk cells divide. The process is controlled by the NOTCH signaling pathway. VEGF activation of VEGFR-2 leads to up-regulation of DLL4 in tip cells. DLL4 then activates NOTCH in stalk cells. NOTCH down-regulates VEGFR-2 and up-regulates VEGFR-1 in stalk cells, making them less sensitive to VEGF-stimulated sprouting. The end result is to maintain the lead of tip cells in vessel development. However, NOTCH stimulates stalk cell proliferation in vivo through activation of WNT signaling. NOTCH up-regulates its own inhibitor Nrarp in stalk cells. It has been observed that the tip cell position is dynamic with stalk cells moving into the tip position depending on modulation of VEGFR-1 and VEGFR-2 expression.

Origin of Endothelium

Asahara et al. have shown that human buffy coat cells can differentiate into cells expressing endothelial markers, including VEGFR-1, VEGFR-2, and CD31. This raises the possibility that circulating endothelial stem cells can be recruited to sites of angiogenesis. This may be particularly relevant for tumor angiogenesis, whereby tumors can develop their vasculature both from recruitment of local endothelium and circulating endothelial stem cells. Factors involved in the recruitment of endothelial stem cells may include stromal cell-derived factor-1, thrombopoietin, and soluble kit ligand.

Angiogenesis in Normal and Malignant Hematopoiesis

There is mounting evidence suggesting the presence of a common precursor for ECs and hematopoietic cells. This hemangioblast gives rise to both ECs and hematopoietic cells in embryonic development. Embryonic stem cells express VEGFR-2 and can give rise, depending on culture conditions, to hematopoietic progenitor cells and angioblasts. Stimulation of hematopoietic stem cells with growth factors, including kit ligand, interleukin-3, granulocyte-macrophage colony-stimulating factor, and granulocyte colony-stimulating factor, induces the release by those cells of VEGF, which then induces the release of hematopoietic growth factors by bone marrow ECs. Thus, there is a dynamic interaction between hematopoietic and endothelial elements in the bone marrow. This interaction seems to modulate, at least in part, hematopoiesis.

Several studies have shown evidence of increased angiogenesis in hematopoietic malignancies. Malignant hematopoietic cells have been shown to produce angiogenic factors, including VEGF. Expression of angiogenic factors has been suggested to have prognostic significance in hematopoietic malignancies, although results have been variable. Similar to the effect observed in normal hematopoiesis, VEGF stimulates the production of hematopoietic growth factors by ECs. Consequently, malignant cells exploit their environment to their advantage by developing a synergistic relationship with ECs (Fig. 19.1). This has led to the active investigation of antiangiogenic agents as a novel therapeutic strategy for hematologic malignancies.

In addition to the effects of vascular endothelium in modulating and responding to angiogenic stimuli, vascular endothelium also influences other functions, including vasoconstriction, selective permeability, hemostasis, antigen presentation, and the inflammatory response. The EC surface is a dynamic interface between soluble and cellular constituents of the blood and the remainder of the body. A brief discussion of ECs structure and regulation of hemostasis follows.

FIGURE 19.1. Hypothesis for the role of angiogenesis in leukemia. (1) Angiogenic factors (AFs) produced by leukemic cells can stimulate cell growth and invasion, or inhibit apoptosis (autocrine mechanism). ENDOTHELIAL CELL STRUCTURE

Individual ECs measure approximately 20 to 50 µm² in surface area. The total vascular surface area in a normal adult is estimated to be at least 4,000 m². However, the geometry of the vascular system is not static. As indicated in Figure 19.2, the surface area facing a unit volume of blood differs, depending on the vascular bed being considered. For example, the surface area-to-volume ratio is approximately 1,000 times greater in capillaries than in large blood vessels. This vascular geometry has implications for regulation of hemostasis and is discussed later.

P.501

ECs are anchored to the vessel wall by basement membrane secreted by ECs and smooth muscle cells. Basement membrane contains a large number of connective tissue components, including collagen, microfibrils, glycosaminoglycans (GAGs), fibronectin, and thrombospondin. These components may serve as ligands for a number of cell adhesion processes that are important in angiogenesis, hemostasis, vascular repair, and inflammation.

ECs typically exist as a cell monolayer, exhibiting contact inhibition and a cobblestone appearance (Fig. 19.3). Two types of cell-cell junctional structures have been reported: adherens junctions and tight junctions. These structures regulate permeability and maintain polarity. Two cell receptors thought to be important in EC monolayer organization are platelet-EC adhesion molecule-1 and vascular cadherin. CD146 (MelCAM) is associated with the EC cytoskeleton and likely serves as an EC junction component. Members of the junctional adhesion molecule family appear to be components of tight junctions.

ECs contain unique intracellular structures called Weibel-Palade bodies; these organelles contain the adhesion protein von Willebrand factor, which is secreted constitutively and also in response to cell stimulation. The Weibel-Palade body membrane contains P-selectin, which is expressed on the EC surface after EC activation. When expressed on the vascular surface, P-selectin mediates neutrophil and monocyte adhesion to the vessel wall. Selectin-independent platelet adhesion to endothelium has also been reported. The role of P-selectin in inflammation and thrombosis is being increasingly recognized. Integrins mediating platelet-EC and leukocyte-EC interactions are discussed in Chapters 17 and 7, respectively. Additional EC proteins have been reported to undergo regulated release or cell-surface expression, including tissue plasminogen activator (TPA), interleukin-8, endothelin-1, and multimerin. These and other proteins may be contained in Weibel-Palade bodies or other distinct organelles. The regulated secretion of these EC proteins has been reviewed.

Endothelial Cell Phenotypes: Resting versus Activated

The concept of differing EC phenotypes (e.g., resting [constitutive] vs. activated) has been applied to numerous EC functions, including the inflammatory response, regulation of coagulation, and angiogenesis. This chapter focuses on EC phenotypes as related to the functions of angiogenesis, and hemostasis and thrombosis. Other EC functions have been reviewed elsewhere.

FIGURE 19.3. Endothelial cell morphology. A: Cultured human umbilical arterial endothelial cells with the typical cobblestone appearance (phase-contrast, ×100). primate. I. Changes that lead to fatty streak formation. Arteriosclerosis 1984;4:323-340, with permission of the American Heart Association.)

THE VESSEL WALL AND HEMOSTASIS: GENERAL CONCEPTS

The three major cell types of the normal vessel wall are ECs (intima), smooth muscle cells (media), and connective tissue elements, such as fibroblasts (adventitia). The circulating coagulation proteins contained in the blood are in immediate contact with quiescent vascular endothelium that normally presents a thromboreistant surface in that ECs are unable to initiate coagulation or promote platelet adhesion and activation. Thus, in the absence of vascular trauma or perturbation (activation), blood remains fluid as a result of antithrombotic activities expressed by ECs. However, after traumatic vascular injury, exposure of blood to cells within the vessel wall, especially fibroblasts, or to extracellular matrix (subendothelium) results in rapid initiation of coagulation because fibroblasts and subendothelium containing EC remnants constitutively express tissue factor (TF) procoagulant activity. Alternatively, perturbation (activation) of EC by stimuli, such as cytokines, may induce altered EC hemostatic function (in the absence of vascular injury), resulting in net EC expression of thrombotic activity. These hemostatic properties of unperturbed and perturbed EC are critical in determining the coagulant balance of the vessel wall and the extent of activation of coagulation.

A cell-based model of hemostasis has been presented in which fibroblasts or perturbed EC express TF to initiate coagulation; amplification and propagation of coagulation then occur on the platelet surface. Modulation of coagulation occurs via EC antithrombotic activities and plasma protease inhibitors.

ANTITHROMBOTIC PROPERTIES OF UNPERTURBED ENDOTHELIUM

Antithrombotic mechanisms responsible for unperturbed (native) EC thromboreistance are illustrated in Figure 19.4. Major antithrombotic properties can be classified as antiplatelet activities, anticoagulant activities, and fibrinolytic activities.

Antiplatelet Activities

Vascular endothelium inhibits platelet function by several mechanisms. The EC plasma membrane does not permit adherence of resting platelets. Additionally, ECs synthesize and secrete three potent antiplatelet agents: prostacyclin (PGI₂), NO, and certain adenine nucleotides. PGI₂ is constitutively synthesized by EC cyclo-oxygenase (prostaglandin H synthase) and phospholipase A₂ in response to thrombin and other vasoactive agonists. In addition to PGI₂’s ability to prevent adhesion of activated platelets to EC, this agent also possesses potent vasodilating properties. PGI₂ inhibits platelet function by increasing levels of platelet cyclic adenosine monophosphate. Aspirin inhibits the synthesis of PGI₂ by irreversibly acetylating and inactivating EC cyclo-oxygenase. Recovery of PGI₂ production by EC occurs with subsequent EC synthesis of cyclo-oxygenase.
FIGURE 19.4. Vessel wall antithrombotic properties. The major antithrombotic properties are depicted in boxes. Heparinlike glycosaminoglycans (GAG), such as heparan sulfate, catalyze inactivation of serine proteases, such as thrombin (T) and factor Xa, by antithrombin (AT). Formation of the T-thrombomodulin complex activates protein C to activated protein C (APC). The endothelial cell (EC) protein C receptor (ECPCR) promotes protein C activation. Binding of APC to EC-bound protein S (and factor V) promotes proteolysis of factors Va and VIIIa (dashed line), inhibiting coagulation. APC also possesses anti-inflammatory properties that are mediated by EC protease-activated receptor (PAR)-1. This APC activity requires ECPCR (not shown). Secretion of vessel wall prostacyclin (PGI\(_2\)) and nitric oxide and expression of CD39 limit platelet thrombus formation at sites of vascular injury. Tissue plasminogen activator (TPA) is secreted and bound to EC to initiate fibrinolysis. Secretion of tissue factor pathway inhibitor (TFPI) by EC suppresses tissue factor-mediated initiation of coagulation. Dermatan sulfate-catalyzed activation of heparin cofactor II and an inhibitor to contact activation are not illustrated in the figure. FDP, fibrin degradation products. (Modified from Rodgers GM. Hemostatic properties of normal and perturbed vascular cells. FASEB J 1988;2:116-123.)

A second inducible form of cyclo-oxygenase, called cyclo-oxygenase-2, has been identified in a variety of cells, including ECs.\(^{86,87}\) Both cyclo-oxygenase proteins are homologous, with similar molecular weights and structural features. Investigators believe that cyclo-oxygenase-2 mediates the vascular response to injury and inflammation.

NO is thought to be important primarily in regulating vascular tone,\(^ {88,89}\) although this agent is also a potent inhibitor of platelet adhesion to vascular endothelium.\(^ {77}\) Constitutive and inducible pathways generate NO from the terminal guanidino nitrogen of arginine in a reaction catalyzed by NO synthetase.\(^ {88,90}\) The constitutive mechanism generates small amounts of NO and mediates physiologic responses. Increased synthesis of NO occurs in response to cytokines (inducible pathway), such as tumor necrosis factor, to mediate inflammatory events.\(^ {88}\) Both the constitutive and inducible forms of NO synthetase are present in ECs. Other stimuli to NO generation include adenosine diphosphate (ADP), thrombin, shear stress, and bradykinin.\(^ {57}\) EC-derived NO also inhibits leukocyte adhesion, as well as vascular smooth muscle cell...
proliferation. Elevated levels of cyclic guanosine monophosphate result from NO stimulation and mediate the biologic activities of this antiplatelet agent. Synthesis of NO is insensitive to the effects of aspirin.

A third EC antiplatelet property is ectoenzymes that rapidly metabolize ADP and adenosine triphosphate to adenosine monophosphate and adenosine. ADP is a potent platelet agonist, and adenosine is a potent inhibitor of platelet function. Thus, ECs can convert a platelet agonist to an antiplatelet agent by this mechanism. EC ectoenzymes are insensitive to the effects of aspirin. This ectoenzyme antiplatelet property of EC may explain earlier reports of EC thromboresistance to platelet adhesion. The EC ecto-ADPase responsible for inhibition of platelet function is CD39. Deletion of this EC receptor in mice results in a prothrombotic state and platelet dysfunction.

Anticoagulant Activities

Vascular ECs synthesize and express heparinlike GAG, such as heparan sulfate and dermatan sulfate, on their luminal cell surface. These GAGs catalyze the inactivation of serine proteases, such as thrombin and factor Xa, by protease inhibitors, such as antithrombin and heparin cofactor II, respectively, via formation of a covalent protease-antiprotease complex. Of these two protease inhibitors, antithrombin is considered to be more important. The molecular basis for the effect of heparin in promoting antithrombin neutralization of serine proteases involves interaction of a specific pentasaccharide sequence of the EC heparinlike molecule with an allosteric site on the antithrombin molecule. This interaction results in conformational changes in antithrombin that permit more efficient binding to and inhibition of protease molecules. In vivo, antithrombin molecules are associated with EC GAG, providing a mechanism for instantaneous control over activation of coagulation. Surprisingly, mice deficient in the enzyme responsible for generating the pentasaccharide activity do not show a procoagulant phenotype. Nevertheless, this heparan sulfate-antithrombin mechanism is considered to be an important natural anticoagulant process because deficiency of antithrombin in humans is associated with a thrombotic tendency. In contrast, the clinical relevance of the heparin cofactor II mechanism is uncertain.

Another key vascular anticoagulant activity is the protein C pathway that consists of two plasma proteins—protein C and protein S—and an EC receptor, thrombomodulin (Fig. 19.4). ECs synthesize and express protein S and thrombomodulin, whereas protein C is synthesized by the liver. Thrombin generation leads to thrombin’s binding to thrombomodulin; the thrombin-thrombomodulin complex then activates protein C to generate activated protein C (APC). APC binds to protein S, resulting in inhibition of coagulation by proteolysis of two coagulation cofactor proteins, factors Va and VIIIa. Inactivation of factors Va and VIIIa prevents further thrombin formation. The involvement of factor V in mediating the anticoagulant effect of APC has been described. It appears that APC down-regulation of coagulation (proteolysis of factors Va and VIIIa) occurs more efficiently on vascular endothelium rather than on platelets.

An additional component of the protein C pathway exists: the EC protein C receptor (ECPCR). This protein binds protein C to enhance protein C activation by the thrombin-thrombomodulin complex. ECPCR is found primarily on large-vessel endothelium and is induced by thrombin stimulation. Blocking ECPCR with a monoclonal antibody in a primate model indicates that ECPCR plays a major role in vivo protein C activation.

Certain components of the protein C pathway possess additional anticoagulant activities. For example, APC also possesses profibrinolytic activity that results from the ability of APC to neutralize plasminogen-activator inhibitor-3 (PAI-3) activity. Thrombomodulin may also inhibit factor Xa. An additional antithrombotic activity of protein S has been described as inhibition of TF activity by enhancing the interaction between TF pathway inhibitor (TFPI) and factor Xa. Recurrent thrombosis has been associated with deficiency or abnormality of the protein C pathway components, indicating that this anticoagulant mechanism is relevant for in vivo hemostasis.

APC possesses activities other than those associated with anticoagulant activity. In gene-expression studies using microarray techniques, APC was found to modulate anti-inflammatory and cell-survival pathways. APC suppressed adhesion molecule expression, decreased activity of the nuclear factorκB transcription pathway, and inhibited apoptosis. Recent information suggests that APC uses the ECPCR to signal EC via the proteaseactivated receptor (PAR)-1 pathway (discussed later).

Regulation of TF procoagulant activity by a plasma protein called TFPI has been described. This protein is synthesized primarily by EC and is an important regulator of TF-factor VIIa activation of factor X (discussed in Chapter 18). Additionally, TFPI can inhibit vascular cell proliferation. TFPI may be important for in vivo hemostasis because administration of this inhibitor in the setting of TF-induced disseminated intravascular coagulation reduces thrombosis.
and low levels of TFPI are a risk factor for thrombosis. Heparin or low-molecular-weight heparin releases TFPI from EC storage sites.

Fibrinolytic Activities

ECs synthesize and secrete plasminogen activators, primarily TPA, in response to stimulation by thrombin or vasoactive stimuli, such as histamine and vasopressin. TPA has been localized to the Weibel-Palade organelles in EC. Specific EC receptors for TPA exist. In response to inflammatory mediators, ECs synthesize another plasminogen activator, urokinase, which activates plasminogen in the fluid phase or bound to fibrin. Activation of plasminogen by TPA generates plasmin; localization of TPA and plasminogen to the fibrin clot leads to physiologic fibrinolysis and release of soluble fibrin degradation products (Fig. 19.4). Fibrin degradation products possess potent antiplatelet and antithrombin activities and contribute to the anticoagulant effect of fibrinolysis. Activation of plasminogen is regulated by PAIs. The major inhibitor of TPA is PAI-1; PAI-1 is secreted by vascular EC but is also present in platelet α-granules. This inhibitor also regulates urokinase activity. PAI-2 is a less significant inhibitor of TPA that is found primarily in placenta. Details of the fibrinolytic mechanism and its regulation are discussed in Chapter 18.

PROTHROMBOTIC PROPERTIES OF UNPERTURBED ENDOTHELIUM

Unperturbed ECs possess procoagulant activities that promote coagulation after vascular injury or perturbation. However, in the absence of initiating stimuli, these activities remain latent and do not contribute to thrombosis. Major prothrombotic activities of resting EC include binding sites (receptors) for coagulation zymogens or proteases (factor XII, factor XI, factors X and Xa, factors IX and IXa, and thrombin) and cofactor proteins [high-molecular-weight kininogen, factor VIIIa, and factor Va] and synthesis and expression of factor V and von Willebrand factor. Resting ECs can also activate bound factor XII and promote functional cleavage of prekallikrein. Investigators have also reported a factor XII-independent pathway for prekallikrein activation on EC; this activation is mediated by an EC-associated thiol protease. In addition, when high-molecular-weight kininogen is bound to EC, factor XI (Xia) can associate with EC to promote factor IX activation. On the other hand, ECs also secrete an inhibitor to contact activation. The role of EC in activation of intrinsic coagulation has been reviewed. These prothrombotic activities are illustrated in Figure 19.5.

EC receptors for coagulation proteases permit assembly of complexes consisting of cofactor proteins, proteases, and zymogen substrates that result in optimal activation and localization of coagulation. Whereas factor V is secreted primarily into the fluid phase, von Willebrand factor is secreted both into plasma and the subendothelium, providing a source of adhesive protein for the platelet response to vascular injury.

HEMOSTATIC PROPERTIES OF PERTURBED ENDOTHELIUM

In this discussion, the term EC perturbation means exposure of EC to diverse stimuli, such as traumatic vascular injury, certain cytokines, atherogenic stimuli (homocysteine, modified low-density lipoprotein [LDL]), lipopolysaccharide (endotoxin), immune complexes, and certain infectious organisms. From this list, it is obvious that a variety of inflammatory, infectious, or malignant disorders, as well as metabolic defects, may be associated with hemostatic dysfunction resulting from altered EC hemostatic properties. With the exception of traumatic vascular injury, alteration of these key EC coagulant properties is not associated with cytotoxicity or EC desquamation. The major hemostatic properties reviewed in this section include TF activity, thrombomodulin activity (protein C pathway), factor V activation, and fibrinolytic activities (TPA, PAI-1). In general, these activities are concordantly regulated, with stimuli that induce TF expression also suppressing protein C activation and fibrinolysis. The net result of these events is that the perturbed EC surface is converted from an antithrombotic surface to a prothrombotic surface.

P.504
FIGURE 19.5. Vessel wall prothrombotic properties. The major prothrombotic properties are depicted in boxes. Expression of tissue factor activity initiates coagulation, and endothelial cell (EC) synthesis of factor V promotes thrombin formation. Thrombin formation is enhanced by feedback activation of factor XI. Vessel wall injury also promotes platelet adhesion and thrombus formation by exposure of subendothelial von Willebrand factor (VWF). An inducible EC prothrombin activator may directly generate thrombin. EC can be induced to express an activator of factor V (Va). Thrombin exerts multiple procoagulant activities, including platelet activation and cleavage of fibrinogen, resulting in the fibrin clot. Thrombin binding to thrombomodulin activates thrombin-activatable fibrinolysis inhibitor to down-regulate fibrinolysis (not shown). EC secretion of tissue plasminogen activator (TPA) inhibitor further stabilizes the fibrin clot by preventing fibrinolysis. Also not shown are EC-binding sites for coagulation zymogens or proteases. Protease-activated receptor (PAR)-2 is activated by the tissue factor-factor VIIa complex and factor Xa to contribute to EC activation by pathologic stimuli. (Modified from Rodgers GM. Hemostatic properties of normal and perturbed vascular cells. FASEB J 1988;2:116-123.)

The key hemostatic activity induced by EC perturbants is TF expression, because TF is considered to be the major initiator of coagulation. Details of the regulation of cellular TF activity are given in Chapter 18. Stimuli reported to induce EC TF activity include cytokines, lipopolysaccharide, oxidized LDL, homocysteine, and certain infectious organisms. Expression of EC TF antigen in pathologic human and primate tissues using immunohistochemical methods has been reported, including vascular tissue from patients with sickle-cell anemia and skin biopsies from patients treated with intradermal cytokines. The importance of vessel wall TF activity in arterial and venous thrombosis has been recently confirmed.

EC TF procoagulant activity may be modulated by a novel EC protease, PAR-2. PARs represent a group of G-protein-coupled receptors present in ECs and other tissues. Thrombin or other proteases cleave the amino terminus of the receptor exodomain; the amino-terminus fragment then binds to the cell-associated domain of the receptor to activate
the protease. In ECs and fibroblasts, activated PAR-1 is internalized and sorted to lysosomes; this process terminates thrombin signaling.

There are at least four members of the PAR family. Human PAR-1, PAR-3, and PAR-4 can be activated by thrombin, and it is proposed that their in vivo role is sensing thrombin generation. ECs contain both PAR-1 and PAR-2, but thrombin does not activate PAR-2. Rather, data indicate that PAR-2 may be activated directly by TF-factor VIIa and indirectly by TF-factor VIIa-generated factor Xa. It has been proposed that PAR-2 may function as a coagulation protease “sensor” and thereby contribute to EC activation by pathologic stimuli. Stimulation of EC PAR-2 also increases TF expression. EC PAR-2 may mediate additional thrombin-induced vascular functions, including leukocyte adhesion and mitogenesis.

Studies investigating embryonic development indicate that PAR-1 messenger RNA is abundant in EC, suggesting that PAR-1 signaling in EC is important in vascular development. PAR-1 mediates the EC response to APC; APC and ECPCR cleave PAR-1 to initiate signaling events. Figure 19.6 illustrates the interactions between the TF-factor VIIa complex and EC PAR-2, with resulting alteration of EC function. The role of PARs in vascular biology and disease has been recently reviewed.

An additional mechanism for EC generation of thrombin has been reported. Perturbed ECs express a prothrombin activator that can generate thrombin independent of the intrinsic and extrinsic coagulation pathways. The description of trypsin expression by P.505 cultured EC and by vascular EC in situ suggests that a variety of EC-derived proteases may also regulate blood coagulation.

FIGURE 19.6. Interactions of the tissue factor (TF)-factor VIIa complex with the endothelial cell protease-activated receptor (PAR)-2 and their consequences. Expression of endothelial cell TF results in TF-dependent factor VIIa activation of PAR-2. Cleavage of the amino terminus of PAR-2 reveals a tethered ligand sequence that binds to PAR-2 to initiate signaling, triggering responses that include calcium influx, expression of surface adhesion molecules for leukocytes, and release of growth factors. Activation of PAR-2 may also enhance endothelial cell expression of TF activity (dashed line).

Because both ECs and platelets can activate prothrombin, the question arises as to the importance of EC in thrombin generation. One study observed synergism of thrombin generation when a reconstituted model containing ECs, platelets, and purified coagulation proteins was tested. Synergy was maximal at platelet concentrations <1 × 10^11/ml. Thus, in thrombocytopenic states, the large surface area of vascular endothelium, especially in the microcirculation, may play a role in amplifying platelet prothrombin activation. Studies with human arterial vascular tissue indicate that vascular tissue alone (in the absence of platelets) is sufficient to generate large amounts of thrombin.

Regulation of the anticoagulant protein C pathway by EC perturbants has also been a subject of interest because of the recurrent thrombotic disorders associated with deficiency of protein C pathway components (proteins C and S). Down-regulation of the protein C pathway has focused on thrombomodulin, the EC membrane protein that activates protein C after complexing with thrombin. Several mechanisms have been identified to explain the role of thrombomodulin in down-regulating protein C activation. Thrombomodulin has structural homology to the native LDL
receptor, a prototypical membrane receptor involved in endocytosis. The effects of tumor necrosis factor on the protein C pathway appear to result from enhanced endocytosis and subsequent degradation of thrombomodulin. Additionally, tumor necrosis factor, a cytokine that reduces protein C activation, has been reported to inhibit transcription of thrombomodulin RNA.

Another important EC hemostatic property regulated by relevant perturbing stimuli is secretion of PAI-1 and TPA. Treatment of cultured EC with interleukin-1 results in both diminished TPA secretion and increased PAI-1 secretion. Increased amounts of PAI-1 relative to TPA diminish vascular fibrinolytic activity, resulting in enhanced thrombotic potential because of failure to lyse fibrin thrombi.

In addition to the humoral and biochemical stimuli discussed earlier, biomechanical forces (shear stress) can regulate EC gene expression and phenotype. For example, either laminar or turbulent shear stress has been reported to regulate a large number of EC genes differentially, including adhesion molecules and growth factors, as well as hemostasis proteins. Shear stress also attenuates cytokine-induced EC TF expression. These data indicate that vascular endothelium is responsive to biomechanical stimuli. A uniquely flow-induced EC gene is the transcription factor, lung Kruppel-like factor, which may be an important regulator of EC function.

Diversity of Endothelial Cell Hemostatic Properties

There is significant heterogeneity in arterial, venous, and capillary EC with regard to expression of hemostatic and other functional activities. For example, aortic EC express more factor V activity than do venous EC, and PGI₂, a major metabolite secreted by human venous EC, is not substantially produced by human capillary cells. Different fibrinolytic and anticoagulant properties have been reported between cultured venous and capillary EC. Increases in blood flow lead to up-regulation of NO synthase messenger RNA in aortic, but not pulmonary, arterial EC. Vascular anticoagulant activity in the microcirculation is reinforced by geometric aspects of the vessel wall. For example, the thrombomodulin concentration in the microcirculation would increase more than a thousandfold compared with a large vessel. Consequently, in large vessels, thrombin circulates freely to catalyze coagulation, whereas in the microcirculation, thrombin exists mostly bound to thrombomodulin, promoting anticoagulation.

The differential concentration of thrombomodulin in large versus small vessels may also affect vascular fibrinolysis in specific vascular beds. Thrombin-activatable fibrinolysis inhibitor is stimulated by low thrombomodulin concentrations but decreases at high concentrations of thrombomodulin. This implies that enhanced fibrinolysis would be seen in the microcirculation that contains high levels of thrombomodulin activity.

These data suggest a vascular model in which procoagulant activities are dominant in the arterial circulation and anticoagulant activities are dominant in the microcirculation. This distribution of vascular hemostatic properties is consistent with the necessity for rapid thrombin generation and fibrin clot formation after arterial injury, while providing the venous and microcirculation with anticoagulant mechanisms to protect against thrombosis. Unique EC environments may also explain localization of certain pathologic processes. For example, verotoxin-induced EC platelet thrombi localized to arterioles and capillaries may be explained by distinct responses of EC to verotoxin, and endogenously generated NO is more effective in inhibiting thrombosis in venules than in arterioles.

The concept of EC diversity is also supported by gene-expression profile studies that have identified characteristic expression patterns of arterial versus venous EC as well as large versus microvascular EC.

Chapter 20 Red Cell, Platelet, and White Cell Antigens

INTRODUCTION

This chapter reviews the biochemistry and importance of various blood group antigens with a focus on red cells, platelets, and white blood cells. Because the circulating blood cells originate from a common progenitor cell, it is not surprising that there are a number of common blood group antigens. But what is surprising is the fact that the various cell lineages have so many unique and different antigens.

Studies characterizing the red cell antigens were first performed approximately 100 years ago, whereas studies investigating the platelet and white cell antigens were performed much more recently. There are a number of explanations for this, including the earlier recognition of red cells and the early attempts to transfuse these cells. Additionally, red cells have proved to be not only more plentiful, but also easier for investigators to work with. Indeed, the early techniques used to study red cell antigens, such as primary and secondary agglutination reactions using direct and indirect antiglobulin tests, proved so robust that they are still used today.

The nomenclature used for red cells is complex, yet historically interesting. Until recently, there was no attempt to be systematic. In the past, some blood groups were named after the individual (Kell is derived from Mrs. Kellner) or animal (Rh is derived from the rhesus monkey) lacking the antigen. Others were named after the discoverers (e.g., LW was named for Landsteiner and Weiner). Finally, some names are best described as quaint (e.g., the Lutheran blood group system was named according to a mislabeled blood sample). As is discussed, a more systematic approach for naming antigenic systems of red cells, platelets, and white cells is now used. However, the traditional names are still frequently used and, to add to the confusion, a number of laboratories continue to use other traditional nomenclatures (e.g., the Fisher-Race terminology continues to be used for the Rh system).
For biologists, a compelling question presents itself: What are the purposes of blood group antigens? For the majority of antigens, the answer is unknown, but there is increasing evidence that suggests certain antigens participate in host defense. Blood group antigens of red cells, platelets, and white cells can be made of proteins, carbohydrates attached to proteins, or lipids. Within each category, the antigen can be intrinsically produced during the formation of that cell, or it can be adsorbed from the plasma. Similarly, the antigens can be attached to the surface of the cell, can be partially embedded within the membrane (phosphatidylinositol glycan), or can be transmembrane. Recognizing this, investigators have grouped red cell antigens according to the functional activities of their associated carbohydrate, lipid, or protein.\(^1\)\(^2\)

These include functions such as membrane stabilization, transport across the membrane, receptor function, enzymatic activity, and others. However, it is important to emphasize that although these blood group antigens are one component of this particular function, there is little evidence that they exist solely for this function. Consequently, although it is interesting to understand how a protein or carbohydrate associated with a blood group antigen contributes to a cell's integrity, it may not be the sole explanation for the presence of the antigen.

Any discussion of blood group antigens must touch on disease associations. In this review, we also comment on generally agreed on associations. Readers should be cautious about the reported associations between certain blood groups and diseases, as these associations could be collateral to other factors. However, there is general agreement that infectious agents, especially parasites and some bacteria, have led to blood group antigenic selection. Perhaps this is best exemplified by the geographic distribution of the Duffy blood group system, which is encoded by two alleles. The Fy(a-b-) phenotype is rare in most populations, with the exception being blacks originating from West Africa. Studies have demonstrated that the Duffy glycoprotein can serve as a receptor for Plasmodium vivax, an etiologic agent of malaria; hence, there is a strong selection advantage for those individuals not expressing this glycoprotein (i.e., Fy \(a-b\)).

These dramatic observations and other studies provide indirect evidence that perhaps the major biologic advantage of antigens on cells is to enhance the ability of the species to distinguish self from non-self. Hence, one can anticipate in the ongoing “evolutionary warfare” between species and their invaders that when a microorganism uses a component of a blood group to invade that cell, spontaneous mutations producing another blood group would have a selective advantage. Additionally, nonhazardous mutations, which do not provide advantage or disadvantage, might not necessarily be deleted. It is likely that this helps to explain the enormous number of blood groups found on red cells, platelets, and white cells. Some of these blood groups are common (typically termed public systems within the platelet nomenclature), whereas others are rare (termed private systems).

This chapter summarizes red cell and platelet blood groups by first summarizing the approach to nomenclature and then reviewing the common blood groups.

P.510

**RED BLOOD CELL ANTIGENS**

In humans, 33 blood group systems with 298 antigens have been identified.\(^3\)\(^4\)\(^5\) Additional antigens have been identified but have not been assigned to established systems. Red blood cell antigens may be proteins, glycoproteins, or glycolipids. Most red cell antigens are synthesized by the red cells; however, some antigens, such as those of the Lewis and Chido/Rodgers systems, are adsorbed onto the red cell membrane from the plasma. Some red cell antigens are specific to red cells; however, others are found on other cells throughout the body.

The importance of red cell antigens is multifold. Since the work of Landsteiner in the early 1900s, it has been recognized that knowledge and understanding of blood groups are essential for transfusion therapy. In routine practice, it is necessary to determine the compatibility of certain red blood cell antigens between the blood donor and the blood recipient. This is because individuals who lack antigens on their red blood cells can form alloantibodies, or be alloimmunized, if they are exposed to blood expressing the antigen. This might occur with transfusion of blood products or during pregnancy. Antibodies that react with red blood cell antigens can cause problems such as delayed and immediate hemolytic transfusion reactions (HTRs) and hemolytic disease of the newborn (HDN). Furthermore, the study of red cell antigens and the associated membrane structures allows for a greater understanding of the physiology of red blood cells. For example, abnormalities of some blood group systems, such as Rh and Kell, may be associated with both functional and morphologic changes in the red cells. Finally, study of the inheritance of blood group antigens provides a greater understanding of the mechanisms of gene expression.

In this chapter, the red cell antigen groups are presented in order of relative clinical importance. The summary tables, given in each antigen section, list important clinical information and the most important antigens of each blood group.
system. As noted, many red cell antigens (as well as the platelet antigens) have an interesting but inconsistent approach to nomenclature. However, because these names are commonly used, they are used along with the nomenclature proposed by the International Society of Blood Transfusion (ISBT).

International Society of Blood Transfusion Terminology

The ISBT Working Party on Terminology for Red Cell Surface Antigens was established in 1980 with the goal of creating a uniform nomenclature. Blood antigens were categorized into systems, collections, and series. The most recent monograph produced by the Working Party was produced in 2004 and included blood group antigens categorized into 29 systems, six collections, and two series. Updates to this monograph have been published online (http://ibgrl.blood.co.uk/ibgrl/ISBT%20Pages/ISBT%20terminology%20pages/terminology%20Home%20page.htm#system) and there are now 30 systems recognized.

Systems

A blood group system is genetically discrete from other blood group systems and consists of one or more antigens governed by either a single gene locus or a complex of two or more closely linked genes with virtually no recombination events occurring among them. Furthermore, it must be defined by a human alloantibody, and the gene encoding it must have been identified and sequenced. There are currently 30 recognized systems (Table 20.1).

Collections

The concept of collections was introduced into the ISBT terminology in 1988 to bring together related sets of antigens (genetically, biochemically, or serologically), which could not correctly be classified as systems because they have not been shown to be genetically distinct from all existing systems. Seven collections are currently recognized (Table 20.2).

Series

An antigen may be assigned a number if it is a low-frequency antigen (the 700 series) or if it is a high-frequency antigen (the 901 series). A low-frequency antigen is an antigen that has an incidence of <1% in most populations tested, similar to the platelet designation of “private.” The 700 series currently consists of 18 antigens (Table 20.3). High-frequency antigens are antigens with an incidence of >90% in most populations, similar to the platelet “public” system. Originally, high-frequency antigens were assigned to the 900 series. However, because so many of the original antigens assigned to the 900 series have been reassigned to collections, the 901 series was created. There are currently six antigens in the 901 series (Table 20.4).

Each blood group antigen is given an identification number consisting of six digits. The first three numbers represent the system to which the antigen has been assigned. The second three digits identify the antigen. Each system also has an alphabetic symbol. For example, the ABO system is number 001, and the A antigen is the first antigen of that system; thus, it has the ISBT number 001001 or ABO001. By convention, the zeros may be omitted, and numbers are separated by a dot (i.e., the A antigen would be 1.1 or ABO1). This terminology is useful for databases and as a classification system; however, most clinical laboratories still use traditional terminology.

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The ABO blood group system was discovered by Landsteiner in 1900 when he noticed that the red cells of some individuals could be agglutinated by the serum of others. It remains the most important of all blood group systems for several reasons: (a) when the ABO antigen is not expressed on the red cell, individuals always have ABO antibodies in their plasma, with the stimulus for antibody production being a variety of environmental agents; and (b) the ABO antibodies
formed are frequently mixtures of both immunoglobulin M (IgM) and IgG antibodies, both having thermal reactivity at 37°C and both capable of activating complement.

These unique characteristics of the antigens and antibodies of the ABO blood group system provide optimal conditions for rapid

P.511

red cell destruction if ABO-incompatible blood is transfused: A clinical scenario termed an acute HTR.

HCNC, HUGO gene nomenclature committee (www.genenames.org); ISBT, International Society of Blood Transfusion; No, number.

Reid ME. The Gerbich blood group system: a review. Immunohematology 2010; 26:124-126; and International Society of Blood Transfusion Working Party on terminology for red cell antigens website:

There are three alleles of the ABO gene in the ABO blood group system (A, B, and O) that are inherited in Mendelian fashion (Table 20.1). Both A and B are codominant alleles, whereas O is a recessive allele. Hence, these three result in four different phenotypes: A, B, AB, and O. An individual with the A phenotype can be homozygous for the A gene (AA) or heterozygous (AO). Similarly, the B phenotype can be the result of homozygous (BB) or heterozygous (BO) gene inheritance. The genotype of the AB phenotype is AB, and the group O phenotype is always genetically OO. Thus, there are four ABO group phenotypes (A, B, AB, and O) that arise from six possible genotypes (AA, AO, BB, BO, AB, and OO). The alleles normally occupy the same position on a paired chromosome. Rarely, individuals may express a cisAB phenotype in which the A and B alleles appear to be carried on the same chromosome. This phenomenon is caused by a collection of mutant ABO alleles that encode a glycosyltransferase capable of synthesizing both A and B antigens.

The frequencies of ABO phenotypes are variable among different ethnic populations. In whites, the O and A phenotypes are the most common, occurring in >40% of the population. The B phenotype is found in approximately 10% of whites, and the AB phenotype is encountered in only 3% of individuals. In contrast, around the world, the O phenotype is the most common ABO phenotype, particularly in South and Central America. The A phenotype is found in 10 to 35% of individuals throughout the world with the highest frequency among the aborigines of northern Scandinavia and northern America.

ABO Gene

The ABO gene is located at 9q34.2. The gene consists of at least seven exons spanning over 18 kb in the DNA genome. The A and B alleles result from differences in seven nucleotides, resulting in different substrate specificity of the encoded enzyme. The difference in substrate specificity is mainly determined by the amino acids 266 and 268 in exon 7. The O phenotype is due to either a frameshift mutation leading to a stop codon or, rarely, a mutation producing a nonfunctional enzyme. Numerous mutations are found in ABO, but the most common mutation results in the A2 phenotype. In A2, the A allele of the ABO gene has two nucleotides different from the A1 phenotype, which results in diminished enzymatic activity and, consequently, weakened antigen expression. For example, a red cell with A1 phenotype carries more than 800,000 A antigens, but only 250,000 A antigens are present in a red cell with the phenotype A2. Similarly, weak subgroups of group B have been described due to mutations of the B allele of the ABO gene.

ABO Antigens

The antigens of the ABO system are located on carbohydrate oligosaccharide chains, which are parts of glycosphingolipids or gp molecules. There are four different types of oligosaccharide chains: Type 2 and type 4 oligosaccharide chains are predominantly on the red cell membrane; type 1 chains are found in plasma, saliva, and body fluids; and type 3 chains are found in the mucins secreted by gastric mucosa or ovarian cysts.

The ABO gene does not encode directly for the antigens but encodes for enzymes that add specific sugars to the red cell membrane. These sugars are the ABO red cell antigens that are detectable with serologic testing. The A allele encodes for the α(1,3) N-acetyl-galactosaminyl-transferase which adds an N-acetylgalactosamine to the red cell membrane. The B allele encodes for the α(1,3) galactosyltransferase which adds a galactose to the red cell membrane. In an individual with the AB phenotype, the A and B transferases coexist and compete for the same substrate. The O allele encodes for a nonfunctional transferase; hence, a specific sugar is not attached to the red cell membrane. Mutations of the A and B alleles result in amino acid substitutions within the transferases, and this translates into weakened expression of the A and B antigens (frequently classified as subgroups). The most common subgroups associated with the A allele are A1 and A2. The A1 subgroup occurs in approximately 80% of group A individuals, and the A2 subgroup is present in approximately 20%. The other subgroups of A are less frequently encountered, with the A3 subgroup being the next most frequent, occurring in 1 in 1,000 individuals. The clinical relevance of A and B subgroups is of greater significance in blood donors than recipients. Because of the weakened antigen expression on the red cells of an individual who has inherited a subgroup allele, it is possible that serologic phenotyping of red cells results in misclassification of the red cell phenotype as group O. For a blood recipient, this would not be a problem, as group O blood is compatible with all other
groups (universal donor); however, if a donor unit of blood from an individual with an A or B subgroup is misclassified as group O and transfused to an O individual, intravascular hemolysis could result.

On the red cell membrane, both the A and B transferases add sugar moieties to a substrate that is encoded by the H (FUT1) gene. FUT1 is located at chromosome 19q13.1-qter, and the genes inherited at this locus are inherited in a Mendelian manner. Two alleles have been identified at this locus: H and h. The allele H, most frequently inherited, encodes for an enzyme termed H transferase type II [\(\alpha(1,2)\) fucosyl-transferases; FUT1], which adds an L-fucose to the terminal galactose molecule of oligosaccharide chains in an \(\alpha(1-2)\) linkage. This structure is called H substance, and it is to this structure that the A and B transferases add specific sugars resulting in A and B antigens. The rare allele sometimes inherited at the H locus is h. This h allele encodes for a nonfunctional transferase. If the h allele is inherited in the homozygous state (hh), L-fucose molecules (H substance) are not present on the red cell membrane. Without the presence of H substance on the red cell membrane, the A and B transferases, even when present, are not able to add the specific sugars that give A and B antigen specificity. This hh genotype is known as the Bombay phenotype: Serologically, the red cells group as O; however, unlike the true O phenotype, which has large amounts of H antigen on the red cells, red cells from the Bombay phenotype lack H antigen (Fig. 20.1). Children of a parent with the Bombay phenotype (hh) may have normal A or B antigen expression, or both, if they inherit

P.514
the dominant H allele from the other parent. The clinical relevance of the Bombay phenotype relates to the ability of these individuals to form not only anti-A and anti-B but also anti-H. The presence of all three of these antibodies makes it difficult to find compatible blood if transfusion is required. The only compatible blood for an individual with the Bombay (hh) phenotype is blood from another Bombay individual, and this phenotype is extremely rare.

ISBT, International Society of Blood Transfusion.
Adapted from International Society of Blood Transfusion Working Party on Terminology for Red Cell Antigens web site:
FIGURE 20.1 Biosynthesis of ABO blood group antigens. The antigens of the ABO system are located on the carbohydrate of type II oligosaccharides. H transferase is required to add fucose to the oligosaccharide chain and form H substance. Without the presence of H substance, A transferase and B transferase are not able to add terminal sugar moieties to the oligosaccharide chain. Fuc, l-fucose; Gal, d-galactose; Glc-NAc, d-N-acetyl-glucosamine.
The ABO(H) antigens are found not only on red cells, but also on other blood cells; in most body fluids (except cerebrospinal fluid); and on the cell membranes of tissues such as intestine, urothelium, and vascular endothelium. The expression of ABO(H) antigens on the red cell membrane and tissue membranes is controlled by the FUT1 (H) gene. The expression of ABO(H) antigens into body fluids is controlled by the FUT2 (Se) gene. The FUT2 gene, similar to the FUT1 (H) gene, is located at chromosome 19 (19cen-qter); however, they are not part of the ABO system. The dominate Se allele codes for H transferase type 1 (α(1,2) fucosyltransferase; FUT2). Without the prior addition of a fucose to the oligosaccharide chains, A and B antigens would not be expressed in the body secretions, irrespective of the presence of A and B transferases (Fig. 20.1).

Despite the wide distribution of ABO(H) antigens in various cell membranes and body fluids, the normal physiologic function of these glycoproteins and glycolipids is largely unclear. The carbohydrate moieties of the ABO(H) antigens might contribute to the formation of glyocalyx. However, based on the observation that individuals who lack all ABH antigens (Bombay phenotype) have normal red cell survival and function, the role of ABO antigens in maintaining a state of health is unknown. There is some evidence that ABO blood groups may be associated with certain diseases. For example, the normal range of von Willebrand factor (vWF) antigen level varies among individuals with different ABO blood groups. Individuals with blood group O have the lowest vWF antigen level, followed by group A, then group B, and the highest levels in those with group AB. However,

The normal range of vWF is generally defined as the level in the normal general population irrespective of the ABO blood group. It has been postulated that ABO antigen expression can affect the glycosylation, thus altering the proteolysis and clearance of vWF. Studies have shown that individuals with blood group O are less susceptible to arterial and venous thromboembolism possibly associated with a lower level of vWF. In addition, blood group ABO may be associated with resistance to certain infections and, therefore, may offer a survival advantage. For example, individuals with blood group O may be less susceptible to severe Plasmodium falciparum malaria, but may be more likely to have severe infection with Vibria cholerae O139, or Escherichia coli O139. Gastric cancer and peptic ulcer disease have been reported to be more prevalent in individuals with blood group O because of the association between blood group O and a gastric pathogen, Helicobacter pylori. It has been shown that H. pylori binds more readily to gastric epithelium in group O individuals because of lack of expression of ABO and Lewis antigens in non-hematopoietic tissue (see also section on Lewis antigens). In contrast, secretors of ABO and Lewis antigens in the gastrointestinal tract are more susceptible to norovirus, rhinoviruses, echoviruses, influenza viruses, and respiratory syncytial virus.

Antibodies and Clinical Significance

All immunocompetent individuals produce antibodies against the missing ABO(H) blood group antigens (Table 20.5). Anti-A and anti-B production does not require red cell stimulation through transfusion or pregnancy but occurs predominately through environmental exposure, such as bacteria. Anti-A and anti-B are usually detectable within 3 to 6 months after birth. By the age of 5 years, the titer of anti-A and anti-B antibodies reach maximum and persist throughout adulthood. The titers of IgM anti-A and anti-B antibodies may gradually decline with advanced age. Newborn infants do not usually have a significant amount of anti-A or anti-B in their plasma; therefore, pretransfusion testing is not usually required for transfusions within the first 4 months of life. Infants born to alloimmunized mothers are an exception to this rule, as other specific blood group antibodies may have crossed the placenta and may be present in the infant’s circulation.

The “naturally occurring” anti-A and anti-B antibodies are predominantly IgM, although variable amounts of IgG may be present. Like most IgM immunoglobulins, ABO antibodies are especially effective at complement activation for two reasons: the antibodies have thermal activity most reactive at body temperature, and the high density of antigen sites on the red cell membrane allows for large numbers of antibodies to bind to the cell membrane. Therefore, the transfusion of ABO-incompatible blood typically presents as acute intravascular hemolysis. Anti-ABO antibodies, anti-human leukocyte antigen (HLA) antibodies, and anti-human platelet antigen (HPA) antibodies can cause alloimmunization resulting in platelet transfusion refractoriness. The ABH expression on the platelet is linked to the red cell phenotype; yet the expression on the platelet may be determined mainly by the enzyme H transferase type II (FUT1).

In allogeneic stem cell transplant, ABO incompatibility may cause hemolysis, pure red cell aplasia, and delayed engraftment of donor cells. However, ABO incompatibility may not affect the long-term survival. After ABO unmatched hematopoietic stem cell transplantation, the patient's red cells will switch to the donor's blood group. Due to the fact that ABO antigens are not limited to the red cells, peripheral tissue may continue to express the recipient's original antigens for life. These isohemagglutinin will be adsorbed onto the red cells and cause ABO discrepancy during crossmatch. Similarly, in kidney transplantation, ABO-incompatible recipients have higher graft loss in the immediate posttransplant period, but the long-term survival is similar to those with ABO-mismatched recipients. Moreover, delay in the production of ABO antibodies in infants may provide an “immunologic gap” for ABO-incompatible organ transplantation.

The antibodies against ABO antigens are not a major cause of HDN for several reasons. First, soluble A or B substance in the fetal plasma can neutralize the alloantibodies. Second, antigens A or B expressed on other body tissues may also bind alloantibodies. Third, alloantibodies against ABO antigens are specific for sugar molecules; these antibodies generally have a weaker binding affinity than anti-bodies reacting with protein antigens such as the D antigen.

In routine blood group typing, the transfusion recipient's red cells are typed using commercial sources of anti-A and anti-B antibodies (forward or cell typing). The presence of anti-A and anti-B in the serum/plasma of the recipient is detected by testing the serum/plasma against group A and group B red cells (reverse or serum typing). The interpretation of these two tests must agree for the patient's blood group to be assigned. Sometimes, the serum and cell grouping do not agree; this is termed ABO discrepancy. In these circumstances, the laboratory should proceed with additional testing to correctly identify the patient's ABO blood group. New technologies in blood group genotyping may identify and resolve these discrepancies.

Discrepancies in ABO grouping can be found in various conditions. For example, the ABO(H) antigens may be weakened in the donors with mutations of the ABO alleles. In patients with some types of leukemia or cancer, or having diseases associated with chromosome 9 translocations, the ABO(H) antigens may also be weakened and serologically typed as negative for that particular antigen. Alternatively, an individual may acquire an ABO antigen on the red cells; for example, one can acquire a B antigen after bacterial infections, or acquire an A antigen associated with Tn activation of the red cells.

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Rh blood group system was discovered by Landsteiner and Weiner in 1940. They injected rabbits with red cells from the rhesus monkey, and the antibody produced was initially termed Rh and is now known as anti-D. Unlike the ABO blood group system, Rh antibodies are not environmentally stimulated; however, the D antigen is highly immunogenic, causing anti-D formation in up to 70% of D-negative individuals who are exposed to D-positive blood. Anti-D is IgG and is known to cause HTRs and HDN.
Rh Terminology

Three different systems of nomenclature have been developed to describe the genes and antigens of the Rh blood group system antigens: The Wiener system, the Fisher-Race system, and the Rosenfield numeric terminology. Wiener proposed that the Rh antigens were the products of a single gene. The Fisher-Race nomenclature was based on the theory that reactions observed with various Rh antisera could be explained by three pairs of allelic genes: Cc, Dd, and Ee. Genetic analysis does not support either of these models. However, both the Wiener notation and the Fisher-Race nomenclature remain widely used today because of familiarity. In 1962, Rosenfield et al. proposed a system of nomenclature that was based on serologic findings. The symbols were used to convey phenotypic information rather than genetic information.

In this system, the antigens are numerically named in order of their discovery or assignment to the Rh blood group system. The various nomenclatures for common Rh system antigens are listed in Table 20.6.

Genes

The Rh antigens are encoded by two genes: RHD and RHCE. The genes are located at chromosome 1p36.11 (Table 20.1). RHD encodes for the D antigen, whereas RHCE encodes for the Cc and Ee antigens. The d antigen does not exist; however, by convention, d is used to connote the absence of the D antigen. RHD and RHCE each contain ten exons and are distributed over 69 kilobase pairs (kbp). Both the RHD and the RHCE genes encode for similar polypeptides of 417 amino acids with 12 membrane-spanning domains. In the red cell membrane, these two polypeptides form a complex with a glycoprotein termed the Rh-associated glycoprotein (RhAG), which is encoded by the RHAG gene (RH50) on chromosome 6. The RhAg and associated antigens have recently been designated the thirtieth blood group system. The structure of the Rh antigens suggests that they are transport proteins and the RhAG protein may play a role in the transport of ammonium. The Rh-associated proteins are transport proteins involved in ammonia/ammonium transport. The physiologic role of the Rh protein is poorly defined, but it has been suggested that these proteins may act to keep total blood ammonia low by trapping ammonium within the red blood cell.

Antigens

There are 54 antigens that have been assigned to the Rh blood group system: D, C, E, c, e, f, Ce, C<sup>+</sup>, C<sup>+</sup>, V, E<sup>+</sup>, G, Hr<sub>RV</sub>, Hr<sub>RV</sub>, V<sub>S</sub>, C<sub>E</sub>, D<sup>r</sup>, c-like, Ce, hr<sup>r</sup>, Rh29, Go<sup>r</sup>, hr<sup>+</sup>, Rh30, Rh31, Rh33, Rh<sup>+</sup>, Rh35, Be<sup>+</sup>, Evans, Rh39, Tar, Rh41, Rh42, Crawford, Nou, Riv, Sec, Dav, JAL, STEM, FPTT, MAR, BARC, JAHK, DAK, LOCR, CENR, CEST, CELO, CEAG, PARG, and CEVF (Table 20.1). Of the 54 antigens in the Rh blood group system, the most common and important are D, C, E, c, and e. Although individuals can become alloimmunized to the C, c, E, and e antigens after red cell exposure through transfusion or pregnancy, these antigens are much less immunogenic than D. Less than 3% of individuals exposed to the C, c, E, and e antigens become alloimmunized; hence, pretransfusion testing is not routinely performed to match for these antigens. The principal phenotypes of the Rh blood group system and their frequencies are outlined in Table 20.7.
An individual is considered to be Rh positive if his or her red cells express the D antigen. The term Rh negative refers to the absence of the D antigen. The absence of the D antigen occurs in approximately 15% to 17% of individuals in white populations and is less frequent in other populations. In white populations, the absence of the D antigen is usually due to the deletion of the RHD gene. In Asian and black populations, the absence of the D antigen is usually due to an inactive RHD rather than a gene deletion.

P.517

Cis Product Antigens. Ce(rh₁) is an antigen that almost always accompanies C and e when they are encoded by the same haplotype.

Cc and Ee Variant Antigens. Various Rh antigens appear to be determined by alleles of the Cc and Ee antigens. Variants of C include C'(Rh8), C¹(Rh9), and MAR. Variants of the E antigen include E⁰(Rh11) and E¹(Rh24). Variants of the e antigen include hr'² (Rh31), hr'³ (Rh19), and e'(Rh20).

G Antigen (Rh12). The G antigen is found on any red cell that also has the C or D antigen.

Weak D Phenotype

Some red cells that express the D antigen require prolonged incubation with the anti-D reagent or application of the antoglobulin test for agglutination to occur. These red cells are considered to be D antigen-positive and are described as weak D, formerly termed D⁺. The weak D phenotype is thought to occur by one of three mechanisms: (a) inheritance of an RHD gene encoding for a weakened expression of D, (b) interaction of the D allele with other genes, and (c) inheritance of an RHD gene missing some epitopes. In the first mechanism, the weak D phenotype is due to an RHD gene encoding for a D protein with reduced D antigen expression. This is more common in the black population and generally occurs in association with the Dce haplotype. In the white population, weak D is less common but may occur in association with the haplotype DCe or DcE. In the second mechanism, the weak D phenotype occurs as a result of the position of the D allele. This is most easily conceptualized using the Fisher–Race terminology. Red cells from individuals with a C allele in a trans position to the D allele (i.e., Dce/Ce) have weakened expression of D due to C being on the opposite chromosome. Individuals with the weak D phenotype by either of these two mechanisms do not form alloantibodies after exposure to D-positive red cells. Finally, the third mechanism, sometimes termed partial D, occurs when individuals lack part of the D antigen complex. The D antigen is thought to be a mosaic consisting of several individual parts or epitopes. Most D-positive individuals inherit the gene encoding the entire D antigen. However, the partial D phenotype describes red cells that are deficient in components of D, resulting in a decreased expression of the D antigen (weak D). Individuals with partial D may produce anti-D if transfused with D-positive red cells.

The weak D and partial D phenotypes have implications for the practice of transfusion medicine. Donors with weak D red cells should be considered Rh(D) positive. It is important that donor blood with weak D not be mislabeled as Rh(D) negative because the weak D antigen could induce an immune response if this blood were transfused to an Rh(D)-negative individual. It is generally recommended that patients who phenotype as weak D can be transfused with Rh(D)-positive
blood. The most common types of weak D do not appear to be at risk of alloimmunization to the D antigen, therefore, these individuals can safely receive D-positive blood and would not require Rh immune globulin prophylaxis during pregnancy. However, it should be noted that some weak D types, identified by molecular analysis or the RHD gene are susceptible to alloimmunization.\(^5\)

R\(\text{h}_{\text{null}}\) Phenotype

The R\(\text{h}_{\text{null}}\) phenotype occurs when red cells do not express Rh antigens. This phenotype occurs because of at least two mechanisms. First, the inheritance of an abnormal RHAG gene appears to result in the absence of the Rh antigen expression despite the presence of normal RHD and RHCE genes.\(^3\) This is termed regulator type Rh\(\text{null}\). The second mechanism is termed amorph type of Rh\(\text{null}\) and involves the inheritance of a mutation in the RHCE genes in association with a D-negative background.\(^5\) The Rh\(\text{null}\) phenotype is associated with abnormalities in the red cell membrane causing stomatocytosis and hemolysis. The presence of the Rh proteins in the red cell membrane appears to be necessary for the expression of other membrane proteins such as the LW, Duffy, and U antigens. Rh\(\text{null}\) cells have been demonstrated to lack the LW and Fy5 antigens and have weakened expression of the S, s, and U antigens.\(^5\) Fortunately, the Rh\(\text{null}\) phenotype is rare, as these individuals form an alloantibody (anti-Rh29) that reacts with all other red cells except Rh\(\text{null}\) when they are transfused. Thus, obtaining compatible blood can be challenging.

Antibodies and Clinical Significance

Most Rh antibodies are IgG, although some may be IgM. They are usually not capable of activating complement. Anti-D is one of the most common Rh antibodies because of the high immunogenicity of the D antigen. Anti-D can cause severe HDN and HTR. The frequency of anti-D has greatly decreased with the use of prophylactic Rh immune globulin administration to Rh(D)-negative mothers during pregnancy and at delivery if the infant is Rh(D) positive. Antibodies against antigens of the Rh system including C, c, E, and e can be associated with mild HTR or HDN.\(^4\)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Kell blood group system was discovered in 1946 and was named after Mrs. Kellner, the mother of the first child discovered to be affected with HDN because of Kell antibodies.\(^5\)\(^6\)

Genes and Antigens

The Kell blood group system consists of 35 antigens: K, k, Kp\(^a\), Kp\(^b\), Ku, Js\(^a\), Js\(^b\), Ul\(^a\), K11, K12, K13, K14, K16, K17, K18, K19, Km, Kp\(^a\), K21, K22, K23, K24, VLAN, TOU, RAZ, VONG, KALT, KTIM, KYO, KUCI, KANT, KASH, KELP, KETI, KHUL, and KYOR. The antigens are coded by a complex of genetic loci, known as the Kell locus, which is located at 7q33 (Table 20.1). The KEL gene contains 19 exons distributed over 21.5 kbp.\(^4\) There are at least four subloci in the complex, each of which has an allele for a high-frequency antigen (K, Kp\(^b\), Js\(^a\), and KEL11) and for one or more alleles for a lower-frequency antigen (K, Kp\(^a\) and Kp\(^b\), Js\(^a\), and KEL17).\(^5\) The most common haplotype is k/Kp\(^b\)/Js\(^a\)/KEL11. The phenotype frequency of the common Kell antigens is shown in Table 20.8. The k antigen is a high-frequency antigen that is present in more than 98% of whites and blacks. The K antigen is much less common.

The KEL gene encodes a type 2 integral membrane protein, called zinc endopeptidase, containing 732 amino acids, which is present at 3,500 to 17,000 copies per red blood cell.\(^5\)\(^6\) The protein has enzymatic activity, and it has been demonstrated in vitro to cleave big endothelin-3, which is a peptide with vasoconstrictor activity.\(^5\) The Kell protein is associated with the Kx protein in the red cell membrane (see section Kx Blood Group System [ISBT 019]).\(^5\) Individuals have been identified who do not express the Kell protein (Kell\(_\text{null}\) phenotype) and who are healthy with no structural or functional abnormalities of their red cells identified.

**Antibodies and Clinical Significance**

The K antigen is very immunogenic. Only the D antigen has greater potential to induce alloimmunization. Because of this, anti-K is often encountered. Anti-K typically is induced by blood transfusion. The antibody tends to be IgG. Anti-K is
clinically significant and has been implicated in both HTR and HDN. There is poor correlation with maternal anti-K titer and disease severity. Furthermore, HDN associated with anti-K tends to be more severe than HDN caused by anti-D. This is thought to occur because the Kell antigens are well expressed on fetal cells and appear on erythroid progenitor cells. It is postulated that anti-K, in addition to causing hemolysis, also causes a suppression of erythropoiesis.

The k antigen is also highly immunogenic. However, because only individuals not expressing the k antigen (i.e., KK phenotype) produce anti-k, and because the k antigen is present in most individuals, anti-k is much less common. Anti-k has been associated with both HDN and HTR. The other Kell blood group system antibodies are much less common but are also clinically significant.

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Duffy blood group system was discovered in 1950 in the serum of a multiply transfused male patient with hemophilia, Mr. Duffy.

Gene and Antigens

The Duffy system consists of six antigens, Fy\(^a\), Fy\(^b\), Fy3, Fy4, Fy5, and Fy6, which are encoded at the Duffy locus on chromosome 1q21-q22 (Table 20.1). The gene, DARC (or FY), contains two exons distributed over 1.521 kbp. The antigens, Fy\(^a\) and Fy\(^b\), are encoded by a pair of codominant alleles. The phenotypes of the Duffy system and their frequencies are presented in Table 20.8. The most common phenotype in the white population is Fy(a+b+), and the most common phenotype in the black population is Fy(a-b-). The Fy\(^a\) antigen represents a form of weak Fy\(^b\). The Fy5 antigen is defined by an interaction of the Duffy and Rh gene products. The antigens Fy\(^a\), Fy\(^b\), and Fy6 are sensitive to denaturation by enzymes such as papain, ficin, or α-chymotrypsin. Fy3 and Fy5 are not sensitive to enzyme denaturation.

The Duffy DARC gene encodes for a glycoprotein (DARC) that is found on red cells as well as other tissues including brain, heart, lung, kidney, and spleen. On red cells, the glycoprotein has been identified as a receptor for various chemokines and may contribute to chemokine-induced leukocyte migration to sites of inflammation. DARC may also play a role in renal disease as increased DARC expression has been noted in different causes of renal injury. It is thought that DARC expression is increased in an attempt to control inflammation. The glycoprotein is also the receptor for P. vivax and P. knowlesi. Therefore, individuals who do not express Fy\(^a\) or Fy\(^b\) on their red cells are not susceptible to these forms of malaria. In parts of Africa where malarial infection is common, most individuals are Fy(a-b-), likely because of natural selection.

Antibodies and Clinical Significance

The Duffy antibodies are usually IgG. Anti-Fy\(^a\) is a common alloantigen. Fy\(^a\) is considered clinically significant, as it has been associated with HDN and HTR. Anti-Fy\(^b\) is uncommon. It has been associated with mild HTR and only rarely with HDN. The other Duffy antibodies are much less common.

Kidd Blood Group System (ISBT 009)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Kidd blood group system consists of three antigens: Jk⁺, Jk⁰, and JK3 (Table 20.1). The system was named for the woman (Mrs. Kidd) whose serum was found to contain the antibody, and the antigen was named Jk for the initials of the woman's child (John Kidd) affected by HDN.⁶⁸

**Gene and Antigens**

The Kidd blood group system gene is located at chromosome 18q11-q12. The gene, SLC14A1, also known as JK or HUT11, is distributed over 30 kbp and contains 11 exons.⁴⁵ It encodes for the urea transporter hUT-B1.⁶⁹ The principal phenotypes of the Kidd blood group system and their frequencies are outlined in Table 20.8. The antigens Jk⁺ and Jk⁰ are found at relatively the same frequencies in the white populations but differ in other ethnic groups such as blacks and Asians.⁴⁵ The Jk(a⁻b⁻) phenotype is rare and is found primarily in the Polynesian population.⁷⁰ These null red cells have been demonstrated to be resistant to lysis by 2M urea; however, this phenotype is not associated with shortened red cell survival or clinical symptoms.⁷¹

**Antibodies and Clinical Significance**

The Kidd antibodies are usually IgG but occasionally are IgM. These antibodies tend to be short-lived; therefore, they are frequently not detected before transfusion. However, they are capable of a rapid amnestic response and have been associated with severe delayed HTRs. The antibodies have rarely been associated with HDN, usually of mild severity.⁵⁶

</tbody>
</table>

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The MNS blood group system was discovered in 1927. The M and N antigens get their names from the letters in the word immune, because anti-M and anti-N antibodies were discovered in the sera of rabbits immunized with human red cells. The letter I was not used because it was felt this would be confused with the number 1.⁷²,⁷³ The S antigen was named after the city in which it was discovered—Sydney, Australia.⁷³

**Genes and Antigens**

The MNS blood group system consists of 46 antigens: M, N, s, U, He, Mi⁺, M⁺, Vw, Mur, M⁶⁺, M⁶⁻, Mt⁺, Mt⁻, St⁺, St⁻, Cl⁺, Cl⁻, Ny⁺, Hut, Hil, M⁺, Far, s⁺, Mit, Danu, Hop, Nob, En⁺, ENKT, N', Or, DANE, TSEN, MINY, MUT, SAT, ERIK, Os⁺, ENEP, ENEH, HAG, ENAV, MAR, END, NH, and MN (Table 20.1). The M and N antigens are carried on glycophorin A, whereas the antithetical antigens, S and s, are carried on glycophorin B. They are encoded by the GYPA, GYPB, and GYPE genes located at chromosome 4q31.21. GYPB is five exons and is distributed over 58 kbp.⁴⁵ GYPB has five exons and is distributed over 58 kbp.⁴⁵ GPA and GPB contribute to most of the carbohydrate on the red cell membrane. The sialic acid of the O-glycans on these sialoglycoproteins results in the Tred cell membrane being negatively charged. This negative charge prevents red cells from sticking together, prevents red cell adherence to endothelial cells of the blood vessel walls, and protects from invasion by pathogens.⁴⁷,⁴⁸,⁷⁵,⁷⁶ The presence of glycophorin A has been demonstrated to be necessary for the adhesion of
certain malarial parasites (P. falciparum) as well as for bacteria and viruses (e.g., influenza virus and encephalomyocarditis virus). Other proposed functions of glycophorin A include regulation of transport of band 3 to the red cell membrane and complement regulation. The main phenotypes and frequencies of the MNS blood group system are listed in Table 20.8.

Antibodies and Clinical Significance

Anti-M and anti-N antibodies are typically IgM and are reactive at cold temperatures. Antibodies against M and N are naturally occurring (environmentally stimulated). They are not generally considered to be clinically significant. Rarely, anti-M has been implicated in cases of HDN and HTR. Anti-N has only rarely been associated with HDN or HTR. In contrast, antibodies against S, s, and U are capable of causing HTR and HDN. Anti-S and anti-s tend to be IgG and occasionally are IgM. Antibodies to many low-prevalence antigens in the MNS system have also been associated with HDN.

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The first P system antigen was discovered by Landsteiner and Levine in 1927. Initially, the system was thought to include the P, Pk, and LKE antigens, but these antigens have subsequently been assigned to the globoside antigens (see section GLOB Collection [ISBT 209]).

Genes and Antigens

The P blood group system consists of a single antigen: P1 (Table 20.1). P1 is the product of a galactosyltransferase encoded by the gene P1, which is located at chromosome 22q11.2-qter. It has been suggested that this transferase is encoded by the gene A4GALT, but this has been contradicted by recent studies. The P1 antigen is similar to the ABO antigens because it is composed of a chain of sugars linked to glycolipids on red cells. P1 is formed when β-D-galactose (Gal) is added in an α(1-4) linkage to paragloboside. In the white population, 79% of individuals express the P1 antigen.

Antibodies and Clinical Significance

Anti-P1 is naturally occurring and is commonly found in individuals lacking the P1 antigen. Anti-P1 is usually IgM. It has not been reported to cause HDN and has been associated with HTR only in rare instances. Identification of anti-P1 is aided by the fact that the activity of the antibodies is inhibited by hydatid cyst fluid or pigeon egg white.

Individuals who lack the P1 antigen who also do not express the P and Pk antigens may produce anti-P,P1,Pk, also known as anti-Tja. This antibody can be either IgM or IgG and has been associated with severe hemolytic reactions.

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.
FIGURE 20.2 Differences between ABO (A) and Lewis (B) blood groups. ABO blood group antigens are synthesized in the red cells on type II oligosaccharides, but Lewis blood group antigens are produced in the plasma on type I oligosaccharides and then adsorbed onto the red cell surface. Type II oligosaccharide chains differ from type I chains in the linking position of the terminal galactose moiety. The Le (FUT3) gene encodes type III H transferase, which adds a fucose group (redcolored fucose group) to the second-last sugar moiety of the type I oligosaccharide chain. Synthesis of the Le^c and Le^d antigens does not depend on the activity of the Le gene. Fuc, l-fucose; Gal, d-galactose; Gal-NAC, d-N-acetyl-galactosamine; Glc, d-glucosamine; Glc-NAC, d-N-acetyl-glucosamine.

The first Lutheran blood group antibody (anti-Lu^a) was found in 1946 in the serum of a previously transfused patient named Lutteran. The label on the sample was misread, and the blood group system was named Lutheran.
Genes and Antigens

The Lutheran blood group system consists of 20 antigens: Four pairs of antigens (Lu⁺/Lu⁻, Lu6/Lu9, Lu8/Lu14, and Au⁺/Au⁻) and 11 independent antigens (Lu3, Lu4, Lu5, Lu7, Lu11, Lu12, Lu13, Lu16, Lu17, Lu20, Lu21, and LURC) (Table 20.1). The antigens are encoded by the B-CAM (LU) gene located at chromosome 19q12-q13. The gene contains 15 exons and is distributed over approximately 12 kbp. The gene products include the Lutheran glycoprotein, which is 597 amino acids long, and a spliced version of the B-cell adhesion molecule (B-CAM), which is 557 amino acids in length. The Lutheran glycoproteins are members of the Ig superfamily and have been demonstrated to act as a receptor for laminin. The Lutheran blood group may play a role in the pathophysiology of sickle cell disease and polycythemia vera. In sickle cell disease, B-CAM and Lu are overexpressed on red cells, which may mediate increased red cell adhesion to laminin. In polycythemia, there is increased phosphorylation of the Lu glycoprotein, which increases red cell adhesion. The principal phenotypes of the Lutheran blood group system and their frequencies are outlined in Table 20.8.

Antibodies and Clinical Significance

The Lutheran antigens are not very immunogenic; therefore, antibodies in this system are rare. Anti-Lu⁺ and anti-Lu⁻ are usually IgG and are reactive on the indirect antiglobulin test. Anti-Lu⁺ has not been implicated in HTR but has been implicated in mild HDN. Anti-Lu⁻ has been associated with mild, subclinical HDN.

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Lewis blood group system is different from other blood group systems, as the antigens (Le⁺ and Le⁻) are formed in the plasma and absorbed onto the red cell membrane. This unique feature has implications for transfusion practices for several reasons: (a) transfused red cells always absorb Lewis antigens from the plasma of the transfusion recipient; hence, within several days of the transfusion, the phenotype of the circulating transfused red cells is the same as the patient’s red cell phenotype; and (b) soluble antigen in transfused plasma has the potential to inhibit Lewis system antibodies that may be in the plasma of some individuals.

Genes and Antigens

The two alleles (Le and le) are inherited in Mendelian fashion. Le is the dominant allele, and le is the recessive allele. The FUT3 (Le) gene is located on chromosome 19 (19p13.3) and is closely linked to the FUT1 (Hh) and FUT2 (Sese) genes. There are 11 different mutations of the FUT3 gene. The silent le allele is due to mutations that result in defective gene products. The FUT3 gene encodes for an enzyme, α(1,3/1,4) fucosyltransferase (FUT3, H transferase type 3), which adds fucose molecules to carbohydrate precursor chains (Fig. 20.3). The enzyme itself is a type II membrane-bound protein of 361 amino acids.
The relationship among ABO, P, and II blood group systems. These antigens are located on terminal oligosaccharides. Among these blood groups, the structure in common is lactosylceramide (red sugar moieties). Lewis blood group antigens also share similar structures, but they are not synthesized in red cells. Fuc, l-fucose; Gal, d-galactose; Gal-NAc, d-N-acetyl-d-galactosamine; Glc, d-glucosamine; Glc-NAc, d-N-acetyl-d-glucosamine.

Antigens

As mentioned previously, Lewis antigens (Le^a and Le^b) on the red cells are not intrinsic to the red cell membrane but are absorbed from the plasma onto the cells. The antigenic epitopes are located at the fucose moieties of glycosphingolipids. The biosynthesis of the antigens Le^a and Le^b involves two different pathways. The formation of antigen Le^a is catalyzed by the enzyme FUT3 that adds a fucose group to the type 1 oligosaccharide precursor chain (Fig. 20.3). In individuals with FUT2 (SeSe or Sese genotypes), most type 1 oligosaccharide precursor chains are converted to an intermediate product similar to the H antigen. The intermediate product is subsequently catalyzed by the enzyme FUT3 and forms the Le^b antigen. Therefore, the phenotypes Le(a-b+) and Le(a+b-) are not due entirely to the FUT3 gene but depend on the presence or absence of the FUT2 (Se) gene. This relationship between the FUT2 and FUT1 genes has practical implications for the laboratory. For example, the easiest way to determine an individual’s secretor status is to apply his or her red cells to determine their Lewis phenotype. The Le(a+b-) phenotype indicates that the individual is a nonsecretor; the Le(a-b+) phenotype indicates that the individual is a secretor; and the Le(a-b-) phenotype does not allow secretor status to be assigned. If the FUT2 product (FUT2) is partially active, such as in individuals with Se^w, some type 1 precursor chain is converted to Le^a antigen, and the remaining is converted to Le^b. The resultant phenotype, Le(a+b+), is rare in whites but common in Asians. The fucose residual may also be added to the type 2 oligosaccharide precursor chain and forms the Le^x and Le^y antigens that are similar to ABO(H) antigens in biochemical structure.

In the Lewis blood group system, the phenotype distribution varies among different ethnic groups. The Le(a-b+) phenotype is found in 70% of the white population and approximately 50% of the black population. The Le(a-b-) phenotype is less common in the white population but is found in approximately 30% of the black population. The Le(a+b+) phenotype is rare in both the white and black populations (Table 20.8).
In addition to red blood cells, Lewis antigens are found on other cell surfaces, such as gastric mucosa. They are also found in the lipopolysaccharide envelope of Helicobacter pylori. Although the gastric mucosa predominately expresses Le\(^a\) and Le\(^b\), the cell envelope of H. pylori mainly expresses Le\(^a\) and Le\(^c\). The relationship between the Lewis antigens and the pathogenesis of H. pylori infection is uncertain. The similarity of the antigens may deceive the host immune system and facilitate the colonization of H. pylori. In a murine model, H. pylori infection has been shown to induce antibodies cross-reactive to gastric mucosa and to contribute to the development of chronic gastritis and peptic ulcers. However, this has not been firmly established in humans because no concordance in the expression of the Lewis antigen has been found between the bacteria and the host. Some studies showed that Le\(^b\) and H antigens on the gastric mucosa mediated the binding of H. pylori via a binding protein (blood group antigen-binding adhesin). However, other studies demonstrated that H. pylori adherence is not dependent on the Lewis antigen. Similarly, it has been disputed whether blood group O is a risk factor for peptic ulcer disease. Also, the isoform antigens Le\(^a\) and Le\(^b\) may be found as neoantigens on malignant tissue.

### Antibodies and Clinical Significance

Like the ABO system, antibodies specific for Lewis antigens are naturally occurring, being formed through exposure to environmental antigens. The antibodies are usually IgM, complement activating, and reactive at or below room temperature. Although Lewis antibodies have been reported to cause HTRs, this does not usually occur for several reasons. First, although Lewis antibodies can activate complement, the process is relatively slow, thus allowing the inhibitors within the complement cascade to stop the process before the membrane attack complex is activated. Second, soluble antigen present in the plasma of the transfused blood product can neutralize the antibody, preventing subsequent binding of antibody to transfused red cells. Finally, within 24 to 48 hours of transfusion, the transfused red cells absorb Lewis antigens from the patient’s plasma, taking on the Lewis phenotype of the patient’s own red cells. This latter mechanism also prevents delayed transfusion reactions from occurring. Lewis antibodies may be clinically relevant if the antibody causes in vitro hemolysis during serologic laboratory testing. When these “in vitro hemolytic antibodies” are detected, they should be considered clinically relevant, and antigen-negative blood should be selected for transfusion. Lewis antibodies do not cause HDN because they are IgM and do not cross the placenta. Furthermore, Lewis antigens are poorly developed on fetal red cells.

Anti-Le\(^a\) antibody is more common than anti-Le\(^b\) antibody. Both anti-Le\(^a\) and anti-Le\(^b\) antibody are found in individuals with the Le(a-b-) phenotype. In contrast, individuals with the Le(a-b-) phenotype do not develop anti-Le\(^a\) because of the presence of residual Le\(^a\) antigen in the secretions.

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Diego blood group system consists of 22 antigens: Di\(^a\), Di\(^b\), Wr\(^a\), Wr\(^b\), Wd\(^a\), Rb\(^a\), WARR, ELO, Wu, Bp\(^a\), Mo\(^a\), Hg\(^a\), Vg\(^a\), Sw\(^a\), BOW, NFLD, In\(^a\), KREP, Tr\(^a\), Fr\(^a\), SW1, and DISK (Table 20.1).

**Gene and Antigens**

The Diego system antigens are carried on the band 3 protein. The antigens are encoded by the gene SLC4A1, which is found at chromosome 17q12-q21 (Table 20.1). SLC4A1 contains 20 exons and is distributed over 228 kbp. Band 3 is a multipass transmembrane protein that serves as an anion transporter. The Di\(^a\) antibody was initially found in the serum of a Venezuelan woman and was implicated in HDN. The principal phenotypes of the Diego blood group system and their frequencies are outlined in Table 20.8. The expression of the antigen Di\(^a\) is almost exclusively restricted to populations of Mongolian descent, such as American Indians, Chinese, and Japanese. An altered version of the band 3 protein is found in a condition known as Southeast Asian ovalocytosis. This condition may confer a degree of resistance to Plasmodium falciparum.
Antibodies and Clinical Significance

Anti-Di\(^a\) and anti-Di\(^b\) are usually IgG and are detected by the indirect antiglobulin test. HDN has been reported with both anti-Di\(^a\) and anti-Di\(^b\).\(^{313,114,115,116}\) and \(^{317}\) HTR is rare but has been reported.\(^{118}\)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Yt system consists of two antigens: Yt\(^a\) and Yt\(^b\) (Table 20.1). The system was named after Cartwright, the individual discovered producing the antibody. Because all of the other letters in the individual’s name were already being used, the last letter, T, was selected. The letter Y was placed first to denote “why not T?”.\(^{70}\)

Gene and Antigens

The ACHE gene is located at chromosome 7q22. It encodes for an acetylcholinesterase, which is a dimerized glycosyl phosphatidylinositol (GPI)-linked glycoprotein in the red blood cell membrane. Its function is unknown; however, the molecule is enzymatically active. Yt\(^a\) and Yt\(^b\) antigens result from a single amino acid substitution, which does not appear to affect the enzymatic activity of acetylcholinesterase.\(^{119}\) The antigens are antithetical. Yt\(^a\) occurs with a frequency of approximately 99%, and Yt\(^b\) has a frequency of approximately 8% (Table 20.8).\(^{120}\) Because they are carried on a GPI-linked protein, Yt antigens may be absent or reduced in individuals with paroxysmal nocturnal hemoglobinuria (see Chapter 31).

Xg Blood Group System (ISBT 012)

</tbody>
</table>

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Xg blood group system consists of two antigens: Xg\(^a\) and CD99 (Table 20.1). The Xg\(^a\) antigen was discovered in 1962 by Mann in the serum of a multiply transfused male. Because the antigen frequency appeared to differ between males and females, the antigen was named Xg\(^a\), as it appeared to be controlled by the X chromosome. The y in the name stands for Grand Rapids, the hometown of the patient.\(^{71}\)

Gene and Antigens

The gene encoding Xg\(^a\), XG, is found at Xp22.32. The gene is not subject to lyonization or X inactivation. The gene that encodes CD99, now also named CD99 (previously MIC2), is closely linked to XG. The Xg\(^a\) antigen is located on a sialoglycoprotein. The antigen is only weakly expressed on the red cells of infants. The Xg\(^a\) antigen is resistant to treatment by sialidase and dithiothreitol (DTT); however, it is sensitive to treatment with proteolytic enzymes. The principal phenotypes of the Xg blood group system and their frequencies are outlined in Table 20.8.

Antibodies and Clinical Significance
Anti-Xgα antibodies are usually IgG and may be able to activate complement. Anti-Xgα can be naturally occurring. Alloantibodies to CD99 have been detected in only two healthy individuals and are not thought to be clinically significant. There have been no documented cases of HTR or HDN with these antibodies.

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Scianna blood group system consists of seven antigens: Sc1, Sc2, Sc3, Rd, STAR, SCER, and SCAN (Table 20.1).

Gene and Antigens

The gene for this system, ERMAP, is located on chromosome 1p34 and is linked to Rh. ERMAP encodes a glycoprotein (erythroid membrane-associated protein), the function of which is not known. However, based on its structure, ERMAP is known to be a member of the butyrophilin-like family of the immunoglobulin superfamily. The Sc1 antigen is a high-frequency antigen, with the incidence in most populations being close to 99.9% (Table 20.8). Sc2 is antithetical to Sc1 and is present in approximately 1% of the population. The antigens are resistant to treatment of red cells with proteolytic enzymes such as papain, ficin, trypsin, α-chymotrypsin, and sialidase.

Antibodies and Clinical Significance

The Scianna antibodies are usually IgG. Scianna antibodies can activate complement and have been reported to cause mild HDN. The antibodies have not been associated with severe HTR.

Dombrock Blood Group System (ISBT 014)

The Dombrock blood group system consists of eight antigens: Doa, DOb, Gyα, Hy, Joα, DOYA, DOMR, and DOLG (Table 20.1).

Gene and Antigens

The gene for the Dombrock blood group system, ART4 (or DO), is found at chromosome 12q13.2-q13.3. The antigens in the Dombrock system have been demonstrated to be carried on a GPI-linked glycoprotein. Homology studies suggest that the Dombrock glycoprotein is a member of the adenosine 5'-diphosphate ribosyltransferase ectoenzyme gene family and has been identified as ADP-ribosyltransferase 4 (ART4). However, the function of this molecule is uncertain, as no enzymatic activity has been demonstrated on the red cells and no pathology has been associated with absence of this glycoprotein. The antigens Doa and DOb are antithetical. The frequencies of the three main phenotypes defined by these antigens are listed in Table 20.8. The antigens Gyα, Hy, and Joα are high-incidence antigens, with gene frequencies of >99% in all populations.
The antigens are resistant to papain or ficin treatment but sensitive to trypsin, pronase, or DTT (200 mmol/L) treatment.

**Antibodies and Clinical Significance**

The Dombrock antibodies are usually IgG and do not activate complement. They have not been associated with clinical HDN, but the antibodies have been associated with severe HTR. A baby born to a mother with an anti-DOMR antibody required phototherapy for hyperbilirubinemia.

**Colton Blood Group System (ISBT 015)**

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Colton blood group system was discovered in 1967. It consists of three antigens: Co\(^a\), Co\(^b\), and Co3 (Table 20.1).

**Gene and Antigens**

The Colton blood group antigens are encoded by a gene located at 7p14. The gene, AQP1 (CO), contains four exons distributed over 2.2 kbp. The gene encodes a glycoprotein called the channelforming integral protein-1 (CHIP-1) or aquaporin 1 (AQP1). AQP1 functions as a water transport channel. The antigen is strongly expressed in the proximal tubules and cortical collecting ducts of the kidney and is responsible for 80% of water reabsorption in the kidney. In red cells, AQP1 is responsible for osmotic water permeability. Most individuals with the null phenotype, Co(a–b–), have red cells with markedly reduced osmotic water permeability but no obvious phenotype abnormality and are apparently healthy; however, a Colton-deficient individual with congenital dyserythropoietic anemia has been described. Also, Colton-deficient individuals have been demonstrated to develop an inability to concentrate urine after water deprivation. The principal phenotypes of the Colton blood group system and their frequencies are outlined in Table 20.8.

**Antibodies and Clinical Significance**

Antibodies against the Colton blood group antigens are usually IgG and may activate complement. These antibodies are clinically significant and have been implicated in acute and delayed transfusion reactions.

**Landsteiner-Wiener Blood Group System (ISBT 016)**

<table>

</tbody>
</table>

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Landsteiner-Wiener blood group system consists of three antigens: LW\(^a\), LW\(^ab\), and LW\(^b\) (Table 20.1).

**Genes and Antigens**

The gene encoding the Landsteiner-Wiener blood group system antigens, ICAM-4, is found at chromosome 19p13.2-cen. The ICAM-4 gene contains three exons distributed over 2.6 kbp. It encodes the LW glycoprotein, also known as intracellular adhesion molecule 4 (ICAM4). The LW glycoprotein is associated with the Rh proteins in the red blood cell membrane as part of a multiprotein macromolecular complex. The LW glycoprotein is an intercellular adhesion molecule and has been demonstrated to bind to CD11/CD18 integrins located on leukocytes. It is hypothesized that its
function may involve being a marker for lymphocyte maturation and differentiation.\textsuperscript{70} LW\textsubscript{null} red cells appear to have normal morphology and survival.\textsuperscript{149}

The frequencies of the Landsteiner-Wiener blood group system phenotypes are outlined in Table 20.5. LW\textsuperscript{a} is the most commonly expressed antigen, found in more than 99% of whites. The expression of LW antigens is influenced by the expression of the Rh blood group system D antigen. Individuals who are D antigen-positive have increased expression of LW antigens compared to those individuals who are D antigen-negative.\textsuperscript{151}

Antibodies and Clinical Significance

Antibodies to the LW antigens are usually IgG but are occasionally IgM. The antibodies have been associated with mild HDN and HTR. Production of LW autoantibodies may occur in conditions associated with transient loss of LW antigens. Conditions associated with loss of LW antigens include pregnancy, Hodgkin disease, lymphoma, leukemia, sarcoidosis, and solid malignancies.\textsuperscript{70,112}

Chido/Rodgers Blood Group System (ISBT 017)

</tbody>
</table>

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Chido and Rodgers system consists of nine antigens: Ch1 to 6, Rg1, Rg2, and WH (Table 20.1). The Chido antigen was initially described by Harris et al.\textsuperscript{152} The antigen was described as “nebulous” because the antigen strength was variable. The Chido and Rodgers system is not composed of true red cell antigens, as they are not actually located on intrinsic structures of the red cell. Instead, they are on the fourth component of the complement system (C4), which becomes bound to red cells. However, the antigens are detected on the surface of red cells by conventional methods and were therefore initially considered to be red cell antigens and were included in the ISBT terminology as the 17th system (ISBT 017).

Genes and Antigens

The genetic loci of the Rodgers and Chido antigens are closely linked and are located on chromosome 6p21.3 in genes closely linked to major histocompatibility complex (MHC) II. Both genes encode complement components. The C4B (CH) gene contains 41 exons and encodes for C4b.\textsuperscript{45} The C4A (RG) gene contains 41 exons distributed over 21 kbp and encodes for C4a.\textsuperscript{45} The Chido antigen is located on the C4d fragment of C4b.\textsuperscript{153,154} and\textsuperscript{155} The expression of the antigen is variable, as it is determined by the concentration of plasma complement, which is genetically determined.\textsuperscript{156} The Rodgers antigen is located on the C4a component of complement.\textsuperscript{153,155} The principal phenotypes of the Chido/Rodgers blood group system and their frequencies are outlined in Table 20.8. Ch1 to 6 and Rg1 and Rg2 have frequencies >90%, whereas WH has a frequency of approximately 15%. The antigens are sensitive to treatment with proteases and resistant to treatment with sialidase, DTT, and acid.

Inherited low levels of C4 have been demonstrated to be associated with various autoimmune disorders, including autoimmune chronic active hepatitis.\textsuperscript{157,158} Individuals who are Ch-(lack C4b) have an increased risk of bacterial meningitis. Individuals who are Rg- (lack C4a) have an increased risk of systemic lupus erythematosus.\textsuperscript{158,159}

Antibodies and Clinical Significance

Antibodies in the Chido/Rodgers system are usually IgG and do not activate complement. They are not clinically significant. Antibodies to these antigens are typically found in individuals who have been transfused. They generally do not cause HTR but may result in anaphylactic reactions if large volumes of plasma are transfused.\textsuperscript{160,161} These antibodies have not been implicated in HDN.

Kx Blood Group System (ISBT 019)

</tr>
</tbody>
</table>

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Kx blood group system consists of one antigen: Kx (Table 20.1).

#### Genes and Antigens

The Kx antigen is carried on the XK protein, which is encoded by the XK gene. The XK gene is located on the short arm of the X chromosome (Xp21.1). The structure of XK resembles a glutamate transporter; however, its actual cellular function has not yet been determined.²⁸ In the red blood cell membrane, the XK protein is found in a complex with the Kell glycoprotein. The two proteins are covalently linked by a disulfide bond.²⁹ It is thought that the expression of the XK protein is required for the normal expression of the Kell antigens on red cells.

The XK protein has the structure of a membrane transporter protein; however, its function is not known.³⁰ Patients with absent XK, due to gene deletions or mutations, are said to have the McLeod syndrome. The McLeod phenotype is inherited in an X-linked pattern, unlike the KEL gene, which has an autosomal mode of inheritance.³⁰ The McLeod syndrome is a condition occurring in males characterized by decreased expression of the Kell blood group system antigens, acanthocytes, hemolytic anemia, and elevated serum creatinine kinase.¹ Associated symptoms include muscle wasting, decreased deep tendon reflexes, choreiform movements, and cardiomyopathy.³⁶ The McLeod phenotype may also occur in patients with X-linked chronic granulomatous disease. X-linked chronic granulomatous disease has been demonstrated to occur because of deletion of or mutations in the CYBB gene, which is also located on the X chromosome at a location discrete from that of the KEL locus. The association between the two disorders is due to deletions of parts of the X chromosome that include both genes.³⁶ Other X-linked conditions that have been associated with the McLeod phenotype include retinitis pigmentosa and Duchenne muscular dystrophy.³⁶

#### Antibodies and Clinical Significance

Patients who lack the Kx antigen form alloantibodies if they are transfused with antigen-positive blood. Patients with the McLeod phenotype who have been transfused have been reported to form anti-Kx.³⁴ It is suggested that these patients receive Kx-negative blood, but there are no reports of the antibody causing HDN or HTR. Furthermore, some patients without clinical or hematologic features of the McLeod syndrome have been demonstrated to form an IgG autoantibody with Kx specificity.³⁵ The autoantibody does not appear to cause hemolysis.

<td>Rare</td>
<td>IgG</td>
<td>HDN: Rare, HTR: Very common (&gt;99%)</td>
</tr>
</tbody>
</table>

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Gerbich blood group system was discovered in 1960 and is named for a patient who lacked the antigen, Mrs. Gerbich.⁷⁰

#### Gene and Antigens

The Gerbich blood group system contains 11 antigens: Ge2, Ge3, Ge4, GEPL, GEAT, and GET1 which occur at high frequencies, and Wb, Ls², An², Dh², and GEIS, which occur at low frequencies (Table 20.1). The principal phenotypes of the Gerbich blood group system and their frequencies are outlined in Table 20.8. The antigens are encoded by the GYPC gene...
on chromosome 2 (2q14-q21). The gene contains four exons distributed over 13.5 kbp. The antigens are carried on glycophorin C or glycophorin D, or both. The functions of glycophorin C and glycophorin D are thought to involve the structural integrity of the red cell membrane, as the glycoproteins are involved in linking the red cell membrane and the membrane skeleton. This is supported by the fact that red cells deficient in the Gerbich antigens, called the Leach phenotype, are elliptocytes. Glycophorin C can serve as a binding site for P. falciparum.

Antibodies and Clinical Significance

The antibodies against the Gerbich blood group system tend to be IgG. These antibodies have only rarely been reported to cause HDN or HTR.

Cromer Blood Group System (ISBT 021)

<table>
<thead>
<tr>

</tbody>
</table>

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Cromer blood group system was discovered in 1965 and named after Mrs. Cromer, the first patient found to produce the antibodies.

Genes and Antigens

The Cromer blood group system consists of 18 antigens: Cr<sup>a</sup>, Tc<sup>a</sup>, Tc<sup>b</sup>, Tc<sup>c</sup>, Dr<sup>a</sup>, Es<sup>a</sup>, IFC, WES<sup>a</sup>, WES<sup>b</sup>, UMC, GUTI, SERF, ZENA, CROV, CRAM, CROZ, CRUE, and CRAG. Most of the antigens are common, occurring with a prevalence of >90% in most populations. The S11 antigen occurs with a much greater prevalence in white populations (98%) than in black populations (60%). Kn<sup>b</sup> occurs at a low incidence.

Knops Blood Group System (ISBT 022)

<table>
<thead>
<tr>
<th>Antibody Specitivity</th>
<th>Clinically Significant</th>
<th>Antibody Class</th>
<th>Frequency of Antigen-Negative Blood</th>
</tr>
</thead>
<tbody>
<tr>
<td>Kn&lt;sup&gt;a&lt;/sup&gt;</td>

<td>No</td>
<td>IgG</td>
<td>No, No Very common (&gt;99.9%)</td>
</tr>
</tbody>
</table>

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Knops blood group system was established in 1991. It is named after Mrs. Knops, the first antibody producer.

Genes and Antigens

The Knops system consists of eight antigens and one provisional antigen: Kn<sup>a</sup>, Kn<sup>b</sup>, McC<sup>a</sup>, S11, Yk<sup>a</sup>, McC<sup>b</sup>, S12, and KCAM. S13 is a provisional antigen (Table 20.1). Most of the antigens are common, occurring with a prevalence of >90% in most populations (Table 20.8). The S11 antigen occurs with a much greater prevalence in white populations (98%) than in black populations (60%). Kn<sup>b</sup> occurs at a low incidence.
The antigens in the Knops blood group system are encoded by the CR1 (KN) gene found at chromosome 1q32. The antigens are found on a glycoprotein called complement receptor 1 (CR1) that is also known as CD35. The gene is located within the regulation of the complement activation cluster. CR1 is a member of the complement control family. It inhibits both the classic and alternate pathways of complement activation by cleavage of C4b and C3b, thus protecting the red cells from hemolysis. It is hypothesized that low levels of CR1 on red cells may increase deposition of immune complexes on blood vessel walls, resulting in damage to the blood vessels. Some antigens in the Knops blood group system may act as a binding site for *P. falciparum*.

**Antibodies and Clinical Significance**

Antibodies in the Knops blood group system are usually IgG and do not bind complement. They have not been implicated in HDN or HTR.

P.528

Indian Blood Group System (ISBT 023)

<table>

</tbody>
</table>

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Indian blood group was so named because 4% of Indians from Bombay express the antigen.

**Genes and Antigens**

The Indian blood group system consists of four antigens: In^a^, In^b^, INFI, and INJA (Table 20.1). The antigens of the Indian blood group system are encoded by the CD44 gene located at chromosome 11p13. The gene contains at least 19 exons and is distributed over 50 kbp. CD44 is thought to be the major human hyaluron receptor and also may bind fibrinogen, laminin, collagen, and osteopontin. The interaction between CD44 and hyaluron is likely required for the adhesion of lymphoid and erythroid cells to the bone marrow stroma during lymphopoiesis and erythropoiesis. A patient with a novel form of congenital dyserythropoietic anemia and CD44 deficiency was noted to have the In(a-b-) phenotype. The principal phenotypes of the Indian blood group system and their frequencies are outlined in Table 20.8.

**Antibodies and Clinical Significance**

Antibodies in the Indian system are usually IgG and do not activate complement. These antibodies have not been associated with HDN, but anti-In^b^ has been implicated in one immediate HTR.

Ok Blood Group System (ISBT 024)

<table>

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Ok blood group system consists of one antigen: Ok^a^, OKGV, and OKVM (Table 20.1). Antibodies against the Ok^a^ antigen were initially identified in 1979 in the serum of a Japanese woman, Mrs. Okbutso.

**Genes and Antigens**

The Ok^a^ antigen is encoded by the BSG (OK) gene, which is located at 19p13.3. The BSG gene contains seven exons distributed over 1.8 kbp. The gene encodes for basigin or CD147, an extracellular matrix metalloproteinase inducer. Basigin has been shown to induce the production of matrix metalloproteinase in fibroblasts and in tumor cells. It plays a role in tumor angiogenesis as it induces expression of vascular endothelial growth factor and hyaluronan.
it regulates lymphocyte responsiveness, monocarboxylate transporter expression and spermatogenesis. It also functions as a signaling receptor for the cyclophilin family of proteins. The Ok\(^3\) antigen is resistant to treatment with proteases, sialidase, DTT, and acid.

Antibodies and Clinical Significance

Antibodies in the initial patient with anti-Ok\(^3\) were IgG and did not activate complement. Anti-Ok\(^3\) has not been associated with HTR or HDN, but it has been demonstrated to cause decreased red cell survival.

**RAPH Blood Group System (ISBT 025)**

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The RAPH blood group system consists of one antigen: MER2 (Table 20.1). The system is named after the first patient known to have antibodies against the antigen. The MER2 antigen was given system status in 1999.

**Genes and Antigens**

The gene, CD151 (RAPH), is found on chromosome 11p15.5 and it encodes for the CD151 protein. Although the exact function of CD151 is unknown, anti-MER2 was found in three individuals. All individuals had renal failure and two had sensorineural deafness and pretibial epidermolysis bullosa. This suggests that CD151 is likely essential for the assembly of the kidney basement membrane, is a component of the inner ear, and has some functional significance in the skin. Ninety-two percent of English blood donors are positive for MER2 (Table 20.8).

**Antibodies and Clinical Significance**

Antibodies against MER2 are IgG. They have not been documented to cause HDN but there is a case report of an anti-MER2 possibly associated with HTR.

**John Milton Hagen Blood Group System (ISBT 026)**

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The John Milton Hagen blood group system consists of six antigens: JMH, JMHK, JMHL, JMHG, JMHM, and JMHQ (Table 20.1). It was recognized as a system by the ISBT Working Party in July 2000.

**Genes and Antigens**

The JMH antigen is encoded by SEMA7A, which is located on chromosome 15q22.3-q23. The gene product is semaphoring 7A. The function of semaphoring 7A is unknown.

**Antibodies and Clinical Significance**

Antibodies against JMH are usually autoimmune and do not tend to be clinically significant. Individuals producing alloanti-JMH have been reported. The antibodies tend to be IgG. They have not been documented to cause HDN or HTR.

**I Blood Group System (ISBT 027)**

**SUMMARY OF IMPORTANT CHARACTERISTICS OF I ANTIBODIES (INCLUDING I COLLECTION)**

<table>
<thead>
<tr>
<th>Antibody Specificity</th>

</table>

P.529
Specificity | Significant | Class | (White Population)
--- | --- | --- | ---
I | Seldom | IgM | No No Very uncommon (adults)
i | Seldom | IgM | No No Very common (adults)

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The I blood group system consists of one antigen: I (Table 20.1). This antigen was previously classified in the Ii Collection but was recognized as a blood group system in 2004.6 The i antigen, the precursor of the I antigen, provisionally remains within the Ii Collection of antigens (ISBT 207).

Genes and Antigens

The I antigen is located on the same carbohydrate chains on which the ABH antigens are located (Fig. 20.3). The enzyme responsible for the conversion of i-active straight chains to I-active branched chains is N-acetylglucosaminyltransferase A and is encoded by GCNT2 on chromosome 6p24.2.

Antibodies and Clinical Significance

The anti-I antibody is found as an IgM autoantibody in most normal individuals. The antibody is generally reactive at low temperatures and is not clinically significant. Anti-I cold agglutinins increase in titer after infection with Mycoplasma pneumoniae and tend to be polyclonal in nature.186 Monoclonal anti-I autoantibodies are found in high titers in cold hemolytic agglutinin disease. These antibodies are clinically significant and cause hemolysis. Anti-I alloantibodies are rare because the i phenotype is very uncommon. When they occur in adults with the i phenotype, they are clinically significant and can cause hemolysis.

Globoside Blood Group System (ISBT 028)

**SUMMARY OF IMPORTANT CHARACTERISTICS OF GLOBOSIDE ANTIBODIES**

HDN, hemolytic disease of the newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

The Globoside blood group system consists of one antigen: P (Table 20.1). This antigen was previously classified in the Globose Collection of antigens along with Pk and LKE. These antigens were initially considered to be part of the P blood group system and are related to the P1 antigen.

Genes and Antigens

The P antigen has been demonstrated to be on almost all human red blood cells.44 It is synthesized from globotriaosylceramide by the action of UDP-N-acetylgalactosaminyltransferase (P synthase) encoded by B3GALNT1 (B3GALT3) found at chromosome 3q25. The function of the P antigen is not known. It has been demonstrated to be a receptor for parvovirus B19 and individuals who lack this antigen have been demonstrated to be naturally resistant to parvovirus B19 infection.190,191

Antibodies and Clinical Significance

Autoantibodies against the P antigen are uncommon and may be idiopathic or secondary to other disorders such as syphilis and infections with various agents (e.g., measles, mumps, Epstein-Barr virus, cytomegalovirus, varicella-zoster virus, adenovirus, influenza A, M. pneumoniae, Haemophilus influenzae, and E. coli).192 Anti-P has been implicated in paroxysmal cold hemoglobinuria and is known as the Donath-Landsteiner antibody. This antibody is IgG and has biphasic activity in that it binds to red blood cells and fixes complement component C1 at low temperatures (0° to 4°C) and causes hemolysis at higher temperatures. Please see Chapter 31 for a more complete discussion of paroxysmal cold hemoglobinuria.

Gill Blood Group System (ISBT 029)

The Gill Blood group system consists of one antigen: Gil (Table 20.2).

**SUMMARY OF IMPORTANT CHARACTERISTICS OF GILL ANTIBODIES**
Genes and Antigens

The Gil antigen is located on the glycerol transporter aquaporin 3 encoded by the AQP3 gene found on chromosome 9p13.193 Aquaporin 3 functions as a water and glycerol channel.194

Antibodies and Clinical Significance

The Gil antigen is a high-frequency antigen. It has not been implicated in HDN but may have possibly been associated with one HTR.195

RhAG Blood Group System (ISBT 030)

The RhAG Blood group system is the newest blood group system. The RhAG blood group system consists of 4 antigens: two high-frequency antigens, Duclos and DSLK (Duclos-like), and 2 low-frequency antigens, OI4 and RHAG4 (Table 20.2). The antigens are encoded by the RHAG gene located at chromosome 6p12.3.

Genes and Antigens

RHAG is the ancestral gene from which RHCE and RHD arose.196 The RhAG protein consists of 409 amino acids. It associates with the Rh proteins and forms the Rh-core complex in the red cell membrane.197 As described earlier, the RhAG protein is important in that it must be present for the expression of the Rh antigens. This may occur because of mutations or deletions in RHAG or the Rh antigens. If the RhAG protein is not present, the red cells lack Rh antigens and are said to be Rhnull.196 The RhAG protein is also believed to contribute to the red cell membrane structure through its interactions with various proteins including band 3, glycophorin A and B, LW, and CD47.196,198 Further, it has been demonstrated to be an ammonia transporter.

Antibodies and Clinical Significance

There are no reports of alloantibodies against the RhAg antigens.

Low-incidence Antigens (700 Series)

An antigen is considered to be a low-incidence antigen if (a) it occurs in <1% of a population tested; (b) it is not part of an existing blood group system or related closely enough to another antigen to merit collection status; and (c) it is serologically distinct from other low-incidence antigens. Furthermore, to allow identification of further examples, red cells containing the antigen and antibody must be available. Table 20.3 lists the 18 low-incidence antigens that comprise the 700 series of the ISBT terminology.

Typically, these antibodies arise as a result of no known stimulus. Occasionally, antibodies to these antigens may be discovered in mothers of neonates with HDN. Because of the low frequency of these antigens, initial screening against a standard red cell panel is negative; however, the serum is positive when tested against paternal cells. Family studies often detect other individuals with the antigen.

High-incidence Antigens (901 Series)

An antigen is considered to be a high-incidence antigen if it is found on >90% of individuals in populations tested. Antigens that are found in >99% of the population are termed public antigens. As noted previously, high-incidence antigens were initially included in the 900 series but are now contained in the 901 series. The 901 series currently contains six antigens (Table 20.4).

The significance of high-incidence antigens is that the rare individual lacking a high-incidence antigen may experience severe HTRs when transfused with antigen-positive blood. Because by definition the majority of the population expresses the antigen, it is very difficult to find compatible blood for such a patient.
Collections of Antigens

In the ISBT terminology, related sets of antigens (genetically, biochemically, or serologically) that cannot correctly be classified as systems, as they have not been shown to be genetically distinct from all existing systems, are designated as collections. Six collections are currently recognized: Cost, li, Er, GLOB, Le^a/Le^b, and Vel and MN/CHO (Table 20.2).

li Collection (ISBT 027)

The I antigen was described in 1956 by Weiner et al.\(^\text{199}\) The antigen was named I for individuality. In 2004, the I Blood Group System (ISBT 027) was created and now contains the I antigen. The i antigen provisionally remains within the li Collection of antigens.\(^6\,\text{200}\)

Genes and Antigens

The li antigens are synthesized on red blood cells and are located on the same carbohydrate chains on which the ABH antigens are located (Fig. 20.2). The I antigens are located below the ABH antigens. The antigens are synthesized by a regulated, stepwise addition of sugars by a series of glycosyltransferases.\(^202\) The i antigen consists of the disaccharides, galactose-N-acetyl-glucosamine, linked in a straight, nonbranched chain. The i antigen consists of the linear chains modified into branched chains.\(^201\) Adult red blood cells express predominantly the I antigen. Conversely, fetal cells predominantly express the i antigen with little or no I expression. However, during the first 18 months of life, the infant’s red cells gradually express more I and less i. Very rarely, adult red blood cells express predominantly the i antigen. The gene involved is most likely GCNT2 (IGnt), which is found on chromosome 6p24.2.\(^200\)

Antibodies and Clinical Significance

The anti-i autoantibody may commonly be found in individuals with lymphoproliferative disorders such as chronic lymphocytic leukemia, lymphoma, and Hodgkin disease. Patients with mononucleosis secondary to Epstein-Barr virus infection may have transient anti-i, which causes hemolysis.

GLOB Collection (ISBT 209)

The GLOB or globoside collection of antigens includes Pk and LKE antigens (Table 20.2). The antigens of the GLOB collection were initially considered to be part of the P blood group system, and they are related to the P1 antigen. Prior to 2004, this collection also included the P antigen.

PLATELET ANTIGENS

Alloantibodies directed against platelet surface antigens can cause isolated thrombocytopenia. The antibodies most commonly play a role in neonatal alloimmune thrombocytopenia (NAT) and posttransfusion purpura (PTP), but they also mediate the destruction of platelets in passive alloimmune thrombocytopenia (PAT), posttransfusion refractoriness (PTR), and transplantation-associated thrombocytopenia (TAT).\(^30\) Although the mechanisms of platelet clearance are understood in some disorders (e.g., NAT), the platelet-antibody interaction and resulting thrombocytopenia are less well understood in others (e.g., PTP). Limiting factors include the lack of appropriate investigational technology and the rarity of some of the disorders. Until recently, the identification of P.531

incompatible antigens relied on serologic methods that require well-characterized antisera. After the identification of the genetic basis for the major platelet alloantigens, a number of different genotyping techniques were developed. This advance has made it possible for more laboratories to perform platelet alloantigen investigations based on DNA methodology rather than relying on the requirements for sufficient platelets and appropriate typing antisera for serology-based phenotyping.

Immunization to platelet alloantigens can occur in normal individuals when exposed during pregnancy, transfusion, or transplantation to alloantigens they lack. Unlike red cell alloantibodies, it is uncommon for alloantibodies against platelets to form spontaneously.

Platelet Glycoprotein Polymorphisms

Alloantigens are expressed on platelet proteins, glycoproteins, and carbohydrates. Many of these proteins are found exclusively on platelets as complexes containing two or more different polypeptide chains and are termed platelet-specific proteins. Most of these platelet glycoproteins also function as cell receptors. These receptors play a major role in the interaction of platelets with the damaged vessel wall (adhesion) and with other platelets (aggregation).
On platelets, most alloantigens are caused by a structural change in a protein due to an alternate amino acid that is encoded by a polymorphism in the gene. Many of these polymorphisms arise from single base pair mutations within the gene. To date, all the polymorphisms on platelets have been diallelic, with only a single mutation recorded at each respective locus (Fig. 20.4).

Because of the tremendous variability in the human genome among individuals, a typical person can be heterozygous for 24,000 to 40,000 substitutions, each encoding a different amino acid. Thus, it is likely that there are many polymorphisms that encode variant forms of platelet proteins that have yet to be identified.

Nomenclature

Like red cells, the initial platelet alloantigens were described and characterized based on the binding of alloantibodies from immunized individuals to platelet proteins. Before the advent of glycoprotein-specific assays, the rate of identifying novel alloantigens was low, and the practice of identifying the antigen by the first few letters of the proband surname was sufficient. Alleles were noted with a superscript a or b and were assigned in the temporal order in which they were identified with serum from alloimmunized patients (e.g., Ko\(^a\) Ko\(^b\); Bak\(^a\) Bak\(^b\)). However, a rapid increase in the detection rate of new antigens also coincided with confusing reports when the same alloantigen was discovered more than once by different investigators and given more than one designation.

This prompted a reconsideration and standardization of the nomenclature in the form of the human platelet antigen (HPA) system. The system was based on organizing the antigens based on their recognition by specific alloantisera. HPA designations were assigned to antigens at a certain locus as they were reported chronologically in the literature. However, to establish consistency in the terminology, the high- and lowfrequency alleles were assigned a and b, respectively. Thus, the PL\(^a1\)/PL\(^a2\) antigens became HPA-1a/-1b, and the Bak\(^a\)/Bak\(^b\) antigens became HPA-3a/-3b. For a few loci, alloantibodies to the low-frequency antigen had been reported first, which resulted in the reversal of a/b allele assignments (e.g., HPA-2a/-2b = Ko\(^a\)/Ko\(^b\); HPA-5a/-5b = Br\(^a\)/Br\(^b\)). It was proposed that the Platelet Nomenclature Committee, a joint panel of the ISBT and the International Society of Thrombosis and Haemostasis, be charged with ensuring the orderly assignment of new HPA designations after confirmation of the alloantibody reactivity and specificity. A list of HPA assignments based on the 2002 platelet workshop describes 16 HPA systems and antigens (Table 20.9). Some alloantibodies have been reported that recognize only the low-frequency antigens at certain loci, mainly on gpIIa. Thus, their HPA designations are not considered at present to be true antigen systems, because there is, as yet, no evidence that the antithetical high-frequency polymorphism induces structural changes that would be immunogenic in an individual homozygous for the low-frequency allele. Only HPA-1 through HPA-5 and HPA-15 alloantigens constitute complete systems in which alloantibodies to both alleles have been reported.

The HPA system is useful when considering the alloimmune thrombocytopenias, especially for the simple identification of the relevant pathologic alloantibody and the zygosity of the patient for that allele. However, it should be noted that the HPA system is misleading from a genetic point of view. Many polymorphisms evolved at different loci on the PL\(^a1\) variant of the gpIIa gene. Thus, there are two HPA designations (i.e., HPA-1a and HPA-4a) for the single gpIIa gene encoding Leu33 and Arg143. Furthermore, Newman noted that if alloantibodies were found to all the high-frequency alleles on gpIIa, then the designations PL\(^a1\), Pen\(^a\), Mo\(^b\), Ca\(^b\), and Sr\(^b\) all would refer to the same molecular entity. However, although a description of the gene by its haplotype would be of benefit when considering the concept that combinations of polymorphisms could have different effects on protein function, at present, there is no nomenclature that can efficiently describe haplotypes.

Platelet-specific Alloantigens: Biochemistry and Genetics

Glycoprotein IIb/IIIa (aIIbβ3)

Glycoproteins IIb and IIIa form a heterodimer complex that is a member of the integrin family of integral membrane proteins, a superfAMILY of noncovalently associated α and β subunits involved in cell-cell and cell-vessel contact. Of these, gpllb/IIla, with 50,000 to 80,000 surface copies, is expressed most abundantly by far on platelets. Activated gpllb/IIla mediates platelet aggregation through binding to fibrinogen and VWF. A complex of the α and β subunits is required for expression of the gpllb and gpIIa subunits on the surface. A deficiency of gpllb/IIla results in Glanzmann thrombasthenia, an inherited bleeding disorder. The gene for gpIIa, located on chromosome 17, may be the most polymorphic of the human integrin subunits. Hence, a large number of platelet alloantigens, including HPA-1 (PL\(^a1\)), HPA-4 (Pen), HPA-6 (Ca/Tu), HPA-7 (Mo), HPA-8 (Sr), HPA-10 (La), HPA-11 (Gro), HPA-14 (Oe), and HPA-16 (Duv) determinants, are located on gpIIa. Polymorphisms of the gene on chromosome 17 encoding the α subunit, gpllb, are responsible for the HPA-3 (Bak) and HPA-9 (Max) alloantigens. Glycoprotein IIb is synthesized exclusively by megakaryocytes; thus,
gPllb/IIa is unique to platelets. However, the gPllla subunit also is expressed on endothelial cells in association with the subunit αv to form the vitronectin receptor, also expressed in low numbers on the platelet surface.

Glycoprotein Ia/IIa (α2β1)

The collagen receptor, gplla/Ila, is a member of the integrin family of cell surface receptors. These membrane glycoprotein heterodimers consist of noncovalently associated α and β subunits. Patients in whom deficiencies of gplla/Ila are reported demonstrate chronic mucocutaneous bleeding associated with prolonged bleeding times. Three or more alleles of the α2 gene regulate the level of expression of gplla/Ila on platelets. Quantitative binding of platelets to type I or III collagens correlates with the number of gplla/Ila molecules expressed on the platelet surface. Alloantibodies to the HPA-5 (Br/Zav) and HPA-13 (Sit) determinants are expressed on gplla.

P.532
FIGURE 20.4 Schematic representation of amino acid substitutions that determine human platelet antigens (HPAs). The relative locations of the various amino acid substitutions encoded by single nucleotide polymorphisms are indicated on the respective platelet glycoprotein (GP). One antigen (HPA-14bw) results from an in-frame deletion of three nucleotides on the HPA-1b allele of the β-IIIa (ITGB3) gene. Immunization to the alloantigens determined by the highly polymorphic gene for GPIIIa accounts for the majority of clinically significant alloimmune thrombocytopenias.

Glycoprotein CD109

CD109 is a monomeric 175-kD glycoprotein that is anchored to the platelet membrane by glycosylphosphatidylinositol (GPI). The precise function for the GPI-anchored protein is not known. However, the recent determination of the cDNA
sequence for CD109 indicates that it is a novel member of the α2M/C3, C4, C5 family of thioester-containing proteins and thus may mediate covalent cell-substrate and cell-cell interactions. Although CD109 expression has been reported to be activation dependent on platelets, this has not been established. It is possible that the protein is constitutively expressed on the resting platelet and undergoes structural changes after activation that expose epitopes for certain monoclonal antibodies. The HPA-15 (Gov) alloantigens are expressed on CD109.

phenotyping and genotyping. An Arg93Gln substitution on the Leu33 allele disrupted the formation of the HPA complex.

Heterogeneity in the binding of anti-HPA antibodies to platelets may be a consequence of a complex and disulfide-linked structure in the amino-terminal portion of gpIIa that imposes a three-dimensional structural constraint on the HPA-1a epitope was recently reported in 1 of 6,000 individuals tested for antigen status using alloimmune thrombocytopenic syndromes.

The HPA-1a/1b alloantigen system has been associated with all of the alloimmune thrombocytopenic syndromes and is the primary cause of NAT and PTP in whites. Alloimmunization to the HPA-1 antigens is important both for the frequency (>75%) and for the severity of thrombocytopenia, which often is greater for syndromes involving the gpIIb/IIIa complex.

A naturally occurring Leu33Val change resulting from a C to G change at position 175 on the ITGB3 gene was shown to affect the binding of some anti-PL antibodies. A second substitution, Leu to Arg at residue 40, of <3% of HPA-1b alleles, has no known clinical significance.

Alloimmunization to HPA-1a is associated with the immune response genes HLA-DRB3*0101 or -DQB1*0201.

Heterogeneity in the binding of anti-HPA-1a antibodies to platelets may be a consequence of a complex and disulfide-bonded structure in the amino-terminal portion of gpIIa that imposes a threedimensional structural constraint on the HPA-1a antigen. Further evidence for structural factors distant to the Leu33Pro substitution in the control over the expression of the HPA-1a epitope was recently reported in 1 of 6,000 individuals tested for antigen status using phenotyping and genotyping. An Arg93Gln substitution on the Leu33 allele disrupted the formation of the HPA-1a antigen.
phenotype in an individual who had been typed positive for PL\textsuperscript{A1} using genotyping.\textsuperscript{249} Alloantibodies to PL\textsuperscript{A1} inhibit clot retraction and platelet aggregation, possibly by blocking fibrinogen binding.\textsuperscript{236,251}

HPA, human platelet antigen; NAT, neonatal alloimmune thrombocytopenia; PAT, passive alloimmune thrombocytopenia; PTP, posttransfusion purpura; PTR, posttransfusion refractoriness; TAT, transplantation-associated thrombocytopenia.

The HPA-15a/15b (Gov\textsuperscript{a/b}) alloantigens have been associated with NAT, PTP, and PTR.\textsuperscript{224,226,253} Large studies on the frequency of the HPA-15 alloantibodies have recently been made possible by the adaptation of the monoclonal antibody immobilization of platelet antigens (MAIPA) technology to include monoclonal capture antibodies for CD109. These studies indicate that immunization to the HPA-15a/15b alloantigens is second only to the HPA-1a antigen, occurring as often as HPA-5a/5b antibodies.\textsuperscript{254} The HPA-15a/15b antigens are the result of a Ser (HPA-15a) to Tyr (HPA-15b) change at residue 703 encoded by a C to A substitution at position 2108 of CD109 cDNA.\textsuperscript{255} Large European studies indicate that the frequencies for the HPA-15a and -15b antigens are 0.59 and 0.41, respectively. The HPA-15a/15b alloantigens are unique because they can be removed from the platelet surface by the action of phospholipase on the membrane anchor.\textsuperscript{224}

HPA, human platelet antigen; NAT, neonatal alloimmune thrombocytopenia; PAT, passive alloimmune thrombocytopenia; PTP, posttransfusion purpura; PTR, posttransfusion refractoriness; TAT, transplantation-associated thrombocytopenia.

The HPA-2a/2b (Ko\textsuperscript{ab}) antigens have been associated with NAT and PTR and are expressed on gpIb\textsubscript{a}.\textsuperscript{259,260,261,262} and \textsuperscript{263} A Thr HPA-2a to Met HPA-2b change at residue 145 is encoded by a G to A substitution at position 524 of gpIb\textsubscript{a} (GP1BA) cDNA. The frequencies in the white population are 0.911 and 0.089 for HPA-2a and HPA-2b, respectively.\textsuperscript{261} Some evidence has been reported that shows anti-HPA-2 alloantibodies prevent ristocetin-induced agglutination;\textsuperscript{261} however, this has not been confirmed in other studies.\textsuperscript{264,265} The HPA-2 antigens may be in linkage disequilibrium with a variable number of tandem repeat (VNTR) polymorphism that is responsible for four different molecular weights for the gpIb\textsubscript{a} molecule. A tandem of 13 amino acids in the mucin-rich domain can be expressed with one to four repeats, thus encoding polypeptides of different lengths (VNTR-A, -B, -C, and -D alleles have 4, 3, 2, and 1 repeats, respectively).\textsuperscript{266} The HPA-2b allele may have originated on the VNTR-B allele, from which the VNTR-A allele was derived. Because \textless 1,000 base pairs separate the HPA-2 and VNTR loci, the rate of cross-over during meiosis would be low, and, in most populations, the HPA-2b antigen is expressed on the VNTR-A and -B alleles.\textsuperscript{260,267} However, there is evidence that crossover may have occurred.\textsuperscript{268}

<sup>a</sup> Anti-HPA-4 alloantibodies are important in the Asian population due to the higher frequency of the
The HPA-4a/4b (Pen\textsuperscript{a/b} /Yuk\textsuperscript{a/b}) alloantigens have been associated with NAT and PTP. An Arg (HPA-4a) to Gln (HPA-4b) change at residue 143 is encoded by a G to A substitution at position 525 of gpIIa (ITGB3) cDNA.\textsuperscript{269} Because the frequencies in the white population are >0.99 and <0.01 for HPA-4a and HPA-4b, respectively, this alloantigen system is of little consequence clinically in North America and Europe. However, HPA-4b is expressed in approximately 1% of Asians and contributes significantly to platelet alloimmunization. Anti-HPA-4a antibodies can inhibit platelet aggregation, consistent with the proximity of the epitope to the RGD-binding domain.\textsuperscript{250}

Low-frequency Antigens

It is now clear that immunization to low-frequency polymorphisms is more common than previously thought. These antigens have been identified following detection of antibody in the maternal serum that reacts only to determinants on the paternal platelets. In some cases the antigen has been found in a few other individuals in the general population. However, the vast majority of cases referred for NAT testing that test negative for antibodies to the common antigens cannot be explained by incompatibility for low-frequency alleles.\textsuperscript{270}

Other Platelet Antigens

The Nak\textsuperscript{a} antibody originally was reported in a multitransfused Japanese patient.\textsuperscript{272} The antibody bound to gpIV on approximately 90% of donor platelets. However, further studies demonstrated that individuals who formed the anti-Nak\textsuperscript{a} antibodies actually lacked gpIV on their platelets.\textsuperscript{273,274} The antibody bound to epitopes on gpIV that were not encoded by polymorphisms; thus, anti-Nak\textsuperscript{a} is more correctly called an isoantibody, similar to the anti-gpIIb/IIIa antibodies induced in transfused individuals who lack gpIIb/IIIa on their platelets (Glanzmann thrombasthenia).

The majority of these have been found as rare polymorphisms on paternal HPA immunization to HPA alloimmunization to HPA alloantibodies to HPA

Although more than 23 different platelet alloantigen systems have been described, most cases of NAT are caused by neonatal intracranial bleeding. Anemia and hyperbilirubinemia occur early during pregnancy. Hydrocephalus, porencephalic cysts, and epilepsy can complicate recovery from fetal and hematuria, and retinal bleeding in <10% of patients falling to <10 × 10^9/L within the first few days after birth, and may take several weeks to return to normal. Clinical findings include petechiae in 90%; gastrointestinal tract hemorrhage in 30%; and hemoptysis, hematura, and retinal bleeding in <10% of patients. Intracranial hemorrhage is found in 10% to 20% of neonates and can occur early during pregnancy. Hydrocephalus, porencephalic cysts, and epilepsy can complicate recovery from fetal and neonatal intracranial bleeding. Anemia and hyperbilirubinemia can occur from extravasation and resorption of blood.

Although more than 23 different platelet alloantigen systems have been described, most cases of NAT are caused by alloantibodies to HPA-1a (PL-α1, Zw^1), HPA-5b (Br^2, Zav^1), and HPA-15b (Gov^1). Recent evidence suggests that alloimmunization to HPA-15 antigens in NAT can occur more often than thought previously and can be as frequent as immunization to HPA-5 antigens. Other alloantigens implicated in NAT include HPA-1b, HPA-2b, HPA-3a, HPA-3b, HPA-4a, HPA-4b, HPA-5a, and HPA-15a. However, it is now clear that immunization to “private” alloantigens also can cause NAT. The majority of these have been found as rare polymorphisms on paternal β3 (ITGB3). The mother carries the common
form of the gene and becomes immunized to alloantigens expressed only on the fetal platelets and on those from the father and his immediate family (e.g., HPA-8bw). In some cases, a polymorphism has also been detected in a few unrelated individuals in the general population and is termed a low-frequency antigen (e.g., HPA-6bw). These rare alloantigens have been, to date, reported only in NAT, which requires only one exposure to paternal alloantigens during pregnancy. This is in contrast to the other classic alloimmune syndrome, PTP, which is associated with two temporally distinct exposures to the immunizing antigen. The PTP patient is usually immunized initially via pregnancy and is later re-exposed via transfusion. This requirement for two exposure events would exclude the rare platelet alloantigens from a role in PTP. However, it is possible that a selection bias could eventually increase the relative frequency of the rare antigens in the general population and allow for their participation in PTP and other transfusion and transplantation-mediated alloimmune disorders. In theory, directed donations of blood, organs, or bone marrow to family members could cause alloimmunization involving a rare alloantigen. It is now apparent that the low-frequency alloantigen HPA-9bw (Max³) may be implicated more frequently in some cases of severe thrombocytopenia and intracranial hemorrhage than was previously suggested. Two recent reports indicate that immunization to HPA-9bw is not uncommon and can account for up to 2% of confirmed cases of NAT.²⁸⁸,²⁸⁹

In large studies, antibodies to HPA-1a are found in the majority (78%) of serologically confirmed cases of NAT, with antibodies to HPA-5a and -5b and HPA-15a and -15b antigens identified in approximately 20%. All other specificities account for the remaining small percentage of alloantibodies found. However, up to 60% of clinically identified cases of NAT lack serologic evidence of antiplatelet alloantibodies.²⁴⁰ In some cases, a portion of clinically identified NAT may be reported “antibody-negative,” possibly due to a lack of assay sensitivity or specificity. The first report of platelet alloantibodies in 1969 was followed by almost 20 years in which only three additional alloantibody specificities were detected using then-current methodology, including the platelet suspension immunofluorescence test and direct binding enzyme immunoassays. When the use of glycoprotein-specific assays for antiplatelet antibody studies became established, the rate of detection of new alloantibodies and antigens increased significantly.³⁶ By measuring the binding of maternal IgG to specific platelet glycoproteins, the MAIPA and radioimmunoprecipitation assays are able to detect specific antiplatelet alloantibodies binding to proteins expressed in low numbers on the platelet surface (e.g., lalla) and discriminate this from background binding of IgG to non-platelet-specific epitopes (e.g., anti-HLA). Although the sensitive and specific MAIPA assay is used widely in reference laboratories to screen for alloantibodies, it too is limited by the requirement for specific monoclonal antibodies to various platelet glycoproteins to detect antiplatelet antibodies. Thus, some clinical NAT cases may not be corroborated with a positive laboratory test for alloantibodies because the maternal immunization is directed against epitopes on platelet proteins to which monoclonal antibodies are unavailable. This was demonstrated by the report of alloimmunization to epitopes on a novel platelet protein, CD109. Although no alloantibodies were detected using the routine MAIPA assay with capture monoclonal antibodies to glycoproteins 1a/lila, 1b/IX, and llib/lila, anti-Gov⁷/b (HPA-15a/15b) reactivity was readily identified using radioimmunoprecipitation. Until monoclonal antibodies to CD109 are used routinely in the MAIPA, the radioimmunoprecipitation assay may be used to detect HPA-15 alloantibodies. The enhanced sensitivity imparted by radiolabeling the majority of platelet proteins, including those expressed in low numbers on the platelet surface, has established the radioimmunoprecipitation assay as a universal screening method for platelet alloantibodies in NAT.

NAT is estimated to occur in 1 in 1,000 to 2,500 births. The alloantibodies most often involved are directed against HPA-1a. Because the HPA-1b/1b (PL₄¹-negative) phenotype is found in approximately 2% of the North American population, the theoretical risk for NAT in newborns is approximately 1 in 50 births, which is much higher than observed cases. Although it is possible that limitations in recognition and technical issues in testing for alloantibodies might play a role in the underdiagnosis of some cases of NAT, the lower-than-expected responsiveness to the HPA-1a antigen in susceptible women demonstrates that additional factors play a role in alloimmunization.²⁹⁰ Maternal immunization to HPA-1a shows an HLA restriction, wherein HPA-1b/1b women who produce alloantibodies are almost exclusively HLA-DRB3*0101 or -DQB1*0201. The risk factor in the case of -DQB1*0201 is 141, similar to that for the HLA-B27 restriction in the autoimmune disease ankylosing spondylitis.²⁹¹ In one case of NAT, T cells were shown to play a role in the HLA restriction. Peptides that contain the same Leu33 polymorphism that is recognized by anti-HPA-1a antibodies were able to stimulate T cells sharing CDR3 motifs.²⁹² However, alloimmunization to the HPA-1b (PL₄₂) antigen is not associated with a specific HLA type and has a much lower incidence in NAT.²⁹³,²⁹⁴ This may explain the observation that although phenotype frequencies for HPA-1a and HPA-1b predict that anti-HPA-1b should be observed six times more frequently than anti-HPA-1a, alloimmunization to HPA-1a accounts for far more cases of NAT than anti-HPA-1b.³⁰ In a large study of clinically suspected
NAT, alloantibodies to HPA-1a were found more frequently by a ratio >100:1 when compared with anti-HPA-1b. Another risk factor may involve blood group antigens. In one report, severe NAT due to HPA-1a immunization was associated with maternal ABO genotypes, with group A mothers having a higher risk of giving birth to children with severe thrombocytopenia, possibly due to genetic linkage. Immunization to the HPA-5a/5b alloantigens also has been associated with specific class II genes. However, unlike the reversed relative risk versus the expected rates of immunization reported for the HPA-1a/1b system, the theoretical ratio of alloimmunization against HPA-5a versus HPA-5b is similar to the observed ratio.

The differences in the rate of immunization to platelet alloantigens also vary between different racial or ethnic populations. The distribution and frequency of platelet alloantigen genes in the worldwide population is a major factor in determining which alloantigens are most important in the investigation of NAT in different countries (Table 20.11). Although studies have shown that the HPA-1a antigen accounts for the majority of NAT cases in the white population, it has rarely been shown to play a role in the Japanese. This may be explained by the lower frequency for HPA-1b in the Japanese population compared with whites (0.02 vs. 0.15). Without accounting for differences in the frequency of immune response genes, alloimmunization to HPA-1a should be at least 50 times less in the Japanese population. Antibodies to HPA-4a/4b are most frequently reported in Japanese cases of alloimmunization. This may be related directly to the higher frequency for HPA-4b in the Japanese population compared with whites (0.0083 vs. <0.001), which would increase the number of individuals homozygous for the rare allele who would then be at risk for alloimmunization to HPA-4a.

Immunization to platelet nonspecific alloantigens such as ABO and HLA is more likely to play a role in transfusion- and transplantation-associated thrombocytopenia rather than NAT. As these antibodies pass from the mother into the fetal circulation, they are likely to be targeted to the larger population of HLA- and ABO-bearing cells rather than to platelets. In cases in which only ABO or HLA antibodies are observed in NAT, it is possible that platelet-specific alloantibodies are present but go undetected due to the technical limitations of current assays.

Diagnostic tests for NAT should be designed to determine the maternal and paternal platelet alloantigen haplotypes to assess the presence of antigen incompatibilities. Genotyping should be used to determine the alloantigen status because few laboratories have adequate typing sera available to perform immunophenotyping for all the relevant alloantigens. Because genotyping uses very little sample, it also allows for the determination of fetal platelet antigens directly, rather than inferring them from the paternal platelet typing. To detect platelet-specific alloantibodies in maternal serum, a specific and sensitive assay should be used that can discriminate the presence of coexisting platelet nonspecific antibodies (e.g., anti-HLA). Due to the possibility of maternal alloimmunization to relatively low-frequency alloantigens, including HPA-5b, it is preferable to test for antiplatelet antibodies using the father’s platelets as a target. Although it is important to assess the risk for NAT in future pregnancies, this can be complicated by the presence of both alleles in a heterozygous father. In such cases, the fetal platelet alloantigens can be determined by genotyping fetal amniocytes obtained between 16 and 20 weeks’ gestation. Although the presence of high-titer anti-HPA-1a is associated with severe neonatal thrombocytopenia when tested before 28 weeks’ gestation, fetal/neonatal morbidity and severe thrombocytopenia have been observed when no antiplatelet antibody can be detected. Therapy with intravenous γ-globulin also can reduce
antibody levels in women who still deliver severely affected children, making it difficult to predict severity of thrombocytopenia based on antibody titer. ²⁹⁹

Posttransfusion Purpura

PTP typically presents as severe thrombocytopenia resulting within 7 to 10 days after an immunogenic blood transfusion. It usually affects elderly women who have been sensitized to the platelet alloantigen during a previous pregnancy. ³⁰,³⁰⁰ Because prior transfusion also has been reported as the initial immunizing event, occasionally males can develop PTP. As in NAT, the most common alloantibody implicated in PTP is directed against

P.538

HPA-1a and follows transfusion of antigen-positive blood to HPA-1b/1b/HLA-DR3-positive individuals. The frequency of PTP has decreased significantly in recent years, likely as a result of routine pre-storage leukoreduction in certain countries. ³⁰¹

Thrombocytopenia can result from the transfusion of any blood product—not only platelets—and is most commonly seen after the infusion of packed red cells. Fever and chills are often observed during the transfusion; this is followed by petechiae and ecchymoses once thrombocytopenia develops. It is important to recognize this rare disorder because the severe thrombocytopenia can cause mucosal surface bleeding and subsequent anemia, with fatal intracranial hemorrhage observed in approximately 10% of patients. Therapy using high-dose intravenous γ-globulin has been shown to be effective and may be augmented with transfusion of antigen-negative platelets. Because PTP often presents in postoperative patients, the differential diagnosis of PTP includes other common thrombocytopenic syndromes such as heparin-induced thrombocytopenia and bacteremia. However, unlike PTP, these other disorders do not commonly present with severe thrombocytopenia (<10 x 10⁹/L). In addition, heparin-induced thrombocytopenia is often associated with thrombotic complications rather than the overt bleeding that characterizes PTP.

The major challenge of PTP is to understand the mechanism underlying the destruction of autologous platelets that follows the exposure and sensitization to immunizing blood product. A number of theories have been proposed to explain the clearance of the antigen-negative (HPA-1b/1b) platelets in the presence of anti-HPA-1a antibodies. The mechanisms proposed include the adsorption of alloantigen-alloantibody immune complexes to receptors on recipient platelets with subsequent clearance mediated by complement or by the reticuloendothelial system (innocent bystander syndrome); the binding to autologous platelets of soluble or microparticle-associated alloantigen derived from the destruction of transfused blood product, thus making the recipient platelets a target for the alloantibodies; or, finally, the presence of pseudospecific alloantibodies that are produced in the early phase of the anamnestic response and can bind to determinants on autologous platelets, leading to their destruction. ³⁰,³⁰⁰ This is supported by evidence that anti-HPA-1a antibodies from patients with PTP not only have a higher titer than NAT, but also react to a broader, more complex epitope. ²⁴²

As in NAT, platelet typing and antiplatelet antibody testing are necessary to identify the pathogenic alloantibodies. However, because of the severe thrombocytopenia in the acute stages of PTP, genotyping is required to assess the risk for alloimmunization. Although anti-HPA-1a is most often implicated, PTP also is reported in association with alloimmunization to other platelet-specific antigens, including HPA-1b, HPA-3a/3b, HPA-4a, HPA-5a/5b, HPA-2b, and HPA-15b. Some of these antigens are distributed with relatively low frequencies in the population, and screening for antiplatelet antibodies should therefore use sensitive and specific assays and an informative panel of target platelets.

Passive Alloimmune Thrombocytopenia

The abrupt onset of thrombocytopenia within a few hours after transfusion of a blood product is a hallmark of PAT. Platelet-specific alloantibodies in the blood product (usually plasma) rapidly clear the recipient’s antigen-positive platelets. This syndrome manifests within hours of transfusion and has a shorter duration of thrombocytopenia than PTP, mediated by the amount and specificity of the transfused alloantibody. Testing for PAT has shown that it is difficult to measure alloantibody in the recipient’s plasma, suggesting that the transfused antibodies are limited and bind to the incompatible platelets soon after transfusion. However, the alloantibody can be detected in the donor plasma, and in one case, sensitization of recipient platelets by the transfused alloantibody in vivo was demonstrated using direct radioimmunoprecipitation to measure IgG bound to platelet gpIaIIa directly on the patient's platelets. ³⁰² Alloantibodies against the HPA-1a and HPA-5b antigens have been implicated in passive alloimmune thrombocytopenia. ³⁰,³⁰⁰ Severe thrombocytopenia is found in association with the transfusion of blood products containing alloantibodies to the HPA-1a antigen. The finding that even red blood cell concentrates can cause PAT due to anti-HPA-1a antibodies correlates with reports that as little as 10 ml of plasma containing alloantibodies can cause thrombocytopenia in transfused volunteers. ³⁰³
Because thrombocytopenia can occur in multiple transfusion recipients, it is important to investigate cases of suspect PAT to ensure that the alloimmunized blood donor does not donate blood in the future.\textsuperscript{304}

Transplantation-associated Alloimmune Thrombocytopenia

Alloimmune mechanisms can explain the rare syndrome of transplantation-associated alloimmune thrombocytopenia that can complicate transplantation either with a solid organ or with allogeneic bone marrow.\textsuperscript{30} Both anti-HPA-1a and anti-HPA-5b alloantibodies can cause thrombocytopenia that may develop very soon or sometimes longer after transplantation. In one case, a man with Ph1 chromosome-positive chronic myelogenous leukemia developed severe thrombocytopenia (17 × 10^9/L) 18 months after receiving an allogeneic bone marrow transplant from his HLA-matched sister.\textsuperscript{305} An immune mechanism was suggested by the repeated platelet count increase after treatment with high-dose intravenous \(\gamma\)-globulin and remission after splenectomy. Anti-HPA-1a antibodies were detected in Ig eluted from the patient's platelets. Although chromosome analysis of the patient's marrow demonstrated a normal Ph1-negative female karyotype, sensitive Southern blot analysis of splenic cell DNA identified a small amount (3%) of residual male cells. The patient's sister was HPA-1a positive, and another brother was HPA-1a negative. Although pretransplant platelet alloantigen studies were not done, it was deduced that the patient was likely HPA-1a negative (HPA-1b/1b) and that the thrombocytopenia was mediated by a host versus donor alloimmune thrombocytopenia in which the patient's residual lymphoid cells developed an anti-HPA-1a alloimmune response to HPA-1a-positive platelets derived from the engrafted bone marrow.

Alloimmune-mediated platelet destruction due to a bone marrow transplant recipient's pre-existing anti-HPA-5b antibodies was suggested by a rapid transient increase in platelet count from 43 to 108 × 10^9/L after administration of intravenous \(\gamma\)-globulins.\textsuperscript{306} The patient received the allogeneic marrow from her HLA-matched brother who typed positive for HPA-5b. The detection of a small amount (<5%) of group A blood cells in the recipient after transplantation with her brother's group O marrow indicated that a chimeric state existed in this patient. The thrombocytopenia eventually improved as the level of circulating antibody decreased.

Thrombocytopenia that may also have an alloimmune mechanism was reported in patients after autologous peripheral blood stem cell transplantation for metastatic breast carcinoma.\textsuperscript{307} Both patients had pre-existing anti-HPA-1a antibodies that rose in titer after transplantation. Because moderate to severe thrombocytopenia is expected soon after transplantation due to marrow ablative treatment, variable rate of engraftment of donor marrow-derived megakaryocyte precursors, and fever and other comorbid clinical factors, it is difficult to determine the pathogenic mechanism in these patients. Although the thrombocytopenia may have resulted from a refractory state caused by the rapid clearance of transfused platelets by alloantibodies, it is also possible that platelets derived from engrafted autologous marrow were destroyed in a PTP-like syndrome.

P.539

Solid organ transplants rarely can lead to alloimmune thrombocytopenia. Donor-derived immunocompetent lymphoid cells contained within the organs transplanted from a single donor to three recipients (two kidneys, one liver) are suspected to be the cause of severe thrombocytopenia (platelet count nadirs: 2, 2, and 12 \(\times\) 10^9/L) that developed within 5 to 8 days.\textsuperscript{308} The severe thrombocytopenia in the renal transplant patients was refractory to intravenous \(\gamma\)-globulins and platelet transfusions. One patient recovered after splenectomy 50 days after transplantation, and the other died due to multiorgan failure associated with bacteremia and severe thrombocytopenia. The thrombocytopenia resolved in the liver transplant recipient after receiving a new liver following rejection of the first transplant. Serum from the multiparous female organ donor was shown to contain anti-HPA-1a alloantibodies. Platelet typing and antibody studies of the transplant recipients showed that although they typed HPA-1a positive, anti-HPA-1a antibodies were detected in their posttransplant, but not pretransplant, sera. These observations suggest that anti-HPA-1a antibodies derived from transplanted immunocompetent lymphoid cells were responsible for the severe thrombocytopenia in these patients. A similar case of donor lymphocyte-induced thrombocytopenia was caused by a liver transplant obtained from a donor who died of bleeding related to severe autoimmune thrombocytopenia. Anti-\(\gamma\)\textsuperscript{IIb}/\(\alpha\)\textsuperscript{IIa} antibodies without allospecificity were detected in both the organ donor and the posttransplant recipient serum.\textsuperscript{309}

Platelet Transfusion Refractoriness

Nonimmune patient-dependent factors usually are involved when unexpectedly poor platelet count increments are observed after transfusion. Although ABO or HLA incompatibility and platelet storage can contribute to reduced platelet
count recovery, \textsuperscript{276,310,311} and \textsuperscript{312} more often septicemia, drugs, and increased platelet consumption in severely thrombocytopenic patients are responsible for platelet transfusion refractoriness.

Although there is only anecdotal evidence that platelet-specific alloantibodies can cause platelet transfusion refractoriness,\textsuperscript{263,313} some refractory patients do benefit from transfusion with platelets that are HLA and platelet alloantigen compatible.\textsuperscript{314} However, in a prospective study, platelet-specific alloantibodies accounted for, at most, 5% of the patients with platelet transfusion refractoriness.\textsuperscript{315} Depletion of leukocytes prior to storage of platelets for transfusion has reduced the incidence of platelet transfusion refractoriness.\textsuperscript{316}

Platelet Polymorphisms as Risk Factors for Cardiovascular Disease

There is increasing evidence that ischemic vascular disease may result from interactions between environmental factors (e.g., smoking), genetic susceptibility, and concurrent diseases (e.g., diabetes). There is good evidence to show that platelets can play a major role in the formation of an occlusive thrombus at the site of a ruptured atherosclerotic plaque.\textsuperscript{317} The rate of formation or the susceptibility for platelets to participate in thrombus formation may depend partly on factors that include certain polymorphisms on the platelet glycoproteins.

Measures of platelet reactivity using in vitro assays demonstrate heterogeneous results, indicating that there is a range of platelet reactivity among individuals. For example, some individuals' platelets may be considered hyperreactive based on the lower epinephrine dose threshold that induces platelet aggregation. The major platelet glycoproteins that function as receptors and mediate aggregation and adhesion can also differ antigenically and structurally between individuals. Recent evidence suggests that certain polymorphisms on glycoproteins IIb/IIIa, Ib/IX/V, and Ia may be associated with enhanced platelet function in vivo.

Platelet aggregation is mediated by gpIIb/IIIa, the major receptor for fibrinogen and VWF. GpIIb/IIIa is highly polymorphic, having four known alleles of the \( \alpha_\text{IIb} \) subunit and eight alleles of the \( \beta_3 \) subunit.\textsuperscript{318} The Leu33Pro alleles on \( \beta_3 \) are the most clinically important. The Leu33 allele encodes the HPA-1a alloantigen, which is highly immunogenic to some Pro33 (HPA-1b/1b) individuals. Although these alleles are distributed within the general white population with frequencies of 0.85 (HPA-1a) and 0.15 (HPA-1b), the frequency for HPA-1b was found to be almost four times higher among younger patients with myocardial infarction or unstable angina.\textsuperscript{319} Since that first report, other studies have not been able either to establish or to exclude HPA-1b as a risk factor for ischemic vascular disease.\textsuperscript{320}

However, in vitro studies indicate that gpIIb/IIIa-mediated functions such as aggregation, adhesion, spreading, and clot retraction demonstrate heterogeneity and that the HPA-1b phenotype was associated with a lower activity threshold.\textsuperscript{321,322} Interactions between platelet integrins and the extracellular matrix are important for cell migration, which is directly involved in restenosis after angioplasty. Recent studies using the HPA-1a or HPA-1b forms of gpIIa transfected into Chinese hamster ovary cells demonstrated enhanced migration activity when the HPA-1b form of the protein was a constituent of the integrin complex, as either \( \alpha_\text{IIb} \beta_3 \) or \( \alpha_\text{V} \beta_3 \).\textsuperscript{323} Further, a reduced affinity of the platelet function inhibitor abciximab for platelets with the HPA-1b phenotype suggested that patients with this allele may have a less favorable outcome to treatment after percutaneous coronary intervention.\textsuperscript{281} Recent reports suggest that postoperative patients on long-term mechanical circulatory support may be at higher risk for bleeding depending on their HPA-1 polymorphism.\textsuperscript{324,325} Other studies involving the Ile843Ser polymorphism responsible for the HPA-3 alloantigens on \( \alpha_\text{IIb} \) have not established an association with cardiovascular disease. Although small studies have reported a link with both the HPA-3a and HPA-3b antigens with either stroke or myocardial infarction, larger studies have not reported a similar association.\textsuperscript{326,327,328} and \textsuperscript{329} However, a recent report in a Chinese population demonstrated an increased incidence of the HPA-3bb genotype in younger patients (<60 years) with acute ischemic stroke.\textsuperscript{330}

Three dimorphisms of gpIbα have potential relevance in thrombotic risk. The Thr145Met alleles encode the HPA-2 alloantigens, which are in linkage disequilibrium with a VNTR polymorphism in the macroglycopeptide region of gpIbα. This results in a duplication of the 13-amino acid sequence one to four times (VNTR D to VNTR-A) and would result in an increasingly longer polypeptide. However, the few studies that report an association between any of the variable polymorphisms and the risk for coronary artery disease have not been supported in others.\textsuperscript{331,332} and \textsuperscript{333} An additional polymorphism in the Kozak region of the molecule may be important for regulating the efficiency of translation of gpIbα, thus affecting the number of receptors expressed.\textsuperscript{334,335} However, an association between this dimorphism and a risk for arterial thrombosis could not be demonstrated in subsequent studies.\textsuperscript{336,337} and \textsuperscript{338} One study from Australia did report an association between the Kozak polymorphism and ischemic stroke, suggesting that further studies may be warranted.\textsuperscript{339}

The level of expression of a major collagen receptor, gpIaIIa, can vary up to threefold depending on the inheritance of linked, allelic polymorphisms in the MMRN1 (αZ or gpIa) gene. The 807-T/C/G polymorphism segregates independently of the alleles encoding the HPA-5a/5b and HPA-13bw alloantigens. Although some studies suggested an association of the
807T allele (high receptor density) with myocardial infarction or stroke, other studies were unable to confirm this observation. However, in a large study of 2,237 male patients, an association between younger patients with the 807T allele and myocardial infarction was reported. Evidence of a functional effect of the HPA-5 alleles was described by Kunicki et al. The binding of platelets to decorin, but not collagen, was attenuated when the platelet donor expressed at least one of the low-frequency HPA-5b alleles. In addition, antibodies to HPA-5a were able to inhibit adhesion to decorin.

WHITE BLOOD CELL ANTIGENS

Antigens expressed on granulocytes, lymphocytes, and monocytes are traditionally known as self antigens. These include the human neutrophil antigens (HNAs) and HLA class I and II. Class I HLA antigens are present on every cell and tissue in the body, except for red cells, sperm, and some placental cells. Class II HLA antigens are expressed mainly on select cells of the immune system (e.g., T and B cells, macrophages, and monocytes). White cells also express some antigens that are shared with other cells, including red cells and platelets.

White cell antigens play a pivotal role in host defense, selfrecognition, and autoimmunity. White blood cell alloantigen sensitization is implicated in fetal neutropenia, febrile nonhemolytic transfusion reactions (FNHTRs), transfusion-associated acute lung injury (TRALI), graft rejection, and graft versus host disease (GVHD). Because of their high degree of polymorphism, these antigens are used as molecular “fingerprints” in forensic medicine, paternity testing, and anthropologic studies. Many white cell antigens are recognized by monoclonal antibodies, which identify proteins that are markers of differentiation, cell adhesion molecules, and various phagocytic, complement, and chemotactic receptors. These antibodies and antigens (discussed elsewhere; see Chapter 10) have been well characterized and are assigned to cluster designation (CD) antigens based on their patterns of reactivity.

In this section the major white blood cell antigens on granulocytes and lymphocytes are discussed and disease states associated with pathologic antibodies directed at these antigens are emphasized. Monocytes share some antigens with lymphocytes (including class I and II HLAs) and neutrophils (HNA-4a), but these cells are not discussed in detail.

Granulocyte Antigens

The HNA antigen system is specific to granulocytes. Granulocytes also express antigens that are shared with other tissues and cells including HLA class I and certain blood group antigens. The antigens on granulocytes were initially defined using human alloantiserum, most often through the diagnosis and investigation of infants with alloimmune neonatal neutropenia. HNA-1a and HNA-1b antigens are most often implicated in alloimmune neutropenia and the availability of monoclonal antibodies has facilitated the detailed characterization of these alloantigens. In addition to alloimmune neonatal neutropenia, alloimmunization to these granulocyte antigens has been implicated in the development of FNHTRs and TRALI. Sensitization occurs when an individual lacking these antigens is exposed through transfusion or pregnancy.

Nomenclature

In 1998, the Granulocyte Working Party of the ISBT introduced the HNA nomenclature for granulocyte antigens, which replaced the old N terminology. Unlike the HPA nomenclature system for platelet alloantigens, the neutrophil alloantigen nomenclature assigns different antigens on the same glycoprotein to the same HNA antigen system, with alleles distinguished by lowercase letters. For example, NA1, NA2, and SH antigens of the old terminology are polymorphisms of the same protein, the FcγRIIIb receptor (CD16b), encoded by FCGR3B gene, and thus are designated as HNA-1a, HNA-1b, and HNA-1c in the new terminology (HNA-1 = FcγRIIIb). Seven alloantigens have been assigned HNA designations on five glycoproteins (HNA-1 to HNA-5) (Table 20.12). The HNA nomenclature does not account for the different haplotypes possible for certain genes (e.g., FcγRIIIb). It works best for antigen systems with two alleles at a single locus, but like the HPA system for platelet alloantigens, the HNA system does not define the haplotypes that may result from crossover between alleles. Thus, although the majority of base substitutions at position 266 of FCGR3B (FcγRIIIb) encoding the HNA-1c antigen have been found on the HNA-Ib form of the gene, HNA-1c can also occur with variants of HNA-Ib. Modifications to the nomenclature may be required in the future to clarify these issues and to address the antigen system by its molecular characterization.

### TABLE 20.12 HUMAN NEUTROPHIL ALLOANTIGENS

<table>
<thead>
<tr>
<th>HNA System</th>
<th>Antigen</th>
<th>Original Designation</th>
<th>Glycoprotein</th>
</tr>
</thead>
</table>
The neutrophil HNA-2a alloantigen has been implicated in alloimmune neonatal neutropenia, FNHTRs, autoimmune neutropenia, and TRALI. It is expressed on CD177, a 58- to 64-kD GPI-anchored glycoprotein on neutrophils in 97% of whites. The function of HNA-2a glycoprotein is unclear but it is assumed to have a receptor role. It belongs to the Ly-6 gene family, which encodes proteins characterized by repeating cysteine-rich domains including the urokinase-type plasminogen activator, the reactive inhibitor of lysis receptor (CD59), and polycythemia rubra vera-1. The HNA-2a negative phenotype seems to be the result of intron fragments in the mature mRNA, which prevents expression of HNA-
2a on the cell surface and not due to a gene deficiency or deletion.\textsuperscript{369} This is supported by the observation that the sensitization of HNA-2a-negative individuals does not produce alloantibodies that react with HNA-2a itself, but rather with a different unrelated antigen.\textsuperscript{370} Unlike other neutrophil polymorphisms, the HNA-2a antigen is expressed only on a subpopulation of neutrophils and the proportion of neutrophils expressing HNA-2a has been reported to remain remarkably stable in an individual over time. HNA-2a has a higher level of expression in women compared with men.\textsuperscript{357,365,371}

HNA-3a (5b)

HNA-3a has been characterized as a 70- to 95-kD glycoprotein on neutrophils, but its presence on lymphocytes, platelets, endothelial, kidney, spleen, and placental cells has been indirectly assumed as a result of adsorption studies.\textsuperscript{366,372} Alloantibodies to HNA-3a are well-known granulocyte agglutinins and have been implicated in neonatal alloimmune neutropenia\textsuperscript{373} and TRALI.\textsuperscript{374,375} Indeed, alloantibodies directed against HNA-3a antigen have been frequently implicated in severe and fatal TRALI reactions.

The molecular nature and cellular distribution of HNA-3a has been recently elucidated.\textsuperscript{376,377} The polymorphism is encoded by an Arg154Gln substitution on choline transporter-like protein-2 (CTL2). Approximately half of HNA-3a-specific antibodies from patients with TRALI bind a cyclic peptide of arg154 CTL2, suggesting that tertiary structures distal to the antigen site may be important in the formation of the epitope.\textsuperscript{378} Approximately 5% of the population is homozygous for HNA-3b and would be at risk for alloimmunization to HNA-3a. The immunogenicity of the HNA-3b antigen is much lower than HNA-3a.\textsuperscript{379}

HNA-4a (Mart) and HNA-5a (Ond)

HNA-4a and HNA-5a are high-frequency antigens localized on leukocyte adhesion molecules on granulocytes and nongranulocytic leukocytes. HNA-4a is located on the αM chain (CR3, CD11b) and HNA-5a is expressed on the αL chain (leukocyte function antigen-1, CD11a) of the leukocyte β2 integrin family. HNA-4a results from a single-nucleotide substitution of G302A, which encodes an Arg61His exchange, and HNA-5a results from a G2446C substitution, which encodes an Arg766Thr exchange.\textsuperscript{380} Although sensitization by these antigens has led to alloantibody formation, only one case of neonatal alloimmune neutropenia has been linked to anti-HNA-4a antibodies.\textsuperscript{381}

Shared Antigens

Granulocytes also express antigens that are associated with other peripheral blood cells and tissues. The class I HLA antigens (HLA-A, -B, and -C) are found on granulocytes, but not in sufficient quantities to allow their detection by cytotoxicity tests used for lymphocytes. No class II HLA antigens can be detected on mature granulocytes; however, they are present on immature cells.

Detecting Antibodies to Granulocyte Antigens

The two most commonly used tests to detect granulocyte-specific antibodies are the granulocyte agglutination test (GAT)\textsuperscript{382} and the granulocyte immunofluorescence test (GIFT).\textsuperscript{364} GAT uses a microtechnique with purified granulocyte suspensions in microtiter plates. GIFT is performed in microtiter plates where cell-bound antibodies are detected with fluorescein-conjugated anti-human Ig. Coexisting antibodies to HLA and other granulocyte-specific antigens may interfere with these assays. Even with the use of well-characterized test sera and procedures to eliminate HLA reactivity (e.g., absorption or chloroquine stripping), the GAT and GIFT assays have limited sensitivity and specificity. Biochemical characterization of granulocyte antigens has facilitated the development of more specific methods for the investigation of granulocyte-specific antibodies. These include antigen capture (e.g., the monoclonal antibody-specific immobilization of granulocyte antigens assay), immunoblot, and immunoprecipitation assays, similar to the assays used to study platelets.

Clinical Significance of Granulocyte Antigens

Alloantibodies

Alloantibodies specific for the HNA-1a, -1b, and -1c antigens on FcγRIIIb are most commonly implicated in alloimmune neonatal neutropenia.\textsuperscript{348,364} Affected neonates are born to mothers who lack the antigen. IgG alloantibodies in the mother may form any time after the first trimester of pregnancy (when the hematopoietic cells are developed and cross the placenta) causing the destruction of fetal neutrophils. Symptomatic infants may present with delayed separation of the umbilical cord, skin infections, otitis media, or pneumonia within the first 2 weeks of life.\textsuperscript{385} Although most infections are mild, overwhelming sepsis can occur, with a mortality rate of approximately 5%. The neutropenia is generally self-limiting, reflecting the transient nature of maternal antibodies in the infant, and most infants recover within 2 weeks to 6 months as the titer of the alloantibody diminishes.
Molecular Structure

products are structurally and functionally distinct. The class III genes encode complement components C2, C4A, C4B, Bf, encode HLA

HNA antigens are encoded by the MHC, a cluster of genes encompassing approximately one thousandth of the human genome. The MHC is located on the short arm of chromosome 6 (band 6p 21.3) and was defined initially by investigation of antibodies in individuals sensitized through pregnancy or transfusion. These antigens are distributed on many types of cells and tissues and are important in the regulation of the immune response. They play a primary role in graft rejection and GVHD in transplantation, refractoriness to granulocyte transfusions, and drug-induced neutropenia.

Autoantibodies

Primary autoimmune neutropenia is caused by granulocyte-specific autoantibodies. The syndrome occurs most often in infancy and usually resolves spontaneously by 1 to 2 years. In a serologic investigation of 240 cases of antibody-positive autoimmune neutropenia in infancy, 31% of autoantibodies showed preferential binding to granulocytes that were homozygous HNA-1a and 3% to granulocytes that were homozygous HNA-2a. Other autoantibody specificities demonstrated were FcyR1llb (27%), CD11b/CD18 (21%), CR1 (14%), and FcyRII (2%). Secondary autoimmune neutropenia is most often associated with another autoimmune disease such as Felty syndrome, systemic lupus erythematosus, or malignancy (e.g., lymphoma). In those cases, granulocyte-specific antibodies are not as readily detectable.

Lymphocyte Antigens

Numerous monoclonal antibodies, assigned a CD designation, recognize a number of molecules associated with various aspects of lymphocyte function and differentiation. The most clinically important lymphocyte antigens are the HLAs, and they will be the focus of this section. Lymphocytes also express a number of shared antigens, including HNA-3a, HNA-4a, and HNA-5a, and blood group antigens ABH, Lewis, li, P1, and P.

HLA Antigens

HLA antigens are encoded by the MHC, a cluster of genes encompassing approximately one thousandth of the human genome. The MHC is located on the short arm of chromosome 6 (band 6p 21.3) and was defined initially by investigation of antibodies in individuals sensitized through pregnancy or transfusion. These antigens are distributed on many types of cells and tissues and are important in the regulation of the immune response. They play a primary role in graft rejection and GVHD in transplantation and transfusion. The immune response to specific antigens is controlled by immune response genes, which are also located in the MHC (for discussion elsewhere, see Chapter 18).

The HLA complex on chromosome 6 has over 200 genes, more than 40 of which encode leukocyte antigens (Fig. 20.5). Of the three coding regions in the MHC, only the class I and II antigens are involved in the immune response. The class I genes encode HLA-A, -B, -C, -E, -F, and -G, and the class II genes encode HLA- DP, -DQ, -DR, -DN, and -DO. These class I and II gene products are structurally and functionally distinct. The class III genes encode complement components C2, C4A, C4B, Bf, 21-hydroxylase, and tumor necrosis factor-α and -β.

Molecular Structure

reduces the risk of FNHTRs. FNHTRs may also occur with the transfusion of plasma containing HLA or neutrophil-specific antibodies.

TRALI is a rare but serious complication of blood transfusion characterized by hypoxemia, respiratory distress, and pulmonary infiltrations on chest radiograph within 6 hours of a completed transfusion. Although the pathophysiology of TRALI remains uncertain, investigators have postulated that antibody-mediated leukocyte activation in the lungs results in inflammation and complement activation causing increased vascular permeability, capillary leakage, and pulmonary tissue damage. HNA-1a, HNA-1b, HNA-2a, and HNA-3a antibodies have been implicated in TRALI reactions, and antibodies against HNA-3a, which are strong granulocyte agglutinins, have been associated with severe TRALI reactions. Risk factors for TRALI include the volume of the blood product transfused, the type of blood product (plasma transfusions are most commonly implicated) and the underlying condition of the patient (critically ill, surgical, etc.). Pooled plasma from multiple donors (including solvent detergent-treated plasma) may reduce the risk of TRALI since the pathogenic antibody is diluted.

Kopko et al. performed a look-back investigation on a TRALI fatality associated with transfused plasma containing anti-HNA3a. Among 36 recipients who were available for review, 15 transfusion reactions were observed in 13 patients including eight severe reactions highly suggestive of TRALI. The association between anti-HNA-3a and severe or fatal TRALI reactions remains unconfirmed in the absence of well-designed prospective surveillance studies.

Granulocyte antibodies have also been implicated in immunemediated neutropenia following bone marrow transplantation, refractoriness to granulocyte transfusions, and drug-induced neutropenia.

Autoantibodies

Primary autoimmune neutropenia is caused by granulocyte-specific autoantibodies. The syndrome occurs most often in infancy and usually resolves spontaneously by 1 to 2 years. In a serologic investigation of 240 cases of antibody-positive autoimmune neutropenia in infancy, 31% of autoantibodies showed preferential binding to granulocytes that were homozygous HNA-1a and 3% to granulocytes that were homozygous HNA-2a. Other autoantibody specificities demonstrated were FcyR1llb (27%), CD11b/CD18 (21%), CR1 (14%), and FcyRII (2%). Secondary autoimmune neutropenia is most often associated with another autoimmune disease such as Felty syndrome, systemic lupus erythematosus, or malignancy (e.g., lymphoma). In those cases, granulocyte-specific antibodies are not as readily detectable.

Lymphocyte Antigens

Numerous monoclonal antibodies, assigned a CD designation, recognize a number of molecules associated with various aspects of lymphocyte function and differentiation. The most clinically important lymphocyte antigens are the HLAs, and they will be the focus of this section. Lymphocytes also express a number of shared antigens, including HNA-3a, HNA-4a, and HNA-5a, and blood group antigens ABH, Lewis, li, P1, and P.

HLA Antigens

HLA antigens are encoded by the MHC, a cluster of genes encompassing approximately one thousandth of the human genome. The MHC is located on the short arm of chromosome 6 (band 6p 21.3) and was defined initially by investigation of antibodies in individuals sensitized through pregnancy or transfusion. These antigens are distributed on many types of cells and tissues and are important in the regulation of the immune response. They play a primary role in graft rejection and GVHD in transplantation and transfusion. The immune response to specific antigens is controlled by immune response genes, which are also located in the MHC (for discussion elsewhere, see Chapter 18).

The HLA complex on chromosome 6 has over 200 genes, more than 40 of which encode leukocyte antigens (Fig. 20.5). Of the three coding regions in the MHC, only the class I and II antigens are involved in the immune response. The class I genes encode HLA-A, -B, -C, -E, -F, and -G, and the class II genes encode HLA- DP, -DQ, -DR, -DN, and -DO. These class I and II gene products are structurally and functionally distinct. The class III genes encode complement components C2, C4A, C4B, Bf, 21-hydroxylase, and tumor necrosis factor-α and -β.
The class I HLA molecule consists of two polypeptide chains, α and β, each encoded by different genes and (Fig. 20.6). The HLA-A, -B, and -C genes encode the larger α-chain, a 45-kD transmembrane protein with three amino acid domains. Two of these, α1 and α2, account for most of the variation in the molecule due to polymorphisms of the HLA genes. A constant region, similar to the constant region of Ig molecules, is in the α3 domain close to the cell membrane. The class I α-chain is noncovalently associated with a smaller molecule, β2-microglobulin. No polymorphisms have been reported on this 12-kD extracellular protein encoded by a gene on chromosome 15. X-ray crystallography demonstrates further similarities to Ig molecules. The membrane-proximal α3 domain and the β2-microglobulin portions of the HLA molecule have Ig-like folds, in contrast with the α1 and 2 portions, which form a platform topped by α helices. A groove between these helices is the binding site for a peptide fragment from a processed antigen.

Class II HLA molecules also share similarities with Igs. Like the class I molecules, they consist of a heavy (α) and a light chain (β) (Fig. 20.6). The heavy α-chain has a molecular weight of 34 kD, and the smaller β-chain has a molecular weight of 29 kD. Both chains are transmembrane molecules, each with two structural domains. Similar to the class I molecule, HLA class II has a functional antigen-binding groove formed by the distal α1 and β1 domains. The α2 and β2 constant regions share homology with Ig constant regions, β2-microglobulin, T-cell receptors, and class I heavy chains. This homology may account for similarity in the crystallographic structure of the class I and class II antigens.

Nomenclature

The nomenclature of the HLA antigens has been standardized by the World Health Organization (WHO) nomenclature committee, which regularly reviews newly reported specificities and genetic loci from results of International Histocompatibility Testing Workshops and (Table 20.13). The nomenclature specifies the region of the gene (e.g., HLA-A) and a number. Because the antigens were originally defined by the reactivity of antisera, some early specificities have been further subclassified. These specificities are called splits and usually are written to incorporate the parent antigen in parentheses (e.g., HLA-A9 is split to HLA-23[9] and HLA-24[9]). It is also common among the HLA-A and -B alleles for specific antisera to cross-react with more than one antigen. Antisera that react with one specificity in these cross-reactive groups (CREGs) may demonstrate reactions with other antigens in the same group (e.g., HLA-A2 and -A28 or -A19 [consisting of A29 to A33]). Those HLA regions and genes that have been defined using molecular techniques are identified using a unique nomenclature. The nomenclature for the class I antigens includes the locus name, an asterisk (*), and a four-digit number (e.g., HLA-A*0101). The first two digits of the number refer to the serologic specificity. Because both the α and β (A and B) genes are polymorphic for the class II antigens, the chain also must be specified (e.g., HLA-DRB1*0101 or HLA-DQA1*0101). The immunogenetics/HLA (IMGT/HLA) database found at http://www.ebi.ac.uk/imgt/hla provides a current database for sequences of the human major histocompatibility complex (HLA) and includes the official sequences for the WHO HLA Nomenclature Committee.
FIGURE 20.5 Organization of the major histocompatibility complex (MHC) on chromosome 6. A partial gene map of the human leukocyte antigen (HLA) complex is shown. The major loci of the genes expressed in the HLA class I and class II regions are depicted, as well as the unrelated class III genes. The following genes are shown in order, but not to scale: BF (complement factor B or CBF), C2 (complement component 2), C21B (cytochrome P450, subfamily 21 or TTC21B), C4A/C4B (complement components C4A/C4B), HSP (heat shock protein), LMP (large multifunctional protease), LTA/LTB (lymphotoxins A and B), MICA/MICB (MHC class I chains A and B), P450 (cytochrome P450), PSMB8 and 9 (proteasome β 8 and 9), TAP1/TAP2 (transporter proteins associated with antigen processing), TAPBP (TAP-binding protein, tapasin), TNF (tumor necrosis factor-α), and HSPA1A/HSPA1B/HSPA1L (heat shock proteins 1A A-type/1A B-type/1A-like).

Class I Human Leukocyte Antigen

HLA-A, HLA-B, and HLA-C antigens (class Ia) are expressed on all nucleated cells and on (anucleate) platelets. In addition, soluble HLA-A and -B antigens can be found in plasma where they circulate in association with high-density lipoproteins. Adsorption of these vesicles into other cell membranes may explain why red cells also carry these antigens. The class I antigens are products of the highly polymorphic HLA-A, -B, and -C genes. Molecular techniques have vastly increased the number of HLA-A specificities; however, it may not be appropriate to designate these as antigens, because the resulting proteins may not initiate alloantibody formation. These alleles are more correctly referred to as genetic polymorphisms. HLA-E, -F, and -G molecules (class Ib) are similar in structure to the class Ia molecule but have a different tissue distribution.
The class I and class II molecules are each composed of two polypeptide chains that are manufactured separately in the endoplasmic reticulum. A peptide-binding groove is created by the α1 and α2 peptide-binding domains of the class I molecule. A similar peptide-binding structure is created in the class II molecule by the association of the α1 and β1 peptidebinding domains. The HLA class I and II molecules also have immunoglobulinlike domains (α3: Class I; α1 and β1: Class II) proximal to a transmembrane domain and cytoplasmic tail. MHC, major histocompatibility complex.

Class II Human Leukocyte Antigen

The class II HLAs are found on lymphocytes, monocytes, macrophages, endothelial cells, activated T cells, and Langerhans cells. Many of these cells play an important role in initiating the immune response. The class II genes are proximal to the centromere on the short arm of chromosome 6 and consist of one α-chain (DRA) gene and one or two β-chain (DRB) genes. Therefore, one DRA- and one DRB1-encoded polypeptide are expressed by all individuals. The other DRB genes
(HLA-DRB2 to HLA-DRB9) do not always encode a polypeptide that is coexpressed with the DRB1 product. Only the DRB3, 4, and 5 gene products are associated with a DRB1-encoded polypeptide. Although two α-chain genes and two β-chain genes are found for the DQ and DP regions, only one product (α + β) is expressed.417

Class III Human Leukocyte Antigen

The class III region of the MHC contains a cluster of genes responsible for complement, hormones, intracellular peptide processing, and other developmental characteristics. Thus, the class III region is not actually a part of the HLA complex, but is located within the HLA region, because its components are either related to the functions of HLA antigens or are under similar control mechanisms to the HLA genes. Complement components encoded by this region include C4A, C4B, C2, and properdin factor B (Bf). The C4A and C4B loci encode C4 variants. These polymorphic genes also are responsible for the Rodgers (C4A) and the Chido (C4B) red cell phenotypes.418,419 Other proteins, including 21-hydroxylase and tumor necrosis factor-α and -β, are also encoded in this MHC region.

Methods of Detecting Class I and II Human Leukocyte Antigens and Antibodies

Both serologic and molecular techniques have been used to identify polymorphisms of the class I genes. Serologic methods use lymphocytotoxic (functional) assays, in which sera with known anti-HLA-A, -B, and -C specificities are incubated with test cells. Cell viability is monitored after the addition of complement, which damages the cell membrane of antibody-sensitized lymphocytes, allowing the uptake of dye such as eosin.421,422 Because of the requirement for a relatively large and informative number of specific typing sera, commercial kits are generally used for serotyping. Molecular methods can detect polymorphisms, and sequencing can identify changes at each locus. Lymphocytotoxic techniques can also identify anti-HLA antibodies. In these assays, patient serum is screened against a panel of typed cells. Generally, 30 to 60 different target cell phenotypes are required to identify the antibody specificities. These methods are used to select potentially compatible platelets for patients who are refractory to platelet transfusions.

The class II antigens have also been detected using both serologic and cellular assays. Serologic typing for the class II antigens is performed using a method similar to that used for the class I antigens; however, instead of using unfractionated lymphocytes, the typing of class II antigens is done using only B lymphocytes. These are first isolated from peripheral blood and incubated with specific anti-DR/DQ sera to determine the class II phenotype. It is now known that a single gene does not exist for HLA-D; however, the term continues to be applied to functional assays such as the mixed lymphocyte culture, the primed lymphocyte typing test, and T-cell clones.423 Because of the limitations of the functional assays, molecular methods have largely replaced the cellular assays for HLA class II typing. This typing is used for the identification of compatible bone marrow donors and recipients.

Inheritance of Human Leukocyte Antigens

Closely linked genes on one chromosome, such as those of the MHC, are often inherited as a unit cluster or haplotype. A child inherits one haplotype from each parent, resulting in four possible phenotypes. In some cases, an individual exhibits only two or three of the four HLA-A and -B antigens as a result of homozygosity or chromosome deletions. Homozygosity at some gene loci is only detectable by molecular-based assays and not the less sensitive serologic assays; for example, an individual may type serologically as homozygous HLA-A2 yet by molecular studies is heterozygous HLA-A*0201/HLA-A*0202.

The chance that any two of the children are completely identical is 25%. However, crossover can occur during meiosis, thus creating a new haplotype. For the MHC, there is a crossover rate of 0.8% between the A and B loci and approximately 0.5% between the B and DR loci. Because of linkage disequilibrium, alleles at linked loci are associated more frequently than would be expected. Thus, HLA-A1 (13.8%) and HLA-B8 (9%) are in linkage disequilibrium because their actual haplotype frequency (6%) is much higher than would be expected (1.3%) if they were independently inherited. Linkage disequilibrium contributes to racial differences in haplotype frequency (e.g., HLA-A1, -B8 is rare in Asians; HLA-A34 is almost exclusive to blacks). Inheritance of the class III gene cluster as a closely linked unit, referred to as a complotype, is associated with certain disease states.419,424

Clinical Significance of the Major Histocompatibility Complex and Human Leukocyte Antigen

The highly polymorphic antigens of the MHC provide useful markers in forensic medicine, in paternity testing, for anthropologic studies and for disease associations.425,426 and 427 Matching across HLAs determines the suitability of donors for solid organ and bone marrow transplantation and HLA antibodies have been implicated in transfusion reactions and in platelet refractoriness.

Association with Disease
Many diseases have been associated with specific HLA-A, -B, -C, and -DR antigens and with complement allotypes and HLA haplotypes (Table 20.14), for example Hodgkin’s lymphoma and the A1, B5, B8, and B18 haplotypes. However, the A1, B8 haplotype is prevalent in long-term survivors, suggesting that it may have a protective effect. Other HLA-associated malignancies include cutaneous T-cell lymphoma, Burkitt lymphoma, cervical squamous cell carcinoma, Kaposi sarcoma, and colorectal carcinoma. Other disease associations were with the HLA-B antigens (e.g., ankylosing spondylitis and HLA-B27); however, the use of molecular techniques has now demonstrated strong associations of some class II molecules with certain diseases, including autoimmune conditions. Three loci, DQB1, DQA1, and DRB1, may be associated with susceptibility or resistance to insulin-dependent diabetes mellitus. The α- and β-chains from each haplotype might form pairs of molecules with modified peptide-binding properties, which, together with a dosage effect, may play a role in accelerating the disease. The importance of specific peptide-binding grooves, possibly controlled by amino acids at key positions, is also demonstrated in the HLA associations with celiac disease and rheumatoid arthritis.

Certain immune response genes are linked to HLA haplotypes, conferring an increased susceptibility to antibody formation. For example, HLA-B8-DR3-positive individuals are more prone to forming alloantibodies to HPA-1a, the major platelet antigen most commonly implicated in NAT and posttransfusion purpura. Although a number of mechanisms have been proposed to explain the association between certain diseases and specific HLAs, including cross-reactive antibody responses, linkage of an HLA locus with a non-HLA disease-associated gene, regulation of T-cell development, thymic selection of T-cell receptor repertoire on HLA molecules with self-peptides, and interaction of class II HLA molecules with superantigens (cross-reactive), the exact mechanisms are unknown.

Transplantation

For solid organ transplants, HLA matching has reduced graft rejection and improved graft survival, with closer matches (6/6 for HLA-A, -B, and -DR) associated with better outcomes. The importance of HLA-A, -B, and -DR matching on graft survival has been consistently observed, especially for second kidney transplants. Similarly, the success of bone marrow transplantation depends on the degree of HLA matching. Related HLA-identical transplants are associated with lower rates of delayed engraftment, rejection, or GVHD than transplants with marrow from non-HLA-identical relatives. Nevertheless, matching for HLA-A, -B, and -DR does not eliminate the risk of acute GVHD and graft rejection; more precise matching for DRB1, DQB, and HLA-C using molecular techniques may further reduce the risk.

Transfusion-associated Acute Lung Injury

HLA antibodies have been implicated in TRALI reactions. In early studies by Popovky and Moore, class I HLA antibodies were detected in the plasma of 59% of donors implicated in 36 cases of TRALI. Since then, reports of the frequency of anti-HLA class I antibodies in implicated donor plasma have varied widely but support an etiologic role of these antibodies in at least some patients. In a review of 26 patients with TRALI in which antibody-antigen concordance had been demonstrated, 12 showed class I HLA specificity, 15 showed class II specificity, and three were specific for neutrophil antigens. The role of class II HLA antibodies in TRALI is uncertain, as neutrophils, the effector cells in TRALI, do not express HLA class II antigens. One hypothesis is monocyte activation, which is supported by the observation of monocyte activation and proinflammatory cytokine generation following the incubation of recipient monocytes with class II HLA antibodies in plasma from donors implicated in TRALI reactions.

Platelet Transfusion Refractoriness

Immune platelet refractoriness is another transfusion complication thought to be mediated by HLA antibodies. Alloantibodies against HLA-A and HLA-B formed after exposure to prior transfusions or pregnancies cause early destruction of transfused platelets. The use of HLA-A and HLA-B-matched platelet transfusions is often beneficial in these difficult cases. When HLA-identical donors are not available, the selection of CREG-compatible HLA antigen matches or matching of highly immunogenic epitopes using molecular techniques can be used.

Chapter 21 Transfusion Medicine

The first documented transfusion of blood in humans occurred in 1667, but it was not until almost 300 years later that transfusion became a therapeutic practicality. Landsteiner's landmark discovery in the early 1900s of blood groups and agglutinating antibodies was the key that unlocked this therapeutic pathway. The development of anticoagulants, blood preservatives, and sterile collection sets in the middle of the 20th century made blood banking possible by enabling the collection and preservation of donor blood for later use.

In the past few decades, the complexity of blood banking and blood component therapy has virtually exploded. The recognition of both infectious and noninfectious complications of transfusion led to numerous practice changes involving blood donor screening, component production and modification, compatibility testing, and blood utilization. The menu of blood component options and therapeutic services has progressively expanded, along with efforts to establish evidence-based guidelines for their optimal use. Specialized recommendations have been developed for supporting specific patient populations such as immunosuppressed patients, chronic transfusion recipients, hematopoietic cell transplant recipients, and neonates. In the United States, all blood establishments (blood banks and transfusion services) are regulated by the US Food and Drug Administration (FDA). FDA regulations govern all aspects of blood collection, component processing, storage, compatibility testing, and administration. The FDA requires blood establishments to comply with highly stringent quality assurance standards that ensure control of processes and restrict variability. The AABB (formerly known as the American Association of Blood Banks) issues accreditation standards and recommendations that further establish the standard of practice in the US.

Today, Transfusion Medicine is itself a Board-recognized clinical specialty. In addition to overseeing the complex donor center and transfusion service operations, Transfusion Medicine physicians are increasingly important participants in the clinical care team. Transfusion Medicine specialists can guide the selection of therapeutic options to best support a patient's medical needs, and can coordinate the supply and delivery of these blood components and therapeutic services. This chapter serves as an introduction to blood components and transfusion services available in the United States.

BLOOD DONATION AND COLLECTION

Donor Selection

In the United States (US), donor eligibility criteria are established and enforced by the FDA and to a lesser degree by the American Association of Blood Banks (AABB). Donor selection is undertaken with two goals in mind: to protect the health of the donor by ensuring that a donation does not place the donor at risk, and to protect the recipient by ensuring that the donor meets all health and screening criteria so that the risk of transmitting infectious agents or causing other adverse
events is minimized. In the US, most fresh blood products are from unpaid volunteers. These donors have decreased risk of transmitting infectious agents, especially in the “window period,” when screening tests fail to detect infection. Paying donors for fresh transfusion products was stopped after studies in the 1970s showed that paid donors had a much higher prevalence of hepatitis. Commercial plasma-derivative manufacturers still use paid donors, but comply with FDA-approved donor eligibility criteria and employ pathogen reduction processes during manufacturing that reduce infectious risks, as discussed later in this chapter.

Donor Identification and Registration

Donor registration must accurately identify the potential donor, including name, birthdate, address, and phone number, so the donor can be traced if needed. Records must link donors to all prior donations and test results and be kept for at least 10 years.

Donor Information

The donor must be given educational material describing signs and symptoms of AIDS and activities associated with increased risk of acquiring human immunodeficiency virus (HIV). The donor must be informed that testing may not detect all infections, and that individuals who have engaged in risk behavior should not donate.

Donor Health History

Information to be elicited is defined by the FDA and the AABB. The medical history is obtained by a trained interviewer, or donors may complete an FDA-approved self-administered questionnaire on paper or a computer. Responses are then reviewed with the donor by qualified staff. The history includes a review of current health, ensuring that the donor feels well, is free of signs of infection, and that his or her cardiovascular status can tolerate an acute blood volume loss of 10% to 15%. The donor is questioned about recent exposures to blood, potential exposure to HIV or hepatitis, sexual contact with individuals at risk for HIV, needle sharing by the donor or sexual partners, travel to or residence in areas endemic for malaria or variant Creutzfeldt-Jakob disease, medications, and immunizations.

The donor must meet certain requirements of age and vital signs. The hemoglobin must be at least 12.5 g/dl. Donor weight must be sufficient so that the donation constitutes no more than a 15% loss of blood volume. There must be no arm stigmata of parenteral drug abuse.

Informed Consent

The donor must sign the health history form verifying that all questions were answered truthfully, that the donation process is understood, and that he consents to testing for infectious agents transmitted by transfusion, including HIV and hepatitis.

Additional Donor Criteria for Specific Components

Donors may be eligible to donate some blood components but not others.

Medications That Impact Therapeutic Effectiveness of Particular Blood Components

Acetylsalicylic acid (ASA) irreversibly acetylates platelet cyclooxygenase and inhibits platelet aggregation. After a single dose of aspirin, ASA-exposed platelets are inhibited for the rest of their lifespan, but platelets produced after clearance of the drug restore hemostatic function. Therefore, platelets from donors who have taken ASA are acceptable as long as 48 hours have elapsed from the last dose. Platelets donated within 2 days of ASA ingestion are acceptable for use if mixed with platelets from unexposed donors.

Nonsteroidal anti-inflammatory drugs (NSAIDs) may impair platelet function, but the effects of many are reversible— that is, platelet function is restored once the platelets are removed from the offending drug. Therefore, individuals taking reversible NSAIDs can donate platelets for transfusion. Individuals who are taking irreversible NSAIDs, however, or other irreversible antiplatelet agents (e.g., ticlopidine) are not eligible to donate platelets for transfusion.

Warfarin reduces levels of functional blood clotting factors (see Chapter 55). Transfusable plasma units or cryoprecipitate cannot be made from donors taking this medication.

TRALI Mitigation Strategies for “High Plasma Volume” Components
Studies in the early 2000s indicated that blood products containing a large volume of plasma (e.g., plasma and apheresis platelet units) were associated with a higher per unit risk of transfusion-related acute lung injury (TRALI) compared to components containing small amounts of plasma (e.g., red cell units and cryoprecipitate). Furthermore, plasma or platelet units containing donor antibodies to white blood cell (HLA and neutrophil) antigens were implicated in a substantial proportion of TRALI cases. In an attempt to reduce the frequency of TRALI, the AABB recommended in 2006 that blood collection agencies take steps to reduce production of high plasma volume products from donors with an increased likelihood of having WBC antibodies. Women with a history of pregnancy are at highest risk of being immunized to WBC antigens. Therefore, in response to AABB recommendations, many blood collection facilities have stopped making transfusable plasma components from women with a history of pregnancy or from all women. Whole blood collections are still accepted from these women, but the plasma portion of their collections is used only for cryoprecipitate production and/or manufacturing into plasma derivatives. It has been more challenging to exclude women with a history of pregnancy from plateletpheresis donations, as the platelet supply is difficult to sustain. Some blood collection facilities exclude multiparous women as platelet donors or screen them for the presence of HLA antibodies.

Directed Donations

A directed donation (DD) is a donation in which the donor directs his/her donated blood product to a specific designated patient. The donation must usually be ordered by the recipient’s doctor. DD programs exist primarily for emotional reasons, although these programs are required to be offered in certain states. In these programs, patients anticipating the need for blood can select who their donors will be. The donor is often a family member or acquaintance of the recipient. DDs are not of medical benefit where an established blood supply exists but can be useful in rare circumstances when specific characteristics of the donor’s blood are medically needed (e.g., for rare HLA or blood types obtained from family members). Directed donors must meet all regular donation criteria; however, exceptions can be made if rare types are needed. Data show DDs are no more safe than regular community donations from an infectious disease perspective. Directed donors are more likely to be first-time donors, who have a higher incidence of HIV and HCV than repeat blood donors. DDs theoretically may have higher risk of causing transfusion complications such as (1) hemolytic disease of the newborn in future pregnancies after a woman has received blood from her husband or his relatives, (2) TRALI in a mother to child transfusion, or (3) transfusion-associated graft-versus-host disease (TA-GVHD) from a related family donation. Directed donations from blood relatives are irradiated to prevent TA-GVHD.

BLOOD COLLECTION PROCESS

Phlebotomy and collection of blood proceed only if the donor is deemed suitable after pre-donation screening. Blood is collected in accordance with established standards and is collected either manually or with an automated collection device.

Whole Blood (Manual) Collection

The phlebotomy site is swabbed with a disinfectant. Blood is collected in a primary plastic collection bag with a large bore needle allowing rapid flow and mixture with anticoagulant. The volume drawn is standardized for the collection bag used (either 450 or 500 ml). The blood draw is controlled by scales that discontinue flow when the desired weight is collected. Blood and anticoagulant are mixed gently during the collection. Specimen tubes for testing are also procured. Because most whole blood units will be separated into components, the primary bag has one to three attached satellite bags allowing separation of components in a sterile closed system. The collection tubing is heat-sealed into segments that are left attached to provide samples for crossmatching. The whole blood is transported to a laboratory where it can be separated into its components (red cells, plasma, platelets).

Blood Component Separation

Whole blood is centrifuged to sediment the red blood cells (RBCs) (Fig. 21.1). Most of the supernatant “platelet-rich plasma” is pushed off into an attached sterile satellite bag. The bag containing platelet-rich plasma may then be centrifuged at a higher rate to sediment platelets. Most of the plasma is then removed into a third satellite bag. This leaves behind a platelet pellet which is then resuspended in 40 to 70 ml of residual plasma resulting in a platelet concentrate. If platelet concentrates are not going to be produced from the donation, the initial centrifugation of the whole blood is done at high speed, and the plasma is removed directly from the red blood cells and frozen. Further processing of plasma and red cell components is discussed later in this chapter.

Terminology

The whole blood in the original collection bag (450 or 500 ml) is referred to as one whole blood unit, and each component made from that unit is defined as one “unit” of that component. Because a whole blood unit constitutes approximately
10% of a donor’s blood volume, each component can be considered roughly 10% replacement therapy for an adult patient.

“Closed” versus “Open” Systems

If blood component manipulation is done without opening the system to air (closed system), all components may be stored to the limit of their viability. If the bag or tubing is entered, however, the system is considered potentially open to air/bacteria, and the product outdates in 4 hours if stored at room temperature or 24 hours if refrigerated. Devices using high-temperature welds can steriley attach additional containers or tubing to the original unit in a way that prevents entry of bacteria. With these “sterile connection devices,” blood components may be split into aliquots, filtered, or otherwise manipulated without loss of shelf life.²

P.549

Automated Blood Collection and Separation Devices: Apheresis

The word apheresis is derived from a Greek word that means to separate or to take away. Initially, it referred to a manual process in which whole blood was withdrawn from the donor and centrifuged, the plasma retained, and the red cells
returned to the donor. In 1914, Abel experimentally removed plasma from anephric dogs, and replaced it with crystalloid.23 It was not until the advent of plastic bags that manual apheresis could be used routinely in humans. Between 1950 and 1980, manual apheresis was the primary source of plasma for fractionation. In the 1970s and 1980s automated cell separator devices changed the approach to apheresis. This technology has become the routine collection method for many blood components and is used in the treatment of many diseases.2,24

In discontinuous centrifugal devices, anticoagulated blood is collected into a spinning disposable bowl. Centrifugal force causes red cells to move to the outside of the bowl, and platelet-rich plasma moves to the inside. White blood cells (WBCs) (buffy coat) settle in between. With optical detectors, the desired component is pumped into an attached plastic blood bag. The remaining components are returned to the donor.

Continuous flow devices continuously subject incoming blood to a centrifugal force, establishing a standing cell gradient. The fraction(s) to be removed is pumped into a bag, and the rest is reinfused continuously. The extracorporeal blood volume is lower than with the discontinuous technique, and the procedure is faster. An increasing proportion of blood components are being collected using automated cell separation. These devices can collect multiple unit-equivalents of platelets, plasma, or red blood cells from one donation. Apheresis is the main source of plasma for fractionation because multiple units of plasma may be obtained without red cells and possible resultant iron deficiency. Apheresis technology is now used to collect the majority of platelets in the US and in many regions apheresis platelets have entirely replaced platelets derived from whole blood units. Apheresis platelets have several advantages. Up to three therapeutic platelet doses (equivalent to 18 whole blood-derived platelet units) can be obtained from one apheresis donation. This minimizes possible recipient exposure to infectious agents. If a donor is large enough, it is possible to obtain two RBC unit-equivalents from one apheresis donation, returning plasma, platelets, and saline to the donor to minimize volume loss. Some apheresis devices can be programmed to collect any desired combination of red cells, plasma, or platelet products from the same donation. Apheresis technology is also used for therapeutic plasma exchange (TPE) and for collection of peripheral blood hematopoietic progenitor cells (HPCs) or donor lymphocytes, as discussed later in this chapter and in Chapter 102.2

Membrane filtration can be combined with apheresis to collect plasma. Blood is pumped over a membrane with a specific pore size that permits passage of plasma but not cells. Such devices have been used to collect plasma for fractionation or to perform TPE.

Complications of Donation

Most people easily tolerate blood donation but occasional problems arise, the most common of which are from venipuncture, consisting of bruises, soreness, and hematoma. These complications may be striking but usually resolve spontaneously. Nerve irritation and/or injury (0.02% to 0.9%) and arterial puncture (0.003% to 0.01%) are less common. Donors normally compensate for volume loss by increasing heart rate and vascular resistance, but 2% to 7% of donors experience vasovagal reactions, with syncope occurring in 0.1% to 0.3%. Fatigue (8%), nausea, and vomiting (1.1%) are also seen.25,26,27,28 and 29 Apheresis donors can develop transient symptomatic hypocalcemia (tingling or muscle cramps) from the citrate infused when anticoagulated blood components are returned to them. These symptoms are treated by slowing the flow of the device and or giving the donor oral calcium supplements.30 Intravenous calcium infusions are needed only during prolonged apheresis procedures such as those for HPC collection.24

Donor Testing

Every blood donation undergoes a series of tests to determine its suitability for transfusion. In the United States, the following tests must be performed on every unit collected: ABO group and Rh type, red cell antibody screen, serologic tests for infectious markers including hepatitis B surface antigen (HBsAg), antibodies to hepatitis B core (HBc) antigen, hepatitis C, HIV-1 and -2, human T-cell lymphotrophic virus (HTLV)-I and -II, and syphilis, and nucleic acid tests for HIV-1 RNA, HCV RNA, and West Nile virus RNA.5 In 2010 the FDA recommended one-time testing of allogeneic donors for antibodies to T. cruzi (the causative agent of Chagas disease).31 Donor testing is discussed more fully later in this chapter.

Blood components are not released for transfusion unless all donor tests for infectious markers are negative.5 This extensive testing results in a delay of 24 to 48 hours from the time of collection until an RBC component can be released for transfusion. Platelet products are typically not available until 36 to 48 hours after collection because of additional bacterial testing (see Bacterial Contamination).
RED BLOOD CELL PRESERVATION AND STORAGE

RBCs are collected and stored in solutions that maintain their viability.

Anticoagulant/Preservative Solutions

Blood banking was not practical until anticoagulant and preservative solutions capable of preserving red cells in viable form were developed.

Citrate anticoagulant is used for essentially all transfusable blood components today. It chelates ionized calcium in blood, blocking calcium-dependent coagulation steps. After transfusion, citrate is readily metabolized by the liver. During World War I, a sodium citrate and glucose solution was developed that permitted blood storage for several days. This citrated blood was used to treat shock in British and American soldiers. During World War II, it was found that the addition of citric acid (acid citrate dextrose [ACD]) preserved RBCs for 21 days. Continued efforts resulted in citrate phosphate dextrose (CPD) solution, a modified ACD, with added NaH₂PO₄ and a higher pH. Stored in CPD, red cell phosphate and 2,3-diphosphoglycerate (2,3-DPG) are maintained at higher levels than in ACD; however, RBC viability was still only 21 days.

In the 1950s, it was noted that red cells that had lost their adenosine triphosphate (ATP) did not survive well during storage. Nakao showed that ATP content and posttransfusion viability of aged red cells could be improved by the addition of adenine, which allows the RBCs to maintain the adenine nucleotide pool. Simon et al. described the maintenance of red cell ATP levels using preservatives containing glucose and low concentrations of adenine, leading to the adenine-supplemented anticoagulants now in use.

CPDA-1, which is CPD fortified with adenine, became available in the United States in 1978. It had been used extensively in Europe for several years before then. Initial concerns about potential toxicity of adenine proved to be unfounded. CPDA-1 is now a common anticoagulant-preservative and allows storage of RBC concentrates for 35 days.

Packed Red Cells versus Red Cells in Additive Solutions

After whole blood is collected into CPD or CPDA-1, the red cells may be centrifuged, allowing removal of most of the plasma (“packed RBCs”). Approximately 20% of the anticoagulant-containing plasma must be left to provide metabolic substrate for RBCs during storage. Another approach to red cell preservation involves more complete removal of the anticoagulated plasma from the red cells (“dry pack”), followed by resuspension of the red cells in 100 ml of an additive solution. Such additive solutions contain saline, adenine, and glucose, with or without mannitol to decrease hemolysis. The storage of RBCs in additive solutions is extended to 42 days. RBCs in additive solution are now the most common preparations for transfusion. RBCs collected in any of the anticoagulants and preservatives must be stored at 1° to 6°C to maintain optimum function.

Changes in Red Cells during Storage

Stored liquid RBCs undergo biochemical and structural changes that have major influences on their viability and function after transfusion.

Structural Changes

A number of red cell changes contribute to decreased cell viability after storage. RBCs are normally disc shaped. Soon after storage they become spherical with surface projections (spheroechinocytosis). Later defects include loss of membrane lipids and protein, as well as alterations in structural proteins. Loss of membrane deformability correlates with viability. The more severe membrane changes are irreversible and probably contribute to decreased posttransfusion RBC survival.

Blood bag plasticizers appear to influence membrane stability. Red cells are stored in polyvinyl chloride (PVC) bags that contain the plasticizer di-2-ethylhexylphthalate (DEHP). Morphologic deterioration is greater in RBCs stored in containers that do not have DEHP, with increased hemolysis and loss of deformability, suggesting that DEHP has a direct membrane stabilizing effect. Adding DEHP can both prevent and repair deterioration of stored red cells, with many of the spherical cells reverting to normal discoid morphology. However, concerns have been raised about potential toxic effects of DEHP. Efforts are being made to find alternatives to DEHP.

Biochemical Changes

During storage, red cells metabolize glucose, producing lactic and pyruvic acid, resulting in lower pH and decreased glycolysis. As glycolysis slows, RBC ATP content falls. Because human RBCs contain no enzymes to synthesize adenine or other purines de novo, the nucleotide pool gradually becomes exhausted. In the presence of adenine, ATP may be
regenerated. Understanding this has led to prolonged RBC storage by the addition of exogenous adenine and inorganic phosphate, both of which improve the cells’ ability to regenerate ATP. 32

Red cells lose potassium and gain sodium during storage. This is because the Na⁺-K⁺ gradient is normally maintained by a Na⁺-K⁺ ATPase that does not function well at 4°C. Gamma irradiation of red cells to prevent graft-versus-host disease (GVHD) (see section GVHD) doubles the rate of potassium leakage. 46,47 Red cells reabsorb potassium after transfusion. 48

Red Cell 2,3-Diphosphoglycerate

Another significant change in stored RBCs is 2,3-DPG depletion, which decreases RBC oxygen delivery. 32,49,50 In blood preserved in ACD, 2,3-DPG drops to below 50% within 48 hours. In CPD, CPDA-1, and additive solution-stored red cells, 2,3-DPG is better maintained but is still depleted after about 2 weeks. Studies show that if RBCs are cooled down rapidly to 17 to 18 degrees C within 1 hour after collection, the fall of 2,3-DPG can be delayed

P.551

significantly. 51 2,3-DPG levels improve rapidly within the first 6 hours after transfusion, and return to near-normal levels within 24 hours. 48,52

The clinical implications of transfusion of blood with decreased 2,3-DPG content is controversial 32,53 The oxygen dissociation curve of cells that are 2,3-DPG-depleted is shifted to the left, resulting in increased hemoglobin oxygen affinity and decreased tissue oxygenation. These changes are thought to be of limited clinical significance because the stored red cells rapidly regain their 2,3-DPG in the circulation. In select patients, such as those in shock, lower RBC 2,3-DPG levels may have a negative effect. However, the acidosis that may be present in such patients shifts the oxygen dissociation curve to the right. Because of such compensatory mechanisms, the need for blood specifically altered to preserve or reconstitute red cell 2,3-DPG has not been demonstrated.

Rejuvenating Solutions

A number of chemical agents—dihydroxyacetone, 54 pyruvate, 55 phosphoenolpyruvate, 56 and inosine 57—are capable of maintaining near-normal red cell 2,3-DPG content during storage, or of replenishing 2,3-DPG after storage. Although none of these chemicals are likely to be used in transfusion because of their side effects, studies with these agents have resulted in the development of rejuvenating solutions.

Rejuvenating solutions contain pyruvate, inosine, glucose, phosphate, and adenine, and may be added to red cells up to 3 days after the expiration date. Treatment with rejuvenating solutions corrects the metabolic defects of the red cell, with a return to normal levels of ATP and 2,3-DPG. These rejuvenated red cells may either be washed and transfused within 24 hours or frozen for later use. 2 Such rejuvenated red cells have a normal survival and oxygen affinity. 58,59 and 60 In practice, rejuvenation is rarely performed.

In Vivo Recovery of Stored Red Cells

After transfusion of stored blood, red cells that have developed lethal degrees of damage are removed promptly from the circulation of the recipient. Red cells that survive the first 24 hours after transfusion have normal survival thereafter. 61,62 Therefore, the criterion by which the adequacy for transfusion of banked blood is assessed is the proportion of transfused red cells that remain in circulation at 24 hours after transfusion. Generally, 75% survival at 24 hours is considered evidence of adequate viability; the anticoagulant systems in current use readily achieve this goal. Work to develop optimal additive solutions capable of maintaining red cell ATP and 2,3-DPG levels and to prolong red cell storage time continues.

Clinical Implications of Stored Blood

Whether the age of transfused blood affects clinical outcomes is highly controversial, with many studies coming to different conclusions 63,64 For a variety of complex methodologic reasons, the ability of even well-designed randomized controlled trials to demonstrate significant clinical differences based on the age of transfused blood has been questioned. 65

Frozen Red Cells

Red cell freezing is a labor-intensive process that is used primarily for storing rare blood types or prolonged storage of autologous red cells in the event of planned or postponed surgery. Glycerol is gradually added to the red cells as a cryoprotectant to a final concentration of 40% (weight/volume). The cells are then frozen at -65°C or colder for up to 10 years. Immediately after thawing, an automated cell processor must be used to wash the glycerol from the cells. The washed cells are resuspended in isotonic saline and glucose. In most cases, postthaw storage is limited to 24 hours
because an open system is used to process the cells. However a closed system maintaining sterility has been developed and RBCs processed in this manner can be stored in a refrigerator for up to 2 weeks after thawing.

Potential new technologies for RBC biopreservation are now under investigation, such as hypothermic storage and lyophilization. Hypothermic red cell storage potentially maintains higher levels of 2,3-DPG but still requires improvements. Lyophilization of red cells potentially would allow stable, indefinite, room temperature storage and would be ideal for remote storage and military applications. These methods have still not been sufficiently developed.

**PLATELET PREPARATION AND STORAGE**

**Preparation of Platelet Concentrates**

Platelets, like erythrocytes, are actively metabolizing cells and require specific conditions for their preparation and storage to optimally maintain viability and function. They are prepared for transfusion either as platelet concentrates from whole blood or by apheresis. Although the preparation differs, both products are stored under the same conditions.

Platelet concentrates may be prepared from whole blood collected into bags with satellites (Fig. 21.1). The anticoagulants in current use, CPD and CPDA-1, are satisfactory for preparation of platelet concentrates. The whole blood is kept at room temperature and must be processed within 8 hours of collection. The unit of whole blood is centrifuged at low speed at room temperature, and the supernatant, platelet-rich plasma is expressed into a satellite bag. The supernatant is centrifuged again to further concentrate the platelets. Most of the supernatant platelet-poor plasma is expressed, and after 1 hour, the platelets are gently resuspended in the remaining plasma (50 to 60 ml). Approximately 60% to 75% of the donor platelets, or a minimum of 5.5 x 10^{11} platelets/unit, are recovered.

In Europe and Canada, whole blood platelet concentrates are prepared from the buffy coat. Briefly, the whole blood unit is spun inverted at high speed, and the platelet-poor plasma and the buffy coat are withdrawn, each into its own satellite bag. The buffy coat is then centrifuged at low speed to separate the platelets from the red and white cells. The functional quality of these platelets is comparable to those prepared by the American method. Platelet concentrates prepared from buffy coat contain fewer white cells than those prepared from platelet-rich plasma, although filtration is necessary to meet the European standards for leukoreduced products. In some European countries, platelet concentrates are pooled, resuspended in an additive solution, and filtered before storage. In the United States and Canada, the pooling of platelets before storage has been evaluated; currently, only one system has been FDA-approved for this use in the US.

**Apheresis (Pheresis) Platelets**

In the US the majority of platelets are collected from single donors by apheresis using the automated collection devices described earlier. Platelets collected in this way must contain at least 3 x 10^{11} platelets in approximately 300 ml of plasma by AABB standards. This is equal to about six whole blood platelet concentrates. With improved apheresis technology many platelet collections are so abundant that they can be split into multiple products that still meet the 3 x 10^{11} requirement. Apheresis platelets are leukocyte-reduced by the collection technology. Because the procedure is carried out in a closed system, the platelets can be stored for 5 days in the appropriate plastic bag.

Apheresis platelets are usually collected from random donors but can also be collected from HLA-compatible donors to support alloimmunized patients. There is no significant functional difference between apheresis platelets and those from whole blood donations. However, apheresis platelets typically contain fewer WBCs and, therefore, are less likely to cause febrile transfusion reactions than whole blood-derived platelet concentrates, unless these concentrates have been leukoreduced prior to storage. The use of apheresis platelets also results in fewer donor exposures for recipients.

**Platelet Storage and Functional Integrity**

Platelet products must be kept under specific conditions to ensure optimal recovery and function. Unlike red cells, platelets stored at 4°C undergo shape changes and lose their viability. Platelet survival and function are optimized by storage at room temperature (20° to 24°C). During storage, platelets metabolize glucose to lactate and hydrogen, which are buffered by bicarbonate present in the plasma, resulting in a release of CO₂. The nature of the bag in which platelet concentrates are stored is important. The plastics used in the early era of platelet transfusion were made of PVC and plasticizers and were not permeable to O₂ and CO₂. In these bags, stored platelets become depleted of oxygen, resulting in a shift from oxidative to glycolytic metabolism, with increased lactate generation, decreased pH, and decreased platelet viability. As the pH decreases below 6.2, platelets undergo shape change, are damaged, and show
PREPARATION OF PLASMA COMPONENTS

reduced in vivo recovery. The platelets could not be stored for longer than 72 hours in the PVC bags. The plastic blood bags currently in use are more gas permeable. This permits continued oxidative metabolism and prolongation of storage time.84,85,86 Although platelet viability is maintained for up to 7 days in the new plastic containers,87,88 storage of platelet concentrates at room temperature is currently approved for only 5 days in the US because of the risk of bacterial growth.89,90 Viability is best preserved if the platelets are gently agitated during storage. Platelets must be stored in sufficient plasma to maintain a pH greater than or equal to 6.2.9

Even under optimum storage conditions, platelets, like red cells, develop a storage lesion.91 After storage at room temperature, the changes that occur in the platelets include decreased aggregation in response to single platelet agonists such as adenosine diphosphate, and reduction in adenosine diphosphate and ATP content both in granules and in the metabolic pool. Beta-thromboglobulin and platelet factor-4 are released, and both dense and alpha-granules are depleted. There is increased surface expression of P-selectin (CD62), a molecule derived from the alpha-granule membrane of the resting platelet. Platelets may develop morphologic changes and impaired responses to hypotonic shock. It has been difficult, however, to correlate the clinical response to platelet transfusions with specific in vitro findings.

The in vivo effectiveness of stored platelets is dependent on the recovery of transfused platelets in the circulation of recipients. This has been assessed through platelet recovery and survival studies in normal volunteers using autologous radiolabeled platelets.9 Platelet recovery is the percentage of transfused platelets that are found in circulation immediately after transfusion. Even when fresh platelets are transfused, only about two thirds of the transfused platelets are recovered in the circulation;93 the remaining 30% to 40% are pooled in the spleen.94 At the end of storage, mean platelet recovery is approximately 40% to 50%.95,96 After the initial recovery, there is little difference in survival of fresh versus stored platelets; both show a half-life of 3 to 5 days in healthy adults.85 In patients, however, the observed recovery and survival of transfused platelets are often substantially lower than these figures (as discussed in the section Dosage and Expected Response).

The in vivo hemostatic efficacy of transfused platelets is difficult to assess. The use of bleeding times in thrombocytopenic patients as an indicator of function is not of value because of great variability in technique and lack of reproducibility of results.96 Function is best assessed through clinical assessment of hemostasis.97 The clinical response generally correlates with the posttransfusion platelet increment.

Platelet Additive Solutions

Platelet additive solution (PAS) use is less developed than additive solutions for RBCs, especially in the US. Removal of variable amounts of plasma and storage of platelet in PAS has many potential advantages, including optimized survival, decreased adverse reactions (e.g., allergic, febrile, TRALI), and pathogen inactivation.98

PAS generally contain acetate, which functions both as a metabolic substrate and as a buffer. Platelets stored in one of these solutions (platelet additive solution-2) showed increased P-selectin expression and decreased in vivo recovery compared to platelets stored in plasma72,98; moreover, platelets stored in the additive solution resulted in lower transfusion responses.99,100 Another solution, platelet additive solution-3, however, appears to show suitable preservation of platelet function for 7 days and is now in use in both Europe and the US. Platelet additive solutions are included in the pathogen reduction systems for platelets that are approved in Europe. These systems include exposure of the platelets to pathogen reduction agents and UV light, as discussed later in this chapter. This processing appears to be associated with some loss of platelet product potency, but the clinical importance of these changes is unclear.101,102

Frozen Platelets

Frozen storage of platelets has been investigated and a potential role of such preparations has been established only for patients with alloantibodies for whom satisfactory donors cannot be found. Autologous platelets may be frozen using dimethyl sulfoxide as the cryoprotective agent. In vitro recovery of frozen and thawed platelets and posttransfusion increments may be satisfactory for clinical use, although only approximately half of the platelets survive the freeze-thaw process.103,104 This recovery may be improved by combining a platelet additive solution with a reduced concentration of dimethyl sulfoxide.105 Theoretically, autologous frozen platelet transfusions may permit support of highly alloimmunized patients through periods of chemotherapy-induced myelosuppression.104,106 Currently, frozen platelets are not available for clinical use; however, studies are beginning to evaluate preserving platelets by freeze-drying with trehalose.107,108

PREPARATION OF PLASMA COMPONENTS
Plasma is obtained from whole blood donations and apheresis collections. The plasma may be used for transfusion, further processed by the blood center into cryoprecipitate, or sent to commercial facilities for manufacturing into plasma derivatives.

Plasma Components for Transfusion

Plasma components such as FFP and cryoprecipitate are produced from individual volunteer blood donations and are briefly described here. As noted earlier, transfusable plasma units are not typically made from donors with an increased likelihood of having antibodies to WBC (e.g., women or women with a history of pregnancy); this strategy reduces the TRALI risk associated with plasma transfusion.

P.553

**Fresh Frozen Plasma, Plasma Frozen within 24 Hours (FP24)**

Fresh frozen plasma (FFP) is prepared by separating citrated plasma from whole blood and freezing it within 8 hours of collection or by freezing citrated apheresis plasma within 6 hours of collection. Each unit of FFP prepared from whole blood contains approximately 200 ml of plasma. Apheresis plasma may be packaged into 200- or 400-ml bags. FFP may be stored at -18°C or below for up to 1 year. Under these conditions, there is minimal loss of activity of the labile coagulation factors V and VIII. One milliliter of FFP contains approximately one unit of coagulation factor activity. After thawing, FFP may be stored in the refrigerator for up to 24 hours before use.

A product called “Plasma frozen within 24 hours after phlebotomy” (FP24) has largely replaced FFP production in the United States. As discussed earlier, TRALI mitigation strategies have restricted the donations from which transfusable plasma units can be made. In order to maintain a sufficient supply of plasma components for transfusion, most blood collection facilities in the US are labeling their plasma units as “Plasma frozen within 24 hours after phlebotomy” rather than “FFP.” This labeling permits blood centers to make transfusable plasma units from donations that reach the component processing facility more than 8 hours after collection. The content of FP24 is identical to that of FFP except that the Factor VIII content may be reduced to 80% that of FFP. This Factor VIII content is more than sufficient for the therapeutic applications in which plasma is utilized, e.g., trauma, liver disease, warfarin reversal, etc. Therefore, FFP and FP24 are typically used interchangeably.

**Liquid Plasma, Thawed Plasma**

Liquid plasma is a term for plasma that is separated from whole blood and stored at 1°C to 6°C without freezing. Thawed plasma is a term for FFP or FP24 that is thawed and stored in the refrigerator for up to 5 days after thawing. The only significant difference between these products and FFP/FP24 is the content of the labile coagulation factors (V and VIII).

After 5 days of refrigerated storage, Factor VIII and V levels are at about 65% to 75% of their original levels. After 28 days' storage, Factor VIII activity is approximately 40% of normal and Factor V levels approximately 50% to 60% of normal.

Other coagulation factors, including fibrinogen, ADAMTS 13, and factors II, VII, IX, X, and XIII, are generally stable under refrigerated storage conditions.

Liquid plasma or thawed plasma should not be used for clotting factor replacement in patients who have specific deficiencies of factor V or VIII. However, these products can be used for plasma replacement in massively bleeding patients, as these products will still maintain clinically hemostatic factor levels in the patient (i.e., 30% of normal). Because Vitamin K-related factors are not depleted during refrigerated storage, these prolonged storage products would be equivalent to FFP or FP24 for warfarin reversal.

**Plasma, Cryoprecipitate Reduced**

This is the supernatant remaining after removal of cryoprecipitate from FFP (see “Cryoprecipitated Antihemophilic Factor”). Storage conditions are the same as for FFP. This product is deficient in fibrinogen, Factor VIII, von Willebrand factor (vWF), and factor XIII. Cryoprecipitate-reduced plasma was initially thought to be superior to FFP for treatment of TTP because of its lower vWF content. Randomized studies have verified that this fluid is therapeutically effective for TTP; however, it is not superior to FFP.

**Cryoprecipitated Antihemophilic Factor**

Cryoprecipitated AHF, or cryoprecipitate, is an extract of FFP that is enriched in high-molecular-weight plasma proteins. It is prepared by thawing one unit of FFP at 1°C to 6°C. Under these conditions, the high-molecular-weight proteins remain
as a precipitate. The precipitated protein is concentrated by centrifugation, and all except approximately 15 ml of supernatant is removed. The remaining 15 ml and the precipitate are refrozen. Each unit of this cryoprecipitate contains approximately 80 to 120 units of Factor VIII and at least 150 mg of fibrinogen. It also contains factor XIII, fibronectin, and the high-molecular-weight multimers of vWF.

Cryoprecipitate was originally developed for the treatment of hemophilia A. It is no longer the treatment of choice for that disorder, because less infectious alternatives are available. At the present time, cryoprecipitate is most often used for correction of hypofibrinogenemia (<100 mg/dl) in bleeding patients. Cryoprecipitate has also been used topically, along with thrombin and calcium, as a “fibrin glue.” However, commercial products that are much more effective as topical hemostatic or sealant agents are now available. A commercial fibrinogen concentrate for intravenous infusion is available, but as of April 2012 this product was approved in the US only for treatment of congenital fibrinogen deficiency.

The typical dose of cryoprecipitate of one unit per 5 to 10 kg can be expected to raise the recipient’s fibrinogen level by approximately 70 mg/dl.\(^2,3\) Multiple units of cryoprecipitate are often pooled before administration.

Commercial Plasma Derivatives

Commercial plasma derivatives are made from pooled plasma collected from hundreds or thousands of donors. In the United States, paid plasmapheresis donors provide most of the plasma derivatives, but excess (“recovered”) plasma from volunteer whole blood donations is used also. Plasma units are pooled and fractionated into a number of purified proteins. The most commonly used fractionation procedure is based on Cohn’s cold ethanol fractionation process, developed in the 1940s.\(^1,119\) As the temperature, ionic strength, pH, and ethanol concentration are varied, plasma can be separated into several fractions. Fraction I contains Factor VIII and fibrinogen, fraction II contains the immunoglobulins, and fraction V contains albumin. Fractions III and IV contain a number of other coagulation factors and proteins. Although other approaches such as ion-exchange chromatography have been applied to the preparation of certain plasma products, Cohn’s method remains the standard.

Because the plasma pools used for the production of plasma derivatives are derived from many donors, contamination with infectious agents is common. All plasma derivatives are treated by methods demonstrated to inactivate HIV, HCV, and hepatitis B virus (HBV), such as prolonged heat and treatment with organic solvents and detergents, which inactivates lipid-coated viruses. Pooled plasma products, however, could still transmit infectious agents that lack a lipid coat and that are resistant to heat. Human parvovirus B19 is one such agent. The FDA requires screening for, and exclusion of, donations that contain high titers of the B19 virus,\(^120\) but low levels of B19 virus can still be present in the pools. Many plasma derivatives undergo additional purification steps such as affinity chromatography, precipitation, or nanofiltration that would further reduce their contamination by infectious agents.\(^119,121\)

There are many commercial plasma derivatives available. Some examples are described in the following.

Solvent/Detergent-treated Plasma

Solvent/detergent-treated plasma is made from hundreds or thousands of units of FFP that have been thawed, pooled, subjected to treatment with organic solvents and detergents, filtered, and refrozen.\(^122\) The product was developed to reduce the risk of transmitting enveloped viruses, such as HIV, HCV, and HBV. It appears to be therapeutically equivalent to FFP.\(^122\) A version of this product introduced in the US in the late 1990s was withdrawn after reports of thromboembolic complications. European versions of this product, however, are in current use and have a good safety record. In contrast to individual plasma units, this pooled plasma product has not been associated with transfusion-related acute lung injury (TRALI), presumably because of dilution of antibodies from individual donors during plasma pooling.

Coagulation Factor Concentrates

The coagulation factor concentrates, both the recombinant products and those made from plasma, are discussed in detail elsewhere as part of the management of inherited or acquired coagulation disorders (see Chapters 53 and 54). Recombinant coagulation products are used when available; these include Factors VIII, IX, and VIIa. Some factors are available only as plasma-derived concentrates, including fibrinogen and protein C.

Immunoglobulins

Intramuscular immune globulin preparations are prepared from pooled plasma by cold ethanol fractionation. They contain dimeric and polymeric IgG, artifacts of the fractionation procedure, which are capable of nonspecifically activating
complement by both the classic and alternative pathways. This mechanism probably explains the major adverse effects that occur if these products are administered intravenously. 119 Products labeled for intramuscular use must therefore not be given intravenously.

Intravenous immune globulin preparations (IVIGs) are produced by various chemical modifications designed to decrease the aggregation of IgG. Nonspecific complement activation is reduced, whereas the ability of the Ig molecules to interact with pathogenic organisms and complement is retained. Many of these products may also be administered subcutaneously.

Nonspecific immune globulin preparations contain a broad spectrum of antibodies naturally present in the donor population. They are most often used for treatment of primary immunodeficiency or as immune modulators. 123 Immune globulins against a particular target are derived from the plasma of donors selected for high concentrations of antibodies to that target. Such preparations include Rh immune globulin, hepatitis B immune globulin, and Varicella zoster immune globulin.

IVIGs have been associated with some adverse reactions, including renal failure, hemolysis, and thrombotic events. Both IM and IV immune globulin products should be used with caution in patients with IgA deficiency, because they may contain small quantities of IgA.

BLOOD COMPONENT MODIFICATION

Leukocyte Reduction

When whole blood is separated by centrifugation, WBCs sediment at the interface between red cells and platelet-rich plasma. Therefore, WBCs typically contaminate both red cell and platelet components, with concentrations of WBCs approximately $10^6$/product. WBCs in blood components can mediate febrile transfusion reactions, stimulate HLA alloimmunization in transfusion recipients, and transmit some cell-associated pathogens such as cytomegalovirus (CMV). 124 Therefore, it is desirable to remove WBCs from transfusable blood components.

Historically, several methods have been used to reduce the number of WBCs in transfusable blood components. Relatively nonspecific methods were used initially, including saline washing of red cells or physical separation of the WBC layer (buffy coat) from the RBCs. 124 Later, microaggregate filters were used to remove WBCs after centrifugation. 125 These methods resulted in white cell reduction of 70% to 90% and were effective in preventing most febrile reactions to red cells. Freezing and deglycerolization of red cells have also been used to remove WBCs and result in approximately 2-log WBC removal. Ultimately selective leukoreduction filters were developed that can reduce WBCs from blood components by 3 or more logs. These synthetic fiber filters remove WBCs by a combination of mesh density, chemical attraction, and active adhesion. 124 All leukocyte-reduced red cells are now produced using these special filters and, by FDA criteria, have less than $5 \times 10^6$ WBCs/unit and at least 85% of the original RBC component.

Leukofiltration of RBC components may be performed at the blood collection center, in the hospital transfusion service, or at the bedside. Filtration prior to storage reduces WBC breakdown products in the blood component and there is some evidence that RBC viability is better preserved. The clinical importance of these benefits has not been demonstrated. 124 In practice, most RBC leukofiltration is performed by blood collection centers within the first few days after collection.

Apheresis platelets usually contain very few WBCs and usually qualify as leukoreduced ($<5 \times 10^6$ WBCs) without the need for filtration. In contrast, whole blood-derived platelet concentrates contain large numbers of WBCs, and many of the febrile transfusion reactions to these products appear to be due to cytokines produced by the WBCs in these products during storage. 126,127,128 and 129 Therefore, removal of WBCs from whole blood-derived platelet concentrates before storage is beneficial. One system is approved in the US that allows prestorage leukocyte reduction and pooling of whole blood platelets.

The use of leukoreduced products has evolved over the last decade or two. Initially these products were indicated for patients with a history of febrile, nonhemolytic transfusion reactions, to reduce the risk of HLA alloimmunization, and as an alternative to cytomegalovirus (CMV) antibody screening of donors to reduce the risk of transfusion-transmitted CMV. Now the use of leukoreduced products has become nearly universal, although the medical necessity of universal leukoreduction remains somewhat controversial. 130

Washed Products

Saline washing with automated cell washers can be used to reduce the amount of plasma in cellular blood products. These washers are capable of removing approximately 99% of plasma proteins from red cell products. 2 Although cell washing was previously also used for leukocyte reduction, it is no longer used for this purpose. Today, washing is primarily used to
reduce incompatible plasma and also prevent severe allergic reactions (which are thought to be triggered by donor plasma proteins). Washing is also used to reduce RBC supernatant potassium, which may be required prior to massive or rapid infusion of stored RBC to neonates. Washing on an automated cell processor takes 30 to 45 minutes/unit. Because the washing procedure is usually performed in an “open” system, the red cells have only a 24-hour shelf life after washing. A closed processing system has been developed that may permit longer storage of washed cells. Although many facilities perform red cell washing, few offer washed platelets. Use of automated cell washers to wash platelets has been described. However, in practice, it may be difficult to ensure adequate platelet recovery and viability after washing.

Irradiation of Blood Products

Gamma irradiation of cellular blood components is used to prevent transfusion-related GVHD by impairing the proliferative capacity of lymphocytes in the blood component. The recommended dose for the irradiation of blood and blood products is 2500 cGy at the center of the irradiation field, with a minimum dose of 1500 cGy at any point in the field. This dose of radiation has no significant adverse effect on red cell, platelet, or granulocyte function. However, there are changes in the red cell membrane that result in an increased loss of potassium from the cell, limiting the storage time of red cell concentrates to 28 days. The amount of accumulated free potassium in the supernatant of irradiated red cells may be clinically important in massive transfusion, especially in the neonate. It may be desirable to irradiate proximate to transfusion, or wash stored irradiated RBCs if massive transfusion of irradiated products is required for a patient at risk for hyperkalemia. The dose of irradiation used for cellular blood components is not sufficient to inactivate pathogens. The irradiation doses required for pathogen inactivation would irreparably damage blood components.

ALTERNATIVES TO ALLOGENEIC DONOR BLOOD

Autologous Blood

Autologous blood donation is blood donated by a patient, intended for transfusion back into the same patient. Blood collected for autologous use is not released to other patients.

Use of a patient’s own (autologous) blood may reduce or eliminate the need for allogeneic blood. There are three types of autologous blood collection procedures. In preoperative autologous donation (PAD), patients donate one or more units of blood to a blood bank during the weeks preceding an elective procedure. In acute normovolemic hemodilution (ANH), blood units are collected in the operating room immediately prior to surgery. In autologous blood cell salvage, blood lost during or after a surgical procedure is salvaged for reinfusion.

Preoperative Autologous Donation

Preoperative blood donation (PAD) is most often used for patients who are expected to require transfusion during elective surgery. It is also used in patients for whom crossmatch-compatible blood cannot otherwise be made available, as in patients with rare blood groups or with multiple alloantibodies. For autologous collections, the donor eligibility criteria are not as stringent as for allogeneic donors. The key consideration is whether the patient can tolerate the acute withdrawal of a unit of whole blood representing 10% to 15% of their blood volume. Patients with significant cerebral or cardiac disease should be evaluated before they are enrolled in a PAD program. Children are also eligible for autologous blood donation, but the volume of blood collected and anticoagulant used must be adjusted to body weight.

An autologous donor may donate blood every 3 days as long as the donor’s hemoglobin remains at or above 11 g/dl. An “aggressive” donation schedule stimulates a more substantial endogenous erythropoietin response, with the potential for more autologous units collected or a higher patient hemoglobin at surgery. In most instances, the units of blood are stored in the liquid state for up to 35 to 42 days. They may be frozen if a longer interval between donation and surgery is required, but this significantly increases the cost and is not routinely recommended.

All autologous collections must be tested for ABO group and Rh type. The units must be labeled For Autologous Use Only. If autologous blood is to be transfused at an institution that is not the collecting facility, the blood unit must be tested for transfusion-transmitted infectious diseases. Units with reactive infectious disease tests must be labeled with biohazard labels. Regulators permit the use of autologous units with positive infectious disease tests. However, some hospitals do not accept such units because of concerns related to the risk of accidental transfusion of the unit into the wrong patient. PAD is not necessarily beneficial to the patient. There is a reported 12-fold increase in the number of autologous donors hospitalized after a donation compared to allogeneic donors, with an increased risk in the elderly. Iron supplementation
is recommended, but may not be sufficient to prevent anemia, especially if the last unit of autologous blood is collected <7 days preoperatively. This anemia may increase the patient’s likelihood of requiring transfusion. PAD is expensive and the logistics of collecting and shipping the blood in the desired timeframe are complex. Autologous blood may be wasted or transfused unnecessarily, particularly if collected for procedures in which transfusion is rarely needed. Transfusion complications such as bacterial contamination, febrile nonhemolytic transfusion reactions (FNHTRs), allergic reactions, and volume overload can occur with autologous transfusion. The possibility of an accident or error such as the transfusion of the wrong unit or an allogeneic unit into the autologous donor/patient has been reported to be as high as 1.2%. The cost-effectiveness of PAD is has been questioned, given its high cost, risks, and limited benefit.

Acute Normovolemic Hemodilution

The second approach to autologous blood procurement involves the withdrawal of blood immediately before the surgical procedure and replacing the blood with crystalloid, colloid, or both, thereby acutely lowering the patient’s hematocrit. The blood lost during surgery is therefore relatively dilute, reducing total red cell loss. The higher hematocrit blood withdrawn immediately prior to surgery is used for transfusion. Patients most likely to benefit from this maneuver are those with anticipated large surgical blood losses who can tolerate low intraoperative hematocrits.

Units collected by ANH can be stored at room temperature for up to 8 hours or at 1°C to 6°C for up to 24 hours. The blood so collected does not undergo any storage-related changes. The relative efficacy of ANH in comparison to other blood conservation techniques has been debated. The cost of ANH is significantly less than that of PAD because there is little incremental cost associated with collecting the blood and no required testing.

Intraoperative and Postoperative Salvage and Reinfusion

A third approach to autologous transfusion is the collection and retransfusion of blood lost during or after surgery. Perioperative salvage has been shown to be effective in reducing the need for allogeneic blood in a variety of surgical procedures. The AABB publishes Standards for Perioperative Autologous Blood Collection and Administration, which provide guidance for use of these blood conservation options.

There are two basic techniques available. Intraoperatively, an anticoagulated vacuum suction device can be used to collect blood from the surgical field and deliver it to a centrifuge- like device that washes the shed blood with saline before it is reinfused. Only red cells are salvaged by this method (platelets and plasma are lost). There has been concern about the safety of reinfusing materials suctioned from obstetric, cancerous, or contaminated surgical fields. Published experience to date, however, suggests that reinfusion of salvaged cells after processing with leukoreduction filters may be safe in these settings. Postoperatively, blood shed into joints or body cavities can be collected into sterile containers. The salvaged material must be filtered to remove fat and particles, and may then be reinfused either directly or after washing. The shed fluid contains red cell stroma, free hemoglobin, activated clotting factors, and fibrin degradation products.

It appears that there is not an increased risk associated with infusion of unwashed shed blood if the volume reinfused is limited to approximately 1 L. There is little value to salvaging shed blood in settings where the volume of fluid drained from the surgical site is small or has a low hematocrit. Because these devices are expensive, patient selection is important.

Erythropoiesis Stimulating Agents

Erythropoiesis stimulating agents (ESA) have been used to stimulate red cell production in patients, either to increase the number of units that can be collected preoperatively or to increase preoperative red cell mass. The use of epoietin alfa has been approved to facilitate autologous blood donation in the European Union, Canada, and Japan, but not in the United States. Epoietin alfa has also been approved for perisurgical use in anemic patients (Hgb ≤13 g/dl) in the US and Canada.

Artificial Oxygen Carriers

Some aspects that make the artificial oxygen carriers particularly appealing include: the prospect of being free of most or all of the infectious risks of allogeneic blood; no need to perform blood grouping and cross match; extended shelf life and possibility of storage at room temperature; the potential for a virtually unlimited supply; and the possibility of development of homogeneous and standardized products with controlled characteristics optimized to achieve the goal of oxygen delivery without raising all other complexities of allogeneic blood. No artificial oxygen carrier is currently approved by the FDA for clinical human use in the US.
Perfluorocarbon (PFC) emulsions boost oxygen delivery by increasing the amount of dissolved oxygen. Use of these oxygen carriers must be coupled with oxygen and increased \( \text{FiO}_2 \) to further increase the amount of dissolved oxygen. The PFCs that reached clinical trials include Fluosol-DA (Alpha Therapeutics, Los Angeles, CA) and Oxygent (Alliance Pharmaceutical Corporation, San Diego, CA). Fluosol-DA was initially used to improve oxygen delivery to the heart muscle during percutaneous transluminal coronary angioplasty, but it was subsequently withdrawn because of difficulties in storage and preparation, and lack of utilization in angioplasty.

Hemoglobin-based oxygen carriers (HBOCs) increase the oxygen delivery by increasing total hemoglobin. Despite being an effective oxygen carrier, vasoconstriction (initially attributed to extravasation of the HBOC to interstitial space and scavenging nitric oxide)\(^{161}\), hypertension, and renal, pancreatic, and liver injury have been described as complications. Approaches such as purification, polymerization, cross-linking, conjugating with other macromolecules, and encapsulating in vesicles or other nanoparticles have been pursued to minimize toxicity and associated complications in subsequent generations of HBOCs.\(^{162}\)

A 2008 meta-analysis of 16 trials on 5 different HBOCs indicated that regardless of the individual product or indication studied, HBOCs are associated with significantly higher risk of death (relative risk of 1.30) and myocardial infarction (relative risk of 2.71) compared to the controls.\(^{163,164,165}\) A new generation of products is in development as “oxygen bridges” until anemia management via compensatory erythropoiesis with production of cellular hemoglobin can be achieved with the use of ESA and intravenous iron therapy.

**USE OF BLOOD COMPONENTS**

Table 21.1 lists the blood components available for clinical use and briefly summarizes the indications for the use of each. The use of each component is discussed in detail in the following sections.

**Patient Informed Consent**

Although approximately 14 million units of RBCs are transfused in the United States each year, their efficacy has never been demonstrated in well-designed trials. For purposes of obtaining the patient’s informed consent, the treating physicians and patient must understand that not all is known about the relative risks and benefits of blood transfusion.

The elements of transfusion consent comprise: a discussion of blood transfusion risks\(^{166,167}\) and benefits; alternatives to blood; an opportunity to ask questions; and patient consent.\(^{168}\) Consent should occur as far in advance of transfusion as possible, so that alternatives to allogeneic blood such as autologous blood can be made available. Some states have legislated that alternatives to allogeneic blood be offered to patients whenever there is a reasonable possibility that a blood transfusion may be necessary. It should also be noted that blood transfusion has been legislated to be a medical service not subject to commerce and trade laws, thus excluding the principle of implied warranty and granting blood banks immunity from strict product liability.\(^{169}\)

**Patient Blood Management**

Of the estimated 39 million discharges in the US in 2004, 5.8% (2.3 million) were associated with blood transfusion.\(^{170}\) The rate of blood transfusion more than doubled from 1997 to 2009. Increased provider awareness of the costs associated with blood transfusion\(^{171}\), and recognition of the potential negative outcomes have stimulated initiatives in Patient Blood Management.\(^{172}\) Blood Management has been defined as the appropriate use of blood and blood components, with a goal of minimizing their use. This goal has been motivated historically by: 1) known blood risks; 2) unknown blood risks; 3) preservation of the national blood inventory; and 4) constraints from escalating costs.\(^{172}\)

Patient-focused blood management\(^{173}\) is an evidence-based approach that is multidisciplinary (transfusion medicine specialists, surgeons, anesthesiologists, and critical care specialists) and multiprofessional (physicians, nurses, pump technologists, and pharmacists). Preventative strategies are emphasized to identify, evaluate, and manage anemia\(^{174,175}\) (e.g., pharmacologic therapy\(^{139}\) and reduced iatrogenic blood losses from diagnostic testing)\(^{176}\); to optimize hemostasis (e.g., pharmacologic therapy\(^{177}\) and point of care testing)\(^{178}\); and to establish decision thresholds (e.g., guidelines) for the appropriate administration of blood therapy (the impact of these activities on blood transfusion outcomes is illustrated in Figure 21.2\(^{172,179,180}\))

In the US, The Joint Commission (TJC) developed Patient Blood Management Performance Measures which have been placed in their Topic Library. These are available to be used as additional patient safety activities and/or quality improvement projects by provider institutions.\(^{181}\)

Patient Blood Management strategies for patients undergoing cardiac surgery have been shown to be safe and effective in reducing transfusion, while at the same time delivering high-quality outcomes. One institution reported that only 11% of
patients undergoing cardiac surgeries received blood transfusions; this program ranked first in their state for lowest risk-adjusted mortality.\textsuperscript{182}

**RED CELL TRANSFUSION**

The main indication for RBC transfusion is inadequate oxygen delivery as a result of anemia and, in some cases, hypovolemia. Wound healing is not impaired in the presence of anemia, and transfusion does not improve wound healing. Patients with chronic diseases should never be transfused simply because of mild asymptomatic anemia or as part of supportive care.

WBCs and platelets are nonfunctional.

Indications for Red Blood Cell Therapy

The therapeutic goal of a blood transfusion is to improve oxygen delivery according to the physiologic need of the recipient. The usual response to an acute reduction in hemoglobin in the normovolemic state is to increase cardiac output to maintain adequate oxygen delivery. The heart is the principal organ at risk in acute anemia. In a normal heart, increased lactate production and an oxygen extraction ratio of 50% occur at a hemoglobin of approximately 3.5 to 4 g/dl. In a model of coronary stenosis, the anaerobic state occurs at a hemoglobin of approximately 6 to 7 g/dl. No single number, either extraction ratio or hemoglobin, can serve as an absolute indicator of transfusion need. However, the use of a physiologic value in conjunction with clinical assessment of the patient status would permit a rational decision regarding the appropriateness of transfusion before the onset of hypoxia or ischemia.

Literature on mortality in surgical patients refusing transfusion provides insight into the circumstances in which transfusion may be of benefit. In a review of 16 reports of the surgical outcomes in Jehovah’s Witness patients who underwent major surgery without blood transfusion, mortality associated with anemia occurred in only 1.4% of the 1,404 operations. A more detailed analysis of 61 studies of Jehovah’s Witness patients found that, with the exception of three patients who died after cardiac surgery, all deaths attributed to anemia occurred in patients with hemoglobin ≤5 g/dl. In one large study of surgical patients refusing transfusion, the risk of death was found to be higher in patients with cardiovascular disease than in those without. A subsequent analysis found that although the risk of death was low in patients with postoperative hemoglobin levels of 7.1 to 8.0 g/dl, morbidity occurred in 9.4%; the odds of death in patients with a postoperative hemoglobin level ≤8 g/dl increased 2.5 times for each gram decrease in hemoglobin level.

A large retrospective study of elderly patients who underwent surgical repair of hip fracture found that transfusion of patients with hemoglobin levels ≥ 8 g/dl did not influence 30-day or 90-day mortality. This was confirmed by a subsequent randomized, prospective study. Prospective, randomized trials in patients undergoing cardiac surgery and receiving critical care have each demonstrated that such patients can tolerate anemia without transfusion to hemoglobin levels between 7 and 8 g/dl, with equivalent clinical outcomes comparable to patients maintained at hemoglobin levels of greater than 10 g/dl. A Cochrane meta-analysis of prospective
randomized trials comparing “high” versus “low” hemoglobin thresholds on more than 3700 patients found that a hemoglobin of 7 g/dl was sufficient for the majority of patients.

FIGURE 21.2. Patient blood management. These principles applied in the perisurgical period enable treating physicians to have the time and tools to provide patient-centered evidenced-based patient blood management in order to minimize allogeneic blood transfusions. (From Goodnough LT, Shander A. Patient blood management. Anesthesia 2012;116:1367-1376, with permission.)

AABB clinical practice guidelines suggest that patients should not be transfused with red blood cells, in the absence of symptoms/signs of anemia, unless the Hgb concentration is less than 7 to 8 g/dl, or less than 8 g/dl for patients with symptoms or known to have cardiovascular disease. Comprehensive blood management guidelines from the Societies of Thoracic Surgeons and Cardiovascular Anesthesiologists contain similar recommendations, suggesting that RBC transfusion may be life-saving when hemoglobin is less than 6 and is reasonable in most patients when hemoglobin is less than 7. However, it is unlikely that a hemoglobin value alone should serve as a “transfusion trigger;” patients should be managed, rather than laboratory values.

Red Cell Transfusion in Specific Settings

Massive Hemorrhage

One of the major indications for blood transfusion is the restoration of circulating blood elements after the loss of large amounts of blood (Table 21.2). In general, adults who lose <20% of their blood volume (or approximately 1 L) do well without red cell transfusion, providing that fluid resuscitation is adequate to maintain the circulating blood volume and that further blood loss is avoided. Young healthy patients can sustain losses of up to 30% to 40% of blood volume as long as intravascular blood volume is adequately maintained with intravenous (IV) fluids.

Massive hemorrhage is generally defined as transfusion of more than 10 U of RBC (one complete blood volume replacement) within 24 hours. Massive hemorrhage is a common complication in a number of clinical settings. In traumatic injury, hemorrhage is a major cause of morbidity and is responsible for almost 50% of deaths occurring within 24 hours of injury and up to 80% of intraoperative trauma mortalities. In addition, cardiovascular and hepatobiliary procedures can frequently result in massive bleeding; postpartum hemorrhage events can complicate...
labor and delivery; and diverticulosis or varices can lead to significant gastrointestinal bleeding. Blood component support before and after control of massive hemorrhage is critical in these scenarios. Despite the need for consensus on the management of patients with massive bleeding, currently no such consensus exists.

An estimated 10% of military trauma patients and 3% to 5% of civilian trauma patients receive massive transfusions (MTs). Within the standard definition of massive hemorrhage there appears to be an important subset of patients who may benefit from blood components in addition to RBCs, specifically, those with rapid massive bleeding. Both Moore et al. and Holcomb et al. demonstrated that patients receiving 10 U of RBCs in the first 6 hours after injury had a higher rate of mortality than those receiving the same quantity of RBCs over a 24-hour period. Early identification of this patient population and specific massive transfusion (MT) support strategies involving multiple blood components have been associated with improved survival.

In response, transfusion services have implemented protocols to quickly and efficiently provide packages of blood products to patients with massive hemorrhage. There are a number of criteria available to help evaluate the effectiveness of different strategies used by transfusion services. Evaluation of the effectiveness of these protocols should include several parameters: clinical outcomes (survival, length of hospital stay, multisystem organ failure, infection rate, etc); post-resuscitation laboratory parameters (hemoglobin, prothrombin time [PT], partial thromboplastin time [PTT], fibrinogen, and PLT count); and 24-hour blood component and crystalloid use. A recent review summarizes the literature to date, highlights some of the limitations of the available evidence, and identifies areas in need of additional study.

Recent data from the US Army's Institute of Surgical Research have shown improvement in outcomes when soldiers requiring MTs received resuscitations with ratios of component types that were similar to whole blood transfusions. Subsequent reports, primarily in the military literature, further support a component therapy transfusion in ratios of 1 U RBC/1 U plasma/1 random donor unit of PLTs. However, these are retrospective studies, with a survivorship bias. The military data also lack adjustment for confounding variables such as injury severity. Nevertheless, these data have led to widespread support of this ratio, particularly the 1:1 ratio of RBC/plasma, although considerable debate remains on this topic.

Civilian trauma studies have also evaluated the impact of more aggressive ratios and noted an association with improved survival with use of MT protocols. However, these are retrospective studies, with survivorship bias. The military data also lack adjustment for confounding variables such as injury severity. Nevertheless, these data have led to widespread support of this ratio, particularly the 1:1 ratio of RBC/plasma, although considerable debate remains on this topic.

Several studies have called into question the benefit of higher plasma ratios. Nevertheless, the cumulative data appear to support early, proactive support with high ratios of plasma to RBC along with additional support with platelets. Not all studies showed a mortality benefit, and in the absence of randomized trials, data to convincingly support a particular ratio or formula are needed. However, the existing data suggest that a well-organized MT protocol
that is activated in a timely fashion is likely to demonstrate improved patient outcomes and result in less overall blood product usage in large trauma centers.\textsuperscript{218,219}

**Elective Surgery**

In preparation for surgery, preoperative requests for typed and crossmatched blood should be based on the predetermined likelihood of a procedure requiring a blood transfusion. “Maximum surgical blood order schedules” or “standard blood orders” specify the number of units that should be crossmatched for a variety of procedures and include guidelines for pretransfusion assessment.\textsuperscript{227,228} A pretransfusion request for type and crossmatch should be sent to the blood bank if it is likely (\geq 10\% probability) that blood will be required for a specific surgical procedure. The request should be for a type and screen if it is unlikely (<10\%) that the patient will require blood. As discussed previously under patient blood management, preoperative evaluation and management of anemia to correct deficits in red cell mass is the single most important determinant of the likelihood of perioperative blood transfusions.\textsuperscript{172}

**Nutritional Deficiencies and Other Anemic States**

RBCs are often transfused in the management of various types of anemia. Published guidelines (see above) advise transfusing on the basis of clinical indications. Physiologic adaptations to anemia, including elevated red cell 2,3-DPG content and increased cardiac output, compensate to preserve oxygen transport and delivery to a significant extent in chronic anemias. Transfusion is rarely indicated in these patients if there is time to correct anemia with alternative therapies.

Patients who are anemic solely because of deficiency of iron, folate, or B\textsubscript{12} rarely require transfusion. Patients with “lifethreatening” anemia (Hgb <6.5 g/dl) by WHO (World Health Organization) and NCI (National Cancer Institute) criteria may require transfusion.\textsuperscript{229} Elderly patients who present with pernicious or severe iron deficiency anemia may require red cell transfusion, particularly when angina or congestive heart failure has been the cause of the patient seeking medical attention. Iron-deficient patients who are also bleeding actively (e.g., from the gastrointestinal tract) may also require red cell transfusion. In such situations, the goal of transfusion is not to correct the patient’s hemoglobin concentration, but to raise it sufficiently to stabilize the patient until specific therapy can be administered.

**Hemolytic Anemias**

Patients with acute or chronic hemolytic anemias may require red cell transfusion; often, this need arises at the time of a hemolytic or aplastic crisis. Such patients are often critically ill, and safe transfusion requires careful clinical attention. In autoimmune hemolytic anemia,\textsuperscript{230,231} the clinician may be faced with a severely anemic patient for whom crossmatch-compatible blood cannot be obtained. These patients produce an antibody that reacts with all RBCs including their own, and the transfusion of serologically incompatible red cells may be necessary. At a hemoglobin <6 g/dl, most patients require transfusion. In these cases, withholding transfusion in the absence of “compatible” RBCs places the patient in needless danger. Although “incompatible” cells will have a shorter than normal lifespan, transfusion reactions are infrequent. The risk of complications is increased if the patient has brisk hemolysis and a large volume of blood is infused, or if the patient has an undetected alloantibody in addition to the autoantibody. If time allows, special techniques should be used to evaluate these patients for alloantibodies prior to transfusion (see “Autoagglutination”). Consultation with a transfusion medicine specialist is recommended in these cases.

**Hypoproliferative Anemias**

In aplastic and sideroblastic anemias, myelodysplastic states, and myelofibrosis, patients often depend on regular transfusion of red cells and may die of transfusion-induced iron overload after several years of such support unless precautions are taken to remove iron. The development and use of erythropoiesis stimulating agents have reduced the need for transfusion in many patients with hypoproliferative anemia, such as those with end-stage kidney disease (see Chapter 41) and in patients with chemotherapy-induced anemia.\textsuperscript{232}

**Hereditary Red Cell Disorders**

In children with thalassemia (see Chapter 34), bone marrow hyperplasia with its undesirable effects on the skeleton may be ameliorated, and iron absorption decreased, by regular transfusions to maintain a near-normal hemoglobin concentration.\textsuperscript{233} Such a program is possible only in conjunction with an aggressive iron chelation program, as the iron load otherwise leads to fatal hemosiderosis. In patients with sickle cell disease and vaso-occlusive crises (see Chapter 33), the adverse microvascular effects of sickle cells can be relieved temporarily by hydration with crystalloid therapy to
restore intravascular volume, rather than with RBC transfusions (to avoid chronically unnecessary risks of alloimmunization and iron overload). Red cell exchange may be indicated when impaired oxygenation leads to <90% O₂ saturation, in order to address the generation of sickle cells in acute chest syndromes. A multicenter trial (STOP trial) showed a significant decrease in the incidence of stroke in patients with abnormal transcranial Doppler studies who were treated with simple or exchange transfusions to maintain their hemoglobin S concentrations <30%, compared to patients who remained on standard supportive care with transfusion only when clinically indicated.²³⁴

Pretransfusion Testing of Red Cells

Compatibility Testing Process

The process of selecting red cells for transfusion involves three stages. Blood grouping involves determination of the ABO group and Rh type of both recipient and donor specimens. The recipient’s serum or plasma is screened for the presence of unexpected red cell antibodies. Crossmatching, either serologically or electronically, after selection of a donor unit of the appropriate group and type determines whether the donor cells are compatible with the recipient's plasma.

Properly selected blood products will be compatible with the recipient, indicating that transfusion should not result in hemolysis of donor red cells. Because only the ABO and Rh(D) red cell antigens are prophylactically matched in routine transfusion practice, there are always significant antigenic differences between donor and recipient, both for red cells and for the accompanying leukocytes, platelets, and plasma. Repeated exposure to foreign antigens with chronic transfusion or pregnancy may result in antibody formation in the recipient.

There is no room for error in the provision of blood for transfusion. If clerical or laboratory error results in donor and recipient being mismatched for the ABO group, transfusion of even a few milliliters of red cells may lead to a life-threatening transfusion reaction with shock, intravascular coagulation, and acute renal failure. Such reactions are uncommon because of rigid adherence to a routine designed to maximize safety at all levels of the transfusion process; however, with the decrease in the risk of transfusion-transmitted infections, such reactions are becoming one of the leading risks of transfusion.³⁶,²³⁵ Careful identification of the patient for whom the blood is ordered, including complete labeling of the specimen at the bedside of that patient, is essential. Careful ABO blood grouping along with comparing results of ABO testing with historical records for each patient adds to the level of safety. Ensuring positive identification of crossmatched units of blood and verifying that the information identifying the unit with the intended recipient is reviewed in the presence of that recipient before the administration of the blood are crucial.²,⁵

Blood Grouping

The presence of ABO antigens is determined by testing the unknown RBCs with anti-A and anti-B sera by one of a variety of methods including slide, tube, gel, or microplate tests.² Identifying which ABO antigens are on the surface of an individual’s RBCs is called the forward grouping or forward typing. Cells agglutinated only with anti-A serum are group A; those reacting only with anti-B are group B. Those reacting with both antisera are group AB, and red cells that fail to agglutinate with either anti-A or anti-B are group O.

“Reverse grouping” or “reverse typing” should be performed to confirm the reaction obtained by the forward grouping test. This involves testing the reactions of the serum or plasma from the person of unknown type with reagent red cells of known A and B type. Agglutination of the red cells indicates the presence of anti-A or anti-B in the individual’s serum. The conclusions of forward and reverse tests should agree as shown in Table 21.3.

The antisera used in blood group antigen detection can be obtained from donors with naturally occurring high levels of antibodies, from people or animals specifically stimulated to produce antibodies against blood groups, or from monoclonal antibodies of mouse or human origin. The advantages of monoclonal antibodies include their high quality and stability and their ease of production in large quantities. Antisera must be of known specificity and potency, and control testing must be done on a routine basis.²

The Rh type of red cells is determined by examining the cells' reaction with anti-D serum from commercial sources. Commercial P.561

antisera may be modified by the manufacturer with the addition of high concentrations of protein or by chemically altering the immunoglobulin (Ig) G molecules in such a way that they perform as direct agglutinins in the laboratory. This permits rapid, reliable testing to determine the D antigen status of the cells. However, these high-protein reagents may cause false positive reactions because of spontaneous aggregation of some red cells in their presence. If this happens, an
Rh-negative patient could be typed as Rh-positive if the recommended Rh control is not tested simultaneously. This problem has led to the development of low-protein, saline-reactive monoclonal reagents. Monoclonal anti-D reagents contain both human IgM and polyclonal IgG antibodies and are currently most widely used. They can also be used in the antiglobulin test for weak D. As with all reagents, the manufacturers’ instructions must be followed.²

Red cells reacting weakly with anti-D reagents are called weak D. If donor blood is being tested, the absence of D must be confirmed. If the initial test for D is negative, a second, more sensitive test must be performed using a method that detects weak D. If D is detected by either method, the unit is labeled Rh-positive.²,³ In patients, testing for weak D is not required. Patients who are typed as Rh-negative, but who are really weak D-positive, will not be adversely affected by the transfusion of Rh-negative products. Patients known to be weak D-positive, however, may be given Rh-positive donor blood. Before concluding that a patient is weak D-positive, care must be taken to ensure that the patient has not recently been transfused with Rh-positive red cells or experienced a large fetal-maternal hemorrhage.

**Testing for Red Cell Antibodies**

Antibodies in potential blood transfusion recipients fall into several categories. The most common blood group antibodies that are clinically significant and may be implicated in hemolytic transfusion reactions or hemolytic disease of the newborn are shown in Table 21.4.

All human plasmas contain naturally occurring antibodies that react with the complementary antigens of the ABH system. These are of great importance in transfusion, as they are complement-fixing IgM antibodies; transfusion of incompatible red cells leads to immediate hemolytic reactions. Many people also have naturally occurring antibodies (usually low-titer IgM antibodies reacting at or below room temperature) that react with some antigens of the Lewis, P, Ii, MN, or other systems; these are rarely active above room temperature and are only occasionally important in transfusion. Finally, people exposed to foreign red cells by prior transfusion or pregnancy may produce IgG antibodies to antigens of certain other systems, primarily Rh (C, c, D, E, e), Kell, Duffy, Kidd, and Ss, but many less common possibilities exist. These red cell antibodies are clinically significant. They do not often lead to intravascular hemolytic reactions, but transfused incompatible red cells may exhibit decreased survival caused by increased clearance in the reticuloendothelial system. Many of these IgG antibodies can also cause hemolytic disease of the fetus and newborn.

There are two major classes of antibodies that react with red cells. Complete or saline antibodies agglutinate red cells suspended in saline solution; these are usually IgM. Antibodies that do not react visibly in saline and are capable of producing agglutination reactions only with special techniques to make their interaction with red cells detectable are called incomplete agglutinins; these are generally IgG antibodies.

The best example of a room temperature saline agglutination test is that used in ABO grouping. Other red cell antibodies that are readily detected in saline suspension are those belonging to the Lewis, MN, P, and Ii blood group systems. With the important exception of ABO system antibodies, many of the others detected with this test are of no clinical significance, as they are not reactive at 37°C.

The best examples of incomplete agglutinins, or IgG antibodies, are those that react with antigens of the Rh system. If such antibodies are not detected in the recipient, immediate hemolysis of transfused, incompatible red cells is extremely rare. However, their presence may lead to a significantly decreased survival of transfused cells and the development of an extravascular hemolytic syndrome (delayed hemolytic transfusion reaction [DHTR]).

Antiglobulin Test

The antiglobulin (Coombs) test (Figs. 21.3 and 21.4) is based on the reaction between an antihuman globulin (AHG) reagent and antibody- or complement-coated red cells. AHG reagents are commercially available and are prepared either by the injection of an animal with human globulin or through hybridoma technology. AHG reagents may be polyspecific or monospecific. The polyspecific reagents contain antibodies with both antihuman IgG and anticomplement activity. Monospecific AHG reagents, anti-IgG, anti-C3b, and anti-C3d, are used to determine which protein is responsible for a positive direct antiglobulin test.

The direct antiglobulin test is performed by washing the patient’s cells with saline, adding polyspecific AHG, and observing for agglutination (Fig. 21.3). Positive reactions (agglutination) suggest the presence of IgG antibodies or complement bound to the red cell. The indirect antiglobulin test is used to determine the presence of red cell antibodies in serum or plasma (Fig. 21.4). Reagent red cells are incubated with the patient’s serum or plasma, washed to remove unbound immunoglobulins, mixed with AHG (usually monospecific anti-IgG), and then centrifuged briefly. The cell button is gently resuspended and examined for agglutination. A positive reaction suggests that IgG antibodies in the patient’s plasma have bound to the reagent cells. A positive indirect antiglobulin test therefore indicates the presence of antibodies capable of reacting with red cells and possibly capable of hemolyzing such cells if they were transfused.
Direct and indirect antiglobulin tests are the simplest approaches to the detection of IgG anti-red cell antibodies. Because many of these serologic reactions are rather weak, the addition of various media has been used to enhance the agglutination reaction. These tests involve procedures that diminish the mutually repulsive electrostatic forces between red cells, permitting visible agglutination by IgG antibodies. Antigens that often require such enhancing tests include those of the Kidd (Jk<sup>a</sup> and Jk<sup>b</sup>), Rh (D, C, E, c, e), Kell, and Duffy (Fy<sup>a</sup> and Fy<sup>b</sup>) systems.

[Image: Direct antiglobulin test with anti-immunoglobulin G (IgG) and anti-C3d. RBC, red blood cell. (Reprinted from Jeter EK, Spivey MA. Pretransfusion testing. In: Jeter EK, ed. Introduction to transfusion medicine: a case study approach. Bethesda, MD: American Association of Blood Banks Press, 1996;56, with permission.)]

**Media That Enhance Agglutination**

Adding albumin, low-ionic-strength saline (LISS) or polyethylene glycol (PEG) solutions to antibody identification tests can enhance the sensitivity of the test system. These solutions augment the antibody-antigen interaction in a variety of ways, enhancing the detection of weak or otherwise undetectable antibodies. Treating reagent red cells with proteolytic enzymes such as papain or ficin also increases the sensitivity for some antibodies such as those reacting with Rh and Kidd system antigens. These enzyme reagents weaken or destroy other red cell antigens (M,N,Fy<sup>a</sup>, Fy<sup>b</sup>, and, in some cases, S, s)—a trait that can be helpful in the identification of multiple red cell antibodies in a single serum sample.

**Other Antibody Identification Tests**

Sera containing several antibodies may be analyzed by absorbing with one or more selected red cells. Antibodies so adsorbed may be eluted from the cells, and their specificity may be determined. Alternatively, the specificity of antibodies not absorbed and remaining in the supernatant can be identified. When necessary, the identity of certain antibodies may be confirmed by their inhibition by soluble antigens, such as A, B, and Lewis substances present in the saliva of secretors. Neonatal (cord) red cells exhibit a number of antigens very weakly and may be used to investigate antibody specificity.

**Selection of Red Cells for Transfusion**

A series of serologic tests is used to select donor blood for patients. Although individual transfusion services prefer different specific methods, the general principles of compatibility testing are the same.

A properly labeled, fresh sample of patient blood must be provided. If the patient has been transfused or has been pregnant within the preceding 3 months, the specimen must be obtained within 3 days of the anticipated transfusion.

Donor
The ABO group of the donor unit must be confirmed. The donor unit Rh typing must also be repeated if the unit is labeled as Rh-negative. These tests are performed to confirm the blood group and to ensure that the unit has not been mislabeled.

Recipient

The recipient’s ABO group and Rh type must be determined. The recipient’s serum is screened for the presence of antibodies that may have been induced by prior pregnancy or transfusion. A set of commercially prepared group O red cells, expressing 18 clinically relevant antigens (D, C, c, E, e, M, N, S, s, P1, Lea, Leb, K, k, Fya, Fyb, Jka, and Jkb), is used in this test in accordance with FDA rules. The use of group O reagent red cells avoids agglutination by anti-A or anti-B. These reagent cells are incubated with the patient’s serum and tested with the indirect antiglobulin test for reactions indicating the presence of antibody in the serum.²

If such screening reactions are positive, the antibody specificity can be determined by reaction of the serum with a commercially prepared panel of reagent red cells of known antigenic composition. If an antibody has been found on the screen and the patient’s clinical status allows, it is best to withhold transfusion until identification is complete. The incidence of unexpected RBC antibodies in patients requiring transfusion is low.²³⁸,²³⁹

Type and Screen

If it is unlikely that blood will be required, for example, for a surgical procedure with <10% likelihood of transfusion, a “type and screen” rather than a crossmatch should be requested. In this instance, the blood bank types the patient’s blood and screens for unexpected antibodies; if antibodies are not found, the blood bank ensures that blood of the appropriate group is available for transfusion if necessary. In such an event, a telephone call can trigger a rapid crossmatch test and blood will be available with minimal delay. The appropriate use of type and screen improves the efficiency of the blood bank. It assists in inventory control by not segregating blood for patients who are unlikely to require it and is therefore more cost-effective.

Crossmatch

If no antibody has been detected on the screen and there is no record of the previous presence of a clinically significant antibody, only verification of ABO compatibility between the donor unit and recipient is required before transfusion. This can be done either by an immediate spin crossmatch or a computer crossmatch.

The immediate spin crossmatch consists of mixing the patient’s serum with donor saline-suspended red cells at room temperature, spinning the tube, and reading the results immediately. The purpose of this test is to detect ABO incompatibility due to the presence of anti-A, anti-B, or both, in the patient’s serum.²

The conditions for computer or “electronic” crossmatch are outlined in the AABB standards.⁵ Briefly, the computer system must be validated to prevent release of ABO-incompatible blood. This computer crossmatch can be used only for patients who do not have a record of clinically significant antibodies. The recipient’s ABO blood group must have been determined.
on at least two separate tests. The system must contain complete information on the donor unit and the recipient, including ABO group and Rh type. Data entered must be verified as correct before the release of blood. The system must contain logic to alert the user to discrepancies for either the donor unit or the recipient, including unit labeling, blood grouping, and ABO incompatibilities.

If a clinically significant red cell antibody has been found when a patient’s plasma or serum is screened for unexpected antibodies, antibody identification should be performed. Once the antibody specificity has been identified, donor units that lack the corresponding antigen should be selected, and a crossmatch using an indirect antiglobulin test should be performed on each unit to ensure compatibility. The physician should also be advised about the nature of the problem, as well as the potential for delays if further units are required.

Once a unit of blood is crossmatched for a patient, there must be positive identification of the patient and the blood product both in the laboratory before release of a blood product to the nursing ward as well as at the patient’s bedside by the transfusionist. Before every transfusion, the requisition, the label on the blood product, and the patient’s identification must be checked. These aspects of patient and blood product identification are critical safety steps and must be documented.5

Uncrossmatched Blood for Emergency Transfusion

For patients in hemorrhagic shock, it is necessary to transfuse blood immediately, and no blood bank testing should be attempted before emergency transfusion. The risk of transfusing group O “uncrossmatched” red cells is extremely low and is certainly much lower than the risk of the patient’s death if blood transfusion is delayed. If a patient is to be given uncrossmatched blood, a specimen of the patient’s blood should be obtained prior to transfusion so that typing and screening can be performed while the transfusion is proceeding.

Once the patient’s blood group has been determined, ABO group-compatible uncrossmatched blood may be used.5 Until the patient’s Rh type is determined, uncrossmatched blood should be Rh(D)-negative when used in women of childbearing age, in whom sensitization to D would be undesirable. As Rh-negative blood is often in limited supply, Rh-positive blood is often used for emergency transfusion of older females and of males of unknown blood group. In such cases, sensitization may occur, but the risk of an immediate hemolytic reaction is low.236

Despite the lack of a crossmatch, transfusion of group-specific blood under emergency situations is safe. The incidence of red cell alloantibodies in healthy people is low, and most such antibodies do not cause dangerous acute intravascular hemolytic transfusion reactions. However, the decision to use uncrossmatched blood is the responsibility of the attending physician, who must weigh the risks against the expected benefits and document in the patient’s record the need for the uncrossmatched blood.

Table 21.5 outlines the selection of blood and plasma by ABO type. If the blood group is known, group-compatible red cells and plasma can be selected. If the blood group is not known, group O

are useful in identifying donors for patients with multiple red cell antibodies or blood donors with rare antigen types. Challenges with widespread application still exist.

Methods for their detection developed. Because these methods do not directly detect the presence of red cell antigens, transfusion. The molecular bases for many

Red Cell Genotyping

The use of DNA-based methodologies to identify donors with rare blood types is a useful tool in these challenging situations. When used with standard serologic testing, however, such methods are useful in identifying donors for patients with multiple red cell antibodies or blood donors with rare antigen types.
Additionally, these methods are helpful in determining a patient's red cell antigen makeup when chronically or recently transfused or when access to a blood specimen increases patient risk (e.g., fetus).

Special Considerations in Neonatal Transfusion

Pretransfusion Testing

The so-called naturally occurring IgM ABO antibodies do not begin to appear until approximately 3 to 6 months of age. However, IgG antibodies of maternal origin, including maternal anti-A or anti-B, may be passively transferred to the fetus. Thus, pretransfusion testing in the newborn consists of ABO and Rh typing of the infant's cells and an antibody screen for passively transferred maternal IgG antibodies, including anti-A or anti-B. If the initial antibody screen is negative, the infant may be transfused with products compatible with the patient's ABO/Rh type, and no further compatibility testing is required for the first 4 months of life. If a clinically significant antibody of maternal origin is detected, units that are antigen-negative or crossmatch-compatible must be issued until the antibody is no longer detectable in the infant's serum.\(^5\)

Selection of Products for Neonatal Transfusion

Preterm infants may require multiple transfusions to replace blood drawn for laboratory tests. It has become common practice to limit donor exposure by reserving one unit or one half unit for a single preterm infant. Serial aliquots may be obtained using a sterile connection device up to the outdate of the unit.\(^{245,246,247}\) Blood products for low-birth-weight infants should be irradiated to prevent transfusion-related GVHD and should be CMV reduced risk (i.e., CMV antibody negative and/or leukoreduced). Either CPDA-1 or additive red cells may be used for aliquot transfusions. However, the safety of additive solutions has not been demonstrated in the setting of massive transfusion of infants (i.e., one unit or more in a neonate). The amount of free potassium in the supernatant of the irradiated blood may also become clinically important in the setting of massive transfusion.\(^{132}\) For massively transfused infants at increased risk of hyperkalemia, the dose of free potassium in the red cell product may be decreased by delaying irradiation until just before issue or by washing the RBCs.

Exchange Transfusion

The most common indication for exchange transfusion in the neonate is hyperbilirubinemia that has not responded adequately to phototherapy, particularly that associated with hemolytic disease of the newborn. Usually, one to two blood volumes are exchanged.

Red cells collected in CPD or CPDA-1 that are less than 1 week old are preferred. Because several clotting factors in newborns are at the low end of hemostatic levels, many centers perform exchanges using whole blood, or red cells reconstituted with plasma, to prevent further lowering of factor levels by the exchange. Red cells used for the exchange transfusion should be irradiated to prevent transfusion-related GVHD.\(^2\)

Administration of Blood

The first step before the administration of blood or of a blood product is to obtain consent for the transfusion from the patient. Every hospital should set its own policy. A note in the chart indicating that the risks of transfusion as well as the indications and alternatives have been discussed with the patient and that the patient has accepted this form of therapy may be adequate, depending on applicable laws and regulations. There must be a written order for the administration of the product.\(^5\)

All blood products should be given through an appropriate blood administration set containing a filter; careful aseptic technique should be practiced at all times. There must be confirmation and documentation that the information identifying the blood product with the patient has been verified in the presence of the patient.\(^5\)

Vital signs should be documented before and after transfusion and as clinically required. For the first 15 minutes after the infusion has begun, the patient should be kept under close observation to detect any signs of a serious transfusion reaction. If none is observed, the infusion rate may be increased. One unit of red cells is often given in 1 to 4 hours, depending on the amount to be transfused and on the patient's cardiovascular status. Infusion of a unit for longer than 4 hours is not recommended, as there is a risk of bacterial proliferation because the opened unit is at room temperature. Normal (0.9%) saline, 5% albumin, or ABO-compatible plasma may be added. No other solution and no medication should be added to or infused through the same tubing as a blood product unless there is documentation of compatibility or FDA
ongoing platelet consumption, many patients return to their baseline platelet count within 1 to 2 days of platelet transfusion. Given the limited absolute increase in platelet count, the rate of consumption may be higher in critically ill patients.

Survival is reduced. A fixed rate of platelet consumption of $7.1 \times 10^9 \text{ cells/day}$ has been measured in otherwise stable patients with severe thrombocytopenia. It is assumed that this platelet consumption is associated with maintenance of vascular integrity. The rate of consumption may be higher in critically ill patients.

Given the limited absolute increase in platelet count achieved with the standard dose of platelets and the presence of ongoing platelet consumption, many patients return to their baseline platelet count within 1 to 2 days of platelet transfusion.

PLATELET TRANSFUSION

Platelet transfusion may be life-saving when hemorrhage is caused by thrombocytopenia. Modern treatment for hematologic malignancies would not be possible without the ability to prevent or treat thrombocytopenic bleeding. Similarly, many surgical procedures would not be feasible without platelet transfusions. Whether this therapeutic modality is effective depends on recipient factors, such as the presence of sepsis, azotemia, drugs, and platelet antibodies, and on the ability of the blood bank to provide functional platelets in sufficient numbers.

Administration of Platelets

Platelet concentrates may be provided by the blood bank in their individual plastic bags or pooled before transfusion. Apheresis platelets do not require any preparation. Once the blood bag is opened by puncturing one of the sealed ports, the platelets must be administered within 4 hours. Platelets must be administered through a filter approved for platelet use, either a standard 170-µm filter or a leukoreduction platelet filter.

Dosage and Expected Response

The usual dose of platelets is one unit for each 10 kg body weight, or approximately six units (or one apheresis platelet product) for a typical adult dose. The in vivo recovery of transfused platelets should be assessed by a platelet count obtained 10 minutes to 1 hour posttransfusion.

As noted earlier, even under ideal circumstances, only two thirds of transfused platelets are expected to be found in the circulation of the recipient. One can estimate the maximum expected increase in circulating platelet count after transfusion of one apheresis platelet product containing the minimum of $3 \times 10^{11}$ platelets into a 70-kg adult with a blood volume of 5 L as follows: Maximum increase in count = $2/3 \times 3 \times 10^{11}$ platelets distributed in 5 L blood volume = $40 \times 10^9 / \text{L}$.

In practice, the observed posttransfusion platelet recovery in patients is often much lower than ideal. Hematology patients typically achieve an increment of approximately $20 \times 10^9 / \text{L}$, about 50% of ideal, after infusion of $3 \times 10^{11}$ platelets. A recovery as low as 30% of the ideal is generally considered “acceptable.” This would correspond to an increase in platelet count of approximately $13 \times 10^9 / \text{L}$ after transfusion of one apheresis platelet product to a 70-kg adult. The expected and “acceptable” increases in platelet count would be proportionately lower in a larger adult and higher with transfusion of a larger dose of platelets.

Many investigators have assessed the acceptability of a posttransfusion platelet increment by calculating a corrected count increment (CCI). With the CCI, the measured increment in circulating platelet count is corrected for the patient’s size and for the dose of platelets given as follows: $\text{CCI} = \frac{\text{posttransfusion count} - \text{pretransfusion count}}{\text{number of platelets administered}} \times \text{body surface area (m}^2)$. The maximum achievable CCI is approximately $25 \times 10^9 / \text{L}$. The typical CCI in patients is approximately one half of this, and the lowest “acceptable” CCI is considered to be approximately $7.5 \times 10^9 / \text{L}$.

Patients with in vivo recoveries or CCIs lower than acceptable values should be evaluated for causes of platelet refractoriness such as an enlarged spleen or alloimmunization (as discussed in the section, “Platelet Refractoriness and Alloimmunization”). In healthy adults, the half-life of transfused platelets is 3 to 5 days. In thrombocytopenic patients, however, platelet survival is reduced. A fixed rate of platelet consumption of $7.1 \times 10^9 / \text{L/day}$ has been measured in otherwise stable patients with severe thrombocytopenia. It is assumed that this platelet consumption is associated with maintenance of vascular integrity. The rate of consumption may be higher in critically ill patients.

Given the limited absolute increase in platelet count achieved with the standard dose of platelets and the presence of ongoing platelet consumption, many patients return to their baseline platelet count within 1 to 2 days of platelet transfusion.
transfusion.\textsuperscript{249} In stable patients, the transfusion-free interval may be increased by administering larger doses of platelets with each transfusion.\textsuperscript{256,257} However, this strategy can result in an increase in the total number of platelets transfused.\textsuperscript{253}

Indications for Platelet Transfusion

The risks of posttraumatic and spontaneous bleeding increase as the platelet count falls. In general, assuming that platelet function

P.566

is normal, there is minimal risk of spontaneous bleeding due to thrombocytopenia at platelet counts >50 × 10^9/L, and this level is usually sufficient to permit surgical procedures.\textsuperscript{258} As the count falls below this level, there is an increasing risk of microvascular bleeding, characterized by petechiae, ecchymoses, oozing at venipuncture and incision sites, epistaxis, menorrhagia, gastrointestinal bleeding, or intracranial hemorrhage.

The precise degree of bleeding risk at any given platelet count is difficult to determine, as many other clinical variables have important effects. These include the cause of thrombocytopenia; the duration of thrombocytopenia; the nature of concurrent disease processes including sepsis, uremia, vasculitis, or malignant processes invading blood vessels or other organs; the coexistence of coagulopathies, such as liver disease, vitamin K deficiency, intravascular coagulation, or heparin treatment; and the presence of drugs such as ASA or semisynthetic penicillins that interfere with platelet function.\textsuperscript{259}

In general, the risk of significant spontaneous hemorrhage increases gradually as the platelet count drops to <50 × 10^9/L\textsuperscript{260} and is high at counts <5 × 10^9/L.\textsuperscript{248,249} (Figs. 21.5 and 21.6).

Clinical practice guidelines\textsuperscript{258,261,262} and a Cochrane metaanalysis\textsuperscript{263} for platelet transfusion therapy have been published. Additionally, a Performance Indicator for prophylactic platelet transfusions has been developed by The Joint Commission\textsuperscript{181} for patients with malignant hematologic diseases or those who undergo stem cell transplantation, in which a platelet count threshold of 10,000/mm is appropriate for prophylactic platelet transfusions.\textsuperscript{264}

Current guidelines from the European Union and United States recommend a transfusion trigger of 10×10^9/L for platelets transfused prophylactically.\textsuperscript{261,265} These guidelines are based on outcomes from four randomized clinical trials that compared prophylactic triggers of 10×10^9/L versus 20×10^9/L in patients with acute leukemia and in autologous and allogeneic hematopoietic stem cell transplant recipients.\textsuperscript{264,266,267} Two additional prospective studies also demonstrated safety with the lower threshold of 10×10^9/L for prophylactic platelet transfusions.\textsuperscript{269,270} The impact of these thresholds on numbers of platelet and blood transfusions is variable, however;\textsuperscript{270} one study demonstrated a 36% and 16% reduction in platelet and blood transfusions, respectively,\textsuperscript{270} while another showed no differences.\textsuperscript{269}
FIGURE 21.5. Stool blood loss as a measure of thrombocytopenic bleeding. When stool blood loss was determined in 20 aplastic thrombocytopenic patients, blood loss was less than 5 ml/d at platelet counts \( >10 \times 10^9 /L \). At platelet counts between 5 and \( 10 \times 10^9 /L \), blood loss averaged \( 9 \pm 7 \) ml/d. At levels \( <5 \times 10^9 /L \), blood loss was markedly elevated at \( 50 \pm 20 \) ml/d. (From Slichter SJ. Controversies in platelet transfusion therapy. Annu Rev Med 1980;31:523, with permission; and modified from Slichter SJ, Harker LA. Thrombocytopenia: mechanisms and management of defects in platelet production. Clin Haematol 1978;7:523. Reprinted with permission from Annu Rev Med 1980;31 by Annual Reviews, www.annualreviews.org.)
A recent trial demonstrated that “low dose” prophylactic platelet transfusions are equally effective as those with “standard” or “high” dose. For therapeutic platelet transfusions, algorithms for platelet transfusions based on point of care testing have demonstrated promise in patients who have platelet-derived bleeding such as in cardiothoracic surgery and in trauma. Additional evidence-based studies in platelet transfusion are needed.

**Prophylactic Platelet Transfusion**

Prophylactic platelet transfusion in the management of acute leukemia prevents major bleeding episodes, except perhaps during the terminal phase of the patient’s illness. However, no difference in mortality has been demonstrated between patients transfused prophylactically and those transfused only when bleeding occurred. Despite lack of such proof, it is common practice to attempt to prevent bleeding problems by administering prophylactic transfusions to thrombocytopenic patients.

The indications for prophylactic transfusion remain controversial. Until recently, it was common practice to transfuse platelets when the count was <20 × 10⁹/L. A number of studies have demonstrated that reducing the trigger for prophylactic platelet transfusion from 20 × 10⁹ to 10 × 10⁹/L resulted in decreased platelet transfusion without an increased frequency of significant hemorrhage. In these studies, however, the trigger for transfusion was liberalized in the presence of clinical factors suspected to increase the risk of hemorrhage, such as fever, an increased WBC count, coagulopathy, bleeding, or invasive procedures. When significant hemorrhagic events occurred, they were often in patients with morning platelet counts >20 × 10⁹/L. Infection, vascular lesions, or prolonged duration of thrombocytopenia may contribute to the risk of significant hemorrhage. Thus, it appears that a prophylactic transfusion trigger of 10 × 10⁹/L is as safe as one of 20 × 10⁹ in most patients with acute leukemia or after myeloablative hematopoietic cell transplant. However, an assessment of individual clinical risk factors is appropriate.

A strategy of therapeutic-only platelet transfusions in patients after autologous peripheral blood stem cell transplantation was found to reduce platelet transfusions by one half, despite 27% of transfusions given in breach of protocol guidelines, with no difference in number of red blood cell transfusions required. Important questions remain regarding whether prophylactic
Platelet transfusions are effective in reducing the risk of bleeding in clinically stable patients. A trial of prophylactic platelet transfusions in thrombocytopenic patients with malignancy, is currently underway in the UK. Prophylactic platelet transfusion is usually recommended before major surgical procedures in patients with platelet count \(<50 \times 10^9/L\) \(^{250,261,279}\). The safety of performing surgical procedures at counts below this level has not been formally evaluated. \(\text{It has been demonstrated that bone marrow aspirations and biopsies, bronchoscopies, and lumbar punctures may be safely performed in patients with platelet counts of }<20 \text{ to } 25 \times 10^9/L. \) However, the minimum safe platelet level for specific invasive procedures remains to be defined.

Prophylactic transfusion of platelets is generally not recommended in patients with platelet consumption disorders, such as idiopathic thrombocytopenic purpura (ITP) and thrombotic thrombocytopenic purpura (TTP). In ITP, there is reduced recovery and survival of transfused platelets; transfusion usually does not result in a measurable increase in platelet count. There is some evidence that platelet transfusion may be harmful in patients with TTP. \(^{280,281}\) However, platelet transfusion may be used to treat lifethreatening bleeding in patients with these disorders. \(^{262}\)

**Therapeutic Platelet Transfusion**

Rapid massive bleeding is unlikely to be due solely to thrombocytopenia and suggests the presence of a vascular injury. Rapid massive bleeding in the postoperative setting is usually surgical in nature and, therefore, not correctable by platelet transfusion. However, bypass-induced platelet dysfunction may contribute to bleeding after cardiac surgery \(^{282}\); platelet transfusion may improve hemostasis in such situations.

Platelet transfusion is most useful in thrombocytopenic patients with microvascular bleeding (e.g., oozing or mucous membrane or gastrointestinal bleeding). Transfusion to achieve a platelet count of \(50 \times 10^9/L\) is generally recommended \(^{250,258,262,279}\) for bleeding patients. However, hemostasis may be achieved through repeated platelet transfusion even in the absence of a demonstrable rise in platelet count. Transfusion is indicated in bleeding patients with platelet dysfunction, regardless of the platelet count.

Dilutional thrombocytopenia may occur after massive transfusion of red cells and plasma volume expanders. In the absence of platelet consumption, a platelet count of \(<50 \times 10^9/L\) is not generally seen unless more than two blood volumes (20 red cell units in an adult) have been replaced. \(^{217,283,284}\) However, in settings such as trauma where there is activation of coagulation and consumption of platelets in addition to blood loss, there is some evidence that pre-emptive use of platelets in the resuscitation support may be of benefit. \(^{212,219,220}\)

In all situations, the clinical decision regarding platelet transfusions requires consideration of several variables, including an estimation of platelet count and function, cause of thrombocytopenia, and state of the coagulation system; the presence or likelihood of bleeding (the development of petechiae, spontaneous mucous membrane oozing, and retinal hemorrhages are often danger signals indicating hemostatic incompetence); and the hazards of transfusion, which include all those encountered with the transfusion of any blood product.

**Platelet Refractoriness and Alloimmunization**

Refractoriness to platelet transfusions is a clinical state that can be defined as an unacceptable recovery of transfused platelets on two or more occasions. As noted previously, a CCI of \(<5\) to \(7.5 \times 10^9/L\) measured at 10 minutes to 1 hour after the transfusion is a commonly used definition of an unacceptable response or, as a general rule of thumb, an absolute increment of \(<13 \times 10^9/L\) after transfusion of six units of platelets to a 70-kg adult. Clinical factors reported to be associated with refractoriness to platelet transfusion are listed in Table 21.6.

**TABLE 21.6 FACTORS REPORTED TO BE ASSOCIATED WITH PLATELET REFRACTORINESS**

### Immune Factors

- Alloantibodies
- Anti-HLA
- Antiplatelet glycoprotein
- ABO
Autoantibodies
Idiopathic thrombocytopenic purpura
Drug-related

**Nonimmune Factors**
Splenomegaly
Fever, infection
Disseminated intravascular coagulation
Immune complexes
Bone marrow transplantation
Amphotericin

**Immune Causes of Refractoriness**

The major immune cause of refractoriness is the presence of anti-HLA antibodies. These antibodies are stimulated by pregnancy or by transfusion of WBC-containing blood products. Platelets bear HLA class I antigens on their surface. Anti-HLA antibodies are produced by 30% to 50% of recipients of WBC-containing blood products (Table 21.7). They are found in up to 30% of untransfused women with a history of pregnancy. After exposure to blood products, up to two thirds of women with a history of pregnancy produce HLA antibodies. Transfusion of platelets that are serologically incompatible with a pre-existing HLA antibody typically results in no increase in platelet counts.

**TABLE 21.7 EFFICACY OF LEUKOCYTE-REDUCED PRODUCTS IN PREVENTING TRANSFUSION-INDUCED HLA ALLOIMMUNIZATION**

Note: This is a summary of prospective controlled trials in hematology and oncology patients. Each numerator indicates the number of patients developing HLA antibodies; the denominator indicates the number of patients transfused with that type of blood product. The number in parentheses represents the calculated proportion of patients making antibodies. Modified from Dzik WH. Leukoreduced blood components: laboratory and clinical aspects. In: Simon TL, Dzik WH, Snyder EL, et al., eds. Rossi's
The incidence of clinically significant alloantibodies to platelet-specific glycoproteins in transfusion recipients is unclear. Antibodies to platelet glycoproteins have been detected almost exclusively in patients who also have broadly reactive anti-HLA antibodies. Using the sensitive MAIPA (monoclonal antibody immobilization of platelet antigen) assays, investigators have reported detection of antibodies to platelet glycoproteins in as many as 25% of HLA-alloimmunized transfusion recipients. A significant proportion of the antibodies detected have ill-defined specificity, and the contribution of such antibodies to platelet refractoriness is unclear. The presence of platelet-specific antibodies in patients who are broadly sensitized to HLA presents an enormous transfusion support challenge. Although many blood centers maintain HLA-typed donor registries, at present, very few of these donors are typed for platelet antigens. The solid-phase red cell adherence or recently developed MAIPA-based platelet crossmatching assays could theoretically be used to test HLA-selected products for compatibility with a patient’s antiplatelet antibodies, although it has not yet been established whether these assays have adequate sensitivity and specificity for this application.

As discussed earlier, high-titered ABO antibodies have been implicated in platelet refractoriness. Many investigators recommend a trial of ABO-compatible products in refractory patients, although studies have not demonstrated a high likelihood of improvement.

Antiplatelet autoantibodies are usually associated with absolute refractoriness to platelet transfusion. However, in the event of life-threatening bleeding, patients with ITP may benefit clinically from repeated infusions of platelets even in the absence of a demonstrable rise in platelet count. Antifibrinolytics or recombinant factor VIIa may also be helpful in this setting, as discussed later (see “Role of Pharmacologic Agents in Managing Thrombocytopenic Patients”).

Nonimmune Causes of Refractoriness

Of the nonimmune factors implicated in refractoriness, splenomegaly is the most potent. Transfused platelets pool in the enlarged spleen; increasing the dose of platelets does not necessarily improve the posttransfusion increment. Each of the other nonimmune factors listed in Table 21.6 has been reported to be associated with refractoriness, although the importance of each factor has not been demonstrated consistently.

Prevention of HLA Alloimmunization

Although platelets express HLA class I molecules on their surface, purified platelets do not appear to induce primary immunization to HLA antigens. It appears that the presence of WBCs is necessary, presumably because of their dual expression of both HLA class I and class II antigens. Multiple studies have demonstrated that the prophylactic use of leukoreduced blood products significantly decreases the incidence of HLA immunization in transfusion recipients (Table 21.7). Use of leukoreduced blood products is recommended for patients who are likely to require intensive platelet transfusion support, because the development of anti-HLA antibodies would complicate such support.

Purified platelets can stimulate a secondary immune response to HLA. Patients with prior pregnancy are highly likely to produce HLA antibodies after transfusion. HLA alloimmunization has been observed in up to two thirds of such patients. The use of leukoreduced products appears to be of limited benefit in such patients: HLA antibodies are produced by 33% to 44% of patients with a history of pregnancy despite the use of leukoreduced products.

As an alternative to removing WBCs from blood products, in vitro studies indicate that ultraviolet (UV) irradiation of WBCs abrogates their ability to present HLA antigens in mixed lymphocyte culture. In vivo studies demonstrate that UV irradiation of blood products is as effective as leukocyte reduction in preventing primary HLA alloimmunization. UV irradiation of platelet products requires special blood containers and equipment and is not currently available in the United States.

Early studies suggested that HLA alloimmunization in platelet transfusion recipients could be reduced by minimizing donor exposure through the use of pheresis platelets rather than pooled platelet concentrates. However, it has been shown that if all products are leukoreduced, there is no incremental benefit to the use of pheresis products.

Diagnosis and Management of Alloimmunization

Historically, anti-HLA antibodies have been detected by lymphocytotoxicity assays. Newer methods of testing for HLA antibodies include enzyme or flow-based immunoassays in which HLA glycoproteins are immobilized on a plastic plate or beads. A commercially available solid-phase red cell adherence assay permits screening for serologic reactivity against platelets selected from inventory.
Early studies demonstrated that thrombocytopenic patients with lymphocytotoxic antibodies could be successfully supported with platelets obtained from donors who were HLA-identical to the patient, or donors who were partially HLA-matched and whose lymphocytes were serologically compatible with the patient’s antibody. 291,292,293 These observations led to the practice of providing apheresis platelets from “HLA-matched” donors for patients with lymphocytotoxic antibodies. Depending on the availability of family members, the rarity of the patient’s HLA type, and the size of the HLA-typed donor registry, it may be difficult or impossible to locate platelet donors who are HLA-identical to the patient.

Therefore, many platelets provided as HLA-matched bear one or more antigens that are foreign to the recipient. Serologic crossmatching of partially mismatched products can be used to identify those that are more likely to result in a good posttransfusion increment. 291,292,293

In most HLA-alloimmunized patients, the specificity of the antibody can be defined. 297,306,310 Patients can be successfully supported with products that lack the HLA antigens(s) to which the antibodies are directed. 297,310 If the platelet inventory is HLA-typed, products lacking the offending antigen(s) can usually be found in inventory; thus, many patients can be supported with products on the shelf, without the need for special donor recruitment or serologic crossmatching.

Alternatively, serologic crossmatching of HLA-untyped products may be used to support patients whose antibodies are not broadly reactive. For many alloimmunized patients, it is possible to identify serologically compatible platelets among HLA-untyped products in the blood center inventory using the solid-phase red cell adherence crossmatching assay. 307 However, compatible products are unlikely to be found in inventory for patients who have broadly reactive antibodies; such patients require specific recruitment of HLA-selected donors.

In summary, HLA-alloimmunized patients may be supported (a) by using products from donors who are HLA-identical to the patient or who lack HLA antigens foreign to the recipient; (b) by using products that are partially HLA-matched and serologically compatible; (c) by identifying the specificity of the patient’s HLA antibody and avoiding products that bear the offending antigen(s); or (d) by serologic crossmatching of products in inventory. These methods are equally effective clinically. 297 The first method is often limited by the inadequate availability of donors. The last method is not applicable to patients with broadly reactive antibodies, who comprise approximately 10% to 15% of alloimmunized patients. 307,311

It should be noted that HLA antibodies may appear or disappear over the course of a patient’s treatment. 93,297 It is important to monitor patients’ responses to platelet transfusion and to reevaluate them serologically if they do not respond to products that were previously acceptable.

Platelet Transfusions for Refractory Patients

Strategies for the optimal use of platelets are undergoing evolution. 278 A published guideline suggests withholding prophylactic transfusion for nonbleeding patients who do not achieve acceptable posttransfusion increments in platelet counts. 261 However, many clinicians arbitrarily transfuse one dose of platelets daily, based on the assumption that some platelets are necessary to maintain vascular integrity. 255 For bleeding patients, many practitioners recommend infusion of larger or more frequent doses of platelets. 254,312

Role of Pharmacologic Agents in Managing Thrombocytopenic Patients

Attempts to improve responses with intravenous immunoglobulin (IgG) therapy in patients refractory to platelets have not convincingly demonstrated benefit; some found improved 1 hour but not 24 hour posttransfusion increments. 313 Fibrinolytic inhibitors were shown to be of value in avoiding platelet transfusions in aplastic patients, 314 by helping stabilize any clots that are being formed. 315 Anecdotal reports 316 have suggested that recombinant factor VIIa (rFVIIa) may stop bleeding, particularly in patients with refractory, severe thrombocytopenia. 317,318 However, a randomized trial failed to demonstrate any difference between the placebo group and the three rFVIIa cohorts combined, in the primary endpoint of bleeding score at 38 hours 319. Raising red cell mass by blood transfusion or treatment with erythropoiesis stimulating agents (ESA) has been shown to improve coagulopathy related to anemia 320 or uremia, 321 but evidence for clinical efficacy is needed. Thrombopoiesis-stimulating agents have been shown to be efficacious in improving platelet counts in patients with immune thrombocytopenias. 322,323 Platelets contain significant amounts of micro RNAs that may provide proteins that affect hemostasis and inflammation. 324,325 Finally, development of fibrinogen-coated, ADP-encapsulated liposomes may offer a promising platelet substitute. 326

Selection of Platelet Products
ABO Group

The clinical importance of ABO compatibility in platelet transfusion is controversial. Platelets bear both intrinsic\(^ {227}\) and adsorbed\(^ {228}\) antigens of the ABH system. Transfusion of ABO-incompatible platelets may be associated with decreased posttransfusion platelet recovery and normal survival.\(^ {329,330,331,334,335,336}\) The reduction in recovery is variable and may be related to the isohemagglutinin titer of the recipient. Rarely, a high titer of anti-A or anti-B may cause frank refractoriness to ABO-incompatible platelets.\(^ {333,334,335}\)

Platelet products contain a significant amount of donor plasma. Rarely, high-titered donor isogglutinins in platelet products may cause intravascular hemolysis of recipient red cells,\(^ {336}\) especially platelets from group O donors.\(^ {337,338}\) Some investigators have suggested that patients who receive platelets mismatched for ABO develop refractoriness at a higher rate than patients who receive ABO-compatible products.\(^ {335,339,340}\) However, these studies were small, did not control for the presence of HLA antibodies, and differed in their observations as to whether it was cell or plasma compatibility that was important. Most important, patients who developed refractoriness to ABO-incompatible products did not show better responses when given ABO-identical products, suggesting that ABO may not have been the cause of refractoriness.\(^ {338,340}\) In practice, it is difficult to ensure availability of ABO-identical platelet products, and many centers simply limit the volume of incompatible plasma transfused.

Rh Type

Platelets do not carry Rh antigens, and the donor’s Rh type is important only because the red cells present in the platelet concentrate may immunize Rh-negative recipients. Although early studies found that as many as 19% of D-negative recipients of D-positive donors developed anti-D, several recent studies in hematology/oncology patients found that immunization did not occur.\(^ {341,342}\) It is possible that the difference in observations is related both to an increase in intensity of chemotherapy as well as to a substantial improvement in the purity of platelet products. The red cell content of most apheresis platelets currently is below the dose thought to be immunizing. For most platelet recipients, anti-D prophylaxis would be of little benefit.\(^ {343}\) For pediatric patients and females with future childbearing potential, however, it may be reasonable to consider administration of intravenous anti-D Ig to prevent D immunization.\(^ {343,344,345}\)

PLASMA TRANSFUSION

Use of Plasma Components

FFP or FP24 are utilized in patients who are bleeding or who are having an invasive procedure and who are deficient in multiple coagulation factors or in a single factor for which there is no specific factor concentrate available. They are also used for replacement of clotting factors during massive transfusion, for reversal of warfarin (if immediate reversal is necessary), and as the replacement fluid for plasma exchange procedures in patients with TTP.\(^ {3,346}\) They should not be used as volume expanders or for therapeutic plasma exchange for other disorders, because alternative fluids with lower risks of infectious diseases, allergic reactions, and TRALI are available for these purposes (e.g., crystalloid, albumin, starch). The typical dose of plasma is 10 to 20 ml/kg.\(^ {7}\) Patients may not tolerate infusion of larger volumes. The expected rise in coagulation factor activity is approximately 10% for each 10 cc/kg of plasma infused.\(^ {347}\)

Efficacy of Plasma Transfusions

In a recent evidence-based review, the Transfusion Practices Committee of the AABB recommended plasma therapy for only a few clinical indications, based on the available evidence in the literature (which was assessed to be of “weak quality”): trauma patients with substantial hemorrhage, patients undergoing complex cardiovascular surgery, and patients with intracranial hemorrhage requiring emergency reversal of warfarin-associated coagulopathy.\(^ {348}\) Patients with mild prolongations of the INR (less than 1.7) are not at risk of bleeding and do not need plasma therapy for minor procedures,\(^ {349}\) so that for the majority of clinical settings there is ample evidence that plasma transfusions are inappropriate. However, logistical/technical barriers that prevent effective and timely plasma therapy (possibly resulting in plasma therapies that are “too little, too late”) have probably contributed to the paucity of evidence demonstrating any benefit for plasma therapy.\(^ {177}\)

One of the largest prospective studies of plasma transfusions and their effect on INR and bleeding included both medical and surgical patients with pretransfusion INR of between 1.1 and 1.85.\(^ {350}\) The authors reported that less than 1% of patients
Granulocyte transfusions may also be indicated in infected patients with severe neutrophil dysfunction (e.g., chronic granulomatous disease and leukocyte adhesion deficiency) who are not responding to appropriate antimicrobial therapy.

The paucity of evidence for the benefit of plasma transfusion therapy has been accompanied by growing evidence that risks of plasma have been underrecognized; in a prospective study, 6% of transfused patients developed transfusion-associated cardiac overload; which is much higher than previously-reported rates in retrospective studies. Transfusion-related acute lung injury is a significant cause of morbidity/mortality from blood transfusions, whose incidence has declined subsequently with use of plasma from male donors or female donors who have no history of pregnancy.

GRANULOCYTE TRANSFUSIONS

Severe bacterial and fungal infections in the setting of prolonged chemotherapy-associated neutropenia are common causes of morbidity and mortality in the treatment of malignancy. Risk of serious bacterial infection appears as the neutrophil count falls below $1.0 \times 10^9/L$ and increases rapidly below $0.5 \times 10^9/L$. Fungal infections occur with much higher frequency as the neutrophil count falls below $0.2 \times 10^9/L$. Other risk factors include the duration of neutropenia and the rate of fall of the neutrophil count. The use of growth factors (e.g., granulocyte colony-stimulating factor [G-CSF]) has reduced the severity and duration of neutropenia, but many patients still have long periods of poor granulocyte production, lasting 2 to 3 weeks or longer. Although the idea of enhancing host defenses with granulocyte infusions dates back 60 years, difficulty obtaining adequate granulocyte yields as well as safety concerns stifled the initial interest generated after early clinical successes in the 1970s.

Modern apheresis techniques, growth factors which increased yields, and positive results from clinical trials led to renewed interest in applying granulocyte therapy to a wider range of patients.

Clinical Indications and Efficacy

Currently, there is no definitive evidence from controlled trials to support or refute the use of granulocyte transfusion therapy in neutropenic patients. A large randomized control trial is being undertaken in an attempt to clarify this situation; nonetheless, prior clinical granulocyte transfusion trials in the setting of neutropenia give insight into populations that may benefit from this therapy. A review of 32 papers revealed that most studies have been uncontrolled, involved small heterogeneous populations of patients, and had different treatment approaches. Approximately 62% of the 206 patients with bacterial sepsis were reported to have benefited from granulocyte transfusion; conversely, 71% of 63 patients with invasive fungal infection did not respond to the infusions. Seven controlled trials were completed between 1972 and 1982: Three showed a positive effect, two showed benefit in specific patient populations, and two demonstrated no benefit. Some studies were likely limited by the cytapheresis techniques used and the low cell yields obtained, as most donors were pretreated with corticosteroids only. Further analysis confirmed the importance of higher neutrophil doses as well as leukocyte compatibility in the three positive trials. More recent trials provide additional evidence supporting the use of granulocyte transfusions in critically ill neutropenic patients with bacterial as well as candida sepsis. Based on this information, granulocyte therapy may warrant consideration in severely neutropenic patients with bacterial infections unresponsive to typical antimicrobial therapy.

The applicability of granulocyte infusions in the setting of invasive fungal infections remains unclear. No study has shown clear efficacy in patients with active aspergillosis, although often the neutrophil dose was not known or was suboptimal. Limited clinical and animal model data give some indication of usefulness in the setting of candidal and noninvasive fungal infections. As the overall data are limited, a brief trial of granulocyte infusions may be warranted in patients with self-limited neutropenia and documented fungal infection who are refractory to standard antifungal therapy.

The effect of the prophylactic use of granulocyte transfusions to diminish the risk of serious infections in severely neutropenic patients during therapy of hematologic malignancies and after bone marrow transplantation has been investigated in a number of controlled trials. Although prophylactic granulocyte transfusion may decrease the risk of septicemia, the increased incidence of adverse effects observed with this therapy may outweigh the beneficial effects. Until there are more published randomized, controlled clinical trials, the use of prophylactic granulocyte transfusions should be carefully considered and viewed as experimental.

Granulocyte transfusions may also be indicated in infected patients with severe neutrophil dysfunction (e.g., chronic granulomatous disease and leukocyte adhesion deficiency) who are not responding to appropriate antimicrobial therapy.

had normalization of their INR and only 15% had at least 50% correction. The median dose of plasma was 2 units (only 5 to 7 ml/kg), and there was no correlation between plasma dose and change in INR. This study had many of the limitations common to other reports in this clinical arena: lack of control groups, only modest prolongation in coagulation tests, poorly-defined clinical endpoints (e.g., change in hemoglobin or need for transfusion), and/or an inadequate dose of plasma therapy.

The increasing incidence of adverse effects observed with this therapy may outweigh the beneficial effects.
Although controlled trials have not been performed, transfused granulocytes do migrate within recipients and appear to be of therapeutic benefit. Because of the adverse effects associated with the transfusion of granulocytes, they should be used judiciously in the patient with severe documented infections, as the infusions may result in alloimmunization of the recipient and render him or her unresponsive to granulocyte transfusion therapy at a later date.

Neonatal bacterial sepsis continues to be a major cause of morbidity and mortality. The neutrophil function in neonates is impaired, with diminished chemotaxis and abnormal adhesion properties. Infection may result in neutropenia and depletion of the neutrophil storage pool. Granulocytes have been used to treat neonatal sepsis with varying results. The efficacy of this approach has been evaluated in six controlled trials with four studies demonstrating a survival benefit. Overall, data analysis does not show clear benefit when other available therapies are considered. When compared with standard therapy of intravenous Ig, neonates with group B Streptococcus may experience increased survival after receiving granulocyte support. Although conflicting data exist, centers that experience a high mortality rate in septic infants with neutropenia and ongoing neutrophil storage pool depletion may consider a trial of granulocyte therapy. The recommended dose is 1 × 10^9 granulocytes/kg of body weight.

Donor Preparation/Selection

High granulocyte yields were initially obtained using preparations from donors with chronic myelogenous leukemia. Subsequently, methods were developed to collect sufficient granulocytes from normal donors. Apheresis became the standard method for collecting granulocyte concentrates. The quantity and quality of granulocytes obtained depend on the apheresis collection technique as well as the level of donor neutrophils. Infusion of hydroxyethyl starch or dextran to improve the sedimentation of donor red cells during centrifugation improves the efficiency of apheresis, but the granulocyte yield remains low. Data suggested a daily granulocyte dose of about 10 × 10^10 cells would be needed to achieve benefit. Oral corticosteroids produce a transient donor neutrophilia, but the collection yield remains in the range of 2 to 3 × 10^10. Studies have shown the ability of G-CSF to increase the dose/collection. Donors treated with G-CSF with or without corticosteroids produce yields ranging from 2.4 to 9.9 × 10^10 granulocytes. Although adverse effects occur in 30% to 69% of donors, most consist of mild to moderate degrees of bone pain, headache, myalgias, and fatigue. Data from the bone marrow transplant literature support the short-term safety of G-CSF use in healthy donors, although rare serious adverse events have been reported. Long-term follow-up data are limited and deserve further attention.

Prospective granulocyte donors should meet all FDA and AABB standards for donation. Because granulocyte products must usually be transfused before completion of donor infectious disease testing, donors who have been tested recently are strongly preferred. Donors should also be free of disorders that might be exacerbated by dexamethasone (e.g., diabetes) or G-CSF (e.g., arthritis, vasculitis, splenomegaly, gout, thrombocytopenia). Donor/recipient pairs should be ABO-compatible because of the large RBC content in the product. RBC compatibility must be verified for each granulocyte product. CMV infections are a significant risk when seropositive donors are used for immunocompromised seronegative patients; therefore, CMV-negative patients should receive CMV-negative products.

Patients requiring granulocyte transfusions may have become alloimmunized to HLA, and or RBC antigens during the course of prior transfusion support or pregnancy. Studies suggest decreased recovery and survival as well as failure of granulocytes to localize at the site of inflammation in patients who have lymphocytotoxic or granulocyte-specific antibodies. Recipients can be screened for the presence of HLA antibodies particularly if clinical suspicion for alloimmunization is high. In alloimmunized patients, HLA-compatible random donors or family members can be used; random donors may be preferred over family members if related allogeneic transplantation is anticipated as part of the treatment for the underlying disease. If laboratory tests for alloimmunization are not readily available, the likelihood of sensitization may be estimated by reviewing the patient's record for a history of platelet refractoriness or febrile transfusion reactions.

Granulocyte Collection/Storage

Once an appropriate donor has been selected and prepared, granulocytes are typically collected by leukapheresis during which 7 to 10 L of blood is processed over 3 to 4 hours. Hydroxyethyl starch is often used to reduce RBC contamination by...
sedimentation. According to AABB standards, at least \( 1 \times 10^{10} \) granulocytes/apheresis are collected. Current techniques achieve mean yields of 2 to 3 \( \times 10^{10} \)/leukapheresis in 200 to 400 ml of plasma, with 10 to 30 ml of RBCs, and 1 to 6 \( \times 10^{11} \) platelets. For pediatric recipients, whole blood buffy coats from donors stimulated with G-CSF may present an alternative to apheresis. Although granulocytes can be stored for up to 24 hours at room temperature, transfusion within 8 hours of collection is recommended. Biochemical assessments of the effects of storage on subsequent function (e.g., nicotinamide adenine dinucleotide phosphate oxidase activity, adhesion protein expression, respiratory burst activity, and bactericidal activity) reveal that effective storage may be possible for up to 48 hours at 10°C. Administration of Granulocytes

Granulocytes should be administered on a daily basis until the patient's endogenous neutrophil count rises to \( 0.5 \times 10^{9} / L \) or until the infection clears. Granulocyte concentrates should be given through a standard filter set to ensure that aggregates are not administered. The concentrate should be given slowly (over 1 to 2 hours) with the patient under constant observation, including the use of pulse oximetry. Transfusion reactions occur in 10% to 50% of patients but are usually mild, consisting of fever and chills. Premedication with antihistamines, acetaminophen, or steroids is common practice before infusion. More severe reactions occur in 1% to 5% of patients and tend to be pulmonary in nature. A serious potential interaction between granulocyte transfusions and amphotericin B has been reported, but this association has not been substantiated by others. Nevertheless, many physicians administer granulocytes and amphotericin at least 8 hours apart to limit the potential for increased pulmonary toxicity. If there are any signs or symptoms of respiratory distress, the transfusion should be discontinued immediately, the recipient should be examined for hypoxemia or pulmonary edema, and a chest radiograph should be done to assess for pulmonary infiltrates. If major adverse effects do occur, the recipient should be studied for the presence of antibodies that react with neutrophils. Granulocyte products contain lymphocytes and are capable of causing transfusion-associated GVHD (TA-GVHD). Thus all granulocyte products should be irradiated with 1500 to 3000 cGy to prevent transfusion-related GVHD without significantly impairing granulocyte function. Pre- and posttransfusion neutrophil counts should be determined to guide therapy. With large doses (>8 \( \times 10^{10} \)), neutrophil increments may exceed \( 2 \times 10^{9} / L \) immediately after infusion and may last for 24 to 48 hours.

ADVERSE EFFECTS OF BLOOD TRANSFUSION

The potential complications of blood transfusion therapy are many, but most present problems only in patients requiring repeated or large numbers of transfusions. The risks associated with the transfusion of any specific unit of blood are low. However, the risks must be weighed against the benefits at the time each transfusion is ordered.

Transfusion complications can be classified as immunologic and nonimmunologic (Table 21.8). Many of the immune reactions are caused by the stimulation of antibody production by foreign alloantigens present on transfused red cells, leukocytes, platelets, or plasma proteins. Such alloimmunization may lead to immunologically mediated reactions when transfusions carrying these antigens are administered in the future. These include hemolytic reactions caused by red cell incompatibility; febrile or pulmonary reactions caused by leukocytes and platelet antigens; allergic or anaphylactic reactions caused by antibodies reacting with soluble antigens, usually plasma proteins, in the transfused material; and GVHD caused by engraftment of transfused lymphocytes in immunosuppressed recipients.

The nonimmune reactions are caused by the physical or chemical properties of the transfused blood products, as well as contaminating infectious agents. Nonimmune reactions include circulatory overload and certain adverse effects encountered specifically when large numbers of transfusions are given.

Immunologic Transfusion Reactions

Alloimmunization to Transfused Antigens

Alloantibodies Reacting with Red Cell Antigens

Although the antigenic composition of transfused red cells always differs from that of the recipient, only a minority of multitransfused recipients develop red cell alloantibodies. The risk of red cell alloimmunization has been estimated at 1.0% to 1.4% per unit transfused; in multitransfused patients, the incidence of such antibodies ranges from 5% to 30%. Multiple red cell antibodies may be encountered. Antibodies to Rh system antigens and to Kell (K) are most often detected. Antibodies to antigens of the Duffy (Fy) and Kidd (Jk) systems also occur, but transfusion-induced antibodies to other red cell antigens are less commonly found.

</table>
The production of such antibodies is a property of both the recipient's immune response and the immunogenicity of the different red cell antigens. The incidence of antibodies does not appear to be related to the patient's diagnosis. For example, patients with hemoglobinopathies, thalassemia, and leukemia and those undergoing surgery requiring multiple transfusions produce antibodies with approximately the same frequency.\textsuperscript{404,406} The reported incidence of RBC alloimmunization for patients with thalassemias is 5% to 10%, versus 20% to 30% for those with sickle cell anemia. The increased incidence of alloimmunization in sickle cell patients has been attributed to the difference in race between the blood donor pool and the patient population.\textsuperscript{407} As a result, there is a greater likelihood of minor-antigen incompatibility between donor and recipient. The differing immunogenicity of various red cell antigens also plays a role. For patients with sickle cell anemia, red cells phenotypically matched for Rh and Kell antigens are recommended. This measure was shown to reduce the alloimmunization rate in this population from 3% to 0.3% per unit transfused.\textsuperscript{408}

Alloantibodies Reacting with Leukocyte Antigens

Alloimmunization to HLA and other leukocyte-associated antigens has been discussed earlier with respect to problems encountered in granulocyte and platelet transfusion. These antibodies occur mainly in multiparous women\textsuperscript{289,409} and multitransfused patients. In patients receiving nonleukoreduced transfusion support for aplastic anemia or acute leukemia, 20% to 70% become immunized to HLA antigens.\textsuperscript{410} Interestingly, HLA alloimmunization is significantly increased in male patients with pre-existing RBC antibodies compared to multiply transfused male patients without such antibodies.\textsuperscript{411} As discussed in the section “Platelet Transfusion” and shown in Table 21.7, the prophylactic use of leukocyte-reduced blood products significantly reduces the incidence of HLA alloimmunization in patients with no prior exposure to these antigens.

Alloantibodies Reacting with Plasma Proteins

Although antibodies to soluble plasma proteins such as lipoproteins and to Gm and Inv determinants on IgG are often detectable in multitransfused patients, transfusion reactions have rarely been attributed to such antibodies.\textsuperscript{412,413} and\textsuperscript{414} Some anaphylactic reactions are attributed to anti-IgA antibodies,\textsuperscript{415,416,417} especially in patients who are IgA-deficient, although the presence of antibodies that react with IgA is not always clearly correlated with the occurrence of this type of transfusion reaction.\textsuperscript{418}

Hemolytic Transfusion Reactions

The development of antibodies capable of reacting with red cell antigens may lead to red cell destruction, usually involving transfused rather than recipient cells. The clinical significance of such reactions ranges from life-threatening to trivial. Whether hemolysis occurs immediately within the circulation, more slowly within the reticuloendothelial system, or not at all depends on the antigen and antibody involved.\textsuperscript{419,420} and\textsuperscript{421,422}

The incidence of such reactions is variably reported. Several studies from the Mayo Clinic document a hemolytic reaction rate, both immediate and delayed, of between 1 in 6,200 and 1 in 1,400 red cell transfusions. In these reports, reactions caused by clerical error and ABO mismatching were virtually nonexistent, but some reactions were attributed to weak atypical antibodies missed in pretransfusion testing.\textsuperscript{419,421} The high reaction rate was related in part to a high index of suspicion and in part to the use of sensitive tests for serologic evidence of minor delayed hemolytic transfusion reactions (DHTRs). In contrast, in a review of fatal hemolytic reactions reported to the US Bureau of Biologics (now the FDA’s Center for Biologics Evaluation and Research or CBER), 86% were caused by ABO incompatibility, and of these, 89% were caused by simple clerical error.\textsuperscript{424,425} More recent FDA data has shown a decrease in deaths due to ABO incompatibility although overall, hemolytic transfusion reactions still represent a leading cause of transfusion-related mortality.\textsuperscript{426}

Immediate (Intravascular) Hemolytic Transfusion Reactions

Immediate hemolytic transfusion reactions (IHTRs) are most typically associated with ABO incompatibility, because anti-A and anti-B antibodies are predominantly IgM and are capable of binding complement and causing immediate destruction of red cells.

An IHTR caused by ABO incompatibility is rare and is usually related to human error. Other red cell antigens such as Jk\textsuperscript{a}, K, and Fy\textsuperscript{a} (which may bind complement) may also lead to such reactions.

Infrequently, hemolytic transfusion reactions may be caused by destruction of recipient red cells after the transfusion of plasmcontaining antibodies.\textsuperscript{427,428} For example, anti-A\textsubscript{1}, occurring naturally in group A donors of subgroup A\textsubscript{2} has been reported to cause hemolytic transfusion reactions.\textsuperscript{429} More recently, hemolytic transfusion reactions have been reported
in association with apheresis platelets containing abnormally high titer (>1:250) anti-A or anti-B antibodies in the plasma. Plasma volume reduction is recommended for such products if the plasma is incompatible with the recipient. Hemolytic reactions caused by the transfusion of plasma containing other antibodies are extremely rare, as blood donors are screened for red cell antibodies other than ABO.

Signs and Symptoms. IHTRs occur soon after the incompatible transfusion has begun. Occasionally, they are mild; more typically, there is a sudden change clinically. Fever with or without chills is one of the most common manifestations of such reactions. Other signs and symptoms include anxiety, chest or back pain, flushing, dyspnea, tachycardia, and hypotension. If the patient is under general anesthesia, these symptoms may not be recognized; only severe hypotension and evidence of oozing or hemoglobinuria serve as clues to the presence of a hemolytic reaction.

IHTRs may be life-threatening, and complications may include acute renal failure, shock, and intravascular coagulation. It has been estimated that a fatal immediate hemolytic reaction occurs in approximately 1/600,000 red cell transfusions. The mortality of a severe IHTR increases with the amount of blood transfused, with a 44% mortality rate in patients receiving more than 1 L of incompatible blood.

Pathophysiology. The primary event in IHTRs is the interaction between the antibody and the red cell membrane, resulting in the development of immune complexes, activation of complement leading to the release of C3a and C5a with anaphylatoxic activity, and the coagulation mechanism via cytokines and factor XII (leading to both consumptive coagulopathy and generation of bradykinin). Vasomotor mediators implicated in the transfusion reaction include histamine, serotonin, and cytokines. Shock results from release of such vasoactive substances.

The renal failure that may occur in this setting is of complex and poorly understood etiology but appears to be primarily ischemic, caused by a combination of hypotension, vasoconstriction (via nitric oxide inactivation by hemoglobin), and intravascular coagulation. The free hemoglobin circulating in such patients was once thought to be the major cause of renal failure by precipitating in and obstructing the renal tubules, but there is adequate evidence to discount this hypothesis. Infusion of incompatible red cell stroma, free of hemoglobin, is sufficient to produce acute renal failure.

Management. On any suspicion of a hemolytic transfusion reaction, the transfusion must be discontinued immediately, as the severity of the reaction is related to the volume of red cells infused. A recheck of the patient’s identity with the information on the discontinued blood unit is necessary to rule out bedside identification errors. The reaction must be reported to the blood bank without delay; a posttransfusion blood sample and the discontinued bag of blood should be sent to the blood bank for investigation of the cause of the reaction. Hydration must be begun immediately to prevent renal failure. An infusion of normal saline is given to maintain the blood pressure and increase the urine flow rate to 100 ml/h. Diuretics may be needed to maintain urine output. If oliguric renal failure develops, fluid challenges must be restricted. Once renal failure is established, the usual supportive measures, including fluid restriction, management of electrolyte balance, and dialysis, are required.

Additional interventions may be needed depending on the severity of the reaction. Some recommend early heparinization at moderate dose as management of coagulopathy if no specific contraindication exists; its use remains controversial. The patient may require support of the defective hemostatic mechanisms with platelets and cryoprecipitate or plasma. In massive intravascular hemolytic transfusion reactions, exchange transfusion has been performed.

Investigation of Immediate Transfusion Reactions. The following steps must be carried out in the investigation of patients with immediate transfusion reactions. The patient’s identity must be confirmed, and all the records on the patient and the donor blood label must be checked for clerical errors. A new, properly labeled sample of blood must be drawn from the patient and sent to the blood bank with the discontinued unit of blood. The posttransfusion sample must be visually checked for hemolysis. In intravascular reactions, free plasma hemoglobin can be detected most quickly by centrifuging a tube of blood anticoagulated with ethylenediaminetetraacetic acid (EDTA) or heparin; pink to red plasma indicates intravascular hemolysis—that is, evidence of red cell destruction. There must be an investigation for possible alloantibodies. A direct antiglobulin test must be performed on the specimen submitted at the time of the reaction. If the test is positive, the pretransfusion sample should also be tested, because the patient may have had a positive direct antiglobulin test before transfusion.

Red cell typing should be repeated on all specimens. If the posttransfusion ABO and Rh types do not agree with pretransfusion results, there has been an error in patient identification or typing. Antibody detection tests should be repeated on the pre- and post-reaction samples. The direct antiglobulin test on the post-reaction specimen may reveal sensitization of red cells in the patient only if the antibody or complement-coated transfused incompatible cells have not been immediately destroyed. A serologic crossmatch should be positive, although the antibody may not be readily demonstrable in serum at the time the reaction is suspected clinically. In a minority of patients in whom there is a high
clinical suspicion of a hemolytic transfusion reaction, no immunologic abnormality may be identified. In some, repeated examination for antibodies over a prolonged period of time may eventually reveal the cause; in others, results may be persistently negative. In such patients, Cr red cell survival testing may be of value in documenting hemolysis caused by incompatibility.\textsuperscript{431,433,434} and\textsuperscript{435}

Patients with major hemolytic transfusion reactions should be assessed for the possible presence of intravascular coagulation, and their renal function should be monitored closely. Urinary hemosiderin or free hemoglobin in the urine may also be detected; wine-colored urine is typical of intravascular hemolysis. The laboratory can confirm the identity of the pigment. Demonstration of methemalbuminemia, reduced serum haptoglobin, or hyperbilirubinemia may provide supportive evidence.

Prevention. Most IHTRs are preventable. The most likely cause is human error, such as mislabeling of the patient sample, drawing the sample from the wrong patient, transcription errors, and improper identification of the unit with the recipient. Mechanisms to ensure positive identification of the patient (recipient), the blood sample, and the transfusion component must be in place to prevent IHTRs.\textsuperscript{5}

Delayed Hemolytic Transfusion Reactions

DHTRs generally are much milder than those occurring immediately, and red cell destruction is predominantly extravascular.\textsuperscript{419,423,436,437} The transfused red cells are destroyed beginning 2 to 10 days after a transfusion. Investigation may reveal the presence of a red cell antibody not detected in the pretransfusion blood sample. The direct antiglobulin test is often positive, but the reaction is transient and may be missed if it is performed too late. The test reverts to negative as the incompatible red cells are removed from the circulation.

DHTRs almost always represent secondary, or anamnestic, antibody responses. On first exposure to an immunogenic red cell antigen, a primary antibody response generally is delayed in onset and slow to reach its peak. For example, anti-D appears a minimum of 4 to 8 weeks after transfusion and may not develop for up to 5 months, after most or all the donor red cells have been removed by the aging process.\textsuperscript{419} The antibody level gradually declines, and antibody screening and crossmatch tests may be negative. After a subsequent transfusion, the previously sensitized recipient manifests a much more brisk immune response, with high concentrations of IgG antibody developing within days. Donor cells remaining in the circulation may become coated with antibody and removed by the reticuloendothelial system. Rarely, primary immunization after transfusion may lead to a DHTR.\textsuperscript{438}

In delayed hemolytic reactions, destruction of the sensitized red cells is predominantly extravascular; that is, the IgG-coated red cells are removed by the reticuloendothelial system. Often, there are no symptoms, with a new red cell antibody and positive direct antiglobulin test detected incidentally.\textsuperscript{439} If present, symptoms and signs may include fever, falling hematocrit, jaundice, and, infrequently, hemoglobinemia and hemoglobinuria. Rarely, the reactions may be dramatic; renal failure is uncommon, but fatalities have been reported. The antibodies responsible for DHTRs are well defined. Antibodies to Kidd (Jk) antigens and to antigens of the Rh system are the major offenders, with anti-Kell and anti-Duffy (Fy) implicated in most other delayed reactions. Anti-Kidd antibodies are particularly troublesome because the plasma concentration of these antibodies declines more rapidly than others, so pretransfusion tests are more commonly negative in patients who are in fact sensitized.\textsuperscript{236}

Investigation of Delayed Hemolytic Transfusion Reaction. If a DHTR is suspected, a fresh blood sample should be obtained from the patient. This sample should be screened for the presence of previously undetectable red cell antibodies. A direct antiglobulin test should be done. If it is positive, the antibodies should be eluted from the red cells and identified. If the transfused cells have already been destroyed, the direct antiglobulin test will not be positive, but an antibody should be detectable in the patient's serum. The physician must be advised and the patient given a card indicating the presence of the antibody. The blood bank must retain a permanent record of clinically significant antibodies because the antibody may again become undetectable.

Management. In most instances, no specific therapy is necessary. The few patients who experience severe reactions should be treated with adequate hydration. If further transfusions are indicated, crossmatch-compatible blood negative for the offending antigen(s) should be administered. The physician and patient should be informed about the antibody so that transfusions may be administered safely in the future.

Pseudohemolytic Transfusion Reactions
In patients manifesting a clinical syndrome consistent with intravascular hemolysis, but in whom no blood group incompatibility can be identified, other explanations should be considered. Conditions that mimic hemolytic transfusion reactions are called pseudohemolytic transfusion reactions. 421 These include bacterial contamination with organisms such as Yersinia, resorption of large hematomas, and hemolysis caused by drug reactions or vascular prostheses. Pretransfusion hemolysis of donor blood caused by mechanical trauma, freezing, heat, or hypotonic solutions, should always be considered a potential cause of such a reaction. 421

Febrile Nonhemolytic Transfusion Reactions

FNHTRs 440,441,442 have been reported in a variable proportion of patients receiving transfusions, ranging between 0.5% and 3.0%; they are more common in multiply transfused patients. The typical reaction consists of a chill followed by fever of 1°C or greater, usually during or within a few hours of the transfusion. Headache, nausea, and vomiting may occur. Occasionally, the reaction may be severe but usually these reactions are mild. Whatever their degree, febrile transfusion reactions usually run their course within a few hours. Some causes of FNHTRs are as follows.

Alloimmunization to antigens on leukocytes and platelets is one of the most common causes of nonhemolytic febrile reactions. Early studies detected the presence of leuкоagglutinins in such patients. 443,444 HLA antibodies are most commonly found, followed by platelet-specific antibodies; granulocyte-specific antibodies are detected in only a minority of patients. 445,446 and 447

Another cause of FNHTRs is the transfusion of cytokines that have developed during product storage, especially in nonleukoreduced whole blood-derived platelet concentrates stored at room temperature. 448 During storage, leukocytes in platelet concentrates release cytokines that appear to be responsible for the febrile reaction. 126 The causative role of accumulated cytokines is supported by the observation that leukoreduction filtration after storage does not eliminate many of the FNHTRs to platelet concentrates. 127 The incidence of FNHTRs to nonleukoreduced platelet concentrates increases with the age of the platelet concentrate and the leukocyte concentration in the product. The reactions appear to be mediated by the supernatant of the platelet products. 126,129,449 The concentration of cytokines in platelet concentrates and incidence of FNHTRs can be decreased by leukoreducing the products soon after collection. Apheresis platelets are leukoreduced by the collection technology and have reduced cytokine levels.

The possibility of bacterial contamination of the product must be considered as a possible cause of FNHTR. Symptoms caused by transfusion of bacteria or their toxins can be mild or may be fatal. Platelet components are involved more often because they are stored at room temperature. However, certain organisms such as Yersinia enterocolitica proliferate in red cells at storage temperatures of 1°C to 6°C. Bacterial contamination is often not considered as a cause of a febrile reaction; it may be more prevalent than reported because of underinvestigation. 453,452 and 453

Management of Febrile Reactions

The approach to management of febrile transfusion reactions must be based on an understanding of all the possible causes. Although many such reactions are caused by WBC alloimmunization or cytokines, fever may also be an indication of an unsuspected hemolytic transfusion reaction or contamination of the donor blood by bacteria or endotoxin. For these reasons, every transfusion complicated by a febrile transfusion reaction should be discontinued until the patient has been carefully assessed by a physician and the blood bank alerted. Although controversial, the physician, depending on the clinical condition of the patient and the institution’s policies regarding such steps, may elect to restart the transfusion if a hemolytic or bacterially contaminated transfusion has been ruled out.

The possibility of a hemolytic reaction should be considered when fever occurs. If suspected, the donor unit, along with a patient blood specimen, should be returned to the blood bank for investigation. Other tests for hemolysis should be done as discussed previously, if clinically indicated. The donor unit and patient blood should be cultured if there is any suspicion of bacterial contamination.

The symptoms of a febrile transfusion reaction may often be ameliorated with an antipyretic such as acetaminophen or hydrocortisone in patients who develop severe reactions. Meperidine may be used to decrease or stop severe shaking chills. Antihistamines are indicated only if the patient also has allergic symptoms such as hives.

Prevention of Febrile Transfusion Reactions

Febrile transfusion reactions to red cells occur most commonly in patients who have been sensitized to WBC antigens by previous
transfusions or pregnancies. In such patients, the risk of a febrile transfusion reaction varies with the leukocyte content of the donor unit. Use of leukoreduced red cells may decrease the incidence of FNHTRs.\textsuperscript{454,455} and \textsuperscript{456} Every patient who experiences a reaction does not routinely need specific preventive measures, because only a minority will have a second reaction.

When whole blood-derived platelets are given, febrile reactions are common. Removal of leukocytes from these components at the time of transfusion often fails to prevent FNHTR because of the high level of cytokines in these products.\textsuperscript{126,129} Reduction of the level of cytokines by using platelet concentrates stored for a shorter time, prestorage leukoreduction of the platelet concentrates, plasma reduction, or use of apheresis platelets reduces the incidence of FNHTR to platelet products.\textsuperscript{79,457} If reactions persist, premedication with antipyretics or corticosteroids may be required. Because granulocyte concentrates cannot be modified by leukoreduction, premedication should be considered in patients who receive these products.

Transfusion-related Acute Lung Injury

Transfusion-related acute lung injury (TRALI) most commonly presents as severe respiratory distress of sudden onset, caused by a syndrome of noncardiogenic pulmonary edema resembling the adult respiratory distress syndrome.\textsuperscript{458,459} Chills, fever, chest pain, hypotension, and cyanosis, as well as the usual manifestations of pulmonary edema, may be seen. TRALI is reported by the FDA as the number-one cause of transfusion-associated fatality.\textsuperscript{426,460} The incidence of TRALI varies greatly, from 1 in 5,000 to 1 in 557,000 depending on the blood component involved.\textsuperscript{355,426}

It is hypothesized that TRALI reactions may be the result of two cumulative events:\textsuperscript{461} the first event is linked to the patient (i.e., underlying sepsis, hematologic disease, and/or postsurgical status), and the second event is related to the transfusion of potential granulocyte primers such as inflammatory cytokines, active lipids, and/or alloantibodies.\textsuperscript{355,462} The diagnosis of a TRALI reaction is based on the onset of acute lung injury (ALI) within 6 hours of transfusion.\textsuperscript{463,464} ALI is characterized by an acute onset of hypoxemia (oxygen saturation <90% by pulse oximetry for a patient breathing room air or a PaO_2/FiO_2 \leq 300 mmHg), bilateral infiltrates on frontal chest radiograph, and no evidence of circulatory overload. Based on studies of adult respiratory distress syndrome, which has similar pulmonary manifestations, it has been suggested that agglutination of granulocytes and complement activation occur in the pulmonary vascular bed, leading to capillary endothelial damage with consequent fluid leak into the alveoli.\textsuperscript{465}

Management involves supportive measures for the pulmonary edema and hypoxia, including ventilatory support if required. Hemodynamic monitoring may be required to determine whether fluid overload is a factor; if not, diuretics are of no proven value.\textsuperscript{466} The AABB requires evaluation of donors implicated in TRALI.\textsuperscript{5} Donors whose plasma is implicated in such reactions should be examined for the presence of granulocyte-specific and HLA antibodies that react with recipient leukocytes. It is recommended to avoid further transfusion of plasma-containing products from implicated donors found to have anti-HLA or antigranulocyte antibodies. In 2006, the AABB recommended that blood banks minimize the production of high-plasma-content components (such as plasma products andpheresis platelets) from donors at risk for alloimmunization (e.g., women with a history of pregnancy).\textsuperscript{18} This change has resulted in a decrease of reported TRALI cases.\textsuperscript{355,356,426}

Allergic Reactions

Allergic reactions are common in transfusion recipients, with an estimated incidence of 1% to 3%,\textsuperscript{441} but their actual incidence may be higher because they are often not reported. They range from urticarial lesions (hives), other skin rashes, bronchospasm, and angioedema to anaphylactic shock. Minor reactions are dose-related, with an incidence related to the volume of plasma transfused. Whole blood and plasma are more likely than concentrated red cells to cause such reactions; washed red cells or albumin are rarely implicated. Minor urticarial reactions are the only transfusion reactions that do not necessitate immediate discontinuation of the transfusion. Fortunately, the incidence of severe anaphylactic transfusion reactions is very low, as such reactions can be life-threatening.

Most allergic reactions are thought to be mediated by recipient IgE to proteins or other soluble substances in donor plasma. The interaction between the antigen and IgE stimulates the release of histamine from mast cells and basophils. Most patients do not have repeated allergic reactions, but those with a history of atopy are at higher risk for additional reactions. For patients with repeated allergic reactions, premedication with an H_1-blocking antihistamine is usually sufficient for prevention. If maximal premedication fails to control the allergic response, reducing the plasma content of the transfused blood product is another option. This can be accomplished by centrifuging the product and removing almost all the plasma or by red cell washing.

1318
In patients with severe anaphylactoid or anaphylactic reactions, antibodies reacting with IgA in donor plasma should be considered. The incidence of genetically determined IgA deficiency in the otherwise normal population is high, ranging from 1 in 400 to 1 in 500. Without necessarily having prior transfusion exposure, approximately 20% to 25% of such patients produce antibodies to IgA, generally class-specific (i.e., reacting with all IgA molecules). Such patients should be transfused, when necessary, with washed red cells or with IgA-deficient blood products. In addition, many patients with normal IgA levels have antibodies that react with some, but not all, IgA molecules; the incidence of such limited-specificity antibodies has been reported at 2% of normal adults, but the incidence may be as high as 21% in multiply transfused patients. The concentration of such limited-specificity antibodies generally is low, and the resulting reactions are usually milder, but the possibility of a major reaction exists.

Posttransfusion Purpura

Posttransfusion purpura is the development of life-threatening thrombocytopenia 5 to 10 days after transfusion. This rare complication is caused by the development of alloantibodies directed against platelet-specific antigens; anti-HPA-1a is often implicated, although antibodies with other specificities have also been reported (see Chapter 47). Posttransfusion purpura is thought to occur as a result of a secondary immunologic response to the platelet-specific antigen, most patients having been sensitized by prior pregnancy or transfusion. The mechanism of destruction of the patient’s own platelets is uncertain. Management includes high-dose IVIG, corticosteroids, or plasma exchange.

Posttransfusion thrombocytopenia may also be associated with the passive administration of a platelet-specific antibody. Both anti-HPA-1a and anti-HPA-5a have been implicated; these cases can be defined as passive posttransfusion purpura, and the resulting thrombocytopenia occurs within hours of the transfusion. It is important to identify the donors of these blood products to prevent further infusion of plasma-containing products from such donors.

Transfusion-related Immunomodulation

Allogeneic blood transfusion results in the transfer of not only RBCs, but also significant amounts of potential immune effector cells, their products (e.g., cytokines), and various substances that may be seen by the host immune system as foreign antigens.

P. 576

A large body of literature exists that substantiates the modulation of host immune systems by transfused allogeneic cells and substances, raising the possibility of the development of clinical syndromes generally referred to as transfusion-related immunomodulation (TRIM). Beneficial transfusion-related immunomodulatory effects have been reported in renal transplant patients, women with recurrent spontaneous abortions, and patients with Crohn’s disease. Despite some reported observations of a transfusion-associated increased risk of cancer recurrence or postoperative infections, many studies include potential confounders or sources of bias. Meta-analyses have concluded that a deleterious clinical effect of transfusion immunomodulation remains controversial.

Transfusion-associated Graft-versus-Host Disease

Most cellular blood products, including red cell, platelet, and granulocyte products, contain viable, immunocompetent T lymphocytes. When transfused into immunoincompetent recipients, these donor lymphocytes may proliferate in the patient and lead to the clinical syndrome of transfusion-associated graft-versus-host disease. TA-GVHD has also been reported in immunocompetent patients, especially those who receive transfusions from family members or from random donors who share HLA antigens, as is the case when the donor is homozygous for a shared HLA haplotype. In these cases, the recipient does not recognize the donor cells as foreign, allowing the transfused lymphocytes to proliferate and cause TA-GVHD. A higher incidence has been reported in countries such as Japan, whose populations are genetically similar.

Transfusion of leukocyte or platelet concentrates or fresh blood has been responsible for most cases of posttransfusion GVHD. Frozen-thawed plasma products (FFP, cryoprecipitate) have not been definitively associated with TA-GVHD. TA-GVHD occurs earlier than that seen after bone marrow transplantation, usually within 1 to 2 weeks, but is otherwise similar. Fever is the most common symptom, followed by a typical erythematous, maculopapular skin rash that begins centrally and spreads peripherally to the hands and feet. Abnormalities of hepatic function, nausea, and bloody diarrhea
often occur as the process progresses. Leukopenia followed by pancytopenia due to marrow failure is quite common in TA-GVHD and is seen most often 2 to 3 weeks after the onset of symptoms. The diagnosis is based on the clinical picture and can be confirmed histologically with a skin biopsy. Laboratory confirmation that the GVHD is transfusion-induced can be obtained by demonstrating the presence of donor lymphocytes in the patient. This can be done by HLA typing of patient and donor cells by DNA methods for class I and II antigens, by cytogenetic analysis, or by analysis of DNA microsatellite polymorphisms or variable-number tandem repeats.493 Severe systemic infections are the most common cause of death, which often occurs within 3 to 4 weeks from the time of the implicated transfusion. Despite aggressive treatment, the fatality rate in TA-GVHD is significantly higher than that associated with bone marrow transplantation and has been reported to be 90%.498

Corticosteroids, antithymocyte globulin, cyclosporine, and growth factors have all been used with minimal success in the treatment of TA-GVHD. Although a few reports of spontaneous resolution have been reported, current treatment approaches have used combinations of immunosuppressant medications with lymphocyte-directed antibody therapy (anti-CD3, anti-interleukin-2 receptor, antithymocyte globulin). Because of the lack of effective treatment regimens, TA-GVHD should be prevented by pretransfusion irradiation of all blood products administered to patients at risk. Irradiation inhibits proliferation of donor lymphocytes with little significant adverse effect on red cell, platelet, or granulocyte function. Changes in the red cell membrane do occur that result in an increased loss of potassium from the cell, limiting the storage time of irradiated red cells to 28 days. This may be important in neonates, as the dose of free potassium may be high in a relatively large-volume transfusion, necessitating the use of freshly irradiated or washed RBCs. The recommended dose for the irradiation of blood and blood products is 2,500 cGy at the center of the irradiation field, with a minimum dose of 1,500 cGy at any point in the field.5,131

Based primarily on case reports and reviews, a number of immunosuppressed and immunocompetent patient groups can be stratified according to risk for developing TA-GVHD (Table 21.9).

Nonimmunologic Adverse Effects of Blood Transfusion

Transfusion-associated Circulatory Overload

Transfusion of red cell preparations or plasma products may result in transfusion-associated circulatory overload (TACO). In chronically anemic patients, the plasma volume expands so that the blood volume is normal. Virtually the entire volume of the blood product infused remains in the circulation; in elderly patients with limited cardiac reserve or in severely anemic patients in congestive heart failure, transfusion may lead to fatal pulmonary edema. Diuretic therapy and other measures to manage heart failure may be of some benefit; partial exchange transfusion may be indicated. Prevention of these reactions is most important. Transfusions should be administered slowly, at a rate of 1 to 2 ml of blood/kg of body weight per hour, with the patient under close observation. Splitting red cell components or volume-reducing apheresis platelets can be helpful in managing the most difficult cases.

**TABLE 21.9 PATIENTS AT INCREASED RISK FOR TRANSFUSION-ASSOCIATED GRAFT-VERSUS-HOST DISEASE**

**High Risk**
Bone marrow transplant (allogeneic and autologous)
Intrauterine transfusions
Granulocyte or HLA-matched platelet transfusions
Transfusions from blood relatives
Congenital immunodeficiencies
Hodgkin disease

**Moderate Risk**
Hematologic malignancy (acute myelogenous leukemia/acute lymphocytic leukemia/non-Hodgkin lymphoma)
Patients treated with purine-analog drugs (e.g., chronic lymphocytic leukemia)
Malignancies treated with intensive chemo-/radiotherapy (i.e., neuroblastoma, sarcoma)
Solid organ transplant recipients
Preterm infants
Newborns receiving exchange transfusion

**Low/Theoretical Risk**

Human immunodeficiency virus/acquired immunodeficiency syndrome

Healthy term newborns

Massive Transfusion

Metabolic Effects

Stored blood differs in its composition from that circulating in the body. If large amounts of stored blood are infused rapidly, one may observe adverse effects related to such differences. The elevated K⁺ content of stored red cells rarely leads to hyperkalemia, but it is a risk in the presence of renal failure, shock with acidosis, or hemolysis. Plasma contains a significant amount of citrate as anticoagulant; recipients with normal circulatory status promptly metabolize this in the liver, but during plasma exchange or in patients in shock or severe liver failure, citrate excess may lead to hypocalcemia. Hypocalcemic reactions caused by citrate may be treated by intravenous calcium infusion.

Hypothermia

Hypothermia may occur if a large volume of cold blood is infused rapidly. Hypothermia is one of the most common complications of massive transfusion and contributes to the associated coagulopathy. Neonates and the elderly are particularly sensitive to this reaction. Hypothermia affects the way the liver metabolizes citrate, resulting in an increased risk of hypocalcemia. Rapid infusions of citrated blood products in such patients, especially through central venous lines, may lead to arrhythmias. Hypothermia interferes with platelet function and clotting, both of which are improved when the patient is warmed. One way of approaching this problem is with the use of warmed intravenous fluids or blood. Blood-warming devices are available that can adequately warm the blood administered, even during a rapid and massive transfusion. All patients who are receiving large amounts of red cells and plasma should have those products administered through blood-warming devices. Blood warmers must be checked regularly to ensure that they maintain their temperature. If the blood is overheated, hemolysis and the associated complications of transfusing hemolyzed blood may result.

Any one of these potential problems alone is rarely significant. However, in the critically ill patient who requires massive transfusion, acidosis, hypoxemia, hypothermia, hypocalcemia, and hypo- or hyperkalemia often coexist, with a consequent risk of cardiac arrhythmias. Neonates receiving exchange transfusions are particularly susceptible to such physical and metabolic effects.

Dilutional Coagulopathy

Massive transfusion of one to two blood volumes in patients results, first, in abnormalities of the prothrombin time (PT) and of the activated partial thromboplastin time (APTT); and second, in thrombocytopenia. Massively transfused patients are often affected by sepsis, shock, and intravascular coagulation, which may aggravate the dilutional hemostatic defects.

In practice, most patients tolerate otherwise uncomplicated dilutional coagulopathy well. Factor VIII activity may rise as a response to stress; factor V falls, but rarely to dangerous levels. Moderately severe thrombocytopenia, accompanied in some cases by a significant degree of platelet dysfunction, may be a more significant problem. Transfusion therapy of such patients is best guided by laboratory measurements, but clinical assessment is most important because conventional coagulation tests take time to obtain. As discussed earlier in this chapter, for patients undergoing rapid massive transfusion, the first line of treatment (with regard to hemostatic blood products) should include plasma to correct the levels of coagulation factors, followed by platelet products.

Age of Transfused Blood
In 2008, a study suggested a relationship between the length of blood product storage and the in-hospital mortality of transfused cardiac surgery patients. The study was retrospective in nature and elicited much discussion and further investigation. Metaanalyses of studies looking at the effect of age of transfused blood on patient outcomes failed to clarify an association. Prospective studies are now ongoing.

The changes that stored red blood cells undergo while awaiting transfusion are referred to as the “storage lesion.” In short, these changes are a decrease in both 2,3-diphosphoglycerate, ATP, and an increase in extracellular potassium. Red cell membrane changes result in decreased flexibility of the cell, hemolysis, and formation of microparticles. Whether the red cell storage lesion is responsible for deleterious clinical effects awaits further investigation.

Miscellaneous

Air embolism is a potential hazard when perioperative infusion devices are used. Fat embolism may occur in the rare situation in which blood products are transfused via the bone marrow. The plastic materials used to ensure the flexibility of some blood storage bags can leach into the product and, although no adverse effects have been demonstrated to date, attempts are being made to identify alternatives.

Iron Overload: Transfusion Hemosiderosis

Iron overload is a major problem in patients who require long-term red cell transfusion support for chronic anemias due to bone marrow failure. Each unit of red cells contains approximately 0.25 g of iron. After a large number of red cell transfusions, in the absence of blood loss, the recipient develops the stigmata of transfusion siderosis: impaired growth, failure of sexual maturation, myocardial and hepatic dysfunction, hyperpigmentation, and, often, diabetes. Patients such as those with thalassemia who are at risk of this complication should receive prophylactic aggressive iron chelation therapy.

INFECTIOUS COMPLICATIONS OF BLOOD TRANSFUSION

Overview of Blood Donor Screening for Infectious Diseases

In the 1960s, transfusion-associated hepatitis (TAH) occurred in more than 30% of multiply transfused patients. The development and implementation of a screening test for HBsAg and the switch to an all-volunteer blood supply resulted in a dramatic reduction in the incidence of both B and non-A, non-B (NANB) TAH (Fig. 21.7). However, a significant risk of NANB hepatitis persisted.

In the early 1980s, the blood banking industry was further challenged with the appearance of AIDS. In the early and mid-1980s, before the identification of the causative agents of AIDS or NANB hepatitis, the idea of using surrogate tests to identify donations at increased risk of transmitting one of these infections was introduced. Candidate tests included those that would detect the consequences of an infection (e.g., elevated alanine aminotransferase [ALT] in the case of NANB hepatitis or inverted helper-to-suppressor T-cell ratio in the case of AIDS) or those likely to be positive in individuals who engaged in high-risk sexual activity or needle sharing (e.g., antibody to the hepatitis B core antigen [anti-HBc]). Before the availability of a specific test for HIV, some blood suppliers implemented HBc antibody testing or donor T-cell testing in an attempt to reduce the risk of transmitting AIDS through blood transfusion.

After the development and implementation of a test for HIV antibody in 1985, it became clear that there is a delay between the onset of infection and the development of detectable antibody. A blood donation made during this “window period” could pass infectious disease screening tests but transmit infection. The FDA required blood centers to inform prospective donors about the window period and to question them directly about specific risk behaviors. Gradually, improvements in the sensitivity of the HIV antibody test led to shortening the HIV window period from 45 days to about 22 days.\textsuperscript{517,518}

During the mid-1980s, surrogate tests for NANB hepatitis and risk activity (ALT and HBc antibody) became required in the United States. A donor screening test for the retrovirus HTLV-I was implemented in 1988. The first donor screening test for antibody to hepatitis C became available in 1990, and an improved test became available in 1992. In 1996, a donor screening test for HIV-1 p24 antigen was implemented because available information suggested that this test could shorten the HIV window period by an additional 6 days.\textsuperscript{518} By this time, the risks of transfusion-transmitted HIV and hepatitis were too low to measure prospectively and could only be estimated with the aid of mathematic modeling (Fig. 21.8).\textsuperscript{519,520} and \textsuperscript{521}
FIGURE 21.8. Decline in risk of human immunodeficiency virus (HIV), hepatitis B virus (HBV), and hepatitis C virus (HCV) transmission by transfusion, 1983 to 2001. Estimates indicated by solid symbols are based on donor prevalence measurements; estimates indicated by shaded symbols are based on recipient follow-up studies; estimates indicated by open symbols represent projections based on mathematical modeling. Estimated risk of infection per unit transfused in 2000-2001 was 1:220,000 for HBV, 1:1.6 million for HCV, and 1:1.8 million for HIV. (From Fiebig E, Busch MP, with permission; modified from Busch MP, Kleinman SH, Nemo GJ. Current and emerging infectious risks of blood transfusions. JAMA 2003;289:959-962.)

Despite the extremely low risk of transfusion-transmitted HIV and hepatitis, there continued to be immense public pressure to further improve transfusion safety. In 1999, nucleic acid testing (NAT) for HIV and HCV RNA was added to blood donor screening via clinical trials. Initially available NAT methods were labor-intensive and could not be applied to rapid screening of large numbers of blood donations. NAT screening was rendered feasible by performing the assays on “minipools” of donor specimens (initially pooling 16 to 24 samples together for testing, more recently 6 to 16 samples). Clinical trials of minipool NAT for HIV and HCV RNA confirmed that this testing detects infection earlier than antigen or antibody assays.\(^{522,523}\) NAT testing for HIV and HCV RNA is now required by the FDA. With implementation of licensed NAT for HIV, the FDA permitted discontinuation of the HIV p24 antigen test.

NAT assays continue to be improved and new assays developed. Donor NAT assays for HIV and HCV RNA are now fully automated and have been multiplexed to include HBV DNA detection. Testing for West Nile virus RNA was initiated in 2003 using investigational assays; this testing is now required by FDA.

Additional donor serologic screening tests have also been developed or are in development. A donor screening assay for antibodies to T. cruzi became available in 2007; FDA now requires every donor to be tested once for this infection (see below). Tests for Babesia infection are in development.

Residual Risks of Infection
Table 21.10 lists the tests currently performed on volunteer blood donations in the United States. It is thought that the residual risk of transmitting HIV and hepatitis by transfusion is related mainly to window period donations. The probability that a donation was made during the window period can be calculated from the observed incidence of new infections in blood donors and the length of the window period. The implementation of nucleic acid testing for HIV and HCV has permitted direct detection of donors with newly-acquired infections (i.e., donors who are NAT-positive, antibody negative). New HIV and HCV infections in repeat blood donors are very rare. However, studies indicate that first-time donors are two to three times more likely than repeat donors to have newly-acquired infection. Thus, current estimates of transfusion risk include an adjustment for a 2- to 3-fold higher probability that a first-time donor is in the window period compared to a repeat donor. Table 21.11 shows the current risk estimates for transfusion-transmitted HIV, HCV, and HBV based on the length of the window period and the estimated frequency of window period donations.

Because the current risks of transmitting HIV and HCV are low, the absolute benefit gained from further incremental improvements in blood donor testing for these infections would be very small. The implementation of individual-unit NAT for HIV and HCV, for example, would be associated with extremely high cost with very little incremental improvement in blood safety in the US. Similarly, the value of processes to chemically inactivate residual pathogens in blood products has been questioned in view of the low residual risks of HIV and HCV. These treatments, however, might represent a reasonable approach toward reducing the risk of transmitting infectious agents for which there are currently no donor screening tests. Some pathogen reduction treatments for platelets and fresh plasma are in use outside the US, but as of April 2012 these were not approved for use in the US. Commercial plasma derivatives are, however, subjected to a solvent/detergent treatment that inactivates lipid-enveloped viruses such as HIV, HCV, and HBV. Solvent/detergent treatment cannot be applied to cellular blood components.

### Transfusion-associated Hepatitis

Before the development of serologic tests capable of determining the cause of TAH, all TAH was thought to be due to hepatitis B (the “serum hepatitis” agent). After the HBsAg test became available, however, it was discovered that hepatitis B accounted for only about 25% to 30% of TAH cases. Subsequent studies excluded hepatitis A virus (HAV), CMV, and the Epstein-Barr virus (EBV) as common causes of TAH. The designation NANB hepatitis was created to describe the majority of TAH cases. In 1988, the major causative agent of NANB hepatitis was identified as HCV. Widespread testing of all blood donations for this virus was implemented in 1990. An improved test for hepatitis C became available in 1992. Since then, TAH has become rare.

#### Hepatitis B

The discovery of HBsAg and application of this test to blood donor screening led to a dramatic reduction in transmission of HBV by transfusion (Fig. 21.7). Screening of all blood products for HBsAg began in 1970 in the United States with low-sensitivity tests and was made mandatory in 1972. The high-sensitivity HBsAg test in current use becomes positive an average of 38 days after the onset of infectivity. This test detects most but not all donors who are infectious for hepatitis B. Three types of individuals with hepatitis B infection may be missed by the current HBsAg test: (1) individuals with early infection whose HBsAg has not yet become detectable; (2) individuals who were previously vaccinated against HBV and have anti-HBs but who acquire HBV infection after subsequent exposure (so-called “vaccine breakthrough” infections); and (3) individuals with chronic infection whose HBsAg has fallen below the limits of detection (“occult HBV infection”). Units from individuals with chronic occult HBV (category 3 above) are currently excluded from the US blood supply by donor testing for anti-HBc. In the US, anti-HBc-positive donations are permitted into pooled plasma derivatives, however, because HBV infectivity is eradicated from these products by the pathogen inactivation processes to which the products are subjected. Based on currently mandated donor screening tests (i.e., HBsAg and anti-HBc), the current estimated risk of HBV transmission by individual blood components in the United States is 1 in 280,000 units (Table 21.11).

As of April 2012, HBV DNA testing of blood donors was not required in the US. However, most US blood donors were, in fact, being tested for HBV DNA because probes for this target were included in the donor screening NAT assays used for HIV and HCV RNA detection. In November 2011 the US FDA issued a draft guidance document indicating its intention to make HBV DNA screening a requirement. HBV DNA tests detect some, but not all, of the HBV-infected donors missed by
HBsAg testing.\textsuperscript{539} HBV DNA screening of blood donors has more value in HBV endemic countries where donors are not screened for anti-HBc.\textsuperscript{540}

Hepatitis C

Donor screening for HCV includes NAT for HCV RNA as well as HCV antibody testing. It is estimated that the donor RNA test detects infection an average of 7.4 days after exposure. Based on window period/incidence modeling, the risk of HCV transmission by transfusion of fresh blood products is now estimated to be approximately 1 in 1,149,000 (Table 21.11).\textsuperscript{525}

Hepatitis A Virus

Transfusion-related transmission of HAV by fresh blood products is rare.\textsuperscript{541,542} However, transmission of HAV has been associated with pooled plasma products.\textsuperscript{543} Because HAV is not lipid-enveloped, infectivity is not eliminated by solvent/detergent treatment. Therefore, immunization to HAV is recommended for patients who are expected to receive pooled plasma products, such as those with clotting disorders.\textsuperscript{543} The FDA does not require donor screening for this agent. Some plasma-derivative manufacturers, however, test plasma pools for HAV nucleic acid in an effort to reduce the risk of transmitting this agent.

Human Immunodeficiency Virus Type 1 and Type 2

Current donor screening for HIV includes nucleic acid testing for HIV-1 RNA and testing for antibodies to HIV-1 and HIV-2. The window period for HIV, based on time to detection of RNA via minipool nucleic acid screening, is currently estimated at 9 days.\textsuperscript{525} The current estimated risk of HIV transmission by transfusion is approximately 1:1,467,000 units (Table 21.11). Donor questioning regarding HIV risk behavior and the temporary exclusion of individuals at increased risk of being in the HIV window period are critical and essential elements of this safety level.\textsuperscript{544} Whether certain deferral periods could be shortened without compromising blood transfusion safety has been the topic of intense public discussion.\textsuperscript{545}

Other Infections

Essentially any infection that can circulate in the blood of an apparently healthy blood donor can be transmitted by transfusion. Recently, the AABB’s Transfusion-Transmitted Diseases (TTD) Committee evaluated a number of potentially transmissible infections, their risks of causing severe disease, and the need for intervention strategies.\textsuperscript{546} This analysis is available online and is updated periodically. Some of the agents that have been the focus of recent interventions or public debate are discussed below.

Infections Transmitted by Arthropods

Over the past decade, much attention has been focused on infectious agents that can be transmitted to donors by insects and further transmitted to patients via transfusion.\textsuperscript{547} This category of pathogens includes West Nile virus, Trypanosoma cruzi, babesia, malaria, and dengue fever.

West Nile Virus

West Nile virus was first detected in the United States in 1999, and has since spread through the North American continent in annual epidemics. Birds are the natural reservoir of the virus, which is spread to humans by mosquitoes.\textsuperscript{547} Eighty percent of infected individuals are asymptomatic, 20% have a relatively nonspecific febrile illness, and <1% develop neuroinvasive disease (meningitis, encephalitis, or flaccid paralysis), which can lead to chronic disability or death.

WNV was first demonstrated to be transmissible by transfusion in 2002, when infection in 23 recipients was linked to blood components later found to contain WNV RNA but no WNV antibody.\textsuperscript{548} In 2003, minipool NAT screening of blood donations for West Nile virus RNA was implemented throughout the United States using investigational assays. WNV NAT assays are now FDA-approved and required. Transmissions despite minipool donor testing led to the discovery that 20% to 30% of donors with WNV infection may be missed by minipool testing because of low levels of circulating virus.\textsuperscript{549,550} Therefore, at times of high WNV activity, donor WNV RNA screening must performed on individual donations.\textsuperscript{551}

Malaria

Malaria is a common infection globally. However, transfusion-transmitted malaria is rare in the United States, with only zero to three cases per year occurring during the last decade.\textsuperscript{552} This degree of safety is remarkable considering that there is no donor screening test for malaria in the United States. Screening is accomplished entirely by donor questioning. According to current FDA guidelines, individuals are deferred from donation for 1 year after travel to a malarious area and for 3 years after living in a malarious area. Almost 3% of otherwise eligible donors are excluded on the basis of this questioning. Of the donors implicated in the recent cases of transfusion-transmitted malaria in the United States, approximately 60% (including the majority of Plasmodium falciparum infections) should have been excluded by donor
Bacterial under development.

the causative agent of vCJD would not be inactivated by any of the pathogen inactivation processes currently in use or attempts to or if they received a transfusion in the UK or France since 1980.

they lived in the UK for 3 months or more between 1980 and 1996, if they lived in Europe for 5 years or more since 1980, of a donor screening test for the infection. that causes bovine spongiform encephalopathy (BSE), or “mad cow disease.” As of Ap

In contrast, variant CJD (vCJD) does appear to be transmissible by transfusion. Human vCJD is caused by the same prion infections of the nervous system caused by prions.

Both classical Creutzfeldt-Jakob disease (CJD) and variant Creutzfeldt-Jakob disease (vCJD) are rapidly progressive fatal infections of the nervous system caused by prions. Individuals at increased risk for classical CJD are currently excluded from blood donation in the United States, despite evidence that this disease is not transmissible by transfusion. In contrast, variant CJD (vCJD) does appear to be transmissible by transfusion. Human vCJD is caused by the same prion that causes bovine spongiform encephalopathy (BSE), or “mad cow disease.” As of April 2012, four cases of apparent transfusiontransmitted vCJD had been identified in the UK, where a BSE epidemic occurred between 1980 and 1996. In addition, one case of vCJD had been identified postmortem in a hemophilia patient in the UK who died of other causes. Worldwide, steps have been taken in an effort to minimize the risk of vCJD transmission by blood products in the absence of a donor screening test for the infection. In the United States, individuals are currently excluded from donating blood if they lived in the UK for 3 months or more between 1980 and 1996, if they lived in Europe for 5 years or more since 1980, or if they received a transfusion in the UK or France since 1980. Filters that may absorb prions are in development, and attempts to develop blood donor screening tests are also underway. Because prions lack lipid coats and nucleic acid, the causative agent of vCJD would not be inactivated by any of the pathogen inactivation processes currently in use or under development.

Bacterial Contamination

P.581
Bacteria are present in approximately 1/3,000 cellular blood components. Potential sources of bacteria include asymptomatic bacteremia in the donor and bacteria from the donor’s skin. Bacterial contaminants multiply fairly readily in platelet components, which are stored at room temperature, but less readily in red cell products, which are refrigerated.

Recognition of morbidity and mortality from transfusion of bacterially contaminated platelets prompted the AABB to implement, in 2004, a requirement for bacterial testing of platelet components. AABB now also requires diversion of the first several milliliters of donor blood into a sample pouch to reduce contamination of platelet units by skin contaminants.5

The quantity of bacteria in blood components just after collection is too low to detect by any diagnostic assay. The platelet bacterial screening process used by most US blood centers involves a 36 to 48 hour quarantine of the platelet components. First, there is a 24-hour hold after collection to allow potentially contaminating bacteria to multiply to detectable levels. Then, a sample is taken from each product and inoculated into a blood culture bottle. If the culture is negative after 12 to 24 hours, the product is made available for use, but the culture is continued for the shelf life of the unit. About 1 in 5,000 apheresis platelets are found by this screening to be bacterially contaminated.5 This screening process is imperfect, however, and still fails to detect some bacterially contaminated platelets. Recently, a strip immunoassay which could be used by hospitals to retest platelets was reported to find bacteria in approximately 1 in 3000 pheresis platelets that had been negative on their culture screen.5 This immunoassay or alternative tests are associated with false positives and logistical challenges, however, and still fail to detect some contaminated products.5 Given the imperfections of current platelet screens, and the lack of any bacterial screen for red cell products, bacterial contamination must remain in the differential diagnosis when transfusion recipients become febrile or hypotensive following transfusions. The pathogen inactivation systems in development for cellular blood components all appear likely to inhibit the growth of bacteria.5

Cytomegalovirus

CMV is a DNA virus in the herpesvirus family. Like other herpesviruses, it remains latent after acute infection, with the potential for reactivation.

In immunologically normal adults, CMV disease manifestations range from none to a mononucleosis-like syndrome. In immunosuppressed or immunodeficient patients, however, both primary and reactivation disease may be associated with overwhelming manifestations including thrombocytopenia, hemolytic anemia, pneumonitis, colitis, hepatitis, meningoencephalitis, and death. Effective antiviral treatment is available. The incidence of severe disease can be reduced by prophylactic treatment of high-risk patients with antiviral drugs or by careful monitoring of such patients and initiation of therapy with the first evidence of infection.5

CMV is transmitted only through cellular blood components. The incidence of transmission of CMV by transfusion appears to be low (<1%) in immunologically normal recipients.5 Immunodeficient patients, however, are at increased risk of acquiring CMV from transfusion. CMV transmission to these patients can be greatly reduced by restricting their cellular blood components to products obtained from CMV-seronegative donors or by use of leukoreduced blood components.5 Most studies have detected no transmission of CMV by leukoreduced blood components. Some transmissions were detected, however, in a large randomized study that evaluated the incidence of CMV infection and CMV disease in 502 bone marrow transplant recipients randomized to receive either leukoreduced (i.e., leukofiltered) or CMV antibody negative blood components.5 CMV infection was observed in 1.3% of recipients of seronegative components and in 2.4% of recipients of leukoreduced components, a difference that was not statistically significant. However, in the leukoreduced arm, all CMV-infected patients developed disease, and five out of six died; in the serologically screened arm, there were no cases of CMV-related disease or death. A meta-analysis estimated that the risk of transfusion-transmitted CMV is approximately 1.5% with use of CMV antibody-screened components, compared to 2.5% with leukoreduced, antibody-unscreened components.5 Most of the cellular components in the US are leukoreduced. Whether it is clinically beneficial to perform CMV antibody screening in addition to leukoreduction remains controversial.5

It is generally recommended that cellular products with a reduced risk of transmitting CMV (leukoreduced or CMV antibody negative) be used for patients at increased risk of severe primary CMV disease, including unborn babies (i.e., intrauterine transfusion), low-birth-weight infants of seronegative mothers, seronegative recipients of seronegative solid organ or HPC transplants, and seronegative patients with severe cellular immunodeficiency (e.g., HIV-infected patients). Products with reduced CMV risk are often provided also for seronegative patients who are likely to require transplantation in the future, in order to reduce their future risk of CMV-reactivation disease.5
There is no clinical benefit of providing products of reduced CMV risk to patients who are already seropositive. Although second-strain infections may occur, these have not been shown to be clinically important given the high risk of reactivation disease these patients face. In CMV-positive recipients of allogeneic hematopoietic progenitor cell transplants, the use of CMV-positive stem cell donors has no detectable adverse effect on patient outcomes. Therefore, it seems that CMV-seropositive blood components would also be acceptable in this setting.

Seronegative recipients of seropositive organ and stem cell transplants are at high risk of CMV disease and are likely to be monitored closely, treated prophylactically, or both. It is unclear whether providing blood products with reduced CMV risk to such patients is of clinical benefit.

Pathogen Reduction Technologies

Donor screening and testing cannot completely eliminate the possibility of transfusion-transmitted infection or blood product contamination. The ideal pathogen reduction technology (PRT) would effectively inactivate residual pathogens without adversely affecting the function, toxicity, or immunogenicity of the blood component. Most commercial plasma derivatives are treated with heat and/or organic solvents and detergents (SD). SD treatment inactivates lipid-coated agents. Cellular blood components, however, cannot withstand this treatment. Most of the PRTs in development for cellular products consist of blood product additives that bind to and damage DNA and thereby prevent residual pathogens from proliferating in the blood component or in the recipient. These treatments would theoretically also prevent transfusion-related GVHD because the DNA of WBCs in the blood product would also be affected. The efficacy of PRT agents is dependent on their ability to penetrate cellular membranes or viral envelopes and reach the target nucleic acid. Because of concern that DNA-altering agents could cause long-term toxicity in transfusion recipients, many of the PRT systems include processes that remove the DNA-binding agent or inactivate it. PRTs in distribution outside the US and in development have been recently reviewed.

PRTs can reduce the residual risk related to window period transmissions of HIV, HCV, and HBV, but these risks are small. The primary benefit of PRTs is to reduce transmission of agents for which there are currently no tests. These treatments are costly. The incremental costs of PRT can be offset if they are approved by regulators as eliminating the need for irradiation, CMV antibody screening, and bacterial testing. Elimination of platelet bacterial testing would also expedite release of these products.

Several PRT systems for plasma are in use outside the US. One (S/D plasma) is a commercial product manufactured from pools of donor plasma. A pooled product has both theoretical advantages and disadvantages. For example, pooling dilutes antibodies from individual donors and thereby theoretically reduces the risk of antibody-mediated transfusion complications such as TRALI. However, pooling could increase a recipient’s risk of exposure to an emerging pathogen that is not removed or inactivated by the manufacturing process. PRTs that involve treatment of individual plasma units are more logistically challenging. All of the plasma PRTs listed in Table 21.12 have been determined to satisfy the Council of Europe plasma quality standards.

As of April 2012, the amotosalen/UV and riboflavin/UV PRTs for platelet products were in distribution in some countries outside of the US. Both of these treatments appear to be associated with some loss of platelet product potency. The clinical importance of the potency changes relative to the theoretical benefit of PRT is unclear.

THERAPEUTIC APHERESIS

Therapeutic apheresis is an important modality of therapy in the management of several diseases and The term plasmapheresis refers to the selective removal of plasma. This includes the collection of plasma from normal donors. A therapeutic plasma exchange, on the other hand, refers to the removal of a large proportion of a patient’s plasma and replacement with crystalloid or colloid fluids and/or plasma product. These terms are often used interchangeably. Therapeutic cytapheresis, the removal of red cells, leukocytes, or platelets, is used infrequently in the management of patients with hemoglobinopathies, leukostasis, or thrombocytosis, respectively.

Guidelines for clinical practice have been developed by the American Society for Apheresis (ASFA) and are regularly updated every 3 to 7 years with a systematic review of the medical literature. The current guidelines published in 2010576 review the therapeutic apheresis procedures most commonly performed (i.e., therapeutic plasma exchange (TPE), red blood cell exchange, erythrocytapheresis, thrombocytapheresis, leukocytapheresis, extracorporeal photopheresis (ECP), immunoadsorption (IA), selective removal methods, adsorptive cytophapheresis, and membrane differential filtration. Additionally, the guidelines contain 59 specific disease fact sheets listing the type of apheresis procedure to be performed and the rationale for it, the recommended blood volume to be exchanged, and the duration of the treatment.

The disorders for which therapeutic apheresis has been used are divided into four categories: category I, for which apheresis is the accepted first line of therapy; Category II, for which apheresis is considered a second-line therapy, after a patient has failed or is unable to undergo the first-line therapy; category III, for which the optimum role of apheresis therapy is not established and decision making should be individualized; and category IV disorders, in which published evidence demonstrates or suggests apheresis to be ineffective or harmful.570,576,577 Some of the indications for TPE (categories I and II) are listed in Table 21.13.

Therapeutic Plasma Exchange

Indications

The therapeutic goal of therapeutic plasma exchange (TPE) is to remove plasma components such as monoclonal proteins and cryoglobulins,573 immune complexes,571 lipoproteins, or toxins573 responsible for physical or metabolic problems. These may include removal of autoantibodies, as in myasthenia gravis574 and Goodpasture syndrome575; or alloantibodies, as in posttransfusion purpura or patients with Factor VIII inhibitors.572 The existence and pathogenic role of antibodies or immune complexes are presumed in several situations often treated with TPE, including neurologic disorders such as Guillain-Barré syndrome,569,574,578,579 and580 polyneuropathy,574 and various nephritides.573,581 In thrombotic thrombocytopenic purpura (TTP), TPE using cryoprecipitate-reduced plasma582 or frozen plasma as the replacement fluid serves to either replace the missing vWF-cleaving metalloprotease or to remove autoantibodies to this protein.118,583 TPE or plasma transfusion584,585 and586 may be life-saving in this disease, as it controls the microangiopathy.

Familial hypercholesterolemia

Technical Considerations

The amount of plasma to be removed from the patient is determined by the physician, depending on the clinical situation. A patient’s plasma volume may be estimated at 40 ml/kg, determined from a nomogram based on the patient’s sex, height, weight, and hematocrit; or estimated according to the weight and hematocrit by the following formula:

\[
\text{Circulating blood volume} = \text{patient weight (kg)} \times 70 \text{ ml/kg}. 
\]

\[
\text{Circulating plasma volume} = \text{circulating blood volume} \times (1.0 - \text{hematocrit [expressed as a decimal]}). 
\]

TPE is typically performed with 1.0 to 1.5 plasma volume exchanges or approximately 3,000 to 4,500 ml. If <1,000 ml is removed from an adult, it may be possible to replace the loss with crystalloid alone; if a more extensive plasma exchange is performed, use of a colloid is necessary. Albumin (5%) is the replacement fluid most commonly used in the United States. FFP or FP24 is indicated in certain instances, such as TTP or as a component of the replacement fluid in the setting of a coagulopathy.

After exchange of one plasma volume, approximately 62% of the original plasma has been removed. The efficiency of plasma exchange decreases with further exchange (Table 21.14).

In practice, measurement of plasma protein concentrations after exchange has confirmed the approximate validity of these estimates. However, efficacy varies with the plasma factor to be removed. IgM and fibrinogen, which are largely confined to the intravascular space, are removed most efficiently. IgG is removed less efficiently by plasma exchange because only 45% to 50% of the body’s IgG is located in the intravascular space, although IgG levels can be reduced by repeated TPE. Patients receiving plasma exchange for immunologic diseases generally have 1.0 to 1.5 plasma volumes exchanged at each procedure; this is often repeated, for a total of 5 to 7 exchanges over a period of 7 to 10 days. Such plasma exchange schedules have been determined empirically; the optimal exchange regimens for different diseases are unknown.

Therapeutic Cytapheresis

Therapeutic leukapheresis is used in the treatment of patients with leukostasis as a result of extremely high circulating concentrations of immature cells. At blast counts >100 × 10^9/L, there is an increasing risk of cerebral and pulmonary leukostasis, resulting in impaired capillary blood flow resulting from obstruction of small vessels. This situation may be encountered in the acute leukemias but rarely in chronic lymphocytic leukemia or chronic myelogenous leukemia. Therapeutic leukapheresis decreases the circulating blast count more rapidly than chemotherapy alone; chemotherapy must be instituted promptly once the patient is stabilized, to prevent rebound leukocytosis. The only exception is in pregnancy, in which leukapheresis may be indicated until after the delivery of the fetus, thereby protecting the fetus from the teratogenic effects of chemotherapy.

| TABLE 21.14 PLASMA EXCHANGE: THEORETICAL EFFICIENCY |
Number of Plasma Volumes Exchanged | Percent (%) of Original Plasma Remaining
--- | ---
0.5 | 60
1.0 | 38
1.5 | 22
2.0 | 15

Therapeutic leukapheresis has also been used in the treatment of patients with other leukemic diseases, such as chronic lymphocytic leukemia that is resistant to drugs, Sézary syndrome, and hairy cell leukemia, and as maintenance therapy in chronic myelogenous leukemia. However, it has not found a distinct role in such conditions. Collection of leukocytes by apheresis, followed by ex vivo exposure of the leukocytes to UV light in the presence of a psoralen, and reinfusion of the treated leukocytes ("photopheresis") has become standard therapy for cutaneous T-cell lymphoma. This procedure may be useful in the treatment of other disorders such as GVHD.

Therapeutic plateletpheresis is performed very rarely and is not considered to be first-line therapy. It is indicated in patients with very high platelet counts, usually >1.0 to 1.5 × 10^{12}/L, in whom the high count is directly responsible for serious thrombotic or hemorrhagic problems, or in whom other urgent clinical situations necessitate immediate lowering of the platelet count. Therapeutic plateletpheresis must be followed by cytotoxic therapy to prevent rebound after the procedure, or its effect is very short-lived.

Erythrocytapheresis (red cell exchange) is used in sickle cell disease to replace sickled cells with normal erythrocytes and thereby prevent thromboses and improve capillary circulation. Stroke prevention by maintaining hemoglobin S level below 30% and acute chest syndrome are the two major indications for red cell exchange in patients with sickle disease.

Therapeutic Absorption of Plasma Constituents

Apheresis technology may be used to selectively remove constituents of plasma implicated in disease processes. In these procedures, a patient’s plasma is withdrawn and separated by apheresis technology, passed over a selective absorption column, and reinfused into the patient. This technique has been used to selectively remove IgG (staphylococcal protein A columns) or low-density-lipoprotein (LDL) cholesterol. Selective apheresis may specifically treat diseases such as LDL-hypercholesterolemia. Patients with LDL-hypercholesterolemia are at risk of developing severe coronary artery disease despite a low-fat diet and cholesterol-lowering agents. Selective LDL apheresis involves separation of the patient’s plasma, followed by selective removal of apoB-containing atherogenic lipoproteins, preserving the cardioprotective HDL cholesterol, after which the cleansed plasma is recombined with the cellular portion of the blood and returned to the patient. This procedure was shown to be safe and efficacious in controlling patients with familial hypercholesterolemia.

Adverse Effects

Adverse reactions to therapeutic apheresis are common but usually mild. In a 1-year period in Canada, there were side effects in 12% of more than 5,235 procedures in 627 patients. They included vasovagal reactions, fluid imbalance with hypovolemia or overload, fever, chills, and hypocalcemic citrate reactions ranging from paresthesias to arrhythmias. If plasma is used as the replacement fluid, urticarial reactions may be encountered. Mild dilutional coagulopathy and thrombocytopenia occur but are rarely significant. Problems related to venous access are common. The possibility of immunologic rebound after plasma exchange has been suggested but has not been observed clinically, perhaps because many patients so treated are also receiving immunosuppressive agents for the underlying diseases. Infections related to indwelling venous lines are not uncommon. Deaths have been reported with therapeutic apheresis. It is important that patients be carefully assessed and the indications reviewed before implementing this form of therapy.

SUMMARY

Blood transfusion is an essential component of therapy for a wide variety of disorders. The menu of blood components and the technologies for collecting, processing, and screening blood are constantly changing. Collaboration between transfusion medicine professionals and patient care teams ensures the most appropriate application of blood transfusion therapies.

Part IV - Disorders of Red Cells

Section 1 - Introduction

Chapter 22 Anemia: General Considerations

This introductory chapter focuses on the general concepts of anemia, the classification of the most common types of anemia, the approach to patients with hemolysis, and the assessment of posthemorrhagic anemia. Anemia rarely is a disease by itself; almost always it is a sign of an acquired or genetic abnormality. The various medical conditions that lead to anemia encompass nearly the full spectrum of human disease.

DEFINITION OF ANEMIA

Red blood cells (RBCs) circulate in the peripheral blood for 100 to 120 days, and approximately 1% of the body's red cells are lost and replaced each day. Red cells recognized as being old are removed from the circulation by macrophages in the spleen, liver, and bone marrow (Chapter 6). An erythropoietic feedback loop ensures that the total red cell mass remains constant. A reduced RBC mass results from loss of RBCs from the circulation at a rate greater than their production: this may reflect increased RBC clearance, decreased RBC production, or both.
Anemia is functionally defined as an insufficient RBC mass to adequately deliver oxygen to peripheral tissues. For practical purposes, any of the three concentration measurements performed on whole blood can be used to establish the presence of anemia: the hemoglobin (Hb) concentration, typically expressed as grams Hb per deciliter (g/dl) in the United States and as grams per liter in Europe; the hematocrit (Hct; also called the packed cell volume [PCV] or volume of packed red blood cells [vPRC]), which represents the proportion of blood volume represented by RBCs, expressed as a percent or as a decimal; and the RBC concentration in cells per microliter (10^6/µl) in the United States or per liter (10^12/L) by international terminology.

In the past, these parameters were measured using manual physical and chemical techniques. The term “hematocrit” originally referred to the graduated tube in which the vPRC was measured following centrifugation. Now these parameters are determined by electronic cell counters and Hb analyzers (Chapter 1). In most of the current analyzers, RBC concentration, Hb concentration, and mean corpuscular volume (MCV in fl) are directly measured. These measured values are used to calculate the hematocrit (Hct), mean corpuscular Hb (MCH), and mean corpuscular Hb concentration (MCHC):

\[
\text{Hct} \, (\%) = \frac{\text{MCV} \, (\text{fl}) \times \text{RBC} \, (10^6/\mu\text{l})}{10} \\
\text{MCH} \, (\text{pg}) = \frac{\text{Hb} \, (\text{g/dl}) \times 10}{(\text{RBC} \, (10^6/\mu\text{l})} \\
\text{MCHC} \, (%) = \frac{\text{Hb} \, (\text{g/dl}) \times 100}{\text{Hct} \, (\%) \text{ concentration}} \\
= \frac{\text{MCH} \, (\text{pg}) \times 100}{\text{MCV} \, (\text{fl})} \tag{1}
\]

Most physicians prefer to define anemia using the Hb concentration, although for practical purposes the Hct is comparably reliable. The electronic counters also generate an index of red cell size, the red cell distribution width (RDW). The RDW is a quantitative measure of the variation in red cell size, and the higher the value, the more heterogeneous the RBC population size. The mean normal Hb and Hct values and the lower limits of the normal ranges of these parameters depend on the age and gender of the subjects, as well as their altitude of residence.

Anemia in Adults

Many references consider Hb concentrations of 14 g/dl and 12 g/dl as the lower limits of normal, at sea level, in adult men and women, respectively, particularly in the industrialized world. However, data from a large, diverse, and carefully selected sample suggest that these values are somewhat high. The sample studied during the second National Health and Nutrition Examination Survey (NHANES II), 1976-1980, was selected statistically as representative of the entire population of the United States. Age, gender, and race, as well as geographic and socioeconomic factors, were figured into the selection process. For the purpose of determining normal values, subjects were excluded if they were pregnant, if a hereditary hemoglobinopathy was detected, or if the transferrin saturation, MCV, or erythrocyte protoporphyrin value was abnormal. By these means, iron deficient subjects were effectively excluded. The values of the remaining 11,547 subjects were used to calculate a 95% reference range. In adult subjects (age 10 to 44 years), the lower limit of normal was 13.2 g/dl in men and 11.7 g/dl in women (Fig. 22.1). Values for African-American subjects were approximately 0.5 to 0.6 g/dl lower than those of Caucasian subjects. Consistent with these observations, the World Health Organization (WHO) defines the lower limit of normal for Hb concentration at sea level to be 12.0 g/dl in women and 13.0 g/dl in men.  

P.588
FIGURE 22.1. The lower limit of normal blood hemoglobin concentration in men and women of various ages. Values were calculated from a sample of 11,547 subjects selected to represent the population of the United States. Subjects with iron deficiency, pregnancy, or an abnormal hemoglobin value were excluded from the sample. (Data from Dallman PR, Yip R, Johnson C. Prevalence and causes of anemia in the United States, 1976 to 1980. Am J Clin Nutr 1984;39(3):437-445.)

Hemoglobin Values in the Elderly

Anemia is a common condition in the older population. In a community dwelling American population of individuals over 65 years, 8.5% have a Hb concentration meeting the WHO definition of anemia. Other investigators have confirmed that the prevalence of anemia rises steadily with age, increasing from approximately 10% in individuals 65 years and older to 20% in individuals over 85 years. It is a significant predictor of morbidity, mortality, and performance status in the elderly, whether considered as a general risk factor or in the setting of a specific clinical circumstance, such as heart failure, and while clinical conditions such as iron deficiency, B12 or folate deficiency, the decline in testosterone production in male aging, and the impact on EPO production of the routine decline in creatinine clearance with advancing age, are likely responsible for a majority of cases, the etiology of a significant proportion of these anemias cannot be readily explained. Studies of the development of otherwise unexplained anemia in the aging population have suggested the involvement of a number of possible mechanisms, from an increased incidence of underlying diseases which may be associated with cytokine activation and the anemia of chronic disease, to changes in the hematopoietic reserve or even in the characteristics of hematopoietic progenitors themselves. Taken together, slightly lower limits of normal Hb concentration may be applicable in evaluating the elderly. However, the too-easy acceptance of mild anemia as a physiologic phenomenon in the elderly runs the risk of ignoring a potentially valuable early clue to an important underlying disorder.

Hemoglobin Values in Infants and Children

At the other extreme of life, the definition of anemia in infancy and childhood is different from that in adults. The lower limit of normal Hb concentration at birth is 14 g/dl, and this decreases to 11 g/dl by 1 year of age. This Hb decrement, referred to as the physiologic anemia of infancy, occurs as part of the normal physiologic adaptation from the relatively hypoxic intrauterine existence to the well-oxygenated extrauterine environment (Chapter 43). Also, as fetal erythropoiesis is replaced, the MCV decreases from birth (100 to 130 fl) to 1 year of age (70 to 85 fl).
Even after the first year of life, normal childhood Hb and MCV values remain considerably lower than those occurring in adolescents and adults (Table 22.1). From the NHANES II study, the lower limit of normal Hb concentration in both male and female children aged 1 to 2 years was 10.7 g/dl, and the value rose with advancing age until adult levels were reached at age 15 to 18 years.

There has been no completely satisfactory explanation for these differences in normal Hb values of children and adults, but it is not due to nutritional deficiencies. Interestingly, it has been demonstrated that serum inorganic phosphate is 50% higher in children compared to adults, and this hyperphosphatemia is associated with elevated erythrocyte adenosine triphosphate and 2,3-diphosphoglycerate content, and thus the erythrocyte oxygen affinity is decreased in children compared to adults. On this basis, it has been postulated that lower Hb values in children may be due to altered Hb-oxygen affinity and may thereby represent a physiologic anemia of childhood.18

At puberty, the Hb concentration in children reaches the same levels seen in adults. The higher Hb levels in males presumably are a reflection of the effects of androgens on erythropoiesis.

Limitations in the Use of Hemoglobin Concentration, Hematocrit, and Red Blood Cell Measurements in Defining Anemia

For practical purposes, the blood Hb and Hct determinations are equally useful in assessing for anemia in most patients, but there are limitations that must be recognized:

- Hb and Hct changes may reflect altered plasma volume, not a change in RBC mass (Table 22.2). In pregnancy, for example, the plasma volume increases, thereby decreasing the Hb concentrations, although in fact, total RBC mass actually is increased, but to a lesser degree than the plasma volume.19,20,21,22 Similarly, individuals with massive splenomegaly may have some anemia because of hypersplenism, but the degree of anemia may appear more severe because of an increased plasma volume. Conversely, burn patients lose plasma, not RBC, through the injured skin, leaving Hb and Hct concentrated at a higher level. Other causes of dehydration with depletion of intravascular space also produce a spuriously high Hb concentration. In chronically ill patients with a reduced red cell mass, the magnitude of anemia may be masked by an associated contraction of the plasma volume.23,24,25,26,27

- Another consideration is that Hb and Hct changes may reflect underlying physiologic conditions with different oxygen needs. For example, chronically hypoxemic subjects, such as individuals who live at high altitudes or patients with a right-to-left cardiac shunt, are typically polycythemic with elevated Hb/Hct levels. A normal Hb/Hct level in such a patient actually may represent anemia by the functional criterion of adequately meeting tissue oxygen requirements.

Hb, hemoglobin.
TABLE 22.2 CONDITIONS ASSOCIATED WITH DISCORDANCE BETWEEN HEMOGLOBIN CONCENTRATION AND RED CELL MASS

Increase in plasma volume relative to RBC mass (Hb disproportionately low)
Hydremia of pregnancy
Congestive splenomegaly
Recumbency (vs. upright)
Decrease in plasma volume relative to RBC mass (Hb high, normal, or low; but high relative to RBC mass)
Dehydration
Protracted diarrhea (especially in infants)
Peritoneal dialysis with hypertonic solutions
Diabetic acidosis
Diabetes insipidus with restricted fluid intake
Burn patients
Stress erythrocytosis, spurious polycythemia
Decrease in plasma volume and RBC mass (Hb normal, RBC mass low)
Acute blood loss
Chronic disease

Hb, hemoglobin; RBC, red blood cell.

- Some abnormal Hb variants have an altered ability to bind and release oxygen, and this can be associated with changes in Hb concentration. For example, Hb Yakima has increased oxygen affinity with a low P50, and higher than normal Hgb levels are characteristic. Conversely, Hb Kansas has decreased oxygen affinity, high P50, and lower than normal Hgb levels. Despite the disparate Hb levels in these cases, both satisfy the criteria of appropriate oxygen delivery for tissue oxygen needs.

- Acute blood loss is another example of the problem of denoting anemia by the Hb concentration or Hct. Immediately after loss of a liter of blood, the Hb concentration/Hct is normal, because the initial response to acute hemorrhage is vasoconstriction. The shift of fluid from extravascular to intravascular space, and thus the decrease in Hb concentration, does not begin for 6 hours, and can continue for 48 to 72 hours. Reticulocytosis occurs after 24 to 48 hours.

- Impaired partial synthesis of one globin chain, as in thalassemia trait, may be reflected in a low Hb (10 g/dl) and a high RBC count (6.5 million/µl), thus giving anemia by one measure (Hb) and erythrocytosis by another (RBC). This is largely why the RBC count is the least reliable and least commonly used indicator of anemia.

In addition to the issues listed above, changes in posture also have effects on red cell concentration that can influence Hb and Hct measurements. When normal individuals assume a recumbent position, the Hct falls an average 7% (range, 4% to 10%) within 1 hour. When the upright position is resumed, the Hct increases by a similar amount within 15 minutes. These changes have been attributed to alterations in plasma volume as fluid moves between the circulation and the extravascular spaces in the lower limbs as a result of hydrostatic forces.

CLINICAL EFFECTS OF ANEMIA

Patients with anemia usually seek medical attention because of decreased work or exercise tolerance, shortness of breath, palpitations, or other signs of cardiorespiratory adjustments to anemia. At times, they feel fine, but their friends or family may note pallor. It is not uncommon that anemia in a child is first recognized by a visiting relative, the process sometimes occurring so slowly as to not be noted by parents or other immediate family members.

Cardiovascular and Pulmonary Features of Anemia
The clinical manifestations of anemia depend on the magnitude and rate of reduction in the oxygen carrying capacity of the blood, the capacity of the cardiovascular and pulmonary systems to compensate for the anemia, and the associated features of the underlying disorder that resulted in the development of anemia. The Hb concentration is not the only determinant of the observed symptoms. Coexistent cardiovascular or pulmonary disease, particularly in older individuals, may exaggerate the symptoms associated with a degree of anemia that would be well tolerated under other circumstances.

If the anemia has been insidious in onset and there is no cardiopulmonary disease, the patient's adjustment may be so effective that the blood Hb concentration may fall to 8 g/dl or even lower before the patient experiences enough symptoms to appreciate the situation. In cases of iron deficiency anemia, pernicious anemia, or other types of slowly developing anemia, Hb concentrations may reach levels of 6 g/dl or lower before patients are motivated to seek medical attention. This is particularly true in children where no limitations of physical activity may be apparent despite the existence of very severe anemia. The physiologic adjustments that take place with a slowly falling red cell mass chiefly involve the cardiovascular system and changes in the Hb-oxygen dissociation curve.

In many patients, respiratory and circulatory symptoms are noticeable only after exertion; however, when anemia is sufficiently severe, dyspnea and awareness of vigorous or rapid heart action may be noted even at rest. When anemia develops rapidly, shortness of breath, tachycardia, dizziness or faintness (particularly upon arising from a sitting or recumbent posture), and extreme fatigue are prominent. In chronic anemia, only moderate dyspnea or palpitation may occur, but in some patients, congestive heart failure, angina pectoris, or intermittent claudication can be the presenting manifestation. In patients with severe chronic anemia, tachycardia and postural hypotension may not be present because the total blood volume actually may be increased because of an expanded plasma volume. In the elderly particularly, cardiovascular adaptation to anemia is predominantly by increasing stroke volume, rather than by heart rate. It is in these cases that rapid administration of a blood transfusion may precipitate congestive heart failure by aggravating an already expanded blood volume. Concern about this possibility should not preclude expansion of the blood's oxygen carrying capacity by transfusion if necessary; rather the judicious use of diuretics in the peritransfusion period should be considered in patients with clinical signs of volume overload.

Heart murmurs are a common cardiac sign associated with anemia. They usually are systolic in time and best heard in the pulmonic area. Often, they are moderate in intensity, and at times may be rough in quality and raise suspicion of organic valvular heart disease. In a study from Bosnia, 25% of the heart murmurs investigated in a pediatric cardiology clinic were attributable to anemia and resolved with its correction.

P.590

Pallor

Pallor is a sign of anemia, but many factors other than Hb concentration affect skin color. These include the degree of dilation of peripheral vessels, the degree of pigmentation, and the fluid content of the subcutaneous tissues. Certain people routinely have pale-appearing skin without being anemic. Patients with myxedema may manifest pallor without anemia. In simple vasovagal syncope, pallor results from cutaneous vasoconstriction and is not a sign of anemia. Jaundice, cyanosis, racial skin pigmentation, and dilation of the peripheral vessels all can mask the pallor of anemia.

The pallor associated with anemia is best detected in the mucous membranes of the mouth and pharynx, the conjunctivae, the lips, and the nail beds. In the hands, the skin of the palms first becomes pale, but the creases may retain their usual pink color until the Hb concentration is less than 7 g/dl.

A distinctly sallow color implies chronic anemia. A lemonyellow pallor suggests pernicious anemia, but it is observed only when the condition is well advanced. Definite pallor associated with mild scleral and cutaneous icterus suggests hemolytic anemia. Marked pallor associated with petechiae or ecchymoses suggests more generalized bone marrow failure due to acute leukemia, aplasia, or myelodysplastic syndromes.

Skin and Mucosal Changes

Other changes in the integument occur with anemia. Thinning, loss of luster, and early graying of the hair may occur, the last especially in patients with pernicious anemia, in whom it may precede the development of anemia. The nails may lose their luster, become brittle, and break easily. This finding is especially noticeable in chronic iron deficiency anemia, in which the nails may actually become concave instead of convex. Chronic leg ulcers may occur, especially in patients with sickle cell anemia and rarely in those with other hemolytic anemias. Glossitis occurs in association with pernicious anemia.
When nutritional deficiency is associated with anemia, symmetric dermatitis may develop, fissures may be present at the angles of the mouth, glossitis may occur, and erythematous lesions on the face, neck, hands, or elbows may be found.

Neuromuscular Features

Headache, vertigo, tinnitus, faintness, scotomata, lack of mental concentration, drowsiness, restlessness, and muscular weakness are common symptoms of severe anemia. Paresthesias are common in pernicious anemia and may be associated with other symptoms and signs of peripheral neuropathy, and more especially with combined system disease.

Ophthalmologic Findings

A variety of ophthalmologic findings have been observed in anemic patients. Approximately 20% of such patients have flame-shaped hemorrhages, hard exudates, cottonwood spots, or venous tortuousness affecting the retina. The hemorrhages occur even in the absence of coexisting thrombocytopenia. Papilledema related solely to anemia has been described, and it clears when the anemia disappears.

Gastrointestinal Changes

Gastrointestinal symptoms are common in anemic patients. Some are manifestations of the underlying disorder (e.g., hiatal hernia, duodenal ulcer, or gastric carcinoma); others may be a consequence of the anemic condition, whatever its cause. Glossitis and atrophy of the papillae of the tongue commonly occur in pernicious anemia and less often in iron deficiency anemia. Painful, ulcerative, and necrotic lesions in the mouth and pharynx occur in aplastic anemia and in acute leukemia, usually reflecting the neutropenia accompanying these conditions. Dysphagia may occur in chronic iron deficiency anemia.

EVALUATION AND CLASSIFICATION OF ANEMIA

History and Physical Examination

All aspects of the history and clinical examination are important. The duration of the symptoms and their onset, whether insidious or acute, should be established. It is very helpful to know the most recent date at which a routine hematologic examination was normal.

The family history is most useful for increasing suspicion of hereditary hemolytic diseases (including hemoglobinopathies) and hereditary bleeding disorders (including hereditary vascular abnormalities like hereditary hemorrhagic telangiectasias). Key clues are histories of bleeding, jaundice, gallstones, and splenectomy (see Approach to Hemolysis). The patient's occupation, household customs, and hobbies must be ascertained because certain drugs, solvents, and other chemicals may produce hemolytic anemia or aplastic anemia, as well as granulocytopenia and thrombocytopenia. Also, social habits (alcohol use), travel history (to malarious or other infectious areas), and drug history are all important in ascertaining the underlying etiology.

The dietary history is critical to the analysis, and questions regarding the diet must be specific in the hope of obtaining quantitative information. In very young children, those who obtain the bulk of their nutrition from cow's milk (good for calories, very low in iron) are at great risk for iron deficiency anemia. Changes in weight are most important in both adults and children. Formerly obese individuals who have undergone bariatric surgery and other individuals who have undergone gastric resection are at risk for anemia from iron, copper, and other nutrient deficiencies.

The patient should be questioned about early graying of the hair, burning sensations of the tongue, skin changes, sores about the angles of the mouth, and discomfort and brittleness of the fingernails, which are symptoms of anemias caused by deficiency of specific nutrients.

Change in stool habits may be an important clue to neoplasms of the colon and rectum underlying the anemia. The significance of tarry stools often is not appreciated by patients, and specific inquiry is necessary. The amount of blood lost from hemorrhoids may be overlooked or overestimated. In men, occult blood loss most often is from the gastrointestinal tract.

In women, additional important information includes an appraisal of the amount of blood lost during menstruation. Data about number of pads or tampons used and the presence or absence of clots should be obtained. The average amount of blood lost per period is approximately 50 ml, representing roughly 25 mg of elemental iron. Menstrual flow should be deemed excessive if more than 12 pads are used each period, if clots are passed after the first day, or if the period duration exceeds 7 days. The number of pregnancies and abortions and the interval since the most recent of these are also important, for each represents significant iron loss.
The presence or absence of fever must be known; its presence suggests infection, lymphoma, other neoplasm, or collagen vascular disease. Pains in the limbs, paresthesias, and difficulty in walking suggest pernicious anemia. Abnormal color of the urine, suggesting blood or Hb, may signify urinary tract disease or hematologic problems. Bilirubin is not detected in the urine of people with uncomplicated hemolytic anemia (“acholuric jaundice”), but a darker than normal color may result from the increased excretion of urobilinogen and its conversion to urobilin.

Bruises, ecchymoses, and petechiae are other important points in the history. Their presence indicates that the disorder producing anemia may also involve platelets or the liver. Alternatively, the anemia itself may be the consequence of blood loss resulting from a disorder of hemostasis.

In all instances, the presence or absence of symptoms suggestive of an underlying disease such as chronic renal disease, liver disease, chronic infection, endocrinopathy, or malignancy must be explored. Anemia can be the presenting feature of many of these disorders.

The physical examination can provide further clues to the cause of anemia. Scleral icterus suggests the presence of hemolytic anemia or ineffective erythropoiesis. Sternal tenderness near the middle or lower third of the sternum, of which the patient may have been unaware, may represent acute expansion of hematopoietic marrow and can be a useful sign in some patients with acute leukemia. Palpation of the liver and spleen and a systemic check for lymphadenopathy can provide clues to infection, lymphoma, leukemia, or metastatic carcinoma.

The initial patient evaluation should include a urinalysis. Even when the color of the urine does not suggest blood, the routine urinalysis should be tested for occult blood. A positive reaction may be due to hematuria, hemoglobinuria, or even myoglobinuria. Hematuria may be differentiated from the other conditions by finding RBCs on microscopic examination of the urine, or by centrifuging a fresh urine specimen, thereby clearing the bloody color from the supernatant and depositing the RBCs in the bottom of the tube. Hematuria reflects disease of the kidneys or urinary tract. Sickle cell trait may be accompanied by innocuous hematuria. Hemoglobinuria implies intravascular hemolysis. The significance of urobilinogen has been noted above.

FIGURE 22.2. Questions to ask in the initial evaluation of anemia. MCV, mean corpuscular volume (fl); ↑, increased; ↓, decreased.

Evaluation of Basic Hematology Laboratory Data
To identify the cause of anemia, information from the medical history and physical examination must be integrated with some key laboratory tests. There is no one simple classification of anemia. A useful approach entails asking several questions, outlined in the following sections (Fig. 22.2).

Is Anemia Associated with Other Hematologic Abnormalities?

Specifically, is the anemia associated with thrombocytopenia or abnormalities in white blood cell numbers or the presence of abnormal leukocytes? If the answer to this question is yes, consideration must be given to the possibility of bone marrow failure due to aplastic anemia, leukemia, or other malignant marrow disease. Alternatively, pancytopenia can be secondary to peripheral destruction or sequestration of cells as in hypersplenism. In most cases, these disorders can be differentiated by careful review of screening hematologic studies and close attention to the medical history and physical examination.

Is There an Appropriate Reticulocyte Response to Anemia?

The number of erythrocytes in the circulation at a given time is the result of a dynamic equilibrium between the delivery of red cells into the circulation on the one hand and their destruction or loss from the circulation on the other. Each day, approximately 1% of the RBC pool is replaced by young erythrocytes released from the marrow. The homeostatic mechanisms of the body bring about recovery from anemia by accelerating erythropoiesis, and this response of the normal marrow is brought about through the release of erythropoietin. At maximum stimulation, the bone marrow is capable of producing erythrocytes at six to eight times the normal rate.

The reticulocyte count provides an initial assessment of whether the cause of anemia is due to impaired RBC production or to increased loss in the peripheral circulation (e.g., blood loss, hemolysis) (Fig. 22.2). The reticulocyte count is traditionally measured by microscopic examination of a smear prepared from fresh blood stained with a supravital stain, such as new methylene blue. The normal reticulocyte count by light microscopy is 0.5% to 1.5% of the total red cells. More recently, automated methods based on flow cytometry have become widely utilized. The automated methods count a larger number of cells, and exhibit a greater degree of reproducibility.

In the presence of anemia, the reticulocyte count must be corrected because it is spuriously elevated when it is related to the reduced number of RBC in an anemic patient. An additional correction of this index needs to be made because reticulocytes released under intense erythropoietin stimulation remain in the peripheral blood for more than the usual 1-day survival time of nonstress reticulocytes. There are a number of ways to adjust the reticulocyte count for the degree of anemia (Table 22.3). While all of these methods have value, the absolute reticulocyte count is traditionally the easiest to estimate.

Automated reticulocyte counting also allows the evaluation of other parameters, such as reticulocyte hemoglobin content (CHr) and the proportion of immature reticulocytes (immature reticulocyte fraction, IRF). Availability of these methods depends on the particular cell counting equipment. A CHr < 28 pg suggests iron deficiency, while a reduced IRF (<0.23) suggests underproduction. The degree to which the IRF adds to information provided by any of the adjusted reticulocyte parameters is unclear.

If Anemia Is Associated with Reticulocytosis, Is There Any Evidence for Hemolysis?

The most characteristic presentation of hemolysis is reticulocytosis with some degree of hyperbilirubinemia as a marker of increased heme catabolism. Other markers reflect direct red cell injury (e.g., increased serum lactic dehydrogenase) or increased excretion of Hb (e.g., low serum haptoglobin, hemoglobinemia, hemoglobinuria, and increased urinary hemosiderin). The evaluation and diagnostic considerations related to hemolytic anemia are complex and are considered separately elsewhere in this chapter (see Approach to Hemolysis).

</tbody>
</table>
above 0.5-1.5%)

Absolute reticulocyte count = % reticulocytes × RBC count/L³

(Normal values for the absolute reticulocyte count are from 25 to 75 × 10⁹/L; values < 100 × 10⁹/L indicate an inappropriately low erythropoietic response to anemia.)

Reticulocyte maturation time = 1 day for Hct ≥ 40%; 1.5 days for Hct 30-40%; 2.0 days for Hct 20-30%; 2.5 days for Hct < 20%.

If Anemia Is Associated with a Less Than Appropriate Reticulocyte Response, What Are the Red Cell Indices?

Anemia with low reticulocytes usually reflects some impairment of normal erythropoiesis, and this can be due to two kinds of defects. Erythropoiesis may be impaired because of a reduction in red cell precursors (hypogenerative). Alternatively, red cell production may be ineffective, a condition characterized by erythroid hyperplasia in the bone marrow, but with the production of essentially nonviable red cells, most of which do not reach circulation.

There are numerous causes of anemia with low reticulocyte counts, and it is in this group that analysis of RBC indices is most helpful. Of these, the MCV tends to be the single most useful measurement, although some clinicians prefer to use the MCH. The MCV and MCH almost always correlate closely.

An initial step in classification of anemias with low reticulocyte counts separates them into three groups on the basis of average cell size: the macrocytic, microcytic, and normocytic anemias (Fig. 22.2). Anemia is classified as macrocytic if MCV exceeds 100 fl. Usually, the MCH is also increased, whereas the MCHC remains within normal limits (Fig. 22.3). Microcytic anemia is identified when the MCV is less than 80 fl in adults. The anemia is normocytic when the indices are within normal limits, with an MCV between 80 and 100 fl. In children, MCV values vary as a function of age, and, correspondingly, the definition of microcytic, normocytic, and macrocytic differ accordingly (Table 22.1). As a practical matter for those who take care of children, it is important to know the age-related differences in RBC size, because many laboratory reports contain only adult normal values, often signaling the child’s age appropriate hematologic values as abnormal.

The MCHC is useful in detecting severe hypochromia, but it is rarely abnormal when the MCV is normal. A reduced value for MCHC is observed most often in association with iron deficiency, and this index tends to be the last to fall as iron deficiency worsens. The changes in MCHC with iron deficiency were seen more frequently in the past when centrifugal methods were used to determine the Hct before the availability of electronic cell counting. Because of plasma trapping, centrifugal Hct methods overestimate the volume of packed red cells and, therefore, underestimate MCHC. Plasma trapping increases from 1% to 3% with normal blood to as much as 6% in iron deficiency, a consequence of anisocytosis and reduced cell deformability.
FIGURE 22.3. Erythrocyte indices in 28 patients with untreated or relapsed pernicious anemia. Dashed lines enclose the 95% confidence limits in normal subjects. Solid dots indicate males; open circles indicate females. MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume. (From Hallberg L. Blood volume, hemolysis and regeneration of blood in pernicious anemia. Scand J Clin Lab Invest 1955;7(Suppl 16):1-127, with permission.)

Is the Anemia Associated with a Low Reticulocyte Response and Microcytic Red Blood Cells?
The large majority of patients in this category have defects in cellular Hb synthesis due to either iron deficiency, thalassemia trait, or Hb E syndromes (see Approach to Microcytic Anemia).

Is the Anemia Associated with a Low Reticulocyte Response and Macrocytic Red Blood Cells?
In these patients, the anemia is characterized by reticulocytopenia with red cells having an increased MCV. Many of these disorders are due to megaloblastic anemia resulting in impaired nuclear development, and the formation of other blood cells is also affected (see Approach to Macrocytic Anemia).

Is the Anemia Associated with a Low Reticulocyte Response and Normocytic Red Blood Cells?
Normocytic anemia, low reticulocyte count, and normal bilirubin levels characterize a large number of anemias. The anemia of chronic disease usually is normocytic, although rarely may be slightly microcytic. In these cases, there usually is clinical evidence of a syndrome associated with cytokine activation. The anemia of renal failure is normocytic and largely is due to reduced erythropoietin production. Acquired pure red cell aplasia (PRCA) is a normocytic anemia, which occurs in adults and children (see Approach to Normocytic Anemia).
Is the Anemia Associated with Populations of Red Cells of Different Size?

The red cell indices represent mean values and do not reveal any variation that may exist within a population of cells. The MCV can be normal if there are combined abnormalities, such as when iron deficiency (decreased MCV) is accompanied by a megaloblastic anemia (increased MCV). For these purposes, it is important to examine the peripheral blood smear. Also, the electronically derived RDW allows for recognition of these phenomena because it quantifies the degree of heterogeneity of RBC size (i.e., anisocytosis) in a population of cells, and this has proven to be of value. An increased RDW value is an early and pronounced finding in iron deficiency and most megaloblastic anemias; no differences from normal are seen in heterozygous thalassemia. In iron deficiency, the RDW value may become abnormal even before the MCV falls below the lower limits of normal.

Is the Anemia Associated with Abnormalities Seen on the Blood Smear?

Despite the technical advances provided by current electronic complete blood cell count (CBC) measurements, review of the peripheral blood smear remains a critical aspect of the diagnostic evaluation for anemia. It confirms the electronically determined classification of RBC size. Most important, it also allows for recognition of the many variations in RBC size and shape that frequently are seen in patients with hemolysis.

Microcytes and macrocytes can be detected on the blood smear on the basis of a change in red cell diameter. Normal red cells approximate the size of the nucleus of a small lymphocyte, and the area of central pallor is one-third to one-half of the diameter of the red cell (Fig. 22.4A). An increase in the area of central pallor of erythrocytes on the blood smear is indicative of hypochromia, and when the change is pronounced, little more than a faint ring of color in the periphery may be apparent (Fig. 22.4B). Hypochromia and microcytosis almost always occur together.

The automated analysis of the blood has made the erythrocyte indices more accurate and reproducible. However, the evaluation of the blood smear still remains important because it may reveal abnormal cell populations too small to affect the erythrocyte indices. For example, as iron deficiency develops, some microcytic cells are produced while the RBC indices are still normal. Furthermore, as B12 deficiency progresses, some characteristic oval macrocytes and hypersegmented neutrophils may appear long before there are MCV or Hb changes (Fig. 22.5B,C). Moreover, examination of the smear is important for detecting conditions characterized by two populations of cells, only one of which is of abnormal size. This dimorphic anemia is particularly characteristic of sideroblastic anemias (Fig. 22.4E). It also is seen in iron deficiency after iron therapy is started (Fig. 22.4C), and in iron deficient individuals who have been transfused.

Review of the blood smear may reveal underlying causes of the anemia. A leukoerythroblastic picture (teardrop RBC, nucleated RBC, early white blood cell precursors, or abnormalities in platelet shape) suggests marrow infiltration by hematologic or other malignant cells (Fig. 22.6). The marked elevation in serum proteins in multiple myeloma may result in a stacking of RBCs in rouleaux formation. The appearance of RBC in agglutinates (as opposed to their stacking into rouleaux) is seen with cold agglutinin disease. Also, probably one of the most valuable outcomes of reviewing the blood smear is that it often reveals abnormal red cell shapes characteristic of certain hemolytic anemias in particular.

Is a Bone Marrow Examination Needed to Clarify the Cause of Anemia?

Examination of the bone marrow is most useful in reticulocytopenic anemias, particularly when there is more than one hematopoietic cell line affected. Both hypoplasia and marrow infiltrative disease due to leukemia, tumor, or granulomas (myelophthisic anemia) may readily be demonstrated in the bone marrow aspirate and biopsy. Myelofibrosis can be recognized as a component of myeloid metaplasia. If the marrow is normocellular except for reduced erythropoiesis, the underlying cause may be red cell aplasia, renal disease, or endocrinopathy.

Examination of iron in bone marrow macrophages was traditionally considered the definitive way to demonstrate decreased iron stores. In most cases, however, the diagnosis of iron deficiency can be made by simple blood tests, thus obviating the need for an iron stain of the bone marrow. On the other hand, to make the diagnosis of sideroblastic anemia, a bone marrow examination is necessary to identify ringed sideroblasts. Megaloblastic anemias usually can be recognized by peripheral blood findings, but a marrow examination will confirm the diagnosis.

In some anemias with low reticulocyte counts, marrow erythropoiesis surprisingly is quite active. This is referred to as ineffective erythropoiesis, and it occurs when developing red cells are defective and are destroyed before they leave the marrow or shortly thereafter. A very small fraction of erythropoiesis is ineffective, even in normal subjects; however, in certain conditions, especially megaloblastic anemias, thalassemias, sideroblastic anemias, and congenital dyserythropoietic anemias, ineffective erythropoiesis becomes greatly exaggerated. The increased intramedullary destruction of erythroblasts in these conditions is associated with accelerated heme catabolism, resulting in an elevated unconjugated bilirubin level in the plasma. Also, the serum lactic dehydrogenase level, a marker of cell destruction, is
markedly elevated. Ineffective erythropoiesis can be confused with hemolytic anemia because signs of excessive red cell destruction and
erythroid hyperplasia of the bone marrow are found in both conditions. However, the two conditions are distinguished from one another by the degree of reticulocytosis, which is increased in hemolytic anemia and usually low in ineffective erythropoiesis.

FIGURE 22.4. Peripheral blood smear of erythrocytes in a variety of hypochromic, microcytic anemia. A: Normal red cells. B: Iron deficiency anemia. Note the large area of central pallor. C: Dimorphic population of cells in iron deficiency anemia responding to treatment. D: Thalassemia minor. The cells are thin and appear pale but nearly normal in diameter. Note the basophilic stippling in several RBC. Sideroblastic anemia. A hypochromic, microcytic population of cells is mixed with relatively normocytic red blood cell. Part C from Tkachuk DC, Hirschmann JV] in Wintrobe's atlas of clinical hematology.
APPROACH TO MACROCYTIC ANEMIA

Macrocytosis is a common finding in clinical settings. In 1.7% to 3.6% of cases involving patients seeking medical care, MCV is increased, often in the absence of anemia. Mild macrocytosis (MCV of 100 to 110 fl) is particularly common and often remains unexplained, even after careful study. Even so, this finding should not be ignored, because it can be an important early clue to reversible disease. For example, it may appear 1 year or more before anemia develops in patients with pernicious anemia, and neurologic disease can progress during that interval.

Morphologic and biochemical criteria allow macrocytic anemias to be divided into two groups: the megaloblastic anemias and the nonmegaloblastic macrocytic anemias. The types of macrocytic anemias clinicians encounter vary considerably depending on the population served. If alcoholism is common in the population, it is likely to be the most common cause. In cancer patients, high MCVs are most likely due to chemotherapy. In hospitals largely serving the elderly, pernicious anemia and other nutritional anemias may predominate.

When confronted with a diagnostic problem involving macrocytic anemia, the physician should first distinguish between megaloblastic and nonmegaloblastic anemia (Fig. 22.7). The most useful steps for this purpose are morphologic examinations.
Megaloblastic Anemias

The term megaloblast is a designation that was first applied by Ehrlich to the abnormal erythrocyte precursors found in the bone marrow of patients with pernicious anemia. Megaloblasts are characterized by their large size and by specific alterations in the appearance of their nuclear chromatin (Fig. 22.8). These distinctive cells are now known to be the morphologic expression of a biochemical abnormality: retarded DNA synthesis. RNA synthesis remains unimpaired while cell division is restricted. As a result, cytoplasmic components, especially Hb, are synthesized in excessive amounts during the delay between cell divisions. An enlarged cell is the product of such a process. Megaloblastic anemias are defined by the presence of these cells or by other evidence of defective DNA synthesis.

A pathogenetic classification of the causes of megaloblastic anemias is presented in Table 22.4. Most often, megaloblastic anemia is the consequence of deficiency of vitamin B₁₂ or folate, or both. Less commonly, megaloblastic anemia results from inherited or drug-induced disorders of DNA synthesis.

Hematologic Features of Megaloblastic Anemia

Examination of the blood smear often reveals the two most valuable findings for differentiating megaloblastic from nonmegaloblastic anemia: neutrophil hypersegmentation and oval macrocytes.

Neutrophil hypersegmentation is one of the most sensitive and specific signs of megaloblastic anemia (Fig. 22.5C). Normally, the nuclei of circulating, segmented neutrophils have fewer than five lobes. In megaloblastic anemia, neutrophils with six or more lobes may be detected. In a large study, more than 98% of patients with megaloblastic anemia had at least one six-lobed neutrophil of the 100 cells examined, as compared with only 2% of normal control subjects. Hypersegmentation is among the first hematologic abnormalities to appear as the megaloblastic state develops. It persists for an average of 14 days after institution of specific therapy.
FIGURE 22.7. Diagnostic approach to a patient with macrocytic anemia.

The main products of megaloblastic erythropoiesis are macrocytic erythrocytes with a distinctly oval shape. Such cells are well filled with Hb, and often central pallor is reduced or absent (Fig. 22.5B). The oval shape may be useful in distinguishing megaloblastic anemias from other causes of macrocytosis; the macroreticulocytes that characterize accelerated erythropoiesis tend to be round and distinctly blue or gray in Romanowsky dyes.

Although oval macrocytes are prominent in megaloblastic anemia, the size and shape of the erythrocytes may vary considerably. Quantitative measures of anisocytosis, such as the RDW, are substantially increased, and the increase may precede the development of anemia.

Morphologic changes on the blood smear, however, are most conspicuous when anemia is pronounced.

Megaloblastic anemias usually develop gradually, and the degree of anemia is often severe when first detected. Hb values less than 7 or 8 g/dl are not unusual. Macrocytosis characteristically precedes the development of anemia and may even do so by several years. The MCV usually is between 110 and 130 fl.

Bone Marrow

A megaloblastic marrow is cellular and usually hyperplastic, with erythrocyte precursors predominating. The characteristic megaloblasts are distinguished by their large size and especially by their delicate nuclear chromatin. The chromatin has been described as particulate or sieve-like, as distinguished from the normal denser chromatin of normoblasts (Fig. 22.8). This morphologic change may be detected at all stages of erythrocyte development; however, the identification of orthochromatic megaloblasts is particularly useful in the recognition of megaloblastic anemia because they differ so markedly from any cell found in normal marrow. In the orthochromatic megaloblast, the abundant cytoplasm appears mature (pink), whereas the nucleus appears immature as a result of the megaloblastic change.

Leukopoiesis is also abnormal; extraordinarily large (up to 20 or 30 µm) leukocytes are found. These abnormalities of cellular development may occur at any stage in the myeloid series, but they are particularly common among the metamyelocytes. The nucleus of these giant metamyelocytes is enlarged, both absolutely and in relation to the total cell size; it may be bizarre in shape and in chromatin structure or staining properties.
In general, megakaryopoiesis is less disturbed than that of either of the other two cell lines; however, when megaloblastic change is severe, megakaryocytes may be reduced in number and abnormalities of nuclear chromatin may be evident.

P.597

Vitamin B₁₂ and Folate Levels in Serum and Erythrocytes
Once it is established that a patient has CBC and morphologic evidence of megaloblastic anemia, it should next be determined if this is due to vitamin B\(_{12}\) or folate deficiency (Chapter 36). Useful studies include measurement of serum and RBC folate levels and serum Vitamin B\(_{12}\) levels. Unlike serum vitamin B\(_{12}\), serum folate is labile, being sensitive to short-term changes in folate balance. Thus, serum folate concentration may increase within a few hours after consumption of folate-containing food. Furthermore, a low intake of folate may result in reduced serum levels before true deficiency develops.\(^7\) The erythrocyte folate level is a much better index of tissue folate stores. Erythrocyte folate levels are established during formation of the red cell and persist throughout its lifespan. Thus, it may take 3 to 4 months of folate deprivation before low values are obtained. Other studies such as serum homocysteine and serum methylmalonic acid can confirm a diagnosis of B12 deficiency, particularly when initial assays are at odds with the clinical and hematologic picture. Vitamin B\(_{12}\) absorption studies (Schilling test) or antibodies to intrinsic factor or parietal cells, can further define the specific causes of these disorders.

Nonmegaloblastic Macrocytic Anemias

Nonmegaloblastic anemias are not united by any common pathogenetic mechanism. They simply represent macrocytic anemias in which the RBC precursors appear normal without the characteristic nuclear and cytoplasmic findings of megaloblastosis. When macrocytosis is found, it tends to be mild; the MCV usually ranges from 100 to 110 fl and rarely exceeds 120 fl. Several causes of nonmegaloblastic macrocytosis are recognized (Table 22.5).

Accelerated Erythropoiesis

Mild to moderate macrocytosis often follows erythropoietin-mediated acceleration of red cell production, as may be induced by blood loss or hemolysis. In part, this increased cell size occurs because reticulocytes are approximately 20% larger than mature red cells. Also, under conditions of accelerated red cell production, a premature release of bone marrow reticulocytes (shift reticulocytes) occurs, and these cells are even larger and contain more RNA than normal circulating reticulocytes. Last, an erythroblast cell division may be skipped under this erythropoietic stress, a phenomenon that results in a macroreticulocyte that is approximately twice the normal size.

Diamond-Blackfan anemia

Hypothyroidism

Spurious macrocytosis (paraproteinemia, inflammation)

Alcoholism

Macrocytosis, usually mild, is evident in 40% to 96% of alcoholics, many of whom have no anemia. The finding is so characteristic of the condition that testing for macrocytosis has been used as part of the screening procedure for the detection of chronic alcohol use. It may be present in both heavy and moderate drinkers. Macrocytosis and anemia in alcoholic individuals have several causes. Folate deficiency can lead to megaloblastic anemia, and alcoholic cirrhosis may be associated with spur cell hemolytic anemia. Most often, however, alcoholic macrocytosis is associated with none of these factors and instead results from poorly defined direct effects of alcohol on the bone marrow. Antibodies against acetaldehyde-modified RBC protein are detected in up to 94% of alcoholics with high MCVs, but less frequently in those with normal MCVs. There are no morphologic stigmata of megaloblastic anemia. Serum and erythrocyte folate levels are usually normal, and the macrocytosis does not respond to folate treatment. If the patient abstains from alcohol use, the MCV returns to normal levels after 2 to 4 months.

Liver Disease

The causes of anemia in liver disease are multifactorial, resulting from intravascular dilution due to hypervolemia, impaired ability of the marrow to respond optimally to the anemia, and in some patients, a severe hemolytic anemia associated with morphologically abnormal erythrocytes (spur cells). The anemia is usually mild to moderate. In cirrhotic patients, the Hb level averages approximately 12 g/dl, and remains above 10 g/dl in the absence of bleeding or severe hemolysis. The anemia of liver disease is mildly macrocytic: the MCV rarely exceeds 115 fl in the absence of megaloblastic changes in the bone marrow. In addition, liver disease is associated with thin macrocytes, defined as cells with increased surface area but without a corresponding increase in volume. The increased surface area of thin macrocytes is the consequence of excessive membrane lipids, especially cholesterol, but also phospholipids. On the blood smear, thin macrocytes are characterized by an increased diameter and a visibly enlarged area of central pallor. The characteristic target cell of liver disease is a thin macrocyte. Because the volume of such cells is normal, their presence has no effect on the erythrocyte indices.

Miscellaneous Anemias

Macrocytosis may accompany various anemias with low reticulocyte counts, including myelodysplastic and myelophthisic conditions. The reason for macrocytosis in these disorders is not well understood.

Congenital red cell hypoplasia or Diamond-Blackfan anemia (DBA) is a pure RBC aplasia in children that is due to impaired differentiation of developing erythroblasts (Chapter 39). This disorder is characterized by a life-long anemia that presents in the first few months of life. Many children with DBA have congenital abnormalities, including short stature and skeletal defects (usually affecting the thumb). The diagnosis of DBA is suggested by a macrocytic (although sometimes normocytic) anemia with reticulocytopenia presenting in the first 6 months of life. Bone marrow examination reveals decreased erythroid precursors.

Congenital dyserythropoietic anemias (CDAs) are a group of anemias characterized by ineffective erythropoiesis and dyserythropoiesis (Chapter 40). The term dyserythropoiesis refers to the presence of morphologically abnormal erythroblasts in the bone marrow with multinuclearity, karyorrhexis, or megaloblastic changes. Three major types of CDA have been distinguished on the basis of morphologic and serologic classification, and these have been designated CDA types I, II, and III. The degree of anemia encountered in the CDAs varies considerably. It may range from a mild to moderate anemia that is only discovered or diagnosed later in life to a severe anemia apparent in infancy. Morphologically, the anemia is generally mildly macrocytic in CDA types I and III and is normocytic in CDA type II. In all of the disorders, the bone marrow findings are consistent with ineffective erythropoiesis: there is erythroid hyperplasia along with morphologically abnormal precursors. An elevation in serum lactate dehydrogenase and indirect bilirubin levels may be observed. Decreased serum haptoglobin often is seen.
Spurious macrocytosis can result from laboratory artifacts. Cold agglutinins, marked leukocytosis, or other acute phase reactants can lead to an incorrect high MCV value. Care is needed so that these situations do not lead to a fruitless search for a disorder known to cause macrocytic anemia. Since reticulocytes are larger than mature RBCs, significant reticulocytosis can increase the MCV. This is not a spurious macrocytosis, but it is misleading.

**APPRAOCH TO MICROCYTIC ANEMIA**

Most microcytic anemias are due to deficient Hb synthesis, often associated with iron deficiency or impaired iron use (Table 22.6). The differentiation of iron deficiency from the anemia of chronic disease and the differentiation of iron deficiency from thalassemia trait syndromes are both common clinical issues. Significant microcytosis is detected in nearly 3% of all patients who require admission to the hospital.

The typical Hb level seen in adults with a variety of microcytic anemias is depicted in Table 22.7. The laboratory evaluation of microcytic anemias focuses on screening hematologic studies, followed by more definitive tests to distinguish iron deficiency anemia, the anemia of chronic disease, hemoglobinopathies, or sideroblastic anemias (Fig. 22.9). A few commonly used studies are described below; others are described elsewhere in this text.

**Iron Pathway Disorders**

The principal source of iron for Hb production is that carried by transferrin, the iron-transport protein in plasma. Under normal circumstances, plasma iron levels are not rate limiting in erythropoiesis, and transferrin is able to supply all the iron required for normal or accelerated production rates. However, in iron deficiency anemia, the storage sites in macrophages are depleted of iron and the plasma iron concentration falls. When transferrin saturation with iron is less than 16%, the red cell production rate decreases, and hypochromic, microcytic cells are manufactured. This state is known as iron deficient erythropoiesis.

In the anemia associated with chronic disorders (Chapter 41), the macrophage iron level is normal or increased, but export of iron from macrophages is downregulated. Thus, iron accumulates in the macrophage, whereas the plasma level falls, and the marrow is deprived of adequate supplies.

Together, iron deficiency anemia and the anemia of chronic disease are among the most common causes of anemia. Iron deficiency predominates in children and young women; but it also occurs in older individuals, in whom it may reflect occult bleeding due to underlying pathology. The anemia of chronic disorders is most common among elderly people, but it also can occur in younger individuals affected by certain chronic inflammatory states.

**TABLE 22.7 TYPICAL HEMOGLOBIN AND MEAN ORPUSCULAR VOLUME VALUES IN ADULTS WITH CERTAIN ANEMIAS**
## Condition | Hb Concentration (g/dl) | MCV (fl)
--- | --- | ---
Normal men | 16 (14-18) | 89 (80-100)
Normal women | 14 (12-16) | 89 (80-100)

FIGURE 22.9. Diagnostic approach to a patient with microcytic anemia. ↑, increased; ↓, decreased.

Distinguishing typical iron deficiency anemia from the anemia of chronic disorders is usually not difficult. Anemia, hypochromia, and microcytosis are typically more pronounced in iron deficiency, as are the degrees of anisocytosis and poikilocytosis. The anemia of chronic disease is usually normocytic. However, when iron deficiency is early and mild, the morphologic findings in the two conditions may be similar.

Measurement of Serum Iron and Iron-binding Capacity
Serum iron levels are a measure of the amount of iron bound to transferrin. Total iron-binding capacity (TIBC) is an indirect measurement of transferrin in terms of the amount of iron it will bind. Transferrin also can be measured directly by immunologic techniques and is available in many laboratories.

A limitation in the use of serum iron determinations is the considerable variability in values. A technical problem relates to contamination of glassware and reagents with iron, although the use of disposable, plastic equipment has significantly reduced such contamination as a clinical issue. Even if technical problems are eliminated, serum iron values in an individual can vary from 10% to 40% within a single day or from day to day, and many normal subjects demonstrate a predictable diurnal variation, with highest values in the morning and lowest values in the evening. In contrast to serum iron, TIBC (or transferrin) values show only slight day-to-day fluctuation or diurnal variation. It also must be recognized that serum iron levels are influenced by the recent ingestion and absorption of iron medication.

The normal mean serum iron value for men is approximately 120 µg/dl (21.8 µmol/L). The composite normal range is approximately 70 to 200 µg/dl (13 to 36 µmol/L); however, values vary substantially from one laboratory to another. The TIBC averages 340 µg/L (61 µmol/L) in both men and women, with a composite normal range of 250 to 435 µg/dl (45 to 78 µmol/L). TIBC saturation is calculated with the following formula: TIBC saturation (%) = (serum iron × 100)/TIBC. The normal value is 20% to 45%. Values below 16% are noted in association with both iron deficiency and the anemia of chronic disorders (Fig. 22.10). The degree of reduction tends to be greater in iron deficiency than in chronic disorders, but considerable overlap exists between these two conditions. In both children and adults, however, a value of less than 5% is almost certainly due to iron deficiency anemia. In sideroblastic anemias, and in transfused thalassemic patients, the TIBC saturation invariably is increased and often approaches 100%. In laboratories that measure transferrin directly, an iron transferrin saturation index is calculated that provides the same information as the TIBC saturation.

The absolute value for TIBC may be helpful in distinguishing between iron deficiency and the anemia of chronic disorders. The TIBC often is increased in iron deficiency and decreased in chronic disease (Fig. 22.11), and some consider it to be the best test to distinguish these two disorders, although in hospitalized patients elevated TIBC is an insensitive marker of iron deficiency.

Serum Ferritin

Determination of serum ferritin concentration also is used for evaluating iron stores in patients with iron deficiency. Ferritin is chiefly an intracellular iron storage protein, but trace amounts are also secreted into plasma. In most clinical circumstances, the serum ferritin concentration is proportional to total body iron stores. In contrast to serum iron measurements, ferritin values are not influenced by recent iron therapy.
FIGURE 22.10. Transferrin iron saturation in patients with several types of anemia. The values are low (>16%) in iron deficiency anemia and the anemia of chronic disorders, with considerable overlap. Values of less than 5% are found only in iron deficiency. Transferrin saturation is increased in sideroblastic anemia.

FIGURE 22.11. Total iron-binding capacity (TIBC) in patients with iron deficiency and in those with chronic disease. A high value indicates iron deficiency. Low to normal values are found in chronic disease but may also occur in iron deficiency. The mean ferritin value for normal adult men is 90 to 95 µg/L, with a range of approximately 20 to 500 µg/L. For women, mean values of approximately 35 µg/L are noted, with a usual range of 10 to 200 µg/L, when iron deficiency anemia is excluded. In infants, values are high at birth but rapidly fall to approximately 30 µg/L, where they remain until puberty. Serum ferritin values in men tend to rise steadily with age. These levels show little or no diurnal variation. Day-to-day variation averages approximately 15%, mostly because of methodologic factors.

In patients with uncomplicated iron deficiency, mean ferritin values of 3 to 6 µg/L have been reported. In patients with excessive iron stores, values are usually greater than 1,000 µg/L and may reach 10,000 µg/L (Fig. 22.12). Also, the serum ferritin level in patients with anemia of chronic diseases may increase disproportionately relative to the increase in iron stores, probably because ferritin is an acute phase reactant. This phenomenon complicates the diagnosis of iron deficiency when it coexists with inflammatory disease. In some other illnesses, the serum ferritin level increases because of factors other than augmented iron stores. One such condition is liver disease, in which damage to the hepatic cell can cause the
release of intracellular ferritin (nonglycosylated and iron-rich). Serum ferritin values also may be inappropriately increased in association with various malignancies, especially hematologic malignancies.99,101,102

Evaluation of Bone Marrow Iron Stores

In bone marrow aspirates, hemosiderin appears as goldenyellow refractile granules. More often, the specimen is stained by the Prussian blue method, which renders hemosiderin blue.103 Experienced observers can grade the marrow hemosiderin stores from 0 to 6+ (Table 22.8).104 Normal marrow is graded 1+ to 3+. In iron deficiency, marrow hemosiderin is absent; in the anemia of chronic disorders, iron is always present, most often of grade 2 or 3+, but sometimes 4 or 5+. Iron stores are greatly increased (5 to 6+) in thalassemia major and in sideroblastic anemias. Nowadays the marrow assessment of iron is used much less, because serum ferritin provides a simple measurement that correlates with clinical iron states in the anemia of chronic disease and in iron deficiency states.
FIGURE 22.12. Measurements of serum ferritin in uncomplicated iron deficiency, inflammation, liver disease, and iron overload. Geometric mean values for each group (horizontal line). Patients with iron deficiency (total iron-binding capacity >400 µg/100 ml and transferrin saturation below 16% or absent marrow iron or both) (open circles). Normal range (shaded area). From Lipshitz D, Cook JD, Finch CA. A clinical evaluation of serum ferritin as an index of iron stores. N Engl J Med 1974;290:1213-1216, with permission.
Transferrin Receptors

Transferrin receptors (TfRs) are disulfide-linked transmembrane proteins that facilitate the entry of transferrin-bound iron into cells (Chapter 23). A soluble, truncated form of the protein can be detected in plasma, and its immunologic quantification can be useful in detecting iron deficiency and distinguishing it from the anemia of chronic disease. Values in iron deficient subjects are clearly increased, and are typically not increased in uncomplicated anemia of chronic disease. Therefore, TfR determination may be useful in distinguishing iron deficiency from the anemia of chronic disease, but must be interpreted in association with the ferritin concentration. It has been proposed that the ratio of serum TfR concentration to the logarithm of the serum ferritin concentration has a better capacity to distinguish iron deficiency from the anemia of chronic disease than does the unadjusted serum TfR concentration (Fig. 22.13). Serum TfR levels also vary with the total mass of red cell precursors. Therefore, the value increases in hemolytic anemia, thalassemia, and polycythemia, and decreases in hypoplastic anemia and renal failure.

TABLE 22.8 CRITERIA FOR GRADING IRON STAINS IN BONE MARROW ASPIRATES

Other Tests to Assess Iron Metabolism

Erythrocyte Zinc Protoporphyrin

Red cell precursors normally synthesize slightly more protoporphyrin than is needed for heme synthesis. The excess remains with the cell throughout its lifespan and has been called free erythrocyte protoporphyrin (FEP). When iron is not available for heme synthesis, protoporphyrin accumulates in excess as zinc protoporphyrin. Measurement of FEP is available as a screening test for iron deficiency, and the test requires only a drop of blood and 1 minute of processing. The level of FEP increases dramatically in iron deficiency and is a sensitive laboratory abnormality in this condition. The erythrocyte zinc protoporphyrin content also is greatly increased in lead poisoning but is normal in thalassemia.

Liver Iron Stores

Iron stores can also be estimated by liver biopsy using both histochemical and chemical methods of analysis. Even gross inspection of a Prussian blue-stained biopsy specimen can provide a reasonably reliable estimate of iron stores. Criteria for grading the preparations from 1 to 4+ have been established, and these correlate well with chemical analysis. Chemical analysis has been important in evaluating hemochromatosis and transfusion iron overload, because a disproportionate amount of iron is in parenchymal cells in the form of ferritin, which does not stain with Prussian blue. Measurement of hepatic iron stores has been used mainly to assess iron overload states, because the correlation between serum ferritin and true tissue iron content is not as good when there is elevated tissue iron content. Currently, however, magnetic resonance imaging using T2* technology is replacing liver biopsy as a noninvasive way to measure liver iron content.
FIGURE 22.13. Ratio of serum transferrin receptor concentration \([\text{TfR}]\) to \(\log_{10}\) serum ferritin concentration \([\text{Ferr}]\) in anemic patients with iron deficiency (IDA; \(n = 19\)), anemia of chronic disease (ACD; \(n = 65\)), and features of both syndromes (IDA/ACD; \(n = 7\)). Bars indicate the mean (dot) and 95% confidence intervals of values in the three groups.

Urinary Iron Excretion

Storage iron has been evaluated by urinary excretion of iron after the administration of a chelating agent.\textsuperscript{120,121,122,123} The chelator most commonly used for this purpose is deferoxamine. A rough correlation exists between iron stores and urinary iron excretion after deferoxamine administration.

Disorders of Hemoglobin Synthesis

The Hb disorders associated with microcytosis include the thalassemias and certain structural Hb variants.

The thalassemias are a group of inherited disorders in which synthesis of one of the normal polypeptide chains of globin is severely deficient (Chapter 34). In mild forms of the disease (thalassemia minor), hypochromia and microcytosis are prominent, whereas anemia is absent or mild. In other thalassemic disorders, including homozygous \(\beta\)-thalassemia (\(\beta\)-thalassemia major) and Hb E \(\beta\)-thalassemia, hypochromic, microcytic anemia is usually quite severe.
The possibility of thalassemia minor is often raised by finding that the microcytosis is more severe than might be expected for the mild degree of anemia. In addition, basophilic stippling and target cells tend to be more prominent in thalassemia than in iron deficiency. An important feature of thalassemia trait-like conditions (which include the Hb E syndromes) is that the RBC count often is very high normal to elevated despite having anemia and small RBC. This characteristic has allowed several different measures for differentiating iron deficiency from thalassemia trait and Hb E disorders. One of the most useful is a modification of the Mentzer index, which is based on the MCV and RBC count:

\[
\text{MCV/RBC} (10^6) > 14 \quad \text{(suggestive of iron deficiency)}
\]

\[
\text{MCV/RBC} (10^6) 12 \text{ to } 14 \quad \text{(indeterminate)}
\]

\[
\text{MCV/RBC} (10^6) < 12 \quad \text{(suggestive of thalassemia trait disorders)}
\]

RDW, a measure of anisocytosis derived from erythrocyte volume distribution, has been advocated for distinguishing iron deficiency from thalassemia minor in patients with microcytosis. Anisocytosis is an early and prominent finding in iron deficiency, often detectable before significant microcytosis, hypochromia, or even anemia is apparent. In contrast, anisocytosis tends to be absent or mild in thalassemia minor. The normal value for RDW is 13.4 ± 1.2% (mean, 2 SD), and the upper limit of normal is 14.6% (40). In iron deficiency, the value is 16.3 ± 1.8%, whereas in β- or α-thalassemia minor, the value is normal (13.6 ± 1.6%). An increased RDW appears to be 90% to 100% sensitive for iron deficiency but only 50% to 70% specific. An increased value for RDW in an otherwise normal complete blood count most often represents early iron deficiency, but other nutritional deficiencies are also possible causes.

P.603

Homozygous hemoglobinopathies, especially Hb C and Hb E, tend to be microcytic and normochromic, and many target cells are apparent in the blood smear (Chapter 34).

Distinguishing homozygous β-thalassemia (β-thalassemia major) from β-thalassemia minor is rarely a problem, because the former is accompanied by signs of hemolysis and ineffective erythropoiesis; there also are characteristic findings on the blood smear, including nucleated red cells, extreme anisocytosis and poikilocytosis, and target cells (Chapter 34). However, it is a common diagnostic problem to distinguish patients with β-thalassemia trait from those with iron deficiency. In almost all cases of β-thalassemia trait, the fraction of Hb A2 is increased, whereas the value for Hb A2 is normal or decreased in iron deficiency. An exception is that if a patient with β-thalassemia trait happens to be iron deficient at the time of evaluation, the Hb A2 be normal. When iron repletes, the same patient’s Hb A2 will be elevated as expected.

α-Thalassemia syndromes result from decreased α-globin chain synthesis that is directed by four structural genes. Four different α-thalassemia syndromes have been recognized on chromosome 16. Silent carrier state (α-thalassemia II) individuals lack one α globin gene; the α, β-globin chain synthetic ratio is decreased from unity, but these individuals are hematologically normal and have no clinical problems. α-Thalassemia trait (α-thalassemia I) individuals lack two α-globin genes, α-globin synthesis is impaired, and there is a mild hypochromic microcytic anemia. Hb H disease is caused by the deletion of three α-globin genes, and the consequence of this is a mild to moderate hemolytic anemia. Beyond the neonatal period, the unbalanced chain synthesis leads to an excess in β-globin chains which form Hb H (β4 tetramers). Hb H is mildly unstable, particularly in the presence of oxidant stress, thereby causing intermittent hemolysis. Homozygous α-thalassemia (hydrops) is due to a deletion of all four α-globin genes, resulting in severe anemia because of the complete absence of α-globin chains. This disorder is incompatible with life, and fetuses are aborted early, are stillborn, or die within the first few hours of life.

A common clinical problem is to identify α-thalassemia trait, which has a similar presentation to β-thalassemia trait and to iron deficiency. The diagnosis often is a presumptive one, made after excluding iron deficiency, β-thalassemia trait, and any other abnormal Hb. The α-thalassemia syndromes occur primarily in those of Asian and African descent, and it is of interest that in Africans with α-thalassemia trait, the globin gene deletions occur on different chromosomes (i.e., trans deletions), whereas in Asians with α-thalassemia trait, the gene deletions occur on the same chromosome (i.e., cis
deletion). As a consequence of these racial differences, Hb H disease and homozygous α-thalassemia occur only in Asians. Moreover, virtually all Africans with α-thalassemia have α-thalassemia trait (Chapter 34).

GENERAL DIAGNOSTIC APPROACH TO HEMOGLOBINOPATHIES AND THALASSEMIAS

The clinical and laboratory features of specific thalassemia and hemoglobinopathy syndromes are discussed in the chapters addressing those syndromes. Thalassemia and hemoglobinopathy syndromes are suspected in patients with microcytosis, in patients with unexplained hemolytic anemia, and in patients with the red cell abnormalities suggestive of hemoglobinopathies, such as sickle cells or the characteristic inclusions of Hb C disease. The principal tool in the identification of hemoglobinopathies and thalassemias is the hemoglobin electrophoresis. Hb C, Hb E, Hb S, and Hb H can be detected by electrophoresis. The presence of increased amounts of Hb A₂ and/or Hb F indicates β-thalassemia variants. The most common approach to Hb electrophoresis uses cellulose acetate at alkaline pH (usually 8.2-8.6); however, Hb A₂ and Hb C migrate to the same position, and must be distinguished by electrophoresis at an acidic pH on citrate agar. Specific quantitative tests using alkali denaturation for Hb F or ion-exchange microcolumns for Hb A₂ are widely available. Isoelectric focusing can separate a number of Hb types not clearly distinguished in cellulose acetate or citrate agar, and high pressure liquid chromatography (HPLC) techniques have replaced electrophoretic methods in many reference laboratories. DNA sequencing is often employed in the analysis of rare or novel Hb variants.

α-Thalassemia syndromes are not associated with increases in Hb A₂ and Hb F, and thus are not detectable on electrophoresis unless three α genes are deleted, resulting in Hb H disease. For this reason, the diagnosis of α-thalassemia trait is usually made presumptively, having excluded iron deficiency and β-thalassemia. Specific DNA-based testing is available, but it is seldom used for routine diagnostic purposes. Its major value is in prenatal diagnosis, and the counseling of potential parents at risk for having children with homozygous α-thalassemia. Unstable Hbs are detected by the heat denaturation test.

Sideroblastic Anemias

The sideroblastic anemias are due to acquired and hereditary disorders of heme synthesis (Chapter 24). A classic morphologic feature of this type of anemia, as seen in the peripheral blood smear, is the presence of erythrocyte dimorphism (Fig. 22.4E), with a microcytic population of cells mixed with a normal red cell population and the presence of occasional, heavily stippled, hypochromic cells. In hereditary (X-linked) sideroblastic anemia, the anemia and microcytosis are pronounced (Table 22.7), and these changes are accompanied by considerable anisocytosis and poikilocytosis. The serum iron concentration usually is elevated, and the TIBC is increased. In all cases of sideroblastic anemia, regardless of the specific etiology, impaired heme synthesis leads to retention of iron within the mitochondria. Morphologically, this is seen in marrow aspirates which reveal many nucleated red cells with iron granules (i.e., aggregates of iron in mitochondria) that have a perinuclear distribution. These unusual cells, known as ringed sideroblasts, are found only in pathologic states and are distinct from the sideroblasts (erythroblasts with diffuse cytoplasmic ferritin granules) seen in 30% to 50% of normal RBC precursors in marrow. Most common sideroblastic anemias occur in middle age and later life, and these acquired disorders can be idiopathic, secondary to drugs, alcohol, or myeloproliferative disorders (Table 22.6). In addition, there are rare congenital sideroblastic anemias that conform to an X-linked pattern of inheritance, usually occurring in males, although skewed lyonization has resulted in affected females. Autosomal-dominant and sporadic cases also occur. Several different genetic mutations have been identified in these congenital sideroblastic anemias. Severe anemias are recognized in infancy or early childhood, whereas milder cases may not become apparent until early adulthood or later. Patients may present with pallor, icterus, moderate splenomegaly, or hepatomegaly. Iron overload is a major complication of this disorder. In some cases in which there is little or no anemia, there still may be clinical evidence of iron overload (i.e., diabetes mellitus and liver dysfunction).

APPROACH TO NORMOCYTIC ANEMIA

Normocytic anemias are those in which the values for MCV are within normal limits, between 80 and 100 fl in adults. At times, however, the anemias that fall into this category also may be macrocytic or microcytic. For example, the anemia associated with hypothyroidism and liver disease may be either normocytic or slightly macrocytic. Also, because of reticulocytosis, the anemia
The normocytic anemias are not related to one another by common pathogenetic mechanisms. In many instances, anemia is only of incidental importance, a minor manifestation of a systemic disease with other, more serious consequences. Importantly, however, sometimes anemia is the first evidence of disease and the sign leading to discovery of the underlying disorder.

Despite the varied etiologic background and the often incidental nature of the normocytic anemias, they can be classified in a way that forms a basis for diagnostic investigation (Fig. 22.14). As a first step, it should be determined whether the erythropoietic response is appropriate to the degree of anemia. When bone marrow function is unimpaired and the iron supply is ample, erythropoiesis can increase manyfold. In most cases, marrow examination is not necessary to determine that the erythropoietic response is adequate, because reticulocytosis may be prominent, and polychromatophilic macrocytes may be detected on routinely stained smears. These manifestations of appropriate marrow response are typical of hemolytic anemia and posthemorrhagic anemia. The history, physical examination, and signs of excessive erythrocyte destruction (e.g., hyperbilirubinemia) provide the information necessary to differentiate these two conditions. The diagnostic approach to anemias due to hemolysis and after acute hemorrhage are discussed separately below.

When anemia is apparent but the erythropoietic response is less than appropriate, most likely the underlying disorder directly or indirectly affects the bone marrow. Indirect effects should be investigated first, because often a diagnosis can be made without resorting to marrow aspiration and biopsy. For example, several disorders are associated with reduced secretion of erythropoietin (Table 22.9). In these conditions, screening tests usually uncover an underlying systemic disease, and for this purpose, renal function, liver function, and thyroid status should be assessed by use of appropriate biochemical tests. Although severe protein-calorie malnutrition is accompanied by reduced erythropoietin secretion and a mild normocytic anemia, such undernutrition is rare in developed countries and thus is not likely to be confused with other systemic disorders. The anemia of chronic disease typically presents as a normocytic anemia with low reticulocytes. This can be recognized by the underlying inflammatory state and the previously described iron studies. One of the causes of this is thought to be a blunted erythropoietic response due to the presence of inflammatory cytokines (Chapter 41).

Normocytic anemia with marked reticulocytopenia also is a characteristic of pure red cell aplasia (PRCA). Acquired PRCA in adults represents a relatively rare group of disorders usually occurring in the fifth to seventh decades of life (Chapter 39). The anemia can occur as a primary disorder or secondary to some other disease. Early studies suggested an association with thymoma, but more recent data indicate this is much less common. Most cases of PRCA are seen with a variety of hematologic malignancies (in particular chronic lymphocytic leukemia) and also with nonhematologic malignancies,
rheumatoid arthritis, systemic lupus erythematosus, and in association with a variety of drugs and chemicals. Laboratory
data reveals isolated anemia, reticulocytopenia, and a bone marrow almost completely void of erythroblasts. The
remainder of the CBC is normal.

Transient erythroblastopenia of childhood (TEC) is a form of RBC aplasia occurring in young children, caused by transient
antibody-mediated suppression of normal erythropoiesis that frequently follows a viral infection (Chapter 39). In contrast
to Diamond-Blackfan syndrome, there are no congenital abnormalities and no abnormal RBC features. The natural history
of transient erythroblastopenia of childhood is one of spontaneous recovery over a few weeks.

Aplastic crises with hemolytic anemia is a self-limiting form of red cell aplasia seen in patients with chronic hemolytic
anemia. It is characterized by a rapid decrease in the steady-state Hb concentration and a very low reticulocyte count (see
Approach to Hemolysis).

When the normocytic anemia with reticulocytopenia is associated with leukopenia and thrombocytopenia, there should
be suspicion for intrinsic marrow disease due to aplastic anemia, leukemia, myelofibrosis, or myelophthisis. Morphologic
abnormalities suggestive of marrow infiltration found on the blood smear include nucleated red cells, teardrop
poikilocytes, immature leukocytes, and large, bizarre platelets or megakaryocyte fragments (Fig. 22.6). When such
changes are detected, as well as in any patient with anemia along with other cytopenias, marrow aspiration and biopsy should be performed.

Of the different congenital dyserythropoietic anemias, type II CDA is the most common, and it is the one that almost always presents as a normocytic anemia. This disorder is recognized by distinct multinuclearity of the marrow normoblasts (Chapter 40).

**APPROACH TO HEMOLYSIS**

Hemolytic disorders are characterized by signs of accelerated erythrocyte destruction together with those of vigorous blood regeneration. Under maximal stimulation, the normal marrow is capable of undergoing hyperplasia until its production rate increases approximately six to eight times. With optimal marrow compensation, the survival of red cells in the circulation can decrease from the normal 120 days to as few as 15 to 20 days without anemia developing. Such an increase in destruction and production of erythrocytes can result in a compensated hemolytic state without anemia being present. In this regard, it is of interest that a significant fraction of patients with hereditary spherocytosis patients are not anemic. However, when red cell survival is so short that anemia develops despite a vigorous erythropoietic response, the term hemolytic anemia is appropriate.

**Pathogenesis and Classification**

Disorders associated with hemolytic anemia have been classified in various ways, none of which is entirely satisfactory. On clinical grounds, hemolytic anemias have been divided into acute and chronic forms, but such a division is of limited usefulness because acute episodes may develop during the course of chronic hemolytic disorders. Of somewhat greater use is a classification based on the site of hemolysis: whether it is predominantly within the circulation (intravascular) or within tissue macrophages (extravascular). Most hemolytic diseases are characterized by extravascular red cell destruction. The intravascular hemolytic disorders are accompanied by unique manifestations, such as hemoglobinemia, hemoglobinuria, and hemosiderinuria, and this type of hemolysis is easily recognized (Table 22.10).

Hemolytic disorders also may be considered to be caused by an intrinsic defect in the cell itself or by extrinsic agents acting on otherwise normal red cells. It is this classification which generally is most useful to the clinician (Table 22.11). Most intrinsic defects are inherited, whereas the extrinsic ones are acquired. Exceptions to this generalization are few; these include paroxysmal nocturnal hemoglobinuria (Chapter 31), an acquired disorder characterized by an intrinsic red cell defect. Also, certain inherited intrinsic defects (e.g., the most common form of glucose-6-phosphate dehydrogenase [G6PD] deficiency) are associated with no ill effects in the absence of an extrinsic agent, usually an infection or exposure to a drug (see Chapter 28).

Intrinsic and extrinsic abnormalities originally were defined by performing cross-transfusion erythrocyte survival studies. When normal erythrocytes are transfused to patients with an extrinsic cause for hemolysis, the donated cells are destroyed as rapidly as the patient’s own cells. On the other hand, when the patient’s RBCs are removed from their unfavorable environment and transfused to a normal recipient, their survival time is normal. In contrast, when the disorder is due to an intrinsic red cell defect, the RBCs of the patient, when given to a normal recipient, are removed from the circulation more rapidly than those of the recipient; the normal erythrocytes, if transfused into the patient, maintain a normal lifespan. While such cross-transfusion experiments played an important role in clarifying the pathogenesis of various hemolytic disorders, obviously they cannot be used in the evaluation of patients.

The intrinsic disorders of the erythrocyte are due to defects affecting the red cell membrane (Chapter 27), disorders of cell metabolism (Chapter 28), or various Hb abnormalities (Chapters 33, 34 and 35) (Table 22.11).

The acquired hemolytic anemias are further subclassified on the basis of the extrinsic factors causing hemolysis. These include antibodies (Chapters 29 and 30) and other nonimmune causes

March hemoglobinuria
Disseminated intravascular coagulation (DIC)

**Infection**
Protozoa (Malaria, Toxoplasmosis, Leishmaniasis, Babesiosis)
Bacteria (Clostridial infection, cholera, bartonellosis, typhoid, etc.)

**Other causes**
Paroxysmal nocturnal hemoglobinuria (PNH)
Spur cell anemia in liver disease
Associated with hemodialysis and uremia
Thermal red blood cell (RBC) injury
Hypophosphatemia
Snake venoms

**Inherited Hemolytic Disorders**

**RBC Membrane abnormalities**
Hereditary spherocytosis
Hereditary elliptocytosis syndromes
Hereditary stomatocytosis
Hereditary xerocytosis

**RBC Enzyme disorders**
Glucose-6-phosphate dehydrogenase (G6PD) deficiency
Pyruvate kinase (PK) deficiency
Glucose-phosphate isomerase (GPI) deficiency
Pyrimidine 5’ nucleotidase deficiency

**RBC Hemoglobin disorders**
Sickle cell anemia syndromes
Thalassemia syndromes
Unstable hemoglobin disorders

Each of these different hemolytic anemias is discussed in detail elsewhere in this book. The remainder of this section focuses on the general clinical and laboratory features that are common to most congenital and acquired hemolytic anemias.

**Clinical Features of Congenital Hemolytic Anemia**

**Degree of Anemia**

The severity of anemia varies greatly, even among patients with the same congenital disorder. Most commonly, the anemia with congenital hemolytic disorders is mild to moderate because the shortened erythrocyte survival is partially offset by increased activity of the bone marrow. Often, patients accommodate remarkably well to the anemia and may exhibit few signs or symptoms. Consequently, detection can be delayed until later in childhood and discovered incidentally. Moreover, some patients have no anemia at all. The disease may then remain unsuspected until late in adult life unless jaundice, a crisis, or complications of gallbladder disease draw attention to the condition. Sometimes, such cases are discovered only in the course of a family study.

In some congenital hemolytic disorders, such as homozygous β-thalassemia, the rate of red cell destruction far exceeds the erythropoietic capacity of the marrow, and these individuals usually have a very severe anemia requiring life-long red cell transfusions.

**Jaundice**

Jaundice often is first noted in the neonatal period, and phototherapy frequently is used to reduce the hyperbilirubinemia and, sometimes, exchange transfusions are required. In some older children and adults with congenital hemolytic anemia, icterus is absent or mild enough to pass unnoticed. Careful inquiry often elicits a history of episodes of jaundice or the passing of dark urine associated with trivial infections. In other cases, jaundice is persistent but never becomes intense. Often, slight scleral icterus is the only sign of hemolytic disease. As noted earlier, the jaundice of hemolytic disease is acholuric; the bilirubin, being unconjugated, is not excreted in the urine. Furthermore, pruritus is absent. These features help to distinguish the icterus of hemolytic disease from that found with disorders of the hepatobiliary system.

**Aplastic Crises**

Aplastic crises result from transient failure of red cell production (Fig. 22.15) caused by infection with the type B19 human parvovirus and The same virus also causes erythema infectiosum (fifth disease, a common childhood exanthem) and may cause an acute polyarthropathy syndrome in adults as well as aseptic meningitis and fetal death with hydrops fetalis. Parvovirus infection may occur sporadically but most often is an epidemic disease that can affect several family members simultaneously or multiple people in a large geographic area. Schoolage children (age 5 to 10 years) are most at risk for parvovirus infection, but cases have been reported of parvovirus infection in young adults. Any patient with moderately severe chronic hemolytic disease who becomes infected with parvovirus is at
risk for an aplastic crisis. Blood Hb concentrations fall several grams, sometimes to life-threatening levels, and the reticulocyte count falls abruptly, usually to less than 1%. The magnitude of the crisis depends on the severity of the underlying hemolytic process. In most cases, leukocyte and platelet counts are unaffected, but neutropenia and thrombocytopenia can occur and, rarely, may be severe. The bone marrow is cellular, but erythroid hypoplasia is the characteristic finding; in particular, the more mature erythrocyte precursors tend to disappear. Giant pronormoblasts may be observed. Recovery is heralded by reticulocytosis. The entire episode, from onset of symptoms to reappearance of reticulocytes, lasts approximately 10 to 12 days.

in subjects with normal immunologic responses, but may persist much longer in patients with defective or suppressed immune systems. Parvovirus infection also produces erythroid aplasia in normal subjects, but the decrease in Hb concentration is minimal when erythrocyte survival is normal, and such small changes go undetected. During the acute phase of aplastic crisis, parvovirus DNA often can be detected in the serum by polymerase chain reaction assays. The appearance of a specific immunoglobulin (Ig) M (IgM) antibody in serum is a marker of recent infection. It is replaced by an IgG antibody that persists for years and is found in 60% of normal subjects. A single infection apparently confers lifelong immunity. However, parvovirus antibody titers are only helpful in the immunocompetent.

FIGURE 22.15. Severe aplastic crisis in a patient with hereditary spherocytosis who previously had well-compensated hemolysis. Note the profound reticulocytopenia during the early phases of the reaction, followed by reticulocytosis. Hb, hemoglobin. (Data plotted from Owren P. Congenital hemolytic jaundice. The pathogenesis of the “hemolytic crisis.” Blood 1948;3:231-248.)

Splenomegaly
The spleen typically is enlarged in patients with congenital hemolytic anemias, except for individuals with sickle cell anemia older than 5 years of age. Most often, the degree of enlargement is mild to moderate. At times, splenomegaly leads to discovery of the disease because the spleen is detected on a routine physical examination. It is not uncommon for children with hereditary spherocytosis to first be recognized by the finding of splenomegaly during a routine physical examination in an otherwise healthy child.

Cholelithiasis
Gallstones and their complications play a significant role in the clinical manifestations of congenital hemolytic anemias. Symptoms of gallbladder disease rarely may be the initial manifestations of a hemolytic process and the ones that bring the illness to the attention of a physician. Gallstones typical of hemolytic anemia are so-called black pigment stones. They differ from brown pigment stones and cholesterol stones, neither of which is associated with hemolysis. The hepatic
Bile of patients with hemolytic anemia contains greatly increased amounts and concentrations of unconjugated bilirubin, decreased concentrations of bile acids, and increased concentrations of ionized calcium.

The prevalence of cholelithiasis in patients with hemolytic anemia increases with age and with the intensity of the hemolytic process. In a large study series involving Jamaican patients with sickle cell anemia, the prevalence ranged from 8% among patients 16 to 25 years old to 55% in patients older than age 35 years with reticulocyte counts greater than 15%.

Leg Ulcers

Chronic ulcerations of the legs are peculiar and uncommon complications of chronic hemolytic disease. They are particularly characteristic of sickle cell anemia but also occur in association with other hemolytic disorders, such as hereditary spherocytosis (Chapter 31). The ulcers often are bilateral and tend to involve the areas overlying or proximal to the medial or lateral malleoli. They tend to be chronic or recurrent and, upon healing, leave the skin indurated and pigmented.

Skeletal Abnormalities

When hemolytic anemia is severe during active phases of growth and development, the pronounced expansion of erythroid bone marrow may lead to a tower-shaped skull, thickening and striation of frontal and parietal bones ("frontal bossing"), maxillary and dental abnormalities, and other distortions of bony structures. Such abnormalities are particularly characteristic of severe thalassemia major, the so-called thalassemic facies (Chapter 34). Nowadays it is much less common to see these skeletal malformations, because patients with homozygous β-thalassemia are transfused aggressively with red cells to maintain a higher Hb level, and this suppresses expansion of the erythroid marrow and its subsequent effects on bone structure. However, in patients with thalassemia intermedia, a slightly milder clinical variant not necessitating RBC transfusions, the characteristic bone changes may occur because of the expanded size of the erythroid marrow. The skeletal changes also may occur in patients with sickle cell anemia and in exceptional patients with other forms of congenital hemolytic anemia.

Clinical Features of Acquired Hemolytic Anemia

Hemolytic anemia sometimes develops acutely, such as after the transfusion of incompatible blood or the ingestion of an oxidant drug by patients with G6PD deficiency or in association with an acute febrile illness. Some instances of autoimmune hemolytic anemia, thrombotic thrombocytopenic purpura, and other hemolytic disorders may also begin abruptly. Aching pains in the back, abdomen, or limbs are common, as are headaches, malaise, vomiting, shaking chills, and fever. Abdominal pain may be severe, and the accompanying muscular spasm and rigidity may simulate the signs of an acute abdominal condition requiring surgical treatment. Pallor, jaundice, tachycardia, and other symptoms of severe anemia may be prominent.

Acquired hemolytic anemia also can begin insidiously, developing gradually over a period of weeks or months. Cardiovascular adjustments to the anemia may be adequate, and patients may have few symptoms. Pallor, scleral icterus, or a jaundiced complexion may be the first evidence of illness, and often, these signs are noticed by friends or associates before they are appreciated by the patient or the family. As in congenital hemolytic anemia, the course may be interrupted by aplastic crises.

In other instances, the clinical setting may be dominated by the manifestations of an underlying disease of which the hemolytic anemia is one manifestation. For example, signs and symptoms of lymphoma, lupus erythematosus, or mycoplasma pneumonia may overshadow those of the associated hemolytic process.

Laboratory Features of Hemolysis

The laboratory studies used to identify a hemolytic process include those related to the increase in erythrocyte destruction and those related to the compensatory increase in the rate of erythropoiesis.

Signs of Increased Red Blood Cell Destruction

Serum Bilirubin

The amount of bilirubin in the circulation depends in part on the rate at which the bilirubin is formed and in part on the efficiency with which it is excreted by the liver. Hyperbilirubinemia is a hallmark of hemolytic anemia (Fig. 22.16), although occasionally the serum bilirubin is within the normal range despite brisk hemolytic disease. The increased serum bilirubin level in hemolysis almost always consists of the unconjugated (indirectreacting) pigment. The conjugated fraction remains within normal limits, and no bilirubin is evident in the urine. Except for during the neonatal period, values greater than 5 mg/dl are unusual in patients with hemolytic anemia and suggest coexisting hepatic dysfunction.
Serum Lactic Dehydrogenase

Serum lactic dehydrogenase (LDH) often is increased in patients with hemolytic anemia, although not to as great an extent as in megaloblastic anemia. The increase in LDH probably results from liberation of the erythrocyte enzyme into the plasma during hemolysis. Increased serum LDH is a nonspecific finding, because it also is elevated in other medical conditions associated with tissue injury.
FIGURE 22.16. Total serum bilirubin values in 48 normal subjects and 72 patients with hereditary spherocytosis. (Data from Mackinney A, Norton NE, Kosower NS. Ascertaining genetic carriers of hereditary spherocytosis by statistical analysis of multiple laboratory tests. J Clin Invest 1962;41:554-567, with permission.)

Serum Haptoglobin
When Hb enters the plasma, it binds to haptoglobin, and the complex is removed by hepatocytes. As a result, serum haptoglobin decreases in individuals with hemolytic disease. Moreover, despite the intravascular site of haptoglobin function, this protein becomes depleted in association with both intravascular and extravascular hemolysis, such as sickle cell anemia, hereditary spherocytosis, hereditary elliptocytosis, and pyruvate kinase deficiency. Haptoglobin also disappears in megaloblastic anemia and other conditions with intramedullary hemolysis (ineffective erythropoiesis) (Fig. 22.17). In microangiopathic hemolytic anemias with intravascular hemolysis, low haptoglobin levels are the most sensitive marker of red cell destruction, and may be seen in the absence of anemia or hemoglobinemia).

The interpretation of haptoglobin levels sometimes is complicated by the fact that haptoglobin is an acute phase reactant, the synthesis of which increases in response to inflammatory, infectious, or malignant disease. Haptoglobin values also may fall in association with liver disease because of impaired synthesis and in hereditary deficiency of the protein.

Erythrocyte Survival

The strictest definition of hemolysis requires demonstration that the red cell lifespan is reduced. From a practical perspective, however, erythrocyte lifespan determinations are rarely necessary, because they provide little additional information beyond what can be assessed by more easily obtained data, such as serial observations of the degree of anemia, reticulocytosis, and jaundice. For these reasons, determination of red cell survival is reserved for use in evaluating patients with especially difficult diagnostic problems.
Rate of Carbon Monoxide Production

Determinations of the rate of endogenous carbon monoxide production provide accurate assessments of the rate of heme catabolism. With these methods, values of approximately two to ten times the normal rate have been detected in small
groups of patients with hemolytic disease. At the present stage of development, however, these methods are not available for routine clinical use.

Signs of Intravascular Hemolysis

When erythrocytes are destroyed within the circulation, and also when extravascular destruction is so rapid that it exceeds the capacity of the macrophage system, Hb is released into the plasma. The disposal of Hb and its heme group occurs by several mechanisms (Chapter 6), and characteristic laboratory abnormalities are found (Table 22.12).

Hemoglobinemia

At low concentrations, plasma Hb may be measured by means of the benzidine reaction, which allows detection not only of Hb but also of any other heme pigments that may be present. If special precautions are observed to avoid artifactual hemolysis during collection of blood, normal values of less than 1 mg/dl of plasma are found. Plasma usually appears visibly red when Hb exceeds 50 mg/dl. At levels greater than 100 mg/dl, Hb can be measured directly by the cyanomethemoglobin method.

**TABLE 22.12 LABORATORY SIGNS OF HEMOLYSIS**

- Accelerated red cell destruction
- Decreased erythrocyte lifespan
- Increased heme catabolism
- Increased serum unconjugated bilirubin level
- Increased carbon monoxide production
- Increased rate of urobilinogen excretion
- Increased serum lactate dehydrogenase
- Decreased serum haptoglobin
- Hemoglobinemia
- Hemoglobinuria
- Hemosiderinuria
- Methemalbuminemia
- Decreased serum hemopexin
- Fall in blood hemoglobin level at a rate > 1.0 g/dl/wk
- Accelerated erythropoiesis
- Complete blood count
- Reticulocytosis
- Macrocytosis
- Blood smear findings
- Polychromatophilia
- Basophilic, stippling
- Erythroblastosis
- Abnormal red blood cell forms
- Bone marrow (erythroid hyperplasia)
Ferrokinetic (increased plasma iron turnover)
Biochemical (increased erythrocyte creatine)

Plasma Hb levels are normal in most patients with hereditary hemolytic anemias, including hereditary spherocytosis, but can be increased in severe, acquired, immunohemolytic anemia, at times reaching 100 mg/dl. Particularly high values, up to 1,000 mg/dl, are found only in patients with disorders associated with intravascular hemolysis.

Hemoglobinuria

When plasma Hb exceeds the haptoglobin binding capacity, Hb dimers are excreted into the urine, resulting in hemoglobinuria. Urine that contains Hb ranges from faint pink to deeper red, or even to almost black, similar to a cola beverage.

Hemoglobinuria can be distinguished from hematuria (whole RBCs in the urine) by microscopic examination of a freshly voided urine specimen. Urine also may appear red because of ingestion of certain drugs (Pyridium) or food (beets), or because of porphyrinuria (Chapter 26) or myoglobinuria. Of these various red urinary pigments, only Hb and myoglobin produce a positive reaction in the commonly available tests for occult blood, which are based on the benzidine or orthotolidine reactions.

Hemoglobinuria must be distinguished from myoglobinuria, which occurs as the result of massive muscle injury. Myoglobin is a heme pigment of low molecular weight (17,000 Da); it is not bound by haptoglobin and therefore does not accumulate to an appreciable extent in plasma. Thus, inspection of the plasma can help to distinguish myoglobinuria from hemoglobinuria, the presence of a red color in the plasma favoring the latter. More precise identification is accomplished by spectroscopic analysis.

Urinary Hemosiderin and Urinary Iron Excretion

Hb in the glomerular filtrate is partially reabsorbed by the proximal tubular cells, and the Hb iron is incorporated into ferritin and hemosiderin. Subsequently, the iron-containing tubular cells are sloughed into the urine. Hemosiderinuria, therefore, constitutes reliable evidence that hemoglobinemia has occurred in the recent past. After an acute episode of intravascular hemolysis, however, several days may pass before increased iron excretion can be detected. Moreover, the abnormality may persist for some time after the episode has terminated. In most conditions associated with chronic intravascular hemolysis, such as in some of the fragmentation hemolysis syndromes, increased iron excretion is a constant finding, whereas hemoglobinuria occurs only intermittently. Hemosiderinuria may be detected by means of a qualitative test based on the Prussian blue reaction.

Methemalbumin and Hemopexin

Hb in plasma is readily oxidized to methemoglobin, from which the heme group easily detaches. The liberated heme binds to hemopexin and also to albumin, forming methemalbumin. Hemopexin-heme and methemalbumin impart a coffee-brown color to plasma. With either combination, a spectral absorption band is observed at 620 to 630 nm, which, unlike a similar band in methemoglobin, does not disappear if hydrogen peroxide is added. With the addition of ammonium sulfide, the 620- to 630-nm band disappears and a band at 558 nm forms (Schumm test). Low hemopexin values are seen in thalassemia major, sickle cell anemia, and the fragmentation hemolytic anemia that follows cardiac surgical procedures. The measurement of hemopexin is seldom used to assess hemolytic anemia.

Signs of Accelerated Erythropoiesis

Laboratory signs of increased erythropoiesis are almost always present in patients with chronic hemolytic disease. In patients who have had an acute hemolytic episode, signs of increased red cell production appear after 3 to 6 days (Table 22.12). These same signs of increased RBC production also occur after hemorrhage and after specific therapy for anemia caused by iron, folate, or vitamin B12 deficiency.

Reticulocytosis

An increased number of reticulocytes continues to be the most readily available and most often used index of accelerated erythropoiesis. In cases of hemolytic anemia, the erythrocyte production rate and the absolute reticulocyte count is usually greatly increased when hemolysis is severe enough to produce anemia. In most types of hemolytic anemia, the reticulocyte count consistently increases to levels that correlate fairly well with the severity of the process. Exceptions occur during aplastic crises. Also, some patients with acquired immunohemolytic anemia may have normal reticulocyte counts, and in one report, values of less than 2% were found in 26% of 35 such patients. In these cases, it is thought that the autoantibodies are directed against marrow erythroid precursors as well as circulating erythrocytes.
Morphologic Findings in the Blood

When reticulocytes are increased, polychromatophilia and fine basophilic stippling are apparent on routinely stained smears of blood. Macrocytosis is found in association with most hemolytic disorders because of erythropoietin-mediated stimulation of Hb synthesis and because prematurely released (shift) reticulocytes are larger than normal erythrocytes. Exceptions occur in hereditary spherocytosis and sickle cell anemia, diseases in which the intrinsic defect of the cell tends to decrease its size.

When hemolysis is brisk, nucleated erythrocytes may be found in the blood (erythroblastosis), usually in numbers below 1% of all the nucleated cells. In infants, however, erythroblastosis may be more striking, especially in hemolytic disease of the newborn.

P.610

Neutrophilic leukocytosis and thrombocytosis may accompany hemolytic anemia. These findings tend to be most common and most pronounced in patients with acute hemolytic anemias. Platelets are not only numerous but also large. The changes are less pronounced in chronic hemolytic processes.

Bone Marrow

The major alteration in the bone marrow in hemolytic anemia is erythroid hyperplasia, as manifested by a reduction in the myeloid to erythroid ratio.

Laboratory Tests Useful in the Differential Diagnosis of Hemolysis

Specific Morphologic Abnormalities

Detection of certain distortions of red cell shape is of particular diagnostic use because their presence suggests only one or a few entities. Descriptive features of certain such abnormal red cells are presented in Table 22.13 and illustrated in Figures 22.18 and 22.19.

Spherocytes, erythrocytes that lack an area of central pallor (Fig. 22.18B), are the hallmark of hereditary spherocytosis. They are also found in most patients with acquired immunohemolytic anemias (Fig. 22.18C), thermal injury, hypophosphatemia, or certain kinds of chemical poisoning.

Oval cells or elliptocytes (Fig. 22.18D) are the sine qua non of common hereditary elliptocytosis, which usually is a morphologic curiosity, but not associated with significant hemolysis. However, some hereditary elliptocytosis variants are also associated with marked poikilocytosis (Fig. 22.18E and F), and these individuals have significant hemolytic anemia.

Stomatocytes (Fig. 22.18G), which suggest a disturbance in red cell cation content, are found in association with a rare inherited hemolytic disease and also in liver disease.

**RBC, red blood cell.**

Acanthocytes indicate disturbed erythrocyte lipid composition; they occur in association with abetalipoproteinemia and the spur cell anemia that occasionally accompanies hepatic cirrhosis.

Echinocytes (sea urchin cells) are a nonspecific abnormality and are also found in uremia.

Sickle cell anemia was named after the unmistakable sickleshaped red cells that characterize that disorder (Figs. 22.19A,B).

Target cells (Fig. 22.19C) are characteristic of thalassemia, Hb E syndromes, and Hb C disorders. Target cells also occur in nonhemolytic states, such as obstructive jaundice and after splenectomy.

Schistocytes, helmet cells, or other fragmented red cells (Fig. 22.19D) suggest hemolysis associated with physical trauma to the erythrocyte or with diseases affecting small blood vessels.

Bite cells are erythrocytes that look as if a semicircular bite has been taken from one edge. Hemighosts are red cells that look as if the Hb has shifted to one side of the cell, leaving the other side clear. These hemighosts also are referred to as blister cells and may appear to contain a coagulum of Hb that has separated from the membrane (Fig. 22.19E). These cells are seen in patients with oxidant-induced injury, such as in G6PD deficiency.

Autoagglutination may be apparent in blood smears (Fig. 22.19F) or may even be visible to the naked eye when the blood is allowed to flow along the side of a glass container. The phenomenon is particularly characteristic of immunohemolytic disease caused by cold agglutinins. Autoagglutination must be distinguished from rouleau formation, a manifestation of multiple myeloma and related diseases and the phenomenon responsible for accelerated rates of erythrocyte sedimentation.

#### Direct Antiglobulin Test

The test used for detection of immunohemolytic anemia is the direct antiglobulin or Coombs test (see discussion in Chapter 29). Positive test results indicate that the red cells are coated with IgG or complement components, especially C3. However, 2% to 5% of patients with immunohemolytic disease have negative test results because the amount of globulin on the cell surface is below the detection limits. Occasionally, patients have weakly positive test results and no clinical evidence of hemolysis. Positive tests are found in as many as 34% of patients with AIDS without other evidence of immunohemolytic disease.

#### Osmotic Fragility Test

The osmotic fragility test is a measure of the resistance of erythrocytes to hemolysis by osmotic stress. The test consists of exposing red cells to decreasing strengths of hypotonic saline solutions and measuring the degree of hemolysis. A symmetric, sigmoidal curve is obtained in most subjects (Fig. 22.20). Increased fragility is indicated by a shift of the curve to the left, whereas osmotic resistance (reduced fragility) is signified by a rightward shift of the curve. Increased osmotic fragility is observed in conditions associated with spherocytosis. With prior incubation of sterile blood for 24 hours, the increased osmotic fragility of spherocytes is greatly accentuated, whereas normal cells become only slightly more fragile. The osmotic fragility of unincubated blood may be normal in some patients with hereditary spherocytosis, and for this reason, the test should be performed on incubated samples. Determination of osmotic fragility is of value chiefly in confirming important morphologic findings, especially the presence of spherocytes. In most cases, however, the osmotic fragility test does not provide information that was not already available from an expert examination of a well-prepared,
stained blood smear. Osmotic gradient ektacytometry is more sensitive and specific than the osmotic fragility test for the diagnosis of hereditary spherocytosis, but is not widely available.\textsuperscript{159}

Tests for Hemolytic Disorders Associated with Heinz Body Formation
In certain disorders, the hemolytic process involves precipitation of Hb, with the formation of inclusions known as Heinz bodies. These inclusions are rapidly removed by the spleen. Heinz body formation is the principal mechanism of hemolysis in G6PD deficiency and related disorders (Chapter 28), in unstable Hb disease (Chapter 35), in the thalassemias (Chapter 34), and in certain kinds of chemical injury (Chapter 32). Heinz bodies are not observed when ordinary staining procedures are used, but require the use of special supravital stains (Fig. 22.21). Cells containing these inclusions may be found in the blood during an acute hemolytic episode in subjects with G6PD deficiency and also in splenectomized individuals with unstable Hb disease. When the spleen is intact, however, the inclusions are removed with such efficiency that the inclusion-containing cells often are not seen.

![Osmotic fragility](image_url)

**FIGURE 22.20.** Osmotic fragility (as manifested by percent hemolysis) of normal and hereditary spherocytosis (HS) erythrocytes after incubation in salt solutions of varying tonicity. In fresh HS erythrocytes, note the “tail” of cells with increased sensitivity as a result of splenic conditioning (left). In the incubated red blood cell (RBC), note that the entire HS population of RBCs is more osmotically sensitive (right). From Glader BE, Naumovski L. Hereditary red blood cell disorders. **Diagnostic Strategy for the Patient with Hemolytic Anemia**

**Establishing the Presence of Hemolytic Anemia**

The most common manifestations of chronic hemolytic anemia include anemia and reticulocytosis, often associated with various signs of excessive blood destruction. In contrast, an acute hemolytic anemia initially may not be accompanied by signs of accelerated red cell production. Such a diagnosis may be suspected because of the abrupt onset of hemoglobinuria or other signs of intravascular hemolysis or because of a rapid fall in blood Hb concentration from previously stable levels.

**Conditions Sometimes Mistaken for Hemolytic Anemia**

Anemias associated with acute hemorrhage and those with partially treated deficiency states are characterized by transient anemia and reticulocytosis (Table 22.14). They usually can be distinguished from hemolytic disease by the absence of icterus and by a rising Hct on subsequent determinations.
Anemias caused by ineffective erythropoiesis often are accompanied by jaundice and erythroid marrow hyperplasia; however, the reticulocyte count usually is not increased.

A particularly confusing situation may arise after occult hemorrhage into the retroperitoneal space or other tissue compartments; anemia develops rapidly, and reticulocytosis follows. Furthermore, indirect hyperbilirubinemia may occur as the result of reabsorption of the products of Hb breakdown at the site of hemorrhage. Thus, the picture of hemolytic anemia may be simulated in several ways. Diagnosis depends on detecting signs of the hemorrhage itself or the disease process leading to it. If occult hemorrhage is suspected, serial observations usually clarify the situation; once the hemorrhage ceases, the Hct, reticulocyte count, and bilirubin values return to normal.

In individuals with acholuric jaundice but without anemia, the differential diagnosis lies between a compensated hemolytic state and Gilbert syndrome or other disorders of bilirubin catabolism. Reticulocytosis or morphologic abnormalities of erythrocytes are typical findings in the former. In mild compensated hemolytic disease, however, one cannot always be certain that the hematologic values will be abnormal. Fasting induces an exaggerated increase in bilirubin levels in patients with Gilbert syndrome, and this phenomenon may be useful in distinguishing Gilbert syndrome from hemolytic anemia.

Anemia associated with marrow invasion may be accompanied by erythroblastosis and bizarre abnormalities of erythrocyte shape. Mild reticulocytosis may develop because of premature release of cells from the marrow. Usually, however, patients do not have jaundice, and evidence of the invasive disease may be detected by examination of the bone marrow.

Determining the Specific Cause of Hemolysis

Information from the medical history and physical examination, careful review of the CBC and peripheral blood smear, and results from the direct antiglobulin test, taken together, form the basis of the initial diagnosis assessment of hemolysis. From these data, five groups of patients can be distinguished.
Those patients in whom the diagnosis is clear because of medical history such as obvious exposure to infectious, chemical, or physical agents. Some infections, such as malaria, can cause hemolysis directly, whereas in other cases it is more indirect, associated with an underlying G6PD deficiency or an unstable Hb, such as Hb H.

**TABLE 22.14 CONDITIONS SOMETIMES MISTAKEN FOR HEMOLYTIC ANEMIA**

Associated with anemia and reticulocytosis

**Hemorrhage**

Crigler-Najjar syndrome

Gilbert syndrome

Marrow invasion (myelofibrosis, metastatic disease)

Myoglobinuria

P.614

Those patients with a positive direct antiglobulin test. Such individuals may be presumed to have immunohemolytic anemia. The subsequent investigation requires a search for an underlying disease as well as a serologic study of the nature of the antibody.

Those patients with antiglobulin-negative, spherocytic hemolytic anemia. Such patients probably have hereditary spherocytosis. It is appropriate to confirm the presence of spherocytes by the osmotic fragility test and also to attempt to establish the familial nature of the illness by studying family members. Immunohemolytic anemia may be associated with spherocytosis and is occasionally associated with a negative antiglobulin reaction. Exposure to chemical or infectious agents producing spherocytosis may not always be easy to establish.

Those patients with other specific morphologic abnormalities of erythrocytes. The significance of various types of abnormally shaped red cells was discussed previously. Some poikilocytes, such as elliptocytes and sickle cells, are virtually pathognomonic findings.

Those with no specific morphologic abnormalities and a negative reaction to the antiglobulin test. These patients warrant a battery of screening tests, including Hb electrophoresis, the heat denaturation test for unstable Hb disease, tests for common red cell enzymes such as G6PD and pyruvate kinase, and a screening test for paroxysmal nocturnal hemoglobinuria.

If all of these procedures yield normal results, making the diagnosis is likely to be difficult. Possibilities include one of the rarer erythrocyte enzyme deficiencies or an unusual variant of congenital dyserythropoietic anemia. These entities can be established only by using specific assays and, soon to be available, genomic sequencing for enzyme and cytoskeletal protein gene mutations.

**APPROACH TO ACUTE POSTHEMORRHAGIC ANEMIA**

When blood loss occurs in small amounts over a prolonged period, no anemia develops until iron stores are depleted. In such circumstances, the hematologic findings are those of iron deficiency anemia. On the other hand, when larger amounts of blood are lost over shorter periods of time, anemia may develop, although iron stores remain adequate. This latter condition is called acute posthemorrhagic anemia.
The patient may be asymptomatic and appear to be in shock, or the entire situation might be confused with an acute hemolytic process.

The physiologic changes that occur with acute blood loss in otherwise healthy individuals are summarized in Table 22.15. The immediate effects of acute hemorrhage are primarily cardiovascular. The plasma volume and red cell mass are reduced in proportional amounts; consequently, no decrease is observed in the Hct. Because of the time required for extracellular fluid to restore the blood volume, the amount of blood loss tends to be underestimated by the degree of anemia, especially early in the disease course. The platelet count increases, often reaching levels above normal within 1 hour, and values greater than 1 million platelets/ul can be observed. There also is a neutrophilic leukocytosis over 2 to 5 hours. Typically, the leukocyte count is 10 to 20 × 10^3/µL. The leukocytosis is explained in part by the effect of epinephrine on granulocyte demargination and release from the marrow granulocyte reserve.

When first detected, the anemia following acute hemorrhage is normocytic with few signs of erythrocyte regeneration. The Hct or Hb may not reach the minimum value until 3 days or more after the hemorrhage ceases.

Some increase in the number of reticulocytes is usually perceptible within 3 to 5 days, and maximal values are reached at 6 to 11 days. The degree of reticulocytosis is related to the magnitude of hemorrhage, but rarely exceeds 15%. Other signs of erythrocyte regeneration include polychromatophilia and macrocytosis, and the MCV may transiently increase. If the patient is seen for the first time during this stage, the findings may be mistaken for those of hemolytic anemia; however, signs of increased bilirubin production are conspicuously absent, unless there has been bleeding into a body cavity or tissue space.

An external hemorrhage of a magnitude sufficient to cause significant anemia is usually evident. Similarly, substantial bleeding from the gastrointestinal or female reproductive tract is likely to be a dramatic event with readily detected signs and symptoms. Internal bleeding, as from a ruptured aneurysm, may be less apparent but should be suspected when there is the abrupt onset of shock or unexplained hypotension and tachycardia. Often, these manifestations are accompanied by symptoms referable to the site of bleeding. Hemorrhage into the retroperitoneal space, a body cavity, or a cyst sometimes presents a diagnostic problem. There may be a rapid onset of anemia accompanied by hyperbilirubinemia arising from the breakdown and absorption of RBCs. Under such circumstances, the picture may be transiently confused with acute hemolytic anemia. In all cases, the onset of a sudden, unexplained anemia should lead to the suspicion of covert bleeding. The suspicion is strengthened if signs of regeneration, such as reticulocytosis, appear and no evidence of excessive blood destruction is found.

Elective surgery is a special circumstance in which hemorrhage is predictable. Surgical mortality is clearly increased when patients are severely anemic. In Jehovah’s Witness patients who refuse transfusion, surgical mortality is approximately 60% at Hb values less than 6 g/dl and more than 30% at values between 6 and 8 g/dl. At values greater than 8 g/dl, no increased mortality is observed. An older guideline requiring preoperative transfusion if the Hb is less than 10 g/dl has been replaced by a lower trigger point, 7 g/dl, in otherwise healthy, younger patients. Surgeons and anesthesiologists use several techniques to avoid the need for allogeneic transfusions. These techniques include the use of autotransfusion of cells harvested during surgery and preoperative harvesting of autologous blood. The preoperative or postoperative use of erythropoietin injection or iron medication has proved disappointing but may have a role with severely anemic Jehovah’s Witness patients.

Section 2 - Disorders of Iron Metabolism and Heme Synthesis

Chapter 23 Iron Deficiency and Related Disorders

Iron deficiency has been recognized since medieval times. Chlorosis, a term derived from the Greek word meaning green, was applied by Varandaeus to a disorder that was later described in 1554 as “De morbo virgineo.” The disease became well known as the “green-sickness,” due to a greenish pallor occurring almost exclusively in teenaged girls. It was depicted in paintings by the Dutch masters and was alluded to by Shakespeare. Other clinical features were breathlessness, palpitations, slight ankle edema, and gastrointestinal complaints. Emotional disturbances, depression, irritability, and moodiness were common.

Chlorosis became especially common in the last decade of the 19th century and then declined in incidence. Today, most believe that chlorosis resulted from a combination of factors affecting adolescent girls: the demands of growth and the onset of menses, an inadequate diet, and a legacy of poor iron stores from early childhood. In the 1830s, anemia, hypochromia, and lack of iron in the blood were linked to this disorder. In 1832, Pierre Blaud described the response of chlorosis to his deservedly famous pills (ferrous sulfate plus potassium carbonate). Many observers, including Niemeyer and Osler, confirmed his findings. Ferrous sulfate remains a cornerstone of modern treatment of iron deficiency.

In the late 1920s and early 1930s, a distinct hypochromic anemia was described. Like chlorosis, chronic hypochromic anemia chiefly affected women. It differed from chlorosis in that it was detected later in life, especially in the fourth and fifth decades. Other distinguishing clinical features were epithelial changes involving the tongue and nails and achlorhydria. The anemia most often affected women with poor diets, multiple pregnancies, or menstrual irregularities. Today, menstruating women continue to be among the most likely individuals to develop iron deficiency, along with young children whose growth outstrips their iron supply. An understanding of normal iron physiology is essential to best appreciate the pathophysiology of iron deficiency anemia.

**NORMAL IRON PHYSIOLOGY**

**Total Body Iron**

Iron endowment varies with age and sex. Full-term infants begin life with approximately 75 mg/kg body weight of iron, primarily acquired from their mothers during the third trimester of gestation. These abundant stores are rapidly depleted over the first few months of life, and most young children have tenuous iron balance, as their intake must keep pace with rapid growth. Requirements decrease after adolescence, and men have a small gradual increase in iron stores throughout life. The body iron content of normal adult men is 50 mg/kg body weight or greater. In contrast, postpubertal women have increased losses of iron due to menstruation, pregnancy, and childbirth, resulting in a body iron endowment averaging 35 mg/kg. After menopause, women accumulate iron linearly in parallel with adult men.

Most of the body iron is found in heme-containing oxygen transport and storage proteins, including hemoglobin and myoglobin (Table 23.1). Smaller amounts are incorporated into enzymes with active sites containing heme or iron-sulfur clusters, including enzymes of electron transport chain, peroxidases, catalases, and ribonucleotide reductase. Most nonheme iron (approximately 1 g in adult men) is stored as ferritin or hemosiderin in macrophages and hepatocytes. Only a tiny fraction of iron (~0.1%) is in transit in the plasma, bound to the carrier protein, transferrin.

**Iron Balance**

Iron is not actively excreted from the body; it is eliminated only through the loss of epithelial cells from the gastrointestinal tract, epidermal cells of the skin, and, in menstruating women, red blood cells. On the basis of long-term studies of body iron turnover, the total average daily loss of iron has been estimated at ~1 to 2 mg in normal adult men and nonmenstruating women. Although iron is a physiologic component of sweat, only a tiny amount of iron (22.5 µg/L) is lost by this route. Urinary iron excretion amounts to <0.05 mg/day and is largely accounted for by sloughed cells.
Menstruating women lose an additional, highly variable amount over each menstrual cycle, from 0.006 (average) to more than 0.025 mg/kg/day.\(^8\)

These iron losses are normally balanced by an equivalent amount of iron absorbed from the diet (1 to 2 mg/day). The bioavailability of iron in the U.S. diet has been estimated to be \(^16\)6.6%, but only a fraction of dietary iron is absorbed and the amount of bioavailable iron is lower in many parts of the world. Fractional absorption of dietary iron can increase up to three- to fivefold (3 to 5 mg/day) if iron stores are depleted. Thus, iron balance is primarily, if not exclusively, achieved by control of absorption rather than by control of excretion.

Intestinal Absorption

Iron is absorbed in the duodenum, and humans and other omnivorous mammals have at least two distinct pathways for iron absorption: one for uptake of heme iron and another for ferrous (Fe\(^2+\)) iron. Heme iron is derived from hemoglobin, myoglobin, and other heme proteins in foods of animal origin, representing approximately 10% to 15% of iron content in the typical Western diet,\(^9\) although heme-derived iron accounts for 2/3 of absorbed iron in meat-eating humans. Exposure to acid and proteases present in gastric juices frees the heme from its apoprotein. Heme is taken up by mucosal cells, but the specific receptor is still unknown.\(^10\) Once heme iron has entered the cell, the porphyrin ring is enzymatically cleaved by heme oxygenase.\(^11\) The liberated iron then probably follows the same pathways as those used by nonheme iron. A small proportion of the heme iron may pass into the plasma intact via heme exporter protein FLVCR (feline leukemia virus, subgroup C receptor),\(^12\) which transfers heme onto a heme-binding protein, hemopexin.\(^13\) Absorption of heme iron is relatively unaffected by the overall composition of the diet.\(^9\)

Dietary nonheme iron is largely in the form of ferric hydroxide or loosely bound to organic molecules such as phytates, oxalate, sugars, citrate, lactate, and amino acids. Low gastric pH is thought to be important for the solubility of inorganic iron. Dietary constituents may also have profound effects on the absorption of nonheme iron, making the bioavailability of food iron highly variable.\(^9\) Ascorbate, animal tissues, keto sugars, organic acids, and amino acids enhance inorganic iron absorption, whereas phytates, polyphenols, and calcium inhibit it.\(^14\) Depending on various combinations of enhancing and inhibitory factors, dietary iron assimilation can vary as much as tenfold.

Molecular Mechanisms of Iron Absorption

Absorption of nonheme iron occurs in the duodenum, where ferrous iron is imported into enterocytes by divalent metal ion transporter 1 (DMT1, also known as Nramp2, DCT1, SLC11A2).\(^15,16\) DMT1 is a protein with 12 predicted transmembrane segments, which is expressed on the apical surface of absorptive enterocytes. Levels of DMT1 are markedly increased in iron-deficient animals\(^17\) and in some animals with increased intestinal iron absorption resulting from other causes.\(^18\) In addition to iron, DMT1 may also contribute to the absorption of other nutritionally important metals (e.g., Mn\(^2+\)).\(^19\) Evidence in vitro demonstrates that DMT1 is a proton-coupled symporter.\(^15,20\) The Na\(^+\)/H\(^+\) exchanger in the duodenum is thought to create the “acid microclimate” that provides the proton electrochemical gradient as the driving force for iron uptake.\(^16\)

DMT1 does not transport the Fe\(^3+\) form of iron, but as discussed previously, most dietary nonheme iron arrives at the brush border as Fe\(^2+\) ion. A duodenal cytochrome b-like ferrireductase enzyme, Dcytb (also called CYBRD1), likely reduces dietary Fe\(^3+\) to make it a substrate for transport by DMT1.\(^15\) Dcytb is induced in response to stimuli that increase iron absorption; however, since knockout mice appear to have normal metabolism, Dcytb may not be the only ferrireductase enzyme involved in absorption of nonheme iron.\(^22\)

A variable fraction of iron taken into the mucosal cell is delivered to the plasma. The remainder is used by the cell or incorporated into ferritin,\(^23\) an intracellular iron storage protein discussed in a later section. Iron retained in mucosal ferritin is not absorbed, rather, it is lost from the body when the senescent mucosal cells are sloughed into the intestine at the end of their 3- to 4-day lifespan (10\(^{11}\) cells/day).\(^24\)

Iron not stored in the absorptive enterocytes is transferred across the basolateral membrane of the cell to the lamina propria and ultimately to the plasma. This is accomplished, at least in part, by the iron exporter ferroportin (also known as FPN1, IREG1, MTP1, SLC40A1), a multi-transmembrane segment protein expressed on the basolateral surface of enterocytes.\(^25,26,27,28\) Ferroportin is also expressed in other tissues involved in handling large iron fluxes including macrophages recycling iron from old red blood cells, hepatocytes storing iron, and placental trophoblast delivering iron from mother to fetus. Complete ablation of ferroportin in mice, including extraembryonic tissues, resulted in embryonic death,\(^29\) whereas selective inactivation that preserved placental ferroportin expression resulted in live births, demonstrating the essential function of ferroportin in materno-fetal iron transfer. Ferroportin is also essential for systemic iron homeostasis as inactivation of ferroportin in all tissues in mice other than placenta led to the development of severe
anemia resembling iron deficiency, and stemmed from the inability to mobilize iron from enterocytes, macrophages, and hepatocytes.

Similar to apical iron uptake, basolateral iron efflux is aided by an enzyme that changes the oxidation state of iron. Ferroportin exports Fe$^{2+}$ and this iron must be oxidized to its Fe$^{3+}$ form to bind to transferrin. A membrane-bound multicopper oxidase, hephaestin, has been implicated in this process. Hephaestin closely resembles ceruloplasmin, which has been shown to be involved in efflux of iron from hepatocytes and macrophages. Mice carrying a large deletion in the X-chromosomal hephaestin gene have impaired placental iron transfer and decreased intestinal iron absorption. Their iron deficiency results in anemia during the neonatal period, but affected animals generally recover and show only subtle evidence of iron deficiency as adults. The simplest interpretation is that hephaestin is important in placental iron transport but dispensable for intestinal iron uptake. The functional relationship between hephaestin and ferroportin has not yet been defined in detail. A model incorporating current knowledge of nonheme iron transport is shown in Figure 23.1.

Regulation of Iron Absorption

Because the total body iron content is largely determined by the efficiency of absorption of iron, the regulation of absorption has been of great interest for many years. Both systemic mechanisms and local mechanisms within enterocytes (discussed later in the chapter) regulate dietary iron uptake. The systemic signals that are of prime importance in determining absorptive rate are the

amount of storage iron in the body and the erythropoietic activity. When storage iron is depleted, iron absorption is increased; when it is excessive, iron absorption is decreased. This has been termed the stores regulator. The erythroid regulator modulates iron absorption in response to erythropoietic need and mediates an increase in intestinal iron absorption when the red cell production rate is increased. This is observed in effective as well as in ineffective erythropoiesis when erythroid precursors are destroyed relatively close to their site of origin in the bone marrow (as seen in thalassemia syndromes, congenital dyserythropoietic anemias, and sideroblastic anemias). It is now known that the hormone hepcidin functions as both the stores and erythroid regulator.
FIGURE 23.1. Nonheme iron absorption in the intestine. The figure shows a drawing of an absorptive enterocyte from the proximal duodenum. The apical brush border is at the top. Dietary nonheme iron enters the gut as the ferric (Fe\(^{3+}\)) ion and is converted to the ferrous (Fe\(^{2+}\)) ion by a surface reductase activity, probably mediated by the duodenal cytochrome b-like (DCYTB) protein. The Fe\(^{2+}\) iron enters the cell through the action of divalent metal ion transporter 1 (DMT1). Within
the cell, some iron is stored, and some is transported across the basolateral membrane. Ferroportin is believed to function as a basolateral \( \text{Fe}^{2+} \) iron transporter. Hephaestin, a ferroxidase, facilitates basolateral iron export, possibly by oxidizing the iron as it exits the cell to the \( \text{Fe}^{3+} \) form to bind to plasma apotransferrin.

Hepcidin and Systemic Regulation of Iron Metabolism

Hormone hepcidin has emerged as the key systemic regulator of iron homeostasis. Hepcidin is a small peptide of 25 amino acids, produced in the liver, secreted into the plasma, and excreted through the kidneys. Hepcidin is structurally similar to antimicrobial peptides involved in innate immunity, but its main role is to inhibit iron fluxes into plasma. Mutations in the human hepcidin gene cause severe, early-onset iron overload. Mice lacking hepcidin also develop severe iron overload, whereas transgenic mice constitutively expressing hepcidin have severe iron deficiency anemia. A single injection of synthetic hepcidin into mice exerts a prolonged hypoferremic effect. All of these effects can be explained by the biologic activity of hepcidin. Hepcidin binds to the iron exporter ferroportin, causing ferroportin endocytosis and lysosomal degradation, and resulting in cessation of cellular iron export. Thus, hepcidin directly and coordinately controls the entry of iron into the plasma from ferroportin-expressing cells, including absorptive cells of the intestine and tissue macrophages (Fig. 23.2).

Alterations in hepcidin production lead to changes in iron absorption and recycling. Multiple signals are known to regulate hepcidin expression, including iron, erythropoiesis, inflammation, and growth factors. As with other hormones that are feedback regulated by the substances whose concentration they control, hepcidin expression is controlled by iron. When iron is deficient, hepatocytes produce less hepcidin, allowing more iron to enter plasma. When iron is abundant, hepcidin production increases, limiting further iron absorption and release from stores. In human volunteers ingesting a single dose of oral iron, hepcidin concentrations in urine increased within several hours and were proportional to the increase in transferrin saturation. Serum hepcidin concentrations in healthy subjects also correlate with body iron stores as reflected by serum ferritin. The specific forms of iron that increase hepcidin synthesis may include diferric plasma transferrin and intracellular iron in hepatocytes, and the transduction pathways that regulate hepcidin synthesis in response to these iron forms are just now being elucidated.

The two transferrin receptors Tfr1 and Tfr2, and HFE, an MHC class I-like membrane protein, may serve as holotransferrin sensors. HFE can interact with both transferrin receptors, but this interaction is modulated by holotransferrin concentrations. Because HFE and holotransferrin binding sites on Tfr1 overlap, increasing concentrations of holotransferrin result in displacement of HFE from Tfr1, and free HFE then interacts with Tfr2. Tfr2 protein is further stabilized by binding of holotransferrin. The holotransferrin/HFE/Tfr2 complex then stimulates hepcidin expression through an incompletely understood pathway, possibly by potentiating BMP pathway signaling. HFE, however, may also regulate hepcidin expression without complexing with Tfr2. The role of HFE or Tfr2 in hepcidin regulation by iron is supported by genetic evidence: HFE and Tfr2 mutations in humans or mice cause hepcidin deficiency and an adult form of hemochromatosis.
FIGURE 23.2. Regulation of systemic iron homeostasis by hepcidin. Hepcidin controls the entry of iron into plasma by causing degradation of its receptor, the iron exporter ferroportin. The major iron flows that are regulated by hepcidin-ferroportin interactions include the release of iron from macrophages that recycle iron in the spleen and the liver, dietary iron absorption in the duodenum, and, at least in part, the release of iron from storage in hepatocytes. The feedback stimulation of hepcidin by plasma holotransferrin and iron stores ensures that extracellular iron concentration and iron stores stay within normal limits. Hepcidin synthesis is suppressed by erythropoietic activity, ensuring a sufficient supply of iron to the bone marrow when demand for hemoglobin synthesis is high. During inflammation, hepcidin production is stimulated and iron entry into plasma is inhibited, causing the hypoferremia and anemia of inflammation. From Ganz T. Molecular control of iron transport. J Am Soc Nephrol 2007;18(2):394-400.

The BMP pathway with its canonical signaling via Smad proteins has a central role in the regulation of hepcidin transcription. BMP receptors are tetramers of serine/threonine kinase receptors, with two type I and two type II subunits. Recent data indicate that type I subunits Alk2 and Alk3 and type II subunit ActRIIA and BMPRII are specific BMP receptors involved in iron regulation. In the liver, BMP pathway signaling to hepcidin is modulated by a coreceptor hemojuvelin and, at least in mice, by the ligand BMP6. Loss of hemojuvelin or BMP6 in mice decreases hepcidin expression and impairs hepcidin response to acute or chronic iron loading. In humans, hemojuvelin mutations result in severe hepcidin deficiency and cause juvenile hemochromatosis. No pathogenic human mutations in BMP6 have yet been identified. It remains to be clarified how BMP receptors and hemojuvelin interact with iron-sensing molecules that regulate hepcidin expression.

Two other membrane proteins, a serine protease matriptase-2 (MT-2, also called transmembrane protease serine 6, TMPRSS6) and the receptor neogenin also influence hepcidin synthesis, likely by modulating hemojuvelin concentration on the cell membrane. Whether these molecules are involved in iron sensing is unclear, but the concentration of hepatic MT-2 is acutely increased by iron deficiency. Mutations in MT-2 in humans and in mice lead to increased hepcidin expression and development of iron-restricted anemia, discussed later in this chapter.
As already mentioned, hepcidin synthesis also increases in response to stored intracellular iron in hepatocytes but the underlying mechanism is yet unclear. Hepatic BMP6 mRNA increases in response to iron loading, suggesting that BMP6 may be a mediator of intracellular iron signal. However, hepcidin increase after chronic iron loading is still observed in BMP6-deficient mice, indicating that additional pathways must play a role in hepcidin regulation by intracellular iron. Figure 23.3 summarizes our current understanding of the molecular mechanisms involved in hepcidin regulation by iron.

Hepcidin synthesis, and consequently absorption of iron and its availability for erythropoiesis, is also regulated by erythropoiesis itself. Increased erythropoietic activity due to bleeding, hemolysis, or administration of erythropoietin in humans or mice causes hepcidin suppression. Very low hepcidin concentrations are observed in patients with absolute iron deficiency anemia, or anemias with high erythropoietic activity. In turn, low hepcidin allows increased absorption of dietary iron and release of iron from stores, thus increasing iron supply to the bone marrow for hemoglobin synthesis. The mechanisms by which erythropoiesis regulates hepcidin production are not well understood, but it is thought that erythroid precursors in the bone marrow secrete a factor which exerts its effect on hepatocytes and causes hepcidin suppression.

The suppressive effect of erythropoiesis on hepcidin is particularly prominent in diseases with ineffective erythropoiesis such as β-thalassemia, where erythrocyte precursors massively expand but undergo apoptosis rather than mature into erythrocytes. The severe suppression of hepcidin, particularly in untransfused β-thalassemia, leads to increased iron absorption and the development of lethal iron overload. Growth differentiation factor GDF-15, a BMP-related protein released by erythroid precursors during cellular stress or apoptosis, may contribute to hepcidin suppression in anemias with expanded but ineffective erythropoiesis. However, GDF-15 does not seem to be involved in homeostatic hepcidin suppression by effective erythropoiesis.

FIGURE 23.3. Molecular mechanisms of hepcidin regulation. Hepcidin is regulated by iron, inflammation, and erythropoiesis, but molecular details for the latter are not understood. In the iron-regulated pathway, extracellular iron in the form of holotransferrin (HoloTf) is sensed by the two transferrin receptors (TfR1 and TfR2). Binding of HoloTf to its receptors promotes HFE interaction with TfR2 instead of TfR1, and HFE/TfR2 complex then sensitizes the BMP receptor to its ligands such as BMP6. Hemojuvelin (HJV), a membrane-linked BMP pathway coreceptor, also potentiates the BMP receptor activation. Once activated, BMP receptors initiate SMAD signaling which increases hepcidin transcription. This pathway is also modulated by matriptase-2 (MT-2) protease which cleaves hemojuvelin, and by neogenin which may augment or stabilize membrane hemojuvelin. Intracellular iron in hepatocytes also increases hepcidin expression, possibly...
through a mechanism that enhances BMP6 production, eventually leading to activation of the BMP receptor. Alternative ligands with BMP6-like activity must exist because mice that lack BMP6 still increase hepcidin mRNA in response to iron stores. Hepcidin transcription is prominently increased by inflammation, predominantly through the activity of IL-6, its receptor, and its canonical JAK-STAT3 pathway. From Ganz T, Nemeth E. Hepcidin and iron homeostasis. Biochim Biophys Acta. 2012 Jan 26 [Epub].

Hepcidin gene expression is induced in response to inflammatory cytokines, accounting for iron sequestration in the anemia of inflammation (see Chapter 45). IL-6 signaling through the STAT-3 pathway seems to be a key regulator of hepcidin expression in inflammation. Apart from increased transcription, elevated hepcidin concentrations in circulation could result from impaired renal clearance of hepcidin. Because of its small size (2.7 kDa), hepcidin is filtered through the glomerular membrane and is then taken up and degraded in the proximal tubule. A fraction of the filtered hepcidin is excreted into urine, and urinary hepcidin concentrations are proportionate to plasma hepcidin levels in healthy subjects. In chronic kidney diseases, however, hepcidin clearance is impaired, contributing to the hormone accumulation in plasma.

Regulation of Iron Absorption by Intracellular Mechanisms

In addition to the regulation by systemic signals, iron absorption is subject to local regulation by intracellular mechanisms in duodenal enterocytes. At least two mechanisms have been described: one related to the enterocyte iron levels and the other to the hypoxia pathway.

Intracellular iron levels in enterocytes (and most other cells) are sensed by two iron-regulatory proteins (IRP1 and IRP2). When cytoplasmic iron is low, IRPs bind to iron-regulatory elements (IREs), stem-loop structures located in the 5’ or 3’ untranslated regions of different mRNAs. Binding of IRPs to 3’ IREs stabilizes mRNAs by protecting them from endonucleolytic cleavage, resulting in increased protein synthesis. mRNAs which contain 3’ IREs encode iron uptake proteins such as transferrin.

P.621

receptor and a DMT1 isoform. In contrast, IRP binding to 5’ IREs blocks translation of mRNA, by preventing the interaction with the cap-binding complex eIF4F and the small ribosomal subunit, resulting in decreased protein synthesis. 5’ IREs are present in ferritin mRNA and one of ferroportin transcripts. In iron-replete cells, neither IRP binds to IREs, resulting in greater degradation of 3’ IRE-containing transcripts (e.g., TfR1), and increased translation of 5’ IRE-containing transcripts (e.g., ferritin), thus shifting the cellular phenotype from an iron-importing to an iron-storing one.

How does intracellular iron concentration modulate IRP binding to IREs? IRP1 contains a 4Fe•4S iron-sulfur cluster that, when saturated with iron, converts IRP1 to a cytosolic aconitase that catalyzes the conversion of citrate to isocitrate. In this enzyme form, IRP1 has low affinity for IREs in mRNAs. When iron-poor, IRP1 loses its aconitase activity and greatly increases its affinity for IREs. IRP2 is less abundant than IRP1 and does not have an identified enzyme function. Instead, intracellular iron levels control its degradation. In iron-replete cells, IRP2 is ubiquitinated by an iron-sensitive E3 ubiquitin ligase complex containing FBXL5 protein, and ubiquitinated IRP2 is degraded by proteasomes.

Targeted inactivation of the genes encoding murine IRPs has shed light on the roles of IRP1 and IRP2 in vivo. It is still not entirely clear why it is necessary to have two IRPs, but they may respond differently over the physiologically relevant range of oxygen tensions. There are no obvious consequences from the loss of IRP1 alone, and loss of IRP2 results in mildly abnormal iron homeostasis and iron-deficient erythropoiesis. Loss of both IRP proteins is incompatible with life. Tissue-specific knockout of both IRPs in the intestine of mice confirmed their role in the regulation of iron transport in enterocytes. These animals had higher protein levels of ferroportin and ferritin and lower protein levels of DMT1. The knockout mice also had impaired intestinal function and died within 4 weeks of birth.

Even though IRPs regulate translation of ferroportin mRNA through its 5’ IRE, duodenal ferroportin protein expression is paradoxically increased in iron deficiency. Recently, an alternative ferroportin transcript (FPN1B) was identified that could explain this phenomenon. FPN1B, which is highly expressed in the duodenum, lacks IRE and thus is not subject to translational repression by IRPs when intracellular levels are low. This ensures that the transfer of iron from absorptive enterocytes into plasma continues even when those cells are iron deficient.

Dcytb mRNA also does not contain an IRE but is strongly upregulated in iron-deficient duodenum, indicating additional regulation of transcription of iron-related genes. Hypoxia-inducible factor (HIF) transcription factors may serve as important local regulators of intestinal iron absorption. Iron deficiency induced HIF signaling in duodenum of mice, and caused increased DcytB and DMT1 expression, and an increase in iron uptake. Accordingly, targeted deletion of Hif-2α in
the intestine resulted in dramatic decrease in the expressions of DMT1-IRE and Dcytb mRNA. In vitro studies further demonstrated that HIF-2α directly binds to the promoters of DMT1 and Dcytb, activating their transcription. Thus, HIF-2α appears to be one of the critical local regulators of iron absorption.

Iron Cycle

Most functional iron in the body is not derived from daily intestinal absorption (1 to 2 mg/day) but rather from recycling of iron (20 to 25 mg/day) from senescent erythrocytes and other cells (Fig. 23.4). The most important source and destination of recycled iron is the erythron. At the end of a 4-month lifespan, effete erythrocytes are engulfed by reticuloendothelial macrophages, which lyse the cells and degrade hemoglobin to liberate their iron. This process is poorly understood, but it appears to involve the action of heme oxygenase for enzymatic degradation of heme. Some of this iron may remain stored in macrophages as ferritin or hemosiderin, but most is delivered to the plasma, and the rate of iron export is determined by the hepcidin-ferroportin interaction. In plasma, iron becomes bound to transferrin, completing the cycle. A small amount of iron, probably <2 mg, leaves the plasma each day to enter hepatic parenchymal cells and other tissues. Here, the iron is stored or used for synthesis of cellular heme proteins, such as myoglobin and the cytochromes.

FIGURE 23.4. Iron cycle in humans. Iron (Fe) enters the body through the small intestine and travels in the plasma bound to transferrin. It is delivered to the erythroid bone marrow, where it is incorporated into hemoglobin and released into the circulation in mature erythrocytes. After a lifespan of approximately 120 days, erythrocytes are engulfed by macrophages in the reticuloendothelial system. There the Fe is extracted from hemoglobin and returned to plasma, where it becomes bound to transferrin, completing the cycle. Fe in excess of tissue needs is stored in the liver.

Plasma Transport

The plasma iron-binding protein, transferrin, is a glycoprotein with a molecular weight of approximately 80 kDa. Transferrin is synthesized chiefly in the liver and actively secreted by hepatocytes, but lesser amounts are made in other tissues, including the central nervous system, the ovary, the testis, and helper T lymphocytes (T4+ subset). The rate of
Iron Delivery to Erythroid Precursors

The biologic importance of transferrin in erythropoiesis is illustrated by abnormalities observed in patients and mice with congenital transferrinemia.\(^94,95\) and \(^96,97,98\) When transferrin is severely deficient, red cells display the morphologic stigmata of iron deficiency. This occurs despite the fact that intestinal iron absorption is markedly increased in response to a perceived need for iron for erythropoiesis. Nonhematopoietic tissues avidly assimilate the non-transferrin-bound metal. Similarly, mutant mice lacking tissue receptors for transferrin die during embryonic development from severe anemia, apparently resulting from ineffective iron delivery to erythroid precursor cells.\(^98\)

Transferrin delivers its iron to developing normoblasts and other cells by binding to specific cell-surface receptors. The transferrin receptor (TFRC, TfR1) is a disulfide-linked homodimer of a glycoprotein with a single membrane-spanning segment and a short cytoplasmic segment. It is a type II membrane protein, with its N terminus located within the cell. The native molecular weight of TfR1 is \(\sim 180\) kDa. Each TfR1 homodimer can bind two transferrin molecules. Diferric transferrin is bound with higher affinity (association constant \(2\times 10^{7}\) M\(^{-1}\)) than monoferric transferrin. As a result, diferric transferrin has a competitive advantage in delivering iron to the erythroid precursors.\(^99\) Apotransferrin has little affinity for the receptor at physiologic pH but considerable affinity at lower pH, an important factor in intracellular iron release.

Transferrin receptor 2 (TfR2), which shares \(\sim 45\%\) homology with TfR1 in its large extracellular domain,\(^100\) binds transferrin with lower affinity, and its role in cellular iron uptake is unclear. TfR2 is highly expressed in the liver and, as discussed earlier in this chapter, acts as an iron sensor that regulates hepcidin expression.\(^98\) TfR2 is also expressed in erythroid precursor cells, where it interacts with the erythropoietin receptor and enhances the delivery of EpoR to cell surface.\(^101\)

The role of TfR1 is relatively well understood. TfR1 numbers are modulated during erythroid cell maturation, reaching their peak in intermediate normoblasts. Very few TfR1 molecules are found on burst-forming-unit erythroid cells, and only slightly greater numbers are found on colony-forming-unit erythroid cells. However, by the early normoblast stage, approximately 300,000 receptors are found on each cell, increasing to 800,000 at the intermediate stages. The rate of iron uptake is directly related to the number of receptors. The number decreases as reticulocytes mature, and later in maturation, erythroid cells shed all remaining receptors by exocytosis and by proteolytic cleavage.\(^102\) The shed receptors (referred to as soluble transferrin receptors, sTfR) can be found in plasma in a concentration that correlates with the rate of erythropoiesis.\(^103\) An increase in plasma sTfR is a sensitive indicator of erythroid mass and tissue iron deficiency.\(^104,105\)

synthesis shows an inverse relationship to iron in stores; when iron stores are depleted, more transferrin is synthesized, and when iron stores are overfilled, the level of transferrin decreases. Transferrin keeps iron nonreactive in the circulation and extravascular fluid, delivering it to cells bearing transferrin receptors.

Transferrin can be measured directly using immunologic techniques; and normal concentration in the plasma is approximately 2 to 3 g/L. Alternatively, transferrin is quantified in terms of the amount of iron it will bind, a measure called the total iron-binding capacity (TIBC; normal values for plasma iron and TIBC are given in Appendix A). In the average subject, the plasma iron concentration is \(\sim 18\) µmol/L (100 µg/dl), and the TIBC is \(\sim 56\) µmol/L (300 µg/dl). Thus, only about one third of the available transferrin binding sites are occupied, leaving a large capacity to deal with excess iron. Plasma iron concentration varies over the course of the day, with the highest values in the morning and the lowest in the evening. Levels of serum transferrin are more constant, and there is no apparent diurnal variation in TIBC. General practice has been to evaluate transferrin saturation using a first morning, fasting sample to standardize the results, but this may not be helpful.\(^91\)

Transferrin has two homologous iron-binding domains, each of which binds an atom of trivalent (ferric) iron.\(^92\) The iron atoms are incorporated one at a time and appear to bind randomly at either or both of the two sites. When binding is complete, the iron lies in a pocket formed by two polypeptide loops. One mole of anion, usually carbonate or bicarbonate, is taken up, and 3 moles of hydrogen ion are released for each mole of iron bound. There are functional differences between the two iron-binding sites,\(^93\) but it is not clear that these have physiologic importance.

Under physiologic circumstances, ferric iron binds to transferrin with very high affinity, with an affinity constant of \(\sim 1\)-\(6 \times 10^{22}\) M\(^{-1}\). The affinity of iron-transferrin interaction is pH-dependent, decreasing as pH is lowered. Other transition metals, such as copper, chromium, manganese, gallium, aluminum, indium, and cobalt, can be bound by transferrin but with less affinity than iron.

Transferrin can be measured directly using immunologic techniques; and normal concentration in the plasma is approximately 2 to 3 g/L. Alternatively, transferrin is quantified in terms of the amount of iron it will bind, a measure called the total iron-binding capacity (TIBC; normal values for plasma iron and TIBC are given in Appendix A). In the average subject, the plasma iron concentration is \(\sim 18\) µmol/L (100 µg/dl), and the TIBC is \(\sim 56\) µmol/L (300 µg/dl). Thus, only about one third of the available transferrin binding sites are occupied, leaving a large capacity to deal with excess iron. Plasma iron concentration varies over the course of the day, with the highest values in the morning and the lowest in the evening. Levels of serum transferrin are more constant, and there is no apparent diurnal variation in TIBC. General practice has been to evaluate transferrin saturation using a first morning, fasting sample to standardize the results, but this may not be helpful.\(^91\)

Transferrin has two homologous iron-binding domains, each of which binds an atom of trivalent (ferric) iron.\(^92\) The iron atoms P.622
After ligand and receptor interact, iron-loaded transferrin undergoes receptor-mediated endocytosis (Fig. 23.5). Specialized endocytic vesicles form, which are acidified to a pH of 5 to 6 by the influx of protons. The low pH facilitates release of iron from transferrin and strengthens the apotransferrin-receptor interaction. Released iron is reduced by an endosomal ferrireductase, STEAP3, and transferred to the cytosol by DMT1. Because DMT1 must cotransport protons with iron atoms, vesicle acidification is also important for the function of this transporter. After the iron enters the cytosol, the protein components of the endosome return to the membrane surface, where neutral pH promotes the release of apotransferrin to the plasma. Both transferrin and TFR1 participate in multiple rounds of iron delivery.

FIGURE 23.5. Cellular uptake of iron-transferrin. Iron bound to plasma Tf (HoloTf) is delivered to the cell by binding to cell-surface transferrin receptor 1 (TfR). The ligand-receptor complex enters the cell through invagination of clathrin-coated pits to form specialized endosomes. The endosomes become acidified through the entry of protons, releasing Fe\(^{3+}\) iron from Tf and strengthening the apo-Tf/TfR complex at low pH. The released iron is reduced to Fe\(^{2+}\) by STEAP3 ferrireductase and exits the endosome through the divalent metal ion transporter 1 (DMT1) to go to sites of storage and use within the cell (ferritin, mitochondria). The apo-Tf/TfR complex then returns to the cell surface, where apo-Tf is released. Both Tf and TFR participate in multiple rounds of iron delivery.

Mutations in DMT1 can have profound effect on erythroid development. Although rare, DMT1 mutations have been described in several patients with congenital iron deficiency anemia. The patients suffer from severe microcytic, hypochromic anemia, due to the inability to transport iron out of Tf/TfR1 endocytic vesicles, thus preventing iron delivery for heme synthesis. Although DMT1 is also involved in duodenal iron absorption, most of these patients develop hepatic overload at a young age, suggesting that iron absorption is at least partially intact, probably due to dietary heme absorption. Blood transfusions to correct the anemia also contribute to patients’ iron overload.

Once inside the cell, erythroid iron must be shuttled to the mitochondrion, where it will be incorporated into protoporphyrin IX by ferrochelatase, the final enzyme of heme biosynthesis. How iron that is exported from endosome
reaches the mitochondrion and is transported across the outer mitochondrial membrane is not well understood. Iron transport across the inner mitochondrial membrane seems to be mediated by mitoferrin-1, a transmembrane iron transporter. Inactivation of the mitoferrin-1 gene in mice prevents red blood cell production, underscoring the importance of this protein in erythroid biology. An alternative mechanism for iron delivery from Tf/TfR endosome to the mitochondrion has also been proposed. The “kiss and run” hypothesis suggests that the Tf-containing endosome directly contacts the mitochondrion, thereby bypassing the cytosol. The details of the mechanism remain to be determined.

P.623

The rate of iron entry into normoblasts is intimately related to heme biosynthesis. In less mature erythrocyte precursors, an optimal amount of heme may be necessary to sustain TfR1 synthesis. Furthermore, a decrease in intracellular free heme concentration induced by inhibitors of heme synthesis (e.g., isoniazid) leads to increased iron uptake, and an increase in intracellular free heme induced by inhibitors of globin synthesis (e.g., cycloheximide) has the opposite effect. These phenomena appear to reflect a feedback inhibition system that regulates the supply of iron according to the needs of the cell for hemoglobin synthesis. This is part of a highly coordinated erythroid regulatory system that acts to balance the amounts of α- and β-globin proteins and heme, avoiding toxic buildup of any intermediates of hemoglobin production.

Iron Metabolism within Normoblasts

In the normal subject, “80% to 90% of the iron that enters erythroid precursor cells is ultimately taken up by mitochondria and incorporated into heme. Most of the remainder is stored in ferritin. Granules of ferritin may sometimes be detected using the Prussian blue reaction. Normoblasts with Prussian blue-positive (siderotic) granules are called sideroblasts, and, if the granules persist after enucleation, the mature cells are called siderocytes. In normal individuals, approximately half of the normoblasts are sideroblasts, each containing less than five small granules. By electron microscopy, these normal siderotic granules are seen to be aggregations of ferritin, often surrounded by a membrane (siderosomes). Isolated molecules of ferritin not surrounded by a membrane may also be seen by electron microscopy but not with light microscopy. Another kind of sideroblast, the ringed sideroblast, is found only under pathologic circumstances (sideroblastic anemias; see Chapter 24). In the ringed sideroblast, siderotic granules form a full or partial ring around the nucleus, and electron microscopy reveals that the iron is deposited in mitochondria. The spleen plays an active role in the removal of the iron-laden mitochondria when cells enter the circulation.

It is intriguing that even though erythroid precursors require large amounts of iron and heme for hemoglobin synthesis, they have been found to express the heme exporter FLVCR and the iron exporter ferroportin. FLVCR, initially identified as the receptor for feline leukemia virus subgroup C which causes erythroid aplasia in cats, is highly expressed in early erythroid precursors. The loss of FLVCR in mice caused embryonic lethality due to the lack of definitive erythropoiesis. When FLVCR was ablated postnatally, the mice developed a hyperchromic macrocytic anemia with proerythroblast maturation arrest. These studies suggest that FLVCR is necessary for survival of erythroid precursors. Because heme is toxic to cells at high concentrations, it is thought that FLVCR functions as a safety valve to prevent accumulation of excess heme early during erythroid differentiation.

Erythroid precursors also express ferroportin but its role in erythroid maturation is yet unclear. It is interesting that erythroid cells preferentially express non-IRE ferroportin transcript during the stages of rapid iron uptake, thus avoiding any ironinduced increase in ferroportin translation dependent on the IRE/IRP system.

Macrophage Iron Recycling

Although there are many types of tissue macrophages, those that participate in the catabolism of red blood cells can be subdivided into two categories. One type, exemplified by pulmonary alveolar macrophages, is able to phagocytose erythrocytes or other cells and convert the iron they contain into storage forms, but lacks the ability to return the iron to the circulation. This type of macrophage appears to retain the iron throughout its life span. The second type of macrophage, comprising the reticuloendothelial system, acquires iron in a similar fashion but is able to return it to the plasma. The latter macrophages, found especially in the sinuses of the spleen and the liver, play a primary role in the normal reutilization of iron from destroyed red cells, allowing completion of the iron cycle shown in Figure 23.4.

After erythropagocytosis by reticuloendothelial macrophages, the red cell membrane is destroyed, heme is released from hemoglobin, and iron is liberated by heme oxygenase. The subcellular location of these events is not well defined. Subsequently, two phases of macrophage iron release are observed: an early phase, complete within a few hours after
erythrophagocytosis, and a later phase, taking place over a period of days.\textsuperscript{122} Iron is exported from macrophages through ferroportin, the iron exporter that is also found on the basolateral surface of absorptive enterocytes.\textsuperscript{28} The early phase probably reflects immediate export of iron resulting from the sequential induction of ferroportin mRNA expression by heme released from hemoglobin, and ferroportin protein translation by heme-derived iron acting via the IRE/IRP system.\textsuperscript{123} The later phase of iron release probably represents mobilization of stored iron in response to iron demand. This is likely achieved by modulating expression of hepcidin, the iron-regulatory hormone that causes degradation of macrophage ferroportin. Expression of hepcidin decreases when erythroid iron needs increase, allowing more ferroportin molecules to remain on the membrane of recycling macrophages.\textsuperscript{124} Iron exported through ferroportin must be oxidized to be bound to transferrin. The ferroxidase reaction is catalyzed by the plasma copper protein, ceruloplasmin.\textsuperscript{125} When the gene encoding ceruloplasmin was disrupted in mice, macrophages failed to release their iron at a normal rate, resulting in hypoferrremia despite the presence of normal iron stores.\textsuperscript{125} The abnormality was corrected by administering ceruloplasmin intravenously. A similar phenomenon was noted in aceruloplasminemic human subjects.\textsuperscript{126} Ceruloplasmin probably acts by catalyzing the oxidation of ferrous iron to the ferric form, which is a prerequisite for iron binding by apotransferrin.

Because of the large daily iron flux through erythrophagocytosing macrophages (20 to 25 mg), iron release from macrophages is a critical determinant of the availability of iron for plasma transferrin and, consequently, for erythropoiesis. The anemia of inflammation, also called the anemia of chronic disease,\textsuperscript{127} characterized by macrophage iron retention, illustrates the deleterious effects of perturbing the delicate balance between macrophage iron storage and release (see Chapter 45).

Intracellular iron in macrophages is stored in two compounds: ferritin and hemosiderin. Iron-free ferritin (apoferritin) exists as a sphere with a diameter of 13 nm.\textsuperscript{128} It has a hollow central cavity, 6 nm in diameter, which communicates with the surface by six channels through which iron and other small molecules can enter and leave. The protein shell is constructed of 24 molecules of two distinct ferritin subunits, designated H (for heavy or heart) and L (for light or liver), and these proteins are ubiquitously expressed. H and L ferritins are highly homologous, suggesting that they were derived from a common ancestral protein. However, there are functional differences between the two subunits. Loss of ferritin H in mice causes early embryonic lethality indicating that there is no functional redundancy between the two ferritin subunits.\textsuperscript{129} H chains contain a ferroxidase center not found in L chains and are able to oxidize iron.\textsuperscript{130,131} Ferritin shells rich in H chains reflect this property and acquire iron more rapidly,\textsuperscript{132} whereas those rich in L chains appear to be more stable and resistant to denaturation. The primary role of ferritin is cellular protection against oxidative damage that would be caused by highly reactive free iron.\textsuperscript{133}

At least 20 distinct ferritin heteropolymers, with varying proportions of L and H chains, have been isolated from human tissue.\textsuperscript{134} Fully assembled, iron-free apoferritin has a molecular weight of approximately 400 to 500 kDa. When iron is incorporated into the molecule, it is deposited in the central core. Theoretically, a single ferritin molecule could hold up to ~4,500 iron atoms. More often, molecules with 2,000 or fewer iron atoms are found. The iron is stored as a trivalent polymer of ferric hydroxide and phosphate.

Although H and L chains make up the abundant cytoplasmic ferritin molecules, a unique ferritin protein is present in mitochondria, and is encoded by a distinct intronless gene.\textsuperscript{135} Mitochondrial ferritin appears to have a ferroxidase activity, making it most analogous to H-ferritin.\textsuperscript{136} Although incompletely understood, the role of mitochondrial ferritin is important enough that it has been conserved among species and can even be found in fruit flies.\textsuperscript{137}

In a wide variety of cell types, the synthesis of apoferritin is stimulated by exposure to iron.\textsuperscript{138} This effect of iron takes place at the translational level of protein synthesis, via the IRE/IRP system described earlier in the chapter. An iron-responsive element (IRE) found at the 5’ end of ferritin mRNAs is both necessary and sufficient for the iron effect.\textsuperscript{139} In red cell precursors, hemin rather than iron itself may exert a similar function.\textsuperscript{115,140}

Apoloferitin is formed first, and iron is added later. A cytosolic iron chaperone, poly(rC)-binding protein 1 (PCBP1), delivers iron in the form of Fe\textsuperscript{2+} to ferritin.\textsuperscript{141} Iron then enters ferritin through one of the six penetrating channels. As it passes into the core, it is oxidized to the Fe\textsuperscript{3+} form by molecular oxygen, with apoferritin catalyzing the oxidative process.\textsuperscript{142} Iron is deposited irregularly and in varying amounts, forming microcrystals. Mobilization of iron from ferritin depends on iron reduction or chelation.
Ferritin is also found in plasma in small amounts (12 to 300 µg/L), and in the absence of inflammation, the circulating ferritin concentration correlates roughly with the amount of iron in stores. Plasma ferritin appears to be actively secreted into plasma, primarily by macrophages and is iron-poor compared to tissue ferritin.

Hemosiderin was formerly distinguished from ferritin on the basis of solubility and the Perls Prussian blue reaction. However, these distinctions are not reliable; as with hemosiderin, ferritin can also be stained with Prussian blue and can exist in insoluble forms. Hemosiderin is not a precisely definable chemical entity. It appears to be formed by incomplete degradation of ferritin and conglomeration of iron, ferritin proteins, and other subcellular constituents. It differs from ferritin in having a higher iron-to-protein ratio as well as being less soluble in aqueous solutions. Standard hemosiderin preparations may contain a variety of organic constituents, including proteins, lipids, sialic acid, and porphyrins. In most instances, hemosiderin appears to be derived from ferritin. Hemosiderin appears to represent a more stable and less available form of storage iron than ferritin. Newly deposited or newly mobilized iron enters or leaves the ferritin compartment. Only after prolonged storage or continued mobilization does the hemosiderin compartment change in size.

Iron Metabolism in Other Tissues

Iron is required in small amounts by all tissues for the synthesis of iron-containing enzymes and proteins, including cytochromes, catalase, ribonucleotide reductase, ferrochelatase, and globins. Cells are generally thought to acquire their iron from transferrin through binding to cell-surface transferrin receptor 1, although there is little experimental evidence that this is the major iron acquisition mechanism in most cases. Aside from erythroid precursors and tumor cells, iron uptake by hepatic parenchymal cells has been most extensively studied. Normally, approximately 5% of iron leaving plasma is accounted for by this pathway. This fraction increases markedly when transferrin saturation increases or when erythropoiesis is depressed. Transferrin is not essential for iron assimilation by hepatocytes or most other nonhematopoietic cells, as demonstrated by a transferrinemic human patients and hypotransferrinemic (hpx) mice, both of which develop marked iron overload in nonhematopoietic tissues.

The placenta also accepts iron from transferrin and may do so even at relatively low plasma iron levels, thus effectively competing with the maternal erythroid bone marrow. The export of iron from placental trophoblast into fetal circulation occurs through ferroportin, and this step is controlled by fetal hepcidin. Some iron in placenta is stored within ferritin and hemosiderin.

Skeletal muscle uses iron for myoglobin synthesis and also maintains an iron storage pool that, although large, is not easily mobilized for use by other tissues. Proliferating cells in many tissues have increased numbers of transferrin receptors compared to their quiescent counterparts, reflecting their need for iron.

IRON DEFICIENCY ANEMIA

Pathogenesis of Iron Deficiency Anemia

Although its handling is frequently termed “iron metabolism”, iron itself is not metabolized; iron disorders are of iron balance or distribution. Iron deficiency anemia, hemochromatosis, and the anemia of chronic disease/inflammation are each examples of this principle.

Three pathogenic factors are implicated in the anemia of iron deficiency. First, hemoglobin synthesis is impaired as a consequence of reduced iron supply. Second, there is a generalized defect in cellular proliferation. Third, survival of erythroid precursors and erythrocytes is reduced, particularly when the anemia is severe.

When transferrin saturation falls below ~15%, the supply of iron to the marrow is inadequate to meet basal requirements for hemoglobin production (generally ~25 mg of iron daily in average adults). As a result, the amount of free erythrocyte protoporphyrin increases, reflecting the excess of protoporphyrin over iron in heme synthesis. Globin protein synthesis is reduced and each cell that is produced contains less hemoglobin, resulting in microcytosis and hypochromia. This is the normal adaptive response to iron deficiency in humans and mice. If globin synthesis was not decreased in heme deficiency, misfolding and precipitation of excess globin chains would lead to apoptosis. Globin synthesis is controlled by heme availability at both the transcriptional and translational levels. Heme regulates globin gene expression by its ability to bind a transcription suppressor Bach1. When heme is deficient, Bach1 associates with small Maf proteins (sMafs) and causes transcriptional repression of globin genes. When heme is abundant, heme binding to Bach1 causes its dissociation from sMafs and Bach1 degradation, permitting sMaf interaction with transcriptional activators to increase expression of globin genes.

On the translational level, heme regulates globin synthesis by binding to and controlling the activity of heme-regulated eIF2α kinase (HRI). HRI functions by phosphorylating the α subunit of a key regulatory translation initiation factor eIF2 and preventing its participation in the initiation of translation. With high intracellular heme concentrations, heme binds to
HRI and renders it inactive, but in heme deficiency, heme dissociates from HRI, and the kinase is activated by
autophosphorylation. HRI then phosphorylates elf2α, preventing the recycling of elf2 for another round of protein
synthesis initiation, resulting in reduced globin protein synthesis and preventing formation of toxic globin precipitates in
the absence of heme. In Hri−/− mice, the adaptive hypochromic and microcytic response to iron deficiency was absent. In
Iron deficiency and consequently decreased heme levels instead resulted in aggregation of globins within the erythrocytes
and their precursors, causing increased apoptosis of

erythroid precursors in the bone marrow and spleen, and accelerated destruction of mature RBCs that were hyperchromic
and normocytic.

Cellular proliferation is also restricted in iron deficiency, and red blood cell numbers fall. Although there is relative
erythroid hyperplasia in the bone marrow, both the degree of erythroid hyperplasia and the reticulocyte count are low for
the degree of anemia. There is a significant component of “ineffective erythropoiesis” in iron deficiency, and a proportion
of immature erythroid cells in iron-deficient subjects are so defective that they are rapidly destroyed. Their iron is reused
within the bone marrow, making the interpretation of ferrokinetic studies more complicated.154,155

In iron deficiency, survival of circulating erythrocytes is normal or somewhat shortened.156,157,158,159 Cross-transfusion
studies indicate that the shortened survival results from an intracorpuscular defect. There is a strong correlation between
the degree to which red cell survival is shortened and the proportion of morphologically abnormal cells on blood smear.156
The principal site of destruction is the spleen.158 The reduced erythrocyte viability is associated with decreased membrane
deformability.160 This abnormality appears to result from oxidative damage to the membrane.160,161

Other iron-containing proteins are also reduced in iron deficiency, and some of these may be responsible for clinical and
pathologic manifestations. It is suggested that many of the enzymes are depleted in proportion to the degree of
anemia.162 Among the iron proteins reduced in iron deficiency are cytochrome c,162,163 cytochrome oxidase,164,165 α-
glycerophosphate oxidase,166,167 muscle myoglobin,162,163 succinic dehydrogenase, and aconitase.

In iron-deficient rats, impaired exercise performance correlated with reduced levels of α-glycerophosphate oxidase in
muscle.166,167 As a result, glycolysis was impaired, which led to lactic acidosis and, in turn, adversely affected work
performance. Lactic acidosis was also noted in a patient with severe iron deficiency anemia.168 Levels of catecholamines
are increased in the blood and urine of iron-deficient patients and animals.169,170 The increase is explained in part by
decreased tissue levels of monoamine oxidase.171,172 Conceivably, a disturbance in catecholamine metabolism may
contribute to the behavioral disturbances seen in iron-deficient children.173,174 As described later, there are several
characteristic epithelial changes in iron deficiency. The pathogenesis of these abnormalities is not understood, but it is
reasonable to assume that deficiencies in tissue iron enzymes are at fault.

Genetic Forms of Iron Deficiency Anemia

Genes involved in hereditary iron deficiency anemia are listed in Table 23.2. The main biologic and clinical difference in genetic forms of iron deficiency anemia are outlined in Table 23.3.

Several forms of genetic iron deficiency anemia are associated with hypochromic microcytic anemia and iron overload outside of the erythron. These are caused by autosomal recessive mutations in several genes and are exceedingly rare. DMT1 (SLC11A2) encodes an iron transporter involved in dietary iron absorption and iron transfer from Tf/TfR endosomes into the cytosol of erythroid precursors. Glutaredoxin 5 (GLRX5) is an enzyme involved in mitochondrial iron-sulfur cluster biogenesis. The human patients carrying these mutations have similar blood films and erythrocyte abnormalities, but also have hepatic iron overload that is not fully explained by their transfusion histories. Deficiency of serum transferrin, called hypotransferrinemia or atransferrinemia, is due to mutations in the transferrin gene itself. This interrupts iron delivery to erythroid precursors, triggering an increase in intestinal iron absorption and consequent tissue iron deposition. Deficiency of another major plasma protein, ceruloplasmin, also causes mild iron deficiency anemia associated with iron accumulation in the liver and brain. Iron deficiency results from lack of ferroxidase activity needed to mobilize iron from storage.

Some patients have congenital, iron-refractory iron deficiency anemia (IRIDA) without iron overload. The disease is caused by recessive mutations in the Tmprss6 gene, which encodes serine protease matriptase-2. This gene is mutated in a novel mouse mutant, Mask. In addition to a hair pattern that led to the strain name, Mask mice have severe iron deficiency anemia attributable to elevated hepcidin expression. Matriptase-2 is highly expressed in the liver, and acts by cleaving hemojuvelin, a BMP pathway coreceptor and a key regulator of hepcidin expression. Measurement of serum hepcidin concentrations in IRIDA patients confirmed that hepcidin levels were much higher than would be expected for the degree of iron deficiency and anemia, where hepcidin is usually undetectable. How Tmprss6 expression or activity is regulated is still unknown. Further studies will be needed to evaluate the possibility that less severe or heterozygous mutations increase susceptibility to common, acquired iron deficiency anemia. In genome-wide association studies (GWAS), common variants of Tmprss6 were associated with alterations in hemoglobin levels, serum iron, or erythrocyte volume, and suggesting that Tmprss6 has a critical role in maintenance of iron homeostasis and normal erythropoiesis.

CLINICAL FEATURES OF IRON DEFICIENCY

Stages in the Development of Iron Deficiency

When it is not a result of major blood loss, iron deficiency is the end result of a long period of negative iron balance. As the total body iron level begins to fall, a characteristic sequence of events ensues. First, the iron stores in the hepatocytes and the macrophages of the liver, spleen, and bone marrow are depleted. Once stores are gone, plasma iron content decreases, and the supply of iron to marrow becomes inadequate for normal hemoglobin production. Consequently, the amount of free erythrocyte protoporphyrin increases, production of microcytic erythrocytes begins, and the blood hemoglobin level decreases, eventually reaching abnormal levels.

This progression corresponds to three recognized stages. The first stage, also called prelatent iron deficiency or iron depletion, represents a reduction in iron stores without reduced serum iron levels. This stage is usually detected by a low serum ferritin measurement, unless inflammation is present in which case serum ferritin does not reflect storage iron. Latent iron deficiency is said to exist when iron stores are exhausted but the blood hemoglobin level remains higher than the lower limit of normal. In this second stage, certain biochemical abnormalities of iron-limited erythropoiesis may be detected, including reduced transferrin saturation, increased TIBC, increased free erythrocyte protoporphyrin, increased zinc protoporphyrin, and increased serum transferrin receptor (sTfR). The mean corpuscular volume usually remains within normal limits, but a few microcytes may be detected on a blood smear. Patients report generalized fatigue or malaise, even though they are not yet anemic.

Finally, in the third stage, the blood hemoglobin concentration falls below the lower limit of normal, and iron deficiency anemia is apparent. Iron-containing enzymes, such as the cytochromes, also reach abnormally low levels during this period. Clinical manifestations include a constellation of constitutional symptoms: fatigue, decreased exercise tolerance with tachycardia, dermatologic manifestations, decreased intellectual performance, dysphagia, depression, and restless legs syndrome. This progression forms the basis for the stages of iron deficiency outlined in Table 23.4. It has been confirmed by experiments in which normal volunteers were gradually depleted of iron by phlebotomy.

Prevalence

Iron deficiency is the most common nutritional deficiency in both developing and developed countries. Iron deficiency anemia may be defined by cutoff hemoglobin values of 12.1 g/dl in women and 13.8 g/dl in men at or near sea level, with
higher cutoff values at high altitude. In the United States, the most comprehensive surveys for iron deficiency anemia have been the National Health and Nutrition Examination Surveys (NHANES). According to data from NHANES III, covering the years 1988 to 1994, the prevalence of hypoferremia in the United States was <1% in adult men <50 years of age, 2% to 4% in adult men >50 years of age, 9% to 11% in menstruating teenagers and women, and 5% to 7% in postmenopausal women. Inasmuch as serum ferritin is an acute phase reactant regulated by inflammation, these data may underestimate the prevalence of anemia in some populations, particularly the elderly. Recent analyses have estimated prevalence of iron deficiency anemia in the elderly (>65 years of age) and extreme elderly (>75 years of age) ranging from 10% to up to 36%.

Iron deficiency is particularly common in young children and pregnant women. Iron deficiency was detected in 9% of infants and toddlers, with anemia in approximately one third of those children. In infancy, the occurrence of iron deficiency was equal in both sexes. It is usually detected between the ages of 6 and 20 months. The peak incidence was at a younger age in infants born prematurely than in those born at term, because premature infants do not have full opportunity to acquire maternal iron during the third trimester. The prevalence of iron deficiency was also higher among people living in chronic poverty. Iron deficiency tends to run in families, possibly as a result of economic factors. If an iron-deficient child is identified, the mother and siblings of that child are frequently also deficient. Despite the prevalence of iron deficiency anemia in these populations, the US preventative services task force recommends screening only for pregnant women.

Etiology

Iron deficiency occurs as a late manifestation of prolonged negative iron balance, as a result of major blood loss, or because of failure to meet an increased physiologic need for iron. The normal mechanisms for maintaining iron balance were discussed earlier in this chapter. Factors leading to negative iron balance, increased requirements, or inadequate iron for erythropoiesis are listed in Table 23.5. In many instances, multiple etiologic factors are involved. The association of a marginal diet with some source of blood loss, such as that associated with menstruation, is a common combination. Another example is hookworm infestation, which produces anemia primarily in those people whose diets are marginally adequate.

Diet

The total amount of iron in the diet roughly correlates with caloric content; in the United States, the average diet contains ~6 mg of iron per 1,000 kcal. The bioavailability of dietary iron in specific foods was described earlier in this chapter. The early stages of human evolution were characterized by hunter-gatherer food patterns and by diets rich in meat. In evolutionary terms, agriculture is a recent development to which humans have not fully adapted. Thus, individuals whose diets are rich in meat, a source of heme iron, usually absorb more iron from their diets than those who subsist on grains and vegetables. The increased prevalence of iron deficiency among the economically deprived and people in developing countries is explained in part by the fact that heme iron is less abundant in their diets.

Because many factors influence the bioavailability of iron, it is difficult to make recommendations about the optimal amount of iron in the diet. In the usual mixed diets of Western countries, adult men should consume 5 to 10 mg/day, and adult women should consume 7 to 20 mg/day. Because women are usually smaller and consume less food than men, and because their requirements are greater, their daily iron intake may be marginal. Iron deficiency is rarely seen in American men as a result of diet alone. Exceptions to this rule are sufficiently unusual to justify case reports.

In many countries, foods are fortified to compensate for the insufficient amounts of iron in the diet. Selection of the food to fortify and the iron compound to use in fortification requires consideration of a number of factors. The iron salt should be absorbable but should not affect appearance, taste, or shelf life. The salt must be chosen with consideration of the food to be fortified, and that choice must be individualized to the target population. In Western countries, wheat flour is a typical choice; its use is widespread, and highly available ferrous salts can be used in such products as bread because their shelf life is inherently short. Target foods in other countries include salt, sugar, rice, and condiments. For infants, fortified milk- or soy-based formulas and dry cereals are important sources of iron in the diet.

TABLE 23.5 ETIOLOGIC FACTORS IN IRON DEFICIENCY ANEMIA

| NEGATIVE IRON BALANCE |
Decreased Iron Intake
Inadequate diet
Impaired absorption
Achlorhydria
Gastric surgery
Celiac disease
H. pylori infection
Duodenal bypass
Drugs that increase gastric pH
Tannins, phytates, bran
Competing metals
Inflammation, ↑ Hepcidin

Increased Iron Loss
Blood donation
Iatrogenic: diagnostic phlebotomy for testing
Gastrointestinal bleeding
Intestinal parasites
Anatomic lesions: hemorrhoids, gastritis, diverticulosis, varices, hiatal hernia, Meckel's diverticulum, arteriovenous malformation, peptic ulcer
Neoplasm
Inflammatory bowel disease
Milk-induced enteropathy (infants)
Use of salicylate or nonsteroidal anti-inflammatory agents (NSAIDS)
Excessive menstrual flow
Gynecologic neoplasm
Bladder neoplasm
Epistaxis
Hemoglobinuria
Self-induced bleeding (autophlebotomy)
Pulmonary hemosiderosis
Tuberculosis
Bronchiectasis
Hereditary hemorrhagic telangiectasia
Anticoagulant, antiplatelet therapies
Chronic hemodialysis
Runner's anemia
Increased Requirements

Infancy

Lactation

Genetic Forms of Iron Deficiency Anemia

P.628

Impaired Absorption

Achlorhydria is common in iron-deficient subjects, both as a result of the deficiency and as a factor in its development.215 Gastric acid facilitates absorption of nonheme iron,216 probably by increasing its solubility rather than affecting the activity of the proton-symporter DMT1, and absorption of inorganic iron is profoundly impaired in patients with atrophic gastritis. Therapeutic measures used to reduce gastric acidity, such as the administration of antacids and drugs that block acid production, also impair iron absorption but usually not to a clinically significant degree. Gastric infection with Helicobacter pylori is now recognized as an important cause of otherwise unexplained iron deficiency anemia, which responds to eradication of the bacterial infection.217

Iron deficiency anemia is a common complication of gastric surgeries, including total gastrectomy,218 partial gastrectomy,219 and vagotomy with gastroenterostomy.220 Reduction in gastric acidity is only one factor in the impaired iron absorption that follows such operations. Other gastric secretions that aid in iron absorption may also be lost.221 Also, because most iron absorption takes place in the duodenum, the rapid intestinal transit that follows loss of the reservoir function of the stomach may lead to decreased absorption. For the same reason, iron deficiency is more common when the duodenum is surgically bypassed.220 Finally, recurrent bleeding, as well as increased sloughing of iron-containing epithelial cells, may contribute to the development of postgastrectomy anemia.221

In addition to gastrectomy, other defects in the gastrointestinal tract may lead to malabsorption of iron, contributing to the development of iron deficiency. The anemia associated with celiac disease (gluten sensitivity, sprue, idiopathic steatorrhea) is often hypochromic rather than megaloblastic222,223, in fact, iron deficiency anemia may be the initial and dominant manifestation of celiac disease, with steatorrhea detectable only by laboratory test analysis.222,224 Both malabsorption and intestinal blood loss are factors in the development of iron deficiency.223 Most patients with tropical sprue are deficient in iron.225

Copper Deficiency

It has long been known that copper deficiency is associated with abnormalities in iron metabolism and iron deficiency anemia. In recent years, it has become clear that this is due, at least in part, to the importance of the copper-containing ferroxidases ceruloplasmin and hephaestin. As mentioned earlier in this chapter, these enzymes are required for the optimal mobilization of iron from cells to plasma. They oxidize Fe^{2+} exported by ferroportin into Fe^{3+} form which can then bind to apotransferrin.

Blood Loss

Blood loss is a significant cause of iron deficiency anemia. It is important not only because of its prevalence, but also because the accurate detection, precise diagnosis, and proper management of the bleeding lesion may be of far greater importance to the ultimate well-being of the patient than repletion of iron stores. Each 1 ml of red blood cells contains ~1 mg of iron. Thus, assuming the consumption of an average diet, chronic RBC loss of as little as 1 to 2 ml/day can result in a negative iron balance.

Gastrointestinal Bleeding

Gastrointestinal bleeding is the most common cause of iron deficiency in adult men and is second only to menstrual blood loss as a cause in women. Any hemorrhagic lesion of the alimentary tract may cause iron deficiency. Most commonly, the lesions cause occult bleeding or the steady loss of small amounts of blood. They may go unnoticed or may be tolerated until the symptoms of anemia supervene. The list of etiologies presented here is not meant to be comprehensive; many other, less common, lesions have been reported to occur in association with isolated cases of iron deficiency anemia.
Two thirds of patients with hemorrhoids experience rectal bleeding, which is usually obvious to the patient. Nevertheless, a large majority of patients allow at least 1 year to elapse before seeking medical attention, and perhaps one third wait for more than 10 years. Nevertheless, although hemorrhoids are frequently associated with iron deficiency anemia, the clinician should be reluctant to accept them as the only bleeding lesions; a careful investigation is warranted because hemorrhoids may divert attention from another, less obvious, lesion elsewhere in the alimentary tract.

Upper gastrointestinal bleeding is typically due to duodenal or gastric ulcers or gastritis, all of which can cause sufficient blood loss to result in iron deficiency. Certain drugs are associated with gastrointestinal bleeding. Of these, nonsteroidal anti-inflammatory drugs (NSAIDs), including aspirin, are the most important. NSAID administration causes mucosal damage manifested by petechial hemorrhage, erosions, and ulcers. The problem is more likely to occur in elderly patients and women and with higher (“anti-inflammatory”) doses than with lower (“analgesic”) ones.

Studies with aspirin demonstrate that at doses of 2 to 6 g daily, 70% of patients have gastrointestinal bleeding at an average rate of 5 ml/day. Regular use of aspirin more often than four times weekly is associated with bleeding. The incidence of aspirin-induced bleeding has probably decreased as the pattern of analgesic use has changed. Acetaminophen, which is not associated with gastrointestinal bleeding, has become more popular than aspirin as an over-the-counter analgesic. Newer NSAID preparations are also less likely to cause significant gastrointestinal blood loss. The popularity of aspirin is on the rise again for prophylaxis of coronary artery disease, but in low doses. Other drugs associated with gastrointestinal bleeding include stanozolol, anticoagulants, antiplatelet agent therapy for coronary artery disease corticosteroids, and ethacrynic acid.

Iron deficiency anemia occurs in ~15% of patients with esophageal hiatal hernia. Anemia is particularly common (30%) with the paraesophageal variety of lesions and in large hernias. Reasons for the bleeding include reflux esophagitis and trauma to the gastric mucosa at the neck of the hernial sac. Anemia may be the presenting manifestation even in the absence of dyspeptic symptoms.

Colonic diverticuli can also bleed in patients with diverticulosis and diverticulitis. Usually, the blood loss is small and intermittent and may resemble the pattern of hemorrhoidal bleeding. Intestinal bleeding can also result from the presence of adenomatous polyps. A careful investigation for other sources of intestinal blood loss is warranted to exclude the possibility of a neoplasm.

Iron deficiency anemia may be the first sign of a malignant neoplasm of the gastrointestinal tract, and management of the bleeding lesion is important. Carcinoma of the cecum is often clinically silent until anemia occurs. Less often, in carcinomas of other parts of the colon, as well as of the stomach and the ampulla of Vater, iron deficiency anemia may be the only initial symptom.

In a survey of 32 patients with ulcerative colitis, 26 (81%) had iron deficiency anemia. Average fecal blood loss of 6 to 25 ml/day was noted in five patients who were moderately anemic with relatively mild symptoms of colitis.

An important cause of gastrointestinal blood loss in tropical areas is infection with intestinal and genitourinary parasites, including whipworm, Trichuris trichiura, hookworm, Necator americanus or Ancylostoma duodenale; and schistosomes. Hookworm is particularly important, affecting some 20% of the world's population. It is endemic in a zone extending from the southern United States to northern Argentina in the Western hemisphere, as well as in Mediterranean countries, South Asia, and Africa. The worms attach to the upper small intestine and suck blood from the host. The amount of blood lost is proportional to the number of worms harbored, which can be estimated by the fecal excretion of hookworm eggs. Female subjects harboring >100 worms (5 ml/day of blood loss) and male subjects harboring >250 worms (12.5 ml/day of blood loss) tend to become anemic. Other factors affecting iron balance including an iron-deficient diet, repeated pregnancies, and achlorhydria are contributory factors in development of hookworm anemia. At one time, many people believed that hookworm anemia resulted from elaboration of a toxin, but this is not the case. The anemia has all of the characteristics of iron deficiency and may be improved with iron therapy, whether or not the worms are removed. Conversely, removal of worms with an effective antihelminthic agent does not correct the anemia unless iron stores are replenished.

Schistosomiasis and trichuriasis are other parasitic infections associated with iron deficiency. With Schistosoma mansoni, blood loss is from the intestine, whereas with Schistosoma haematobium the loss is from the urinary tract. Trichuris (whipworm) has caused iron deficiency in inhabitants of Central America.

Menstruation
Menstrual blood loss is the most common cause of iron deficiency in women. In healthy normal women, menstrual blood flow averages ~35 ml per menstrual period, and the upper limit of normal is ~80 ml per period. Although flow varies considerably among different women, it is remarkably constant from one period to the next in the same person. In Swedish women with a dietary intake of ~10 mg of iron per day, 67% of women with menstrual blood loss >80 ml per period were anemic. In another study, British women with iron deficiency anemia lost an average of 85 ml per period. In contrast, a Canadian population with flows >80 ml per period had no overt anemia or hypoferremia.

Menstrual blood flow is increased by the use of certain intrauterine contraceptive devices and is reduced by the use of oral contraceptives. Estimating menstrual blood loss from information obtained in interviews is difficult because few women have a basis for determining the normality of their flow. It is important to elicit a history including a detailed description of the events during each menstrual period. Any of the following findings are indications of excessive menstrual flow: (a) inability to control flow with tampons alone; (b) use of more than 12 pads per period or 4 per day, unless the patient is unusually fastidious; (c) passage of clots, especially if they are larger than ~2 cm in diameter or if they persist after the first day; and (d) period duration exceeding 7 days.

Blood Donation

There are 5 million regular blood donors in the United States, and regular blood donation is an important source of iron loss. Each unit of blood donated contains 200 ml RBC equaling ~200 mg of iron. In most blood centers, a hemoglobin concentration, which is an insensitive determination for iron status, is the only indicator for iron deficiency anemia. As assessed by serum ferritin concentration, iron stores were reduced in 8% of male and 23% of female blood donors. The authors concluded that the use of iron supplements decreased the incidence of deficiency, and should be recommended to people who choose to donate more than once or twice a year. In a recent analysis of the RISE (Retrovirus Epidemiology Donor Iron Status Evaluation) study, for frequent blood donors, two thirds of women and almost half the men were iron deficient: the true prevalence among regular donors is even higher, inasmuch as the RISE study enrolled only frequent donors who had been accepted for donation, and excluded those deferred because of anemia. The unavoidable conclusion is that presently, blood collection practices fail to protect committed blood donors from iron deficiency. Re-examination of measures to prevent iron deficiency in women of child-bearing age by iron replacement after donation may now be in order to protect donors better, including changes in evaluation of iron status, in the hemoglobin standard, and internally between donations.

Alveolar Hemorrhage

Acute hemorrhage into the pulmonary alveoli may be severe enough to cause the blood hemoglobin level to fall 1.5 to 3.0 g/dl in 24 hours. Reticulocytosis and hyperbilirubinemia often accompany such episodes, leading to an incorrect diagnosis of hemolytic anemia. Iron in the shed blood is converted to hemosiderin by pulmonary macrophages, but it cannot be used for hemoglobin synthesis. Thus, repeated hemorrhages can lead to iron deficiency despite a normal total amount of body iron. Hemoptysis and alveolar infiltrates are the other prominent manifestations. However, if the hemorrhages are small, the hemoptysis may be unnoticed, making the diagnosis difficult without a chest x-ray examination. Patients may swallow the blood-containing sputum, rendering the stools positive for occult blood and resulting in further diagnostic confusion.

Idiopathic pulmonary hemosiderosis, an illness of children and young adults, is characterized by alveolar hemorrhage that is not due to another form of lung disease. Iron deficiency anemia almost invariably accompanies the disease and may be the initial and only symptom. Hemoptysis and alveolar infiltrates, however, are common manifestations. Interstitial fibrosis may develop after repeated episodes, with dyspnea, clubbing, and even cor pulmonale.

Anemia is also a common finding in antiglomerular basement membrane antibody disease (Goodpasture syndrome). The presence of renal disease distinguishes this illness from other forms of pulmonary hemosiderosis, but kidney involvement may not be evident early in the course of the disease or the degree of proteinuria or microscopic hematuria may be modest. Eventually, however, most patients develop azotemia. Focal or diffuse glomerulonephritis is evident from renal biopsy, and linear deposits of immunoglobulins are characteristic of, although not completely specific for, the disease. Detection of antibasement membrane antibodies in serum is ~80% to 85% sensitive and 98% specific for the diagnosis.

Other illnesses associated with pulmonary alveolar hemorrhage include rapidly progressive glomerulonephritis, systemic lupus erythematosus, and certain other collagen vascular diseases and systemic vasculitides. The presence of antineutrophil cytoplasm antibodies or other autoantibodies is considered a particularly poor prognostic sign in patients with pulmonary hemosiderosis. Alveolar hemorrhage is also observed as a toxic reaction to trimellitic anhydride, d-penicillamine, or lymphangiography.
Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria can result in urinary iron losses averaging 1.8 to 7.8 mg/day. Consequently, this rare disorder often is complicated by hypoferremia and hypochromic anemia. Hemoglobinuria in other disorders, such as the erythrocyte fragmentation syndromes associated with prosthetic cardiac valves, also may be complicated by iron deficiency.

Factitious Anemia

Self-induced blood-letting (autophlebotomy) is an unusual cause of iron deficiency. In almost all reported instances, such anemia occurred in unmarried women in paramedical occupations. Blood was removed by venipuncture or injuring preexisting hemorrhoids, by laceration of the gastrointestinal tract with such instruments as knitting needles, or by means that remained obscure. A single case was reported in which an infant apparently developed severe iron deficiency as a result of deliberate parental action in which all iron from the child's diet was removed.

Hereditary Hemorrhagic Telangiectasia

Hereditary hemorrhagic telangiectasia is an uncommon disorder characterized by recurrent hemorrhages from the nose, gastrointestinal tract, and other sites. Iron deficiency anemia, sometimes very difficult to control, is an important complication of the illness.

Iatrogenic Blood Loss

Diagnostic phlebotomy can result in substantial iron losses in patients with chronic disorders, particularly in hospitalized patients. In a study of 100 adult hospital inpatients in the 1980s, the average blood loss from diagnostic phlebotomy was 12.4 ml/day or 175.0 ml over the course of hospitalization on general wards. Patients in intensive care units lost an average of 41.5 ml/day or 762.0 ml during their stay. Of the 100 patients, 36 required blood transfusions, in part because of the losses from phlebotomy. Phlebotomy can contribute to a negative iron balance, and in patients with marginal iron stores, may precipitate or aggravate iron deficiency anemia and prevent compensatory erythropoiesis.

Chronic Renal Failure Treated with Hemodialysis

Iron deficiency affects a significant fraction of patients treated with hemodialysis now that the anemia related to chronic kidney disease is treated with pharmacologic agents and blood transfusions are restricted. Absolute iron deficiency results from the loss of blood associated with the dialysis process and diagnostic tests. Gastrointestinal blood losses may also be substantial, averaging 6.27 ml/day in one study. Telangiectasias are among the most common bleeding gastrointestinal lesions in patients with renal failure. Other factors contributing to negative iron balance include reduced dietary iron intake and malabsorption of iron caused by the aluminum hydroxide used to control hypophosphatemia.

Administration of erythropoiesis stimulating agents (ESA) results in a “functional iron deficiency” even when body iron stores are replete. The intense, periodic erythropoietic stimulus due to ESA therapy exceeds the mobilization of iron from macrophages, so that adequate transferrin-bound iron is not available to red blood cell precursors. For this reason, parenteral iron supplementation is often provided as an adjunct to ESA therapy in patients with ESKD.

Runner’s Anemia

Iron deficiency anemia can occur in long-distance runners. Over 50% of regular joggers and competitive runners become iron deficient. Mild mechanical hemolysis accompanies strenuous exercise, resulting in hemoglobinemia and hemoglobinuria (also called march hemoglobinuria). Gastrointestinal bleeding contributes to blood loss and iron deficiency. Fecal blood excretion increases substantially after a race or an intense training exercise and may reach 5 to 7 ml/day. Stress, intestinal ischemia, and the jarring effect of running have been advanced as possible explanations for the gastrointestinal blood loss.

Decreased Total Body Iron at Birth

Body iron concentration in normal neonates averages ~75 to 100 mg/kg weight. Similar concentrations are found throughout fetal development, resulting in a linear relationship between body iron and body weight. Newborn babies in the upper range of normal birth weights have more iron than those in the lower range. Premature infants are at higher risk of iron deficiency during the first year of life, because they have not had the full opportunity to accumulate iron stores during the third trimester of gestation.
Newborn iron levels can be influenced by the technique that the obstetrician uses to clamp the umbilical cord at delivery.\textsuperscript{275} As much as 100 ml of fetal blood may remain in the placenta with early clamping of the cord. Cord clamping delayed for only 3 minutes can result in a 58% increase in red cell volume. If delayed clamping is impractical, as in cesarean section procedures, a similar effect can be achieved by clamping the cord at the placental end, raising the clamp, and allowing gravity to drain the cord.\textsuperscript{276} Although the newborn has no immediate need for these erythrocytes, the iron they contain can be used later to meet the demands of growth.

The fetus is an effective scavenger of maternal iron, in which fetal hepcidin controls the placental transfer of iron from maternal plasma to the fetal circulation,\textsuperscript{124} therefore, maternal iron stores have little or no effect on the body iron stores of the newborn.\textsuperscript{277} No difference was found between the hemoglobin values in infants of anemic mothers and those in infants of nonanemic mothers either at birth or later.\textsuperscript{278} Furthermore, iron supplementation during pregnancy has no effect on the subsequent development of iron deficiency in the infant, although it may be protective for the mother. Finally, as measured by serum ferritin levels, maternal iron stores bear no relation to fetal stores.\textsuperscript{279} These observations are consistent with results of studies in animals that demonstrate iron transported across the placenta against a gradient, even at the expense of maternal iron stores.\textsuperscript{279}

Growth

In the absence of disease, iron requirements of an adult man are relatively low and vary little. In contrast, in infancy, childhood, and adolescence, the requirements for iron are relatively great because of the increased needs of rapidly growing tissues. The most rapid relative growth rates in human development occur in the first year of life. Body weight and blood volume approximately triple, and the circulating hemoglobin mass nearly doubles. Still greater relative growth occurs in premature and low birth-weight infants. Premature infants weighing 1.5 kg may increase their weight and blood volume sixfold and may triple the circulating hemoglobin mass in 1 year. To meet the demands imposed by growth, the normal-term infant must acquire 135 to 200 mg of iron during the first year of life. A premature infant may require as much as 350 mg in the same period.\textsuperscript{280}

The relatively slower rates of growth in children through the remainder of the first decade require a positive iron balance of \textasciitilde0.2 to 0.3 mg/day. The growth spurt that occurs in the early teens requires a positive balance of \textasciitilde0.5 mg/day in girls and 0.6 mg/day in boys.\textsuperscript{296} Toward the end of this period, the onset of menstruation occurs in girls, and their requirements then equal those of adult women.

Diet in Infancy and Childhood

Iron stores in the infant are typically depleted by 4 to 6 months of age as a result of the demands of growth. During this critical period, a normal full-term infant must absorb \textasciitilde0.4 to 0.6 mg of iron daily from the diet. To achieve this level of absorption, an iron intake of 1 mg/kg/day is recommended for full-term infants, 2 to 4 mg/kg/day for preterm infants, and at least 6 mg (to a maximum of 15 mg) for preterm infants receiving erythropoietin therapy.\textsuperscript{281} These amounts may be difficult to achieve without supplementation.

Both human milk and cow’s milk contain relatively small amounts of iron, but the infant more readily absorbs the iron in human milk. In one study, 49% of the iron in human breast milk was absorbed, compared with 10% of the iron in cow's milk.\textsuperscript{282} As a result, iron deficiency is relatively uncommon in the first 6 months of life in infants exclusively fed breast milk.

Formula-fed infants are likely to become iron deficient unless iron-supplemented formulas are used. In the United States, such formulas are often supplemented with iron (10 to 12 mg/L) as ferrous sulfate, of which a variable proportion is absorbed.\textsuperscript{281} Approximately 7% to 12% of the iron in cow's milk-based formulas is absorbed, with the lower percentage seen when formulas with higher iron content are given.\textsuperscript{283} Less iron is absorbed from soy-based formulas, but soy formulas containing 12 mg/L of iron appear to be adequate.\textsuperscript{284} Fortified dry cereals for infants are another important source of iron in the diet of both breast-fed and formula-fed infants. Currently, infant cereals are fortified with small-particle elemental iron at a concentration of 0.45 mg/g, from which \textasciitilde4% is absorbed.\textsuperscript{285} Two servings per day will supply the needs of most infants.

Excessive intake of cow’s milk is an important cause of iron deficiency in the first 2 years of life.\textsuperscript{280,286} Not only is cow’s milk a poor source of iron, it may cause gastrointestinal blood loss (see next section). In general, cow’s milk should not be given to infants <1 year of age, although it may be tolerated if the remainder of the diet is iron-rich.\textsuperscript{287} Some parents allow their toddler children to use the bottle as a pacifier and constant companion, and the children become addicted (“milkaholics”). In one study, inadequate diet was considered the only factor in the development of iron deficiency in 20 of 55 infants\textsuperscript{288};
few patients in this series had iron deficiency resulting from defective stores at birth, unless the diet was also inadequate. A unique disorder termed Bahima disease, described in Uganda, was attributed to the practice of feeding children a diet of cow’s milk almost exclusively.

Blood Loss in Infancy

Occult hemorrhage, often without obvious anatomic lesions, may be observed in some iron-deficient infants.\textsuperscript{285,290,291} The process is often accompanied by diffuse disease of the bowel with protein-losing enteropathy and impaired absorption of other nutrients.\textsuperscript{292,293} It probably results from hypersensitivity to a heat-labile protein in cow’s milk.\textsuperscript{294,295} The daily loss of 1 to 4 ml of blood, along with increased serum albumin turnover, was observed while fresh cow’s milk was consumed, and these abnormalities ceased abruptly with the substitution of heat-treated or soybean-protein feeding formulas.

Pregnancy and Lactation

Pregnancy is a major drain on the limited iron reserves of young women. Each pregnancy results in an average loss to the mother of 680 mg of iron, the equivalent of 1,300 ml of blood. An additional 450 mg of iron must be available to support the expanded blood volume during pregnancy. The latter amount of iron does not represent a net loss after delivery because the iron is returned to stores; it must be available. However, during the pregnancy or iron deficiency will supervene.

Prorated over the full term of pregnancy, the iron requirement amounts to \( \sim 2.5 \) mg/day (Table 23.6). Because most of the loss occurs during the third trimester, the requirement is small early in pregnancy and rises to as much as 3.0 to 7.5 mg/day in the third trimester. These amounts are greater than those that can be absorbed from even the best of diets, and stores may be insufficient to meet them. For this reason, iron supplementation is frequently recommended as a component of prenatal care. In the absence of supplements, maternal iron deficiency may occur, usually manifesting in the third trimester.

Lactation results in a daily iron loss of \( \sim 0.5 \) to 1.0 mg. The iron content of human breast milk is probably not affected by the maternal iron stores.\textsuperscript{296} Because normal menstruation is usually inhibited while breastfeeding continues, iron requirements in the lactating mother approximate those of the menstruating woman.

Signs and Symptoms of Iron Deficiency

The onset of iron deficiency anemia is usually insidious, and the progression of symptoms is gradual. As a result, patients accommodate remarkably well to advancing anemia and may delay a visit to their physicians for prolonged periods.

Fatigue and Other Nonspecific Symptoms

Iron deficiency anemia can be associated with irritability, palpitations, dizziness, breathlessness, headache, and fatigue. Fatigue is a particularly common complaint among patients. Even latent iron deficiency (i.e., iron deficiency without any anemia at all) has been described to result in fatigue,\textsuperscript{297} but others were unable to confirm this observation.\textsuperscript{298} Nevertheless, iron therapy has been shown to ameliorate fatigue: a group of 44 nonanemic women reporting fatigue were treated both with iron and with placebo in random order. Symptomatic improvement in women receiving iron was significantly better than that of women given the placebo, but only in women whose iron stores were depleted. In a recent randomized clinical trial of intravenous iron therapy in 90 premenopausal nonanemic women presenting with
fatigue, serum ferritin ≤50 ng/ml and Hgb ≥12 g/dl, fatigue scopes decreased significantly within 6 weeks of therapy compared to placebo, particularly in women with baseline serum ferritin ≤15 ng/ml.  

Neuromuscular System  

Despite the lack of symptoms at rest, investigators have demonstrated that even mild degrees of iron deficiency anemia impair muscular performance, as measured by standardized exercise tests. Total exercise time, maximal workload, heart rate, and serum lactate levels after exercise are all affected adversely in proportion to the degree of anemia. Furthermore, work performance and productivity at tasks requiring sustained or prolonged activity are impaired in iron-deficient subjects and improve when iron is administered. As a result, measures directed toward iron nutrition of a workforce can produce important economic dividends, more than offsetting the costs of the treatment program. Abnormalities in muscle metabolism are noted even when deficiency is mild. Blood lactate levels were measured in mildly iron-deficient female athletes after standardized exercise tests. Peak lactate levels fell significantly after 2 weeks of iron treatment. This observation led to the suggestion that iron deficiency forces the muscles to depend to a greater extent on anaerobic metabolism than occurs in normal subjects.  

Animal studies demonstrate that muscle function is disturbed in iron deficiency. The spontaneous activity level of iron-deficient rats decreased, and short-term exercise tolerance in treadmill running tests was reduced, even at mild degrees of deficiency. These abnormalities could not be explained by anemia alone, because they persisted after anemia was corrected by exchange transfusion. All were corrected promptly when iron was administered. In contrast, in a patient study no abnormalities of muscle function were noted in six nonanemic patients with long-standing iron deficiency, induced for the treatment of polycythemia vera.  

A variety of behavioral disturbances have been observed in iron-deficient children. These children have been reported to be irritable and disruptive, with short attention spans and a lack of interest in their surroundings. Neurologic development in infants and scholastic performance in older children may be impaired. Cognitive performance is defective in iron-deficient rats. All of these behavioral abnormalities are ameliorated with the initiation of iron therapy. The ability to maintain body temperature on exposure to cold is impaired in iron-deficient patients and animals. Occasional patients experience neuralgia pains, vasomotor disturbances, or numbness and tingling. In children, iron deficiency has been associated with neurologic sequelae, including developmental delay, ischemic stroke, increased intracranial pressure, papilledema, and the clinical picture of pseudotumor cerebri. The pathogenesis is probably complex, involving severe anemia, thrombocytosis, and reduced levels of tissue iron enzymes.  

Epithelial Tissues  

Patients with long-standing iron deficiency may develop a constellation of symptoms characterized by defective structure or function of epithelial tissues. Especially affected are the nails, the tongue and mouth, the hypopharynx, and the stomach. These epithelial lesions tend to occur together in the same patients at the same time but also may occur as isolated findings.  

In iron-deficient subjects, the fingernails may become brittle, fragile, or longitudinally ridged, but these findings are quite nonspecific. Alterations more typical of iron deficiency are nail thinning, flattening, and ultimately the development of koilonychia, concave or “spoon-shaped” nails (Fig. 23.6). Koilonychia is now rarely seen in clinical practice, but of 400 babies attending a wellbaby clinic in West Virginia before 1970, 5.5% had koilonychia, and nearly all of these infants appeared to be iron deficient. Koilonychia is a relatively nonspecific finding, which can also result from prolonged repeated exposure to hot soapsuds and other caustic agents.
FIGURE 23.6. Koilonychia in a 1.5-year-old child with iron deficiency anemia.
FIGURE 23.7. Tongue of a patient with iron deficiency anemia. Moderately severe papillary atrophy evident before therapy (A) and restoration after iron repletion (B). (Courtesy of R. W. Monto, Detroit, MI.)
Oral abnormalities, including atrophy of the lingual papillae, are the most common of iron deficiency-induced epithelial changes (Fig. 23.7, Table 23.7). These may present as soreness or burning of the tongue, either spontaneously or stimulated by food or drink, and by varying degrees of redness. The filiform papillae over the anterior two thirds of the tongue are the first to atrophy and may disappear completely. In severe cases, fungiform papillae also may be affected, leaving the tongue completely smooth and waxy or glistening. These changes are generally reversed after 1 to 2 weeks of iron therapy. Angular stomatitis, characterized by ulcerations or fissures at the corners of the mouth, is a less specific sign of iron deficiency, and it also occurs in riboflavin and pyridoxine deficiencies.

The association of dysphagia, angular stomatitis, and lingual abnormalities with hypochromic anemia was reported as early as the beginning of the 20th century. Dysphagia affects women more often than men and is relatively uncommon in patients younger than age 30 years. However, it has been observed in adolescents and even toddlers. Patients with sideropenic dysphagia (also known as Paterson-Kelly syndrome and Plummer-Vinson syndrome) note a gradual onset of difficulty swallowing and describe discomfort localized to the area of the neck near the cricoid cartilage. They experience dysphagia with solid foods but have little problem with liquids. If not treated, the dysphagia worsens, and ultimately the diet is so restricted that it interferes with the maintenance of balanced nutrition.

The most common anatomic lesion is a “web” of mucosa at the juncture between the hypopharynx and the esophagus. These webs, which may be multiple, usually extend from the anterior wall into the lumen of the esophagus, but they may encircle the lumen completely, forming a cufflike structure. In some patients, a benign stricture is noted, and the opening into the esophagus at the cricoid area may be reduced to the size of a pinhole or slit. Postcricoid webs may occur in the absence of documented iron deficiency, but nearly all affected patients were iron deficient in one investigative series. Both webs and strictures may be demonstrated by radiographic examination (lateral view) of the neck after barium swallow (Fig. 23.8). Multiple exposures or cineradiography are required for optimal demonstration of these abnormalities.

At biopsy, the webs appear to be constructed of normal epithelium with underlying loose connective tissue, sometimes showing a chronic inflammatory reaction. In a small percentage, hyperchromatic nuclei and increased mitotic activity are observed in the basal cell layer. Biopsy of the strictures demonstrates chronic nonspecific inflammation and degeneration of striated muscle. Carcinoma in the postcricoid area has been noted as a late complication of the syndrome in 4% to 16% of patients. For relief of the dysphagia, clinicians often must rupture the webs, dilate the stenosis, or both, although treatment with iron supplements relieves dysphagia in mild cases if the associated webs are small.

The variation in the prevalence of sideropenic dysphagia suggests that factors other than iron deficiency may contribute to oroesophageal abnormalities. Genetic factors may be important, as may some unrecognized coexisting nutritional abnormalities.

Immunity and Infection
The relationship between iron deficiency and infection is complex.\textsuperscript{326,327,328} Iron deficiency clearly results in at least two abnormalities in the immune response: defective lymphocytomediated immunity and impaired bacterial killing by phagocytes. Evidence of defective cellular immunity includes as much as a 35\% reduction in the number of circulating T cells. Both helper and suppressor T cells are affected.\textsuperscript{329} In addition, iron-deficient subjects do not respond as well as normal subjects to certain skin test antigens, such as to Candida, diphtheria, and Trichophyton. These abnormalities can be corrected by the administration of iron. No abnormalities have been noted in testing with tuberculin or dinitrochlorobenzene. Ribonucleotide reductase is an iron-containing enzyme required for the synthesis of DNA for cell division. Some authors have suggested that reduced levels of this enzyme might lead to impaired ability of the T cells to proliferate, thereby accounting for the defects in cell-mediated immunity, but others have reported changes in cytokine production in iron-deficient patients.

\includegraphics[width=\textwidth]{image}
\caption{Esophageal web (arrows) in Plummer-Vinson syndrome.}
\end{figure}

The nitroblue tetrazolium dye test of phagocyte function yielded abnormal results in iron-deficient children, and the abnormality could be corrected by iron administration.\textsuperscript{330,331} Furthermore, a decrease in the magnitude of the “oxidative burst” accompanying phagocytosis was observed.\textsuperscript{332} Finally, killing of several types of pathogenic bacteria by neutrophils was defective.\textsuperscript{330,333}
The sequence of changes in neutrophil function was studied as iron deficiency developed in rats. Myeloperoxidase activity was reduced to a greater extent and responded more slowly to iron therapy than did defects in the oxidative burst.  

Because the oxidative burst is considerably more important in bacterial killing than is myeloperoxidase, the observations suggest that the neutrophil conserves its most important function as the deficiency develops. The defect in the oxidative burst could be demonstrated only with the use of agents that induced phagocytosis; no defect was noted when the burst was stimulated by soluble agents. Thus, phagocytosis, rather than the oxidative burst itself, may be at fault.

In experiments in an iron-deficient mouse model, lack of hepcidin was responsible for the high inflammatory response to lipopolysaccharide treatment. Taken together, these abnormalities provide a basis for an expectation that resistance to infection may be impaired in iron deficiency. However, a clinically relevant relationship between states of iron deficiency and susceptibility to infections remains controversial. Conversely, considerable data suggest that iron deficiency and iron sequestration by binding proteins protect against infection by depriving the invading organisms of the metal. Thus, optimal immune function is highly dependent on iron balance; both iron-deficient and iron overloaded hosts are at higher risk for infection.

Pica

Pica is a striking symptom of iron deficiency. Hippocrates wrote that a “craving to eat earth” was associated with “corruption of the blood.” Abnormal eating patterns were also a prominent manifestation of chlorosis. Pagophagia, defined as the purposeful eating of at least one tray of ice daily for 2 months, is a common form of pica. In one study, the ingestion of ice averaged nearly 2 kg/day, and some patients ate an astounding 4 to 9 kg/day. This dramatic symptom was relieved within 1 to 14 days after iron was administered. Another study found that pagophagia was a symptom of iron deficiency in 23 of 38 consecutive adult patients, and iron therapy was curative. Pica is especially striking when the patient consumes bizarre, nonfood substances.

Skeletal System

Changes in the skull similar to those found in association with thalassemia or chronic hemolytic anemia have been reported in children with iron deficiency anemia of long duration. The diploic spaces may be widened, and the outer tables thinned, at times with vertical striations producing a hair-on-end appearance. In addition, abnormalities of the long bones are noted, especially the metacarpals and phalanges, with expansion of the medulla and thinning of the cortices. These changes likely result from expansion of the erythroid marrow during bone growth and development.

LABORATORY EVALUATION

Complete Blood Count and Peripheral Smear

The severity of anemia depends on the presenting circumstances of iron deficiency. If discovered when the patient is being evaluated for preadmission testing for elective surgery (Fig. 23.9), or for an underlying or unrelated disease, the anemia can be mild to moderate (Hgb 8 g/dl to 12 g/dl). If symptoms of anemia are the presenting complaint, the blood hemoglobin level may be 8 g/dl or lower.

Anisocytosis is an important early sign in iron deficiency and one that has differential diagnostic value when quantified. The red cell distribution width (RDW) is increased in iron deficiency, and this often is useful in distinguishing iron deficiency from thalassemia trait conditions in which the RDW is normal. Both the percentage and the absolute number of reticulocytes may be normal or slightly increased. In experimentally induced iron deficiency in certain animal species, including rats, mice, and pigs, reticulocytosis is pronounced. The chief finding on blood smear is

P.634
hypochromia, observed as an increase in the size of the region of central pallor (Fig. 23.10). The more severe the anemia, the more severe the hypochromia and the greater the percentage of erythrocytes affected. When hypochromia is extreme, most of the red blood cells appear as mere rings. Tiny microcytes and a moderate number of poikilocytes, particularly tailed and elongated elliptical forms (pencil cells), are also found. In almost all instances, however, a variable number of well-filled red corpuscles are present, and some macrocytes, often polychromatophilic, can be distinguished. The mean corpuscular volume and mean corpuscular hemoglobin values are reduced in most patients, and the mean corpuscular hemoglobin concentration is reduced in long-standing or severe disease. The degree of change in the red cell indices is related in part to the duration and in part to the severity of the anemia. In mild iron deficiency of short duration, the indices may be within normal ranges.

Iron-related Indices

The laboratory diagnosis of absolute iron deficiency has traditionally been based on low serum iron, low percent transferrin saturation, and low ferritin. However, it has long been known that inflammation can mimic some aspects of iron deficiency by impairing the utilization of existing iron stores for red cell production, and inducing an iron-sequestration syndrome and hypoferremia. The molecular mechanisms that underlie the redistribution of iron during inflammation are discussed in Chapter 45, but may center on cytokine-stimulated overproduction of hepcidin, particularly IL-6.

Serum ferritin has the potential to differentiate true iron deficiency from inflammatory iron sequestration. However, both inflammation and intracellular iron accumulation stimulate the production of the iron storage protein ferritin whose soluble form is detectable in plasma and serum. Therefore, interpretation of serum ferritin in patients with inflammation due to comorbidities is more challenging. The generally accepted cut-off level for serum ferritin to indicate absolute iron deficiency has been ≤12 ng/ml. However, studies correlating the presence or absence of stainable iron with serum ferritin in patients and in normal individuals, and also patients with anemia responsive to iron therapy, indicate that this threshold level of ferritin had only a sensitivity of 25% for detecting iron deficiency. The sensitivity could be improved to 92%, with a positive predictive value of 83%, by using a diagnostic cutoff value of ≤30 ng/ml.

The differentiation among absolute iron deficiency, functional iron deficiency, and iron-sequestration syndromes (Fig. 23.11) is important for patient management. Functional iron deficiency is manifest by a fall in iron saturation either during endogenous erythropoietin-stimulated erythropoiesis, or with initiation of ESA therapy even in normal volunteers with adequate iron stores. The manifestation of functional iron deficiency is reduced transferrin saturation, as illustrated in Figure 23.12. Absolute iron deficiency may be the presenting sign of occult blood loss from gastrointestinal lesions including malignancy, whereas an iron sequestration phenotype is indicative of an underlying inflammatory disorder. Commonly used laboratory tests such as serum iron, total iron-binding capacity, mean corpuscular volume, transferrin saturation, and ferritin provide limited diagnostic value.

Increased soluble transferrin receptor (sTfR) has been reported to be an indicator of iron deficiency, because sTfR is released by erythropoietic precursors in proportion to their expansion, and is not increased by inflammation. However, this assay was found to have a specificity of 84% and a positive predictive value of only 58% in a population of patients likely to be typical of the most difficult diagnostic environments for assessing iron status. Interpretation of increased sTfR therefore may be challenging, even in the absence of known causes of increased erythropoiesis other than iron deficiency. Similarly, attempts to combine ferritin and sTfR results (sTfR/log ferritin) still fall short when analyzed for diagnostic sensitivity and specificity, and must be corrected for acute phase reactant changes in the setting of inflammation.
FIGURE 23.10. Blood smear from a patient with microcytic anemia due to iron deficiency. (Courtesy of Irma Pereira MT [ASCP]SH.)
FIGURE 23.11. Iron deficiency states. The relationships between absolute iron deficiency, iron sequestration, and functional iron deficiency are illustrated. Patients can have one or more combinations that all result in iron-restricted erythropoiesis. (From Goodnough LT. Transfusion. 2011 Dec 12 [Epub].)

FIGURE 23.12. The impact of endogenous erythropoietin-mediated erythropoiesis or ESA (erythropoiesis stimulating agent) mediated erythropoiesis, on iron saturation. Patients undergoing autologous blood donation prior to elective
orthopedic surgery are shown at baseline and after treatment with placebo or one of two doses of recombinant human erythropoietin (rHuEPO) at each visit during the donation period. All patients received supplemental oral iron. Mean transferring saturation in 24 patients receiving placebo (Δ), 300 U per kg rHuEPO (Z), or 600 U per rHuEPO (θ). (From Mercuriiali F, Zanella A, Barosi G, et al. Use of erythropoietin to increase the volume of autologous blood donated by orthopedic patients. Transfusion 1993;33:55-60.)

The development of sensitive, accurate, and reproducible immunoassays and mass-spectrometric assays for human hepcidin has allowed detailed definition of physiologic and pathologic changes of hepcidin in healthy volunteers and in patients. In contrast to ferritin, changes in hepcidin concentrations are frequently the cause of, rather than the result of, iron disorders. Measurements of hepcidin may be useful for diagnosing absolute iron deficiency or differentiating it from iron-sequestration syndromes. In absolute iron deficiency, serum hepcidin concentrations are very low. Low hepcidin would also identify patients most likely to respond to iron therapy. In iron sequestration syndromes, on the other hand, hepcidin would be expected to be high as the pathogenic mediator of iron restriction in inflammation. In patients with mixed presentations, hepcidin may be regulated by opposing stimuli and its levels tend to be variable. For example, in conditions with mixed iron deficiency and inflammation, hepcidin may be low, normal, or elevated depending on the degree of iron deficiency or inflammation. In resistance to ESA therapy due to chronic kidney disease, hepcidin levels may be high because of decreased hepcidin renal clearance and possibly inflammation. In the absence of inflammation, in conditions of accelerated erythropoiesis due to endogenous erythropoietin or ESA stimulation, hepcidin levels will be low. Thus in patients with mixed conditions, hepcidin levels may not help treating physicians arrive at a definitive diagnosis but may give guidance in identifying patients who are likely to respond to iron (oral vs. IV) therapy (i.e., hepcidin levels are low with marginal storage iron or accelerated erythropoiesis). More complex algorithms will need to be developed and tested to provide optimal guidance in the evaluation and management of anemia. Expected changes in hepcidin levels and iron parameters in various clinical conditions, in iron therapy strategies, and in the potential use of hepcidin-targeted therapies in patients with various forms of anemia, are summarized in Table 23.8.

From Goodnough LT. Iron deficiency syndromes and iron-restricted erythropoiesis. Transfusion. 2011 Dec 29 [Epub].

Clinically, it would be helpful to detect the earliest changes in red cell indices that reflect iron-restricted erythropoiesis. One approach would be to identify newly formed iron-deficient cells when they are released from the bone marrow as reticulocytes. Flow cytometric analysis of reticulocytes allows determination of reticulocyte hemoglobin content.
(CHr)\textsuperscript{365,366} or percentage of hypochromic reticulocytes (% HYPO).\textsuperscript{367} As illustrated in Figure 23.13, this approach can also identify functional iron deficiency in iron-replete volunteers receiving ESA therapy.\textsuperscript{368} The % HYPO measure is regarded as a time-averaged marker of iron-restricted erythropoiesis (20 to 120 day), whereas the CHr measure is a real-time parameter (48 hours).\textsuperscript{369} Many existing laboratory analyzers are capable of measuring CHr but may require modification with software patches.

Leukocytes and Platelets

The leukocytes are usually normal in number, but mild granulocytopenia may occur in long-standing cases of iron deficiency. Recent large-volume hemorrhage may cause a slight neutrophilic leukocytosis, and occasional myelocytes may be found in peripheral blood. In iron deficiency due to parasitic infestation, eosinophilia may be present.

Thrombocytosis commonly accompanies iron deficiency.\textsuperscript{370} The platelet count often increases to approximately twice the normal level, and values return to normal after iron therapy. The cause of the thrombocytosis of iron deficiency is unknown.

Bone Marrow

Macrophage iron is absent or severely reduced in the marrow, spleen, and liver of iron-deficient subjects. Fewer than 10% of the marrow normoblasts are sideroblasts. In addition, the iron-deficient bone marrow is characterized by mild to moderate erythroid hyperplasia. There may be striking nuclear distortions, resembling those found in dyserythropoietic anemias.\textsuperscript{371} Karyorrhexis and nuclear budding are particularly common, but multinuclearity, nuclear fragmentation, and even intranuclear bridging may be observed. The individual normoblasts appear small and may have scanty cytoplasm,
often with irregular ragged borders. When therapy is given, erythroid hyperplasia initially increases, but as erythropoiesis is restored to normal, the cellularity of the marrow likewise becomes normal.

MANAGEMENT OF IRON DEFICIENCY

Management is primarily focused on repletion of iron stores. Most of the time, this therapy is straightforward, simple, and inexpensive. The response to treatment is predictable and gratifying. There is, however, an important caveat: correction of the iron deficiency is only part of the task confronting the clinician. Particularly in older adults, iron deficiency may be an early sign of a serious illness, such as an occult gastrointestinal malignancy. Clearly, correction of the anemia without recognition and treatment of a possible underlying disease is poorly practiced medicine. The cause of iron deficiency anemia can be identified in the great majority of cases. Once an etiologic diagnosis is made, appropriate therapy can begin.

Iron can be administered orally or intravenously. The oral route is the safest and least expensive. It is important to note that therapeutic doses are quite different for oral and intravenous preparations. Most iron-deficient patients respond well to oral therapy, but intravenous administration of iron may sometimes be required.

Oral Iron Therapy

The most common preparation used orally is ferrous sulfate, which has been a mainstay of treatment for iron deficiency since it was first introduced by the French physician Pierre Blaud in the 19th century. It is effective, reasonably well tolerated, and inexpensive. If equivalent amounts of elemental iron are given, ferrous gluconate and ferrous fumarate are equally satisfactory and have approximately the same incidence of side effects. Although iron deficiency clearly promotes increased absorption, individual variations are great, and absorption may be vastly different at varying degrees of anemia and in the presence of complicating illnesses.

The dose is best calculated in terms of elemental iron. For adults, the optimal response occurs when ~200 mg of elemental iron is given orally each day. The usual ferrous sulfate tablet (325 mg) contains ~65 mg of elemental iron. Iron is absorbed more completely when the stomach is empty; when iron ingestion occurs after or with a meal, absorption decreases substantially. However, gastrointestinal irritation is common when the stomach is empty. Consequently, patients are frequently advised to take oral iron immediately after or even with a meal. The gain in patient acceptance may be more important than the reduced absorption of iron. However, it is important to remember that, whereas absorption is enhanced by the presence of orange juice, meat, poultry, and fish, other substances such as cereals, tea, and milk inhibit it. This is particularly important in toddlers, because administration of oral iron with milk often compromises therapy.

For iron-deficient children, the optimal dosage is 1.5 to 2.0 mg elemental iron per kilogram of body weight given orally three times per day. Palatable elixirs and syrups are the most satisfactory pediatric preparations, although they can stain the teeth if not given carefully. Children usually tolerate this form of therapy on an empty stomach.

In adults, a 200-mg daily oral dose produces a maximal rate of hemoglobin regeneration. However, the maximal rate is not necessarily the only legitimate therapeutic goal. If the underlying disease has been corrected and the anemia is mild to moderate, a slower rate of response may be acceptable. Thus, if such patients cannot tolerate 200 mg/day of elemental iron, it is reasonable to reduce the dose to 100 mg/day. Because less iron is given, tolerance improves. In this circumstance, speed of response is exchanged for increased patient compliance, although it may be necessary to treat for longer. Regardless of the form of oral therapy used, treatment should be continued for at least 3 to 6 months after the anemia is relieved. If treatment does not continue, relapse is common. The continued therapy allows for repletion of iron stores.

Side Effects of Oral Iron Therapy

Some patients given oral iron report gastrointestinal symptoms, including heartburn, nausea, abdominal cramps, and diarrhea. However, functional gastrointestinal symptoms are common in the general population, and patients may incorrectly ascribe them to iron treatment. In one double-blind study, ferrous sulfate, ferrous gluconate, ferrous fumarate, and placebo were administered in identically appearing tablets. No significant differences were found among the three iron salts. Approximately 12% of subjects had symptoms that could reasonably be ascribed to iron ingestion. Often, tolerance of iron salts improves when a small dose is given at first and increased over the course of several days to the full dose. A polysaccharide-iron complex is marketed that is alleged to be as effective as ferrous sulfate while causing fewer side effects. The question of whether it is as well absorbed as ferrous sulfate has not been definitively resolved.

Enteric-coated preparations are designed to reduce side effects by retarding dissolution of the iron. However, this effect may markedly decrease absorption, especially in achlorhydric individuals, whose gastric juice cannot dissolve the coating.
Failure of Oral Iron Therapy

Clinicians often encounter patients said to have iron deficiency anemia unresponsive to oral therapy. The most common explanations for failure to respond to oral iron include (a) incorrect diagnosis, (b) complicating illness, (c) failure of the patient to take prescribed medication, (d) inadequate prescription (dose or form), (e) continuing iron loss in excess of intake, and (f) malabsorption of iron.

In managing a problem of alleged failure to respond to iron, it is important to review the data on which the diagnosis of iron deficiency anemia was based and to take note of any laboratory procedures that might have yielded erroneous information. At times, even though iron deficiency is present, a coexisting cause for anemia may impair response. Examples are iron deficiency as a complication of the anemia of inflammation in rheumatoid arthritis, H. pylori infection, as well as so-called dimorphic anemia, in which iron deficiency and pernicious anemia coexist.

In some patients, blood loss is so great that oral iron therapy cannot keep up with it. If this situation is not correctable (e.g., in the case of hereditary hemorrhagic telangiectasia), parenteral therapy must be given. Finally, rare patients may be unable to absorb iron. This is unusual; even patients with sprue or total gastrectomy are usually able to absorb adequate amounts of ferrous sulfate. Patients with iron-refractory iron deficiency syndrome (IRIDA) have a mutation in the protease TMPRSS6 causing increased hepcidin production and are refractory to oral iron therapy but partially responsive to intravenous iron therapy.

In individuals who are compliant with oral therapy and not actively bleeding, but still poorly responsive to treatment, addition of ascorbic acid (usually 500 mg twice a day) may improve iron absorption and the hemoglobin response. Subclinical ascorbic acid deficiency has been suggested as an etiology of refractory iron deficiency anemia.

Even under the best of circumstances, oral iron supplementation is poorly tolerated and patients may be noncompliant, not only from side effects of oral iron but because of their diagnosis or the therapy they are undergoing for their disease. Nevertheless, in stable patients with mild to moderate anemia in which there is some time for management strategies, and particularly in those patients in whom diagnostic laboratory testing has not definitively ruled out iron-restricted erythropoiesis, a therapeutic trial of oral iron therapy can be recommended. In general, absorption of oral iron inversely correlates with hepcidin levels. Thus, hepcidin measurements may help to determine a priori which patients are good candidates for oral iron therapy. Exceptions may be patients who malabsorb iron because of damage to the intestinal lining such as in celiac disease, and in patients undergoing treatment with proton-pump inhibitors.

In a study of patients with anemia, 5 of 54 who had bone marrow examinations had absent iron stores indicating absolute iron deficiency. There were an additional eight patients who were categorized as iron deficient because of their response to oral iron therapy; half of these had serum ferritins >12 ng/ml and one of the patients had a serum ferritin >100 ng/ml. This analysis suggests that in the absence of a diagnostic bone marrow examination, it is difficult to rule out iron deficiency confidently, and an empiric trial of iron therapy may be desirable to identify patients who have absolute iron deficiency for successful patient management, because it may be a sign of serious underlying illness, including malignancy.

Failure to respond to a trial of oral iron therapy does not rule out iron-restricted erythropoiesis or even true iron deficiency in the setting of inflammation, as inflammatory hepcidin elevation would cause impaired iron absorption. Furthermore, ongoing blood (and iron) losses may exceed even maximal gastrointestinal absorption of iron. Clinical situations are often complex, and blood loss, iron-restricted erythropoiesis and high hepcidin levels can coexist in patients in whom absorption of dietary or oral iron supplements is impaired. In these instances, and in circumstances of ongoing blood loss, intravenous iron therapy may be needed either as a diagnostic trial or as definitive therapy.

Intravenous Iron Therapy

Therapy with ESAs in management of the anemia of chronic renal failure has led to substantial clinical experience in supplemental intravenous iron therapy in this setting. Hyporesponsiveness to ESA therapy is a common phenomenon due to a variety of comorbid conditions, but particularly related to functional iron deficiency. Patients with anemia undergoing dialysis may show suboptimal or no response to oral iron therapy for several reasons.
During ESA therapy, although absorption of iron can increase up to fivefold, presumably due to hepcidin suppression by increased erythropoiesis, ongoing external iron losses due to hemodialysis and blood testing can exceed the intake. Furthermore, some patients have poor compliance with iron therapy or significantly reduced gastrointestinal iron absorption. Absorption of oral iron can be enhanced with ascorbate by at least 30%, because it prevents formation of insoluble and unabsorbable compound and reduces ferric iron to ferrous iron. Iron absorption and release from stores may be impaired due to high hepcidin levels from diminished clearance by the kidneys, not completely corrected by routine hemodialysis, as well as from inflammation.

IV iron administration is recommended in renal dialysis patients undergoing ESA therapy. Patients treated with IV iron (100 mg twice weekly) achieved a 46% reduction in ESA dosage required to maintain hematocrit (Hct) levels between 30% and 34%, compared to patients supplemented with oral iron. To further address the management of iron-restricted erythropoiesis in CKD patients undergoing dialysis, a randomized controlled trial evaluated the efficacy of IV iron supplementation in patients with ferritin between 500 and 1,200 ng/mL. The administration of IV iron (and increasing the dose of ESA by 25%) resulted in a greater correction of anemia compared with increasing the dose of ESA alone. After the end of the trial, there was greater success in reducing the dose of ESA in the patients receiving IV iron, compared to the non-iron-treated arm.

IV iron therapy also improves responses to ESA therapy in patients with inflammatory bowel disease compared to responses in a similar patient group who received oral iron supplementation. Decreased reticulocyte hemoglobin (CHr) is an indicator of the inadequacy of iron supply in the face of increased iron demand stimulated by ESA therapy. The requirement for a kinetic balance between iron delivery and level of erythropoietin stimulation may explain the need for intravenous iron supplemental therapy in ESA-treated patients, even those with replete iron stores. The clinical response to the combination of IV iron and ESA therapy may be attributed to the ability of the parenteral route to circumvent the inflammation-induced block to intestinal iron absorption and deliver a large dose of iron to the reticuloendothelial system, which could increase iron efflux from macrophages, perhaps by increasing the translation of ferroportin mRNA.

Currently approved intravenous iron preparations are listed in Table 23.9. The risk-benefit profile of IV iron continues to undergo evaluation in renal dialysis patients, as well as in patients with anemia of chronic diseases. IV iron can allow up to a fivefold greater erythropoietic response to significant blood loss anemia in normal individuals. A greater rate of red cell production is probably not possible unless red marrow expands into yellow marrow space, as is seen in patients with hereditary anemias. One potential limitation to IV iron therapy may be that much of the administered iron ends up in the reticuloendothelial system as storage iron, from where it is not readily available for erythropoiesis, particularly if hepcidin concentrations are elevated. However, for patients with iron deficiency, 50% of IV iron is incorporated into hemoglobin within 3 to 4 weeks. For patients with anemia of chronic disease or renal failure, IV iron is mobilized less rapidly from the reticuloendothelial system. Nevertheless, when iron dextran was given intravenously to patients with the anemia of rheumatoid arthritis, cellular hemoglobin concentrations increased significantly.

*Not approved in the United States.

Note: Ferric gluconate and iron sucrose are also referred to as iron salts.

TDI, total-dose infusion.

In patients with malignancy and chemotherapy-induced anemia, five trials have studied IV iron in the setting of therapy with ESAs. In one study of patients undergoing chemotherapy, 155 patients were treated with ESA and randomized to receive either no iron; oral iron as 325 mg if ferrous sulfate twice daily; 100-mg boluses of IV iron dextran weekly until the total calculated iron deficit was administered; or a single of IV iron dextran to the same calculated dose. There were significant improvements in hemoglobin levels and hematopoietic responses in both patient groups treated with IV iron arms, compared to those receiving oral iron or no iron therapy.

Another study assigned 189 patients to receive ESA weekly plus no iron, oral iron as 325 mg of ferrous sulfate thrice daily, or IV ferrous gluconate as 125 mg weekly boluses. The cohort treated with IV iron had improved hemoglobin and hematopoietic responses compared to the other cohorts. A third study randomly assigned 67 patients with lymphoproliferative malignancies not receiving chemotherapy with IV or no iron. Again, IV iron resulted in improved hemoglobin and hematopoietic responses. A fourth study of 398 patients with chemotherapy-induced anemia who were treated with ESA therapy, found significant improvement in hemoglobin levels and hematopoietic responses in the patient cohort treated with IV iron, further confirmed by a fifth study.

Iron-restricted erythropoiesis has been shown to be a consideration at time of cancer diagnosis even before ESA therapy: 17% of carefully screened patients were found to have serum ferritins <100 ng/ml and 59% had transferrin saturations (TSAT) less than 20% at diagnosis. Additionally, renewed attention has been placed on the dose-response relationship between ESA dosage and red cell production responses in ESA-treated patients. Once ESA therapy is administered, even subjects with normal baseline levels develop TSAT and ferritin decreases to levels indicating iron-restricted erythropoiesis. Accordingly, guidelines by the National Comprehensive Cancer Network (NCCN) have recommended that iron studies be obtained at baseline in order to identify patients who are candidates for supplemental iron therapy, and that if subsequent hemoglobin levels after 4 weeks of ESA therapy indicate no response (<1 g/dl increase in hemoglobin), then IV iron supplemental therapy should be considered, along with an increase in ESA dose.
Despite these beneficial effects in treatment of iron deficiency, intravenous iron administration may generate oxidative stress and other inflammatory changes. A mouse model showed that red cell transfusion of aged blood resulted in oxidative stress and inflammatory cytokine secretion in response to macrophage-internalized iron from membrane-encapsulated hemoglobin, but not from stroma-free lysate derived from stored red cells. Long-term effects of the intravenous iron preparations will require careful study in relevant clinical settings.

The hypoferremia and anemia of inflammation can be viewed as a mechanism of defense against providing iron to unwanted pathogens, and therefore adaptive. On the other hand, others are not convinced that iron deficiency or iron-restrictive anemia should be regarded as a desirable condition that benefits patients with infection or inflammation. Although more evidence is clearly needed, in patients who show symptoms attributable to moderate or severe anemia of inflammation, and who do not suffer from overwhelming or difficult to control infection, iron-restricted erythropoiesis can and should be treated, an argument that is not new. In iron-restricted anemias other than absolute iron deficiency, the optimal treatment is still evolving and may be improved by the ongoing development of hepcidin-targeted therapies.

Important clinical subjects for further study in this area should include improving the diagnosis of various forms of iron-restricted anemia in complex clinical settings, testing optimal combinations of ESA and IV iron treatments, analysis of the relative risk-benefits of ESA and IV iron therapy, and the appropriate use of adjuncts such as anti-inflammatory therapy or frequent dialysis. Basic scientific insights that could facilitate the progress in this area include understanding the molecular nature of the erythropoietic iron regulator and suppressor of hepcidin, details of the mechanisms by which circulating and stored iron regulates hepcidin, the contribution of hepcidin-independent mechanisms to anemia of inflammation, and the role of genetics in sporadic iron deficiency.

Side Effects of Parenteral Iron Therapy

Side effects may be local or systemic. With intravenous injection, rates of administration greater than 100 mg/minute are associated with pain in the vein injected, flushing, and a metallic taste. Such reactions are brief in duration and relieved immediately by slowing the injection. Systemic reactions may be either immediate or delayed. Immediate side effects include hypotension, headache, malaise, urticaria, nausea, and rare anaphylactoid reactions, particularly to iron dextran. Delayed reactions include lymphadenopathy, myalgia, arthralgia, and fever. Most of the reactions are mild and transient, but the anaphylactoid reactions may be life-threatening. For iron dextran therapy, the clinician should be prepared for the possibility of anaphylaxis by having epinephrine, oxygen, and facilities for resuscitation available. Sodium ferric gluconate, iron sucrose, and iron saccharates are generally better tolerated than the iron-dextran complex, as long as the recommended dosages are not exceeded.

Response to Therapy

When specific iron therapy is given, patients often show rapid subjective improvement, with disappearance or marked diminution of fatigue, lassitude, and other nonspecific symptoms. This response may occur before any improvement in anemia is observed. Similarly, pica has been reported to be relieved within 1 week of therapy.

The earliest hematologic evidence of response to treatment is an increase in the percentage of reticulocytes and their hemoglobin content. The reticulocytes attain a maximal value on the fifth to tenth day after institution of therapy and thereafter gradually return to normal. The maximal value usually ranges from 5% to 10% and is inversely related to the level of hemoglobin. The reticulocyte response may not be detectable in mild iron deficiency anemia.

The blood hemoglobin level is the most accurate measure of the degree of anemia in iron deficiency. During the response to therapy, the red cell count may increase temporarily to values above normal, but the hemoglobin value lags behind. The red cell indices may remain abnormal for some time after the normal hemoglobin level is restored. As recovery occurs, a normocytic cell population gradually replaces the microcytic cell population, and one of the early signs of response to therapy is an increase in the RDW from pretreatment levels. When treatment is fully effective, hemoglobin reaches normal levels by 2 months after therapy is initiated, regardless of starting values.

Of the epithelial lesions in iron deficiency, those affecting the tongue and nails are the most responsive to treatment. After 1 to 2 weeks, small regenerating filiform papillae are observed. After 3 months, the tongue has usually returned to normal; however, in patients with severe anemia, some atrophy may persist. Koilonychia usually disappears in 3 to 6 months, with the concavity moving toward the end of the nail as the nail grows. Gastritis and the associated defects in gastric secretion often do not respond to therapy, especially in older adults. In patients younger than 30 years of age, gastric acid secretion and normal epithelial architecture may be restored.
Dysphagia may be relieved by iron therapy if the associated postcricoid webs are small or medium sized. The webs themselves are not altered, however, and relapse of the anemia is associated with recurring dysphagia. With more severe lesions, dilatation of the esophagus is required for relief.

Relapse occurs in a significant fraction of patients who respond to iron treatment, in part because of failure to complete the full course of therapy and in part because of recurrence (or continuation) of the predisposing condition or illness.

Preventive Treatment

Certain people are at such high risk for developing iron deficiency that prophylactic measures may be considered. These include infants, pregnant women, adolescents, regular blood donors, women with menorrhagia, and patients receiving continuous, high-dose aspirin therapy. Iron supplementation has been recommended for pregnant women for almost half a century. Although the advantages of this practice have not been definitively established, the large iron cost of pregnancy and delivery to the mother (Table 23.6) indicate that it is warranted, evidenced by recommendations by the US preventative services task force that pregnant women be screened for iron deficiency.

In 1999, the Committee on Nutrition of the American Academy of Pediatrics made recommendations for iron supplementation in infants. They suggest that breastfeeding is preferable for the first 5 to 6 months of life if it is feasible, and beyond 6 months of age, breast-fed infants should receive supplemental iron at 1 mg/kg/day. Infants who are not breast-fed should be given formula supplemented with 12 mg/L of iron through the first year of life. The Committee recommends using iron-fortified cereal at the time that a solid diet is begun. Finally, fresh cow’s milk should be avoided until after the first birthday.

Recovery from Anemia after Acute Hemorrhage

Morphologic evidence of active red cell regeneration should disappear after 10 to 14 days, if hemorrhage does not recur. The leukocyte count should be normal after 3 to 4 days. Sustained reticulocytosis is suggestive of continued bleeding. Persistent leukocytosis may result from the same cause, from hemorrhage into body cavities, or from complications. The latter, particularly infections, tend to delay the hematopoietic response.

Acute Iron Intoxication

The accidental ingestion of iron compounds by children who have mistaken the tablets for candy is a common problem, particularly with toddlers whose mothers are taking iron-containing prenatal vitamin supplements. A few cases have also been reported in adults. At one time, the associated mortality rate was as high as 50%. Those persons who died had swallowed 3 to 10 g or more.

Symptoms of iron intoxication have been classified in four stages. In the first stage, gastrointestinal symptoms predominate (vomiting, diarrhea, and melena). Shock may ensue, followed by dyspnea, lethargy, and coma. These events occur in the first 6 hours after ingestion. In the second stage, lasting from 6 to 24 hours after ingestion, transient improvement occurs and may continue to recovery. In stage three, metabolic acidosis is present. Death may take place 12 to 48 hours after ingestion. Stage four consists of intestinal obstruction as a late complication caused by scarring of the intestine.

These ill effects are the consequence of the local irritative action of the iron, resulting in mucosal ulceration and bleeding. Capillary dilatation and diapedesis of red cells may occur. Many factors cause the shock, including the absorption of iron in amounts far above the binding capacity of the plasma. Serum iron values as high as 3,000 µg/dl have been observed. Late coma is the result of hypoxia, metabolic disturbances, and hepatic damage.

The introduction of deferoxamine as a therapeutic agent has greatly modified the outlook. In the setting of acute iron poisoning this hexadentate chelator, which has a high specific affinity for iron, can be given orally and intravenously. The molecular complex is small and is excreted quickly by the kidneys. Nonetheless, it is prudent to manage iron poisoning in consultation with an experienced toxicologist.

ACKNOWLEDGMENTS

Substantial portions of this chapter were adapted from previous chapters written by G. Richard Lee and Nancy Andrews.

The sideroblastic anemias are a heterogeneous group of disorders and uniquely characterized by pathologic iron deposits in erythroblast mitochondria (Fig. 24.1A) that are housed within a distinct, mitochondrial ferritin. The iron-glutted mitochondria account for the so-called ring sideroblast, an erythroblast in which numerous Prussian blue-positive granules often appear in a perinuclear distribution, particularly in the later stages of its maturation (Fig. 24.1B).

The basis for the mitochondrial iron accumulation in the various sideroblastic anemias can be regarded as either insufficient generation of heme as a result of primary defects in the heme biosynthetic pathway or from faults in mitochondrial functions that involve iron pathways, creating an imbalance between mitochondrial iron import and its utilization. Iron delivery to the erythroid cell does not appear to be downregulated in the face of these alterations, and iron continues to be transported normally to mitochondria, where it accumulates. Globin synthesis is also reduced, but this effect is secondary, as it can be corrected in vitro by the addition of heme.
Kinetically, the sideroblastic anemias are characterized by ineffective erythropoiesis, like other erythroid disorders with defective cytoplasmic or nuclear maturation. Erythroid hyperplasia of the bone marrow is accompanied by a normal or only slightly increased reticulocyte count. The plasma iron turnover rate is increased, but iron incorporation into circulating red cells is reduced. Red cell survival tends to be normal or slightly reduced. Slight hyperbilirubinemia may be noted, as well as an increase in urobilinogen excretion, as a result of a raised erythropoietic
component of the “early-label” bilirubin peak. Thus, it can be inferred that a substantial proportion of the developing ring sideroblasts are nonviable, and their expiration through enhanced apoptotic mechanisms within the marrow accounts for the kinetic abnormalities.

The progeny of surviving ring sideroblasts are often but not always hypochromic and microcytic erythrocytes, a finding that provides morphologic evidence of impaired hemoglobin production as well as an initial clue to the diagnosis. The degree of hypochromia and microcytosis varies considerably from one form of sideroblastic anemia to another (Fig. 24.1C,D). Often, dimorphism is pronounced, with a hypochromic/microcytic population of cells existing side by side with a normal or even a macrocytic one. The siderotic mitochondria of the developing cell may be retained in some circulating erythrocytes (Pappenheimer bodies) and are regularly found with concurrent hypofunction or absence of the spleen; these cells are the nearly pathognomonic siderocytes in the Wright-stained blood smear (Fig. 24.1E,F).

A common feature of many sideroblastic anemias that are not reversible is an excess of total body iron. The serum iron concentration is increased, often to the point of complete saturation of transferrin, and the level of serum ferritin roughly reflects the degree of iron overload. The ineffective erythropoiesis mediates increased intestinal absorption of iron by suppressing hepcidin production. The consequent iron overload state is called erythropoietic hemochromatosis, and its clinical and pathologic features and course can rival those of hereditary hemochromatosis (see Chapter 25). The occasional concomitant presence of alleles for genetic hemochromatosis accentuates the iron overload, but their prevalence in patients with sideroblastic anemia does not appear to be greater than in the general population.

Diverse defects affecting the utilization of iron by the developing red cell are reflected in the various forms of sideroblastic anemia (Table 24.1). Within the congenital group, the majority appear as isolated anemia, the X-linked and a recently identified autosomal recessive type being the most frequent; however, in a large proportion of cases the cause remains unexplained. Very uncommon are several genetically defined syndromic forms involving multiple systems. Acquired sideroblastic anemia is considerably more common than the congenital forms and occurs as a clonal disorder manifesting only anemia or multilineage dysplasia or even myeloproliferative features. Several diverse factors, such as ethanol, certain drugs, copper deficiency, and hypothermia, produce the ring sideroblast abnormality that is fully reversible.

HISTORICAL ASPECTS

The history of sideroblastic anemias can be said to have begun in 1945 with Cooley's report of a family with X-linked microcytic hypochromic anemia (Table 24.2). Near that time iron-containing granules in erythroblasts, including their perinuclear distribution, were described separately, and 10 years later were demonstrated to represent iron-laden mitochondria. Over the next two decades these ring sideroblasts were recognized in pyridoxine-responsive anemia and in numerous patients with "refractory" anemia of unknown cause, hereditary or acquired, forming the basis for a 1965 symposium and adoption of the term sideroblastic anemia. By then, the iron overload of these disorders had also become fully appreciated.

The spectrum of the sideroblastic anemias was widened further by finding various reversible causes of the phenotype as well as by descriptions of certain congenital syndromic forms (Table 24.2). With the advent of molecular biology tools, the genetic causes of several clinically distinct types of congenital sideroblastic anemia and in part their pathogenesis have been elucidated during the last two decades.

HEME SYNTHESIS IN ERYTHROID CELLS

Developing erythroid cells have the greatest requirement of any cell type for heme for hemoglobin, and they produce more than 80% of the heme in the body. The expression and regulation of erythroid heme synthesis are unique in that they are linked (a) to the differentiation events after the signaling action of erythropoietin on erythroid precursors when they acquire the machinery for hemoglobin synthesis, (b) to the availability of iron, and (c) to the production of globin during development of the red cell. As in hepatocytes, 5-aminolevulinate (ALA) synthase and porphobilinogen deaminase have considerably lower relative activities than the remaining enzymes in the heme biosynthetic pathway (see Chapter 6) and are sites of pathway regulation. In contrast to the liver, the relative activity of ferrochelatase, the terminal enzyme in the pathway, appears also to be low in erythroid cells. Furthermore, developing red cells express erythroid-specific isozymes or messenger RNA (mRNA) transcripts of the first four enzymes of heme synthesis, namely ALA synthase, ALA dehydratase, PBG deaminase, and uroporphyrinogen III synthase.

ALA synthase, the first and rate-controlling enzyme of heme synthesis, is generated in the cytosol as a precursor protein with an N-terminal signal sequence that is proteolytically cleaved and processed on transport of the protein into the mitochondrial matrix. The mature mitochondrial protein catalyzes the formation of ALA from glycine and succinylcoenzyme A (CoA) and requires pyridoxal 5′-phosphate (PLP) as an obligate cofactor. Recently it was discovered that the erythroid-specific mitochondrial carrier family protein SLC25A38 importing glycine across the mitochondrial inner membrane is likely to have the high molar requirement of this substrate by the ALAS enzyme.

P. 645

necessary for normal erythroid heme synthesis. Two separate genes encode the ALA synthase isoenzymes. The housekeeping gene (ALAS1), located on chromosome 3, is expressed ubiquitously, whereas the erythroid-specific gene (ALAS2) is on the X chromosome. Expression of the housekeeping gene, at least in hepatocytes, is controlled by glucose levels and is increased by certain steroids, various drugs, and chemicals (see Chapter 26). This gene is repressed by administration of heme, the end product of the pathway, so that heme levels tightly regulate transcription of its mRNA in a feedback manner. Expression of the erythroid gene is essential for hemoglobin production, and ALAS1 cannot compensate if ALAS2 is lacking. ALAS2 is activated and transcribed in concert with other erythroid genes through the action of erythropoietin (Fig. 24.2); it is not repressed by heme but is upregulated by hypoxia. Cellular iron supply may also control ALAS2 mRNA levels, whereas exogenous heme inhibits translation of ALAS2 mRNA, although the mechanisms by which these occur are not known. Translational regulation of erythroid ALA synthase mRNA is mediated through interaction of its cis-acting iron-responsive element (IRE) with iron regulatory proteins (IRP1 and IRP2; also called IRE binding proteins 1 and 2) that are modulated through iron-sulfur (Fe-S) clusters generated in mitochondria and by cellular iron status (Fig. 24.2) (see Chapter 23). In this manner, regulation of protoporphyrin production is linked to iron availability and to mitochondrial function for the formation of heme. The low ALA synthase activity observed in erythroid cells in iron deficiency is consistent with such a control mechanism. While the signal sequences of the ALAS1 and ALAS2 precursor proteins contain two heme-binding motifs implicated in regulating translocation of the enzyme into mitochondria by interaction of heme with these motifs (Fig. 24.2), mitochondrial import of ALAS2 does not appear to
be affected by heme.\textsuperscript{85} Within the mitochondrion, the ALAS2 isoform uniquely associates with the succinyl-CoA synthetase βA subunit, seemingly to stabilize the ALAS2, to control the generation of its substrate succinyl-CoA, or both.\textsuperscript{86} The role of a major splice isoform of ALAS2 that is functional in vivo\textsuperscript{87} in the regulation of the enzyme or erythroid heme synthesis remains to be determined.

ALA dehydratase, a cytosolic enzyme, catalyzes the formation of the pyrrole PBG from two molecules of ALA. For this enzyme, two tissue-specific isozymes are produced by a single gene, which contains two promoter regions, generating housekeeping and erythroid-specific transcripts with alternative first noncoding exons (exons 1A and 1B). 88,89 Although both transcripts encode identical polypeptides, the erythroid-regulated form would provide for the production of the large amounts of heme for hemoglobin. Not being a rate-limiting enzyme for heme biosynthesis, its expression in erythroid cells in manyfold excess amounts 62 may also serve as the proteasome inhibitor CF-2 to inhibit protein degradations. 90
In the case of PBG deaminase, which acts in the cytosol to form the linear tetrapyrrole hydroxymethylbilane from four molecules of PBG (see Chapter 6), two tissue-specific isoenzymes also are produced by a single gene. The gene has two
overlapping transcription units, each with its own promoter: an upstream ubiquitous promoter and another downstream promoter active only in erythroid cells. Two mRNAs are generated by alternative splicing, one encoding the ubiquitous PBG deaminase isoenzyme and the other encoding the erythroid isoenzyme. To what extent the erythroid-specific enzyme has a regulatory role in the overall production of heme in erythroid cells is not known. In response to erythropoietin or hypoxia, bone marrow PBG deaminase activity increased 3.5-fold, apparently by de novo synthesis.92

The gene for uroporphyrinogen III synthase likewise has two promoters generating housekeeping and erythroid-specific transcripts with unique 5′-untranslated sequences (exons 1 and 2A).93 As for ALA dehydratase and PBG deaminase, the erythroidpromoter activity is increased during erythroid differentiation. Uroporphyrinogen decarboxylase, the fifth enzyme of the pathway with its site of action in the cytosol, is not known to have erythroid-regulatory features; however, its mRNA is markedly increased in erythroid tissue94 and the enzyme activity is higher in erythroid cells than in the liver.62

After translation, all three terminal enzymes of heme biosynthesis (coproporphyrinogen oxidase, protoporphyrinogen oxidase, ferrochelatase), like ALA synthase, are transported to their mitochondrial sites of action. Single genes encode these enzymes, and erythroid-specific transcription products are not known for them. However, erythroid-specific regulation of their expression is accommodated by the presence of promoter sequences in their genes for binding of erythroid transcription factors (e.g., GATA-1, NFE-2)95,96 and97 to enhance production of these enzymes during erythropoiesis.98 Ferrochelatase, the last enzyme of the heme synthetic pathway, catalyzes the insertion of iron into protoporphyrin to form heme. A repressor sequence in the promoter region of its gene is believed to be involved in the regulation of the binding of the erythroid transcription factors GATA-1 and NFE-2 to their recognition sites.99 The activity of ferrochelatase relative to the activity of ALA synthase is in considerable excess,62,99 but the enzyme becomes rate-limiting as a defective protein in erythropoietic protoporphyria (see Chapter 26). As it contains an Fe-S cluster, its expression and stability are also dependent on cellular iron levels and intact Fe-S cluster assembly machinery,100,101 and its activity is regulated by the essential mitochondrial ATPase inhibitory factor 1 (Atpi1) through modulation of mitochondrial pH and redox potential.102

The large amounts of iron required for erythroid heme synthesis are delivered through transferrin receptor-mediated endocytosis of iron transferrin (see Chapter 23), and iron availability ultimately limits the normal rate of heme synthesis in erythroid cells.103 High expression of transferrin receptors is also linked to erythropoietin-induced differentiation68,103; an erythroid-specific isoenzyme of human transferrin receptor has been described104; and erythroid-active elements have been identified in the promoter of the murine gene.105,106 During the height of hemoglobinization, the erythroid cell may not depend upon the “standard” mode for regulation of intracellular iron homeostasis via the IRE/IRP system to ensure a maximal supply of iron to mitochondria.107 With erythroid maturation and the accumulation of cellular hemoglobin, the transferrin receptor number progressively decreases.103 While surface transferrin receptors and iron uptake are increased in iron-deficient erythroblasts,108,109 they are not altered in states of impaired heme synthesis, such as in the presence of succinylacetone110 or in erythroid cells from patients with sideroblastic anemia.8 Transport of iron out of the endosome by the divalent metal transporter DMT1 requires an endosomal ferrireductase (Steap3) in erythroid cells.111 How the further transfer of iron to mitochondria and to apoferritin is accomplished is not understood. It may be facilitated by a cytoplasmic chaperone,112 or through direct interaction of endosomes with mitochondria.113 Iron is imported across the mitochondrial inner membrane by mitoferrin 1 that is highly expressed in erythroid cells and stabilized by interacting with the ATP-binding cassette protein ABCB10.114,115 An oligomeric complex of mitoferrin 1, ABCB10 and ferrochelatase appears to facilitate the incorporation of iron into protoporphyrin to form heme.116 Iron imported into the mitochondrion is also used for the generation of Fe-S clusters, which in part are exported to the cytosol for their addition to IRP1 in the regulation of cellular iron uptake81 and translation of ALAS2,117 and for expression of ferrochelatase.100,101

A repressor sequence in the promoter region of its gene is believed to be involved in the regulation of the binding of the erythroid transcription factors GATA-1 and NFE-2 to their recognition sites. The activity of ferrochelatase relative to the activity of ALA synthase is in considerable excess, but the enzyme becomes rate-limiting as a defective protein in erythropoietic protoporphyria (see Chapter 26). As it contains an Fe-S cluster, its expression and stability are also dependent on cellular iron levels and intact Fe-S cluster assembly machinery, and its activity is regulated by the essential mitochondrial ATPase inhibitory factor 1 (Atpi1) through modulation of mitochondrial pH and redox potential.

The large amounts of iron required for erythroid heme synthesis are delivered through transferrin receptor-mediated endocytosis of iron transferrin (see Chapter 23), and iron availability ultimately limits the normal rate of heme synthesis in erythroid cells. High expression of transferrin receptors is also linked to erythropoietin-induced differentiation; an erythroid-specific isoenzyme of human transferrin receptor has been described; and erythroid-active elements have been identified in the promoter of the murine gene. During the height of hemoglobinization, the erythroid cell may not depend upon the “standard” mode for regulation of intracellular iron homeostasis via the IRE/IRP system to ensure a maximal supply of iron to mitochondria. With erythroid maturation and the accumulation of cellular hemoglobin, the transferrin receptor number progressively decreases. While surface transferrin receptors and iron uptake are increased in iron-deficient erythroblasts, they are not altered in states of impaired heme synthesis, such as in the presence of succinylacetone or in erythroid cells from patients with sideroblastic anemia. Transport of iron out of the endosome by the divalent metal transporter DMT1 requires an endosomal ferrireductase (Steap3) in erythroid cells. How the further transfer of iron to mitochondria and to apoferritin is accomplished is not understood. It may be facilitated by a cytoplasmic chaperone, or through direct interaction of endosomes with mitochondria. Iron is imported across the mitochondrial inner membrane by mitoferrin 1 that is highly expressed in erythroid cells and stabilized by interacting with the ATP-binding cassette protein ABCB10. An oligomeric complex of mitoferrin 1, ABCB10 and ferrochelatase appears to facilitate the incorporation of iron into protoporphyrin to form heme. Iron imported into the mitochondrion is also used for the generation of Fe-S clusters, which in part are exported to the cytosol for their addition to IRP1 in the regulation of cellular iron uptake and translation of ALAS2, and for expression of ferrochelatase.

<sup>a</sup> Often normal or increased in females expressing the disorder.

The export of heme out of the mitochondrion into the cytosol for its pairing with globins of hemoglobin and other heme proteins is mediated at least in the mouse by an isoform of the feline leukemia virus C receptor (FLVCR1), named FLVCR1b<sup>118</sup>. This heme exporter is essential for erythropoiesis as its loss leads to heme accumulation in the mitochondrion and termination of erythroid differentiation.

The events coordinating the production of globin chains with the rate of heme synthesis are well understood, and appear to occur at more than one level. Heme is required for initiation of globin mRNA translation and it acts by inhibiting a protein kinase called heme-regulated inhibitor (HRI), which inactivates the translational initiation factor 2 (eIF-2α) in the absence of heme<sup>119</sup> (Fig. 24.2). Moreover, absence of this kinase adversely modifies the phenotype of disorders of heme synthesis (iron deficiency, protoporphyria) and of globin production (β-thalassemia).<sup>119</sup> In addition, heme controls globin gene expression at the transcriptional level.<sup>120,121</sup>
CONGENITAL SIDEROBLASTIC ANEMIAS

Congenital sideroblastic anemias have emerged as not uncommon disorders. They are clinically and genetically heterogeneous, with diverse underlying causes, inheritance patterns, phenotypes, and associated features. Genetic analysis and molecular approaches have revealed a spectrum of specific defects, some appearing as isolated anemia and others involving multiple systems. Defined underlying defects affect heme biosynthesis directly or indirectly by disrupting Fe-S cluster biogenesis, or they involve pathways related to mitochondrial protein synthesis. However, in at least one third of cases the root cause remains undiscovered. Severity of anemia is highly variable within some types, and morphologic features overlap among them.

Genetic Defects Expressed Only in the Erythron

Inheritance Patterns and Pathogenesis

X-Lined Sideroblastic Anemia

The inheritance follows an X-linked pattern, the anemia occurring most commonly in males and their maternal uncles and cousins. Minimal expression of the erythroid abnormality may be seen in carrier females that is consistent with variable X inactivation affecting the mutant locus of the disorder. However, in many kindreds, the anemia has occurred only in females and may have been lethal in hemizygous male conceptions. Early observations already implicated defects in ALA synthase as underlying the impaired heme biosynthesis in this form of sideroblastic anemia. In patients who responded to pyridoxine supplementation, the incorporation of glycine, but not of ALA, into heme was reduced in reticulocytes. ALA synthase activity in bone marrow was low before pyridoxine administration and returned to normal or supranormal levels after an erythropoietic response. It was presumed that the residual activity or stability of a defective erythroid ALA synthase was enhanced by additional supply of its coenzyme PLP through a mass action effect (e.g., if the enzyme had a reduced affinity for the coenzyme or was abnormally sensitive to proteolysis). Usually, pharmacologic amounts of pyridoxine are required when an erythropoietic response occurs, but the response is variable and rarely complete. Individuals may present with profound anemia only in adulthood or even late in life, suggesting that the disorder can progress with time. Some cases, prior additional dietary or medicinal intake of pyridoxine, possible changes in pyridoxine metabolism with advancing age, or initiation of hemodialysis can be factors in unmasking mild phenotypes that were not symptomatic at a younger age. In female patients expressing the disease, skewed X inactivation in hematopoietic tissue that occurs with advancing age and involves progressive inactivation of the X chromosome bearing the normal allele has been the explanation as the anemia usually evolved in adulthood or late in life. Constitutive skewed X inactivation to account for disease expression in females in childhood is very uncommon.

FIGURE 24.3. Diagram of the structure of the human erythroid 5-aminolevulinate synthase gene (ALAS2) and the location of mutations identified to date in X-linked sideroblastic anemia. Two mutations in the promoter region (c.-206C>G; c.-91_-44del) and two mutations disrupting the intron 1 enhancer of ALAS2 are not indicated. IRE, iron-responsive element; kb, kilobases. *Codon K391, the pyridoxal 5′-phosphate binding lysine. (Data from HGMD® Professional 2012.2 and unpublished material.)

After the cloning and characterization of the erythroid ALA synthase gene75,149 and its localization to the X chromosome, linkage of the disorder to the ALAS2 locus was established,129,150 and many heterogeneous missense mutations involving invariant or highly conserved amino acid residues in the catalytic domain of the enzyme have been found to cause the disorder151 (Fig. 24.3). A nonsense mutation in one case,135 nucleotide deletions, and regulatory mutations in the promoter region and in the intron 1 enhancer sequence151a of the ALAS2 gene have been the exceptions. Hence, in at least four families described up to 68 years ago,29,125,128,152 the underlying molecular defect in ALAS2 could also be defined.25,153,154 and 155 A majority of the mutations identified to date reside in exons 5 and 9 (Fig. 24.3); the latter contains the PLP-binding lysine (K391) of the enzyme.156 Among the 66 distinct mutations so far encountered, only 22% occurred in more than one unrelated family or proband, and nearly one third of the probands are female. An apparent somatic mutation in the ALAS2 gene was found in an older male patient with acquired sideroblastic anemia.157

Sites of ALAS2 mutations and severity of anemia or extent of its responsiveness to pyridoxine supplements can be correlated to a considerable extent. The activity of the recombinant enzyme is reduced for many, but not all, ALAS2 mutants so far examined and is variably enhanced by PLP.52,129,130,142,153,158,159 Some mutants have altered substrate kinetics159,160 or fail to bind to the β-subunit of succinyl-CoA synthetase.86,160 A three-dimensional structure model of the human enzyme161 and the resolved crystal structure of the significantly homologous ALAS of Rhodobacter capsulatus162 made it possible to explain how altered structure by many of the naturally occurring mutations that give rise to X-linked sideroblastic anemia (XLSA) affects the function of the enzyme. For example, mutations changing an amino acid located in the vicinity of the PLP-binding site exhibit a response to pyridoxine, whereas mutations involving sites of substrate binding, enzyme stability, or folding are refractory to pyridoxine.162 However, while clinical severity can thus be related at least in part to the effect of a specific mutation on enzyme function, marked variation in severity of anemia has been observed between some kindreds bearing the same mutation as well as within a few
implicating undefined genetic differences or environmental factors for the apparent variable penetrance.

Mitochondrial Carrier Protein SLC25A38 Deficiency

A significant segment of congenital sideroblastic anemias (≈15%) is associated with biallelic mutations in the gene encoding the erythroid-specific mitochondrial inner membrane carrier protein SLC25A38. The SLC25A38 gene has an amino terminal targeting signal and three mitochondrial carrier family protein domains that encode six transmembrane helices. From its structural features, the protein is predicted to function as an amino acid transporter. Data so far obtained in the yeast Saccharomyces cerevisiae deficient in the protein indicate a heme biosynthetic defect and suggest that it serves as a glycine importer across the mitochondrial inner membrane.

Heterogeneous mutations spread throughout the SLC25A38 protein domains have been reported in 26 families, including three sibling pairs. The mutations are missense type occurring in conserved amino acids at substrate contact points as well as nonsense and splicing errors. Two thirds of patients are homozygous and one third are compound heterozygotes for defects.

Glutaredoxin 5 Deficiency

The human counterpart of a zebrafish mutant (shiraz) deficient in glutaredoxin 5, which is essential for the synthesis of Fe-S clusters such as for IRP1 and thus ALAS2 translation, was identified in a single patient. A homozygous mutation in the GLRX5 gene that affects intron 1 splicing and markedly reduces GLRX5 RNA production was associated with microcytic sideroblastic anemia. The anemia was detected in the fifth decade, became severe by age 60, and improved with iron chelation therapy for the associated iron overload. Studies in cell lines derived from the patient indicated severe impairment of Fe-S cluster biogenesis and also revealed markedly reduced levels of ferrochelatase.

Sideroblastic Anemia in Protoporphyria

Marked deficiency of ferrochelatase underlies erythropoietic protoporphyria as a result of a large variety of mutations in the gene encoding the enzyme (see Chapter 26). The defect is manifested mainly, if not exclusively, in erythroid cells and leads to marked accumulation of free protoporphyrin, the substrate of the enzyme, during the final stages of erythroid maturation when the defective ferrochelatase becomes rate-limiting for heme production. Erythroid heme synthesis appears to be compromised in most patients as reflected in a mild microcytic hypochromic anemia. In ten patients marrow ring sideroblasts with typical mitochondrial iron deposits were observed but not in one sibling pair with mild microcytosis without anemia. Bone marrow examination has generally not been performed in this disorder so that the incidence of the ring sideroblast feature is not known. The genetic heterogeneity in protoporphyria may account for the phenotypic variation of hematologic features.

Undefined Congenital Sideroblastic Anemia(s)

It is estimated that at least one third of nonsyndromic cases of congenital sideroblastic anemia are currently molecularly unexplained. These may have autosomal or X-linked defects not yet detectable in the known causative genes, or defects in novel genes to be discovered. Novel genetic defects are also likely in some previously described kindreds. For example, in two families sideroblastic anemia occurred in a vertical distribution including father-to-son transmission and consistent with a dominant trait. In another family manifesting the anemia in both genders, a defect in mitochondrial DNA was postulated; the mild anemia was characterized by erythrocyte dimorphism and macrocytosis.

Clinical and Laboratory Features of XLSA and SLC25A38 Deficiency

If severe, XLSA is recognized in infancy or early childhood. However, not infrequently the disorder is milder or asymptomatic and may be discovered only in young adulthood or even in later life. Because severity of anemia can also vary within kindreds, diagnosis in family members may be delayed or overlooked unless complete pedigree studies or DNA analyses for an ALAS2 mutation identified in the proband are performed. In contrast, patients with SLC25A38 genetic defects typically present at birth or in early childhood with severe anemia.

All patients develop manifestations of iron overload. Linkage to human leukocyte antigen (HLA) is not evident as HFE mutations were underrepresented in a series of XLSA patients examined. Mild to moderate enlargement of the liver and spleen is common, but liver function usually is normal or only mildly disturbed at presentation. Liver biopsy reveals iron deposition that is indistinguishable from hereditary hemochromatosis (Fig. 24.4). In the X-linked form the iron burden does not correlate with the severity of anemia, and, not infrequently, well-established but asymptomatic micronodular cirrhosis is discovered in the third or fourth decade. Hepatocellular carcinoma developed in two reported cases.
cases. Clinical diabetes or abnormal glucose tolerance may or may not be related to the iron overload process. Skin hyperpigmentation is uncommon. The most dangerous manifestations of the iron overload are cardiac arrhythmias and congestive heart failure, which usually occur late in the disease course. In severely affected infants or young children, growth and development tend to be impaired.

The hallmark is a microcytic anemia. In severe cases, microcytosis and hypochromia are pronounced (mean corpuscular volume [MCV], 50 to 60 fl), and striking anisocytosis, poikilocytosis, target cells, and occasional siderocytes are prominent findings on blood smear (Fig. 24.1C). The red cell volume distribution is usually abnormally wide and, notably, dimorphism is seen in males with the X-linked form as well as in autosomal forms of the disease. Some female carriers of the X-linked trait have a biphasic Coulter counter red cell histogram (Fig. 24.5), or only a very small microcytic erythrocyte population. However, most women who express XLSA exhibit macrocytosis, although dimorphism may be evident (Fig. 24.1D). Presumably few viable erythrocytes with a markedly defective or nonfunctional mutant ALAS2 enzyme as often encountered in women reach the circulation, so that most of the erythrocytes are progeny of the residual normal clone that are released from the marrow at an accelerated rate in response to the anemic hypoxia. Leukocyte and platelet values usually are normal; they may be reduced in the presence of splenomegaly (hypersplenism). Erythroid hyperplasia is found on marrow examination, and maturation is usually normoblastic with poorly developed cytoplasm. Megaloblastic changes may be observed if complicating folate deficiency is present. Marrow reticuloendothelial iron is increased, and the telltale ring sideroblast emblem is prominent in late, nondividing erythroblasts. Transferrin saturation is increased, as is the serum ferritin level, and transferrin levels tend to be decreased. Ferrokinetic studies reflect ineffective erythropoiesis. A reduced serum haptoglobin level is consistent with the ineffective erythropoiesis.

The erythrocyte protoporphyrin level usually is low or normal. In one female patient, the low protoporphyrin level was shown to be restricted to the microcytic red cells. Kindreds in which the erythrocyte protoporphyrin is increased can be considered to represent disorders other than XLSA or SLC25A38 deficiency.

Treatment and Prognosis

Approximately two thirds of patients with sideroblastic anemia due to identified ALAS2 defects can be expected to respond to pyridoxine administration. Doses of 50 to 100 mg/day are large compared with the estimated adult daily requirement for vitamin B₆ of 1.5 to 2.0 mg and are sufficient for a maximal response, although in some cases a supplement of only 2 to 4 mg/day was found to be effective. Higher doses may be toxic. No convincing evidence is available that the parenteral route or PLP, the active coenzyme form, is more effective than oral administration. However, the response to pyridoxine is quite variable. With an optimal response, reticulocytosis is observed, blood hemoglobin concentration returns to normal or near-normal levels in 1 to 2 months, and low erythrocyte protoporphyrin levels increase to normal. The morphologic red cell abnormalities then diminish but very rarely completely resolve, even when ALA synthase activity and the hemoglobin level are restored with pyridoxine supplementation. Approximately two thirds of responding patients experience a distinct but suboptimal improvement with pyridoxine administration, and the hemoglobin concentration stabilizes at less than normal levels. When an effect of pyridoxine is achieved, continued maintenance treatment is necessary because relapses follow within several months after discontinuance of the vitamin. In a few instances, subsequent remissions with resumed treatment were less complete. In the occasional case with accompanying megaloblastic changes, folic acid should be given, which usually leads to normoblastic maturation, suboptimal reticulocytosis, and some increase in the hemoglobin level. In severely anemic individuals who do not respond to pyridoxine, periodic red cell transfusions are necessary to relieve symptoms and to allow normal growth and development of children. Transfusion of red cells should be kept to a minimum to lessen or delay the development of iron overload.
FIGURE 24.4. Histopathology of the iron overload in congenital sideroblastic anemia. A, B: Liver section of a 26-year-old man with SLC25A38 deficiency and moderate hemochromatosis. C, D: Autopsy liver section of a 45-year-old man with X-linked sideroblastic anemia, micronodular cirrhosis, and hemochromatosis. E, F: Section from the heart of the latter patient with marked hemosiderosis. (A, C, and E: Hematoxylin stain; B, D, and F: Prussian blue stain.)
FIGURE 24.5. Dimorphic red cell distribution in a female patient with mild X-linked sideroblastic anemia. Redrawn from the output of a Coulter analyzer. RBC, red blood cell.

Based on the assessed extent of iron overload, including liver biopsy, an iron depletion program should be instituted to prevent or stabilize already established organ damage. Therapeutic phlebotomies are well tolerated and preferred in patients with mild or moderate anemia in the absence of contraindications such as heart disease. After the initial removal of all storage iron, maintenance phlebotomies should be continued indefinitely. For patients with severe anemia, or for those who depend on regular transfusions and thus become massively iron loaded, an iron-chelating agent is administered. As recommended for thalassemia, deferoxamine is infused over 12 hours subcutaneously or intravenously, at 40 mg/kg/day, and for at least 5 days each week. Although iron removal with deferoxamine is enhanced by ascorbate, large supplements can cause acute cardiac toxicity by facilitating excessive mobilization of ferritin iron, and any intake of the vitamin should be limited to 200 mg daily. The risks of deferoxamine treatment are minimal. Occasional local reactions can be controlled with inclusion of small amounts of hydrocortisone in the infusate. Rare hypersensitivity is amenable to desensitization. Reported visual and auditory neurotoxicity is unlikely without excessive doses of the drug. The new, orally active tridentate iron chelator deferasirox (Exjade) has an efficacy similar to deferoxamine or better, the recommended initial daily dose is 20 mg/kg and can be increased to 30 mg/kg. Although the long-term safety profile of this agent is not known, it has emerged as a preferred iron chelator. The goal of iron chelation therapy is to maintain the serum ferritin concentration below 500 µg/L. The increased risk of infection with Yersinia (and perhaps other organisms) in iron overload, although uncommon, increases further with deferoxamine treatment. Removal of the iron excess has occasionally reduced severity of the anemia by improving erythroblast mitochondrial function, such as restoration of secondary ferrochelatase deficiency; by enhancing pyridoxine responsiveness; and by diminishing the ineffective erythropoiesis.

Splenectomy in congenital sideroblastic anemia appears to be invariably complicated by thromboembolic complications and, often, a fatal outcome. Factors other than persistent thrombocytosis seem to play a role. Control of the platelet count and anticoagulant therapy usually are not effective, so splenectomy is contraindicated.

These supportive measures provide for a favorable prognosis and often for normal survival. Curative bone marrow transplantation was achieved in seven reported patients without known molecular defects, including recovery from chronic graft-versus-host disease after subsequent orthotopic liver transplantation in one of these cases; one patient succumbed to graft-versus-host disease and prior iron overload. Hematopoietic stem cell transplantation has also been successful in several unreported cases with SLC25A38 deficiency.

In contrast to acquired clonal sideroblastic anemia, predisposition to leukemic evolution has not been observed.
Sideroblastic Anemia as a Component of Genetic Syndromes

X-Linked Sideroblastic Anemia with Ataxia

In a large kindred with XLSA associated with nonprogressive ataxia (XLSA/A),\textsuperscript{49} linkage to the phosphoglycerate kinase locus at Xq13 was demonstrated\textsuperscript{149} and linkage to ALAS2 was excluded using a highly polymorphic repeat sequence within intron 7 of the ALAS2 gene.\textsuperscript{70} Cloning and chromosomal mapping to Xq13.1-q13.3 of the human ABCB7 gene,\textsuperscript{200,201} an ortholog of the ATM1 gene in yeast that encodes a transporter protein required for mitochondrial iron homeostasis,\textsuperscript{202} led to identification of a mutation in this gene as the underlying defect in the kindred.\textsuperscript{203} Distinct mutations in the ABCB7 gene have been identified in three additional families.\textsuperscript{203,204,205} All the mutations result in substitutions of conserved amino acids (Ile400Met, Glu433Lys, Val411Leu, Glu209Asp) and affect a region of the protein involved in binding and transport of a substrate. It is postulated that ABCB7 participates in the export of Fe-S clusters generated in mitochondria for assembly of cytosolic Fe-S cluster-containing proteins.\textsuperscript{206} Expression of wild-type ABCB7, but not mutant ABCB7, in Atm1p-deficient yeast restores phenotypic defects as well as the production of cytosolic Fe-S proteins.\textsuperscript{203} As in yeast,\textsuperscript{206} a defective ABCB7 protein leads to mitochondrial siderosis in the human disorder. How heme synthesis becomes impaired in erythroid cells has not been elucidated and may be a consequence of reduced Fe-S cluster biogenesis impacting on the translation of ALAS2.\textsuperscript{80,167} Because free protoporphyrin, as well as zinc protoporphyrin, accumulates in erythrocytes, the generation of ferrochelatase, an Fe-S-containing protein, is probably affected. Neither ALA synthase nor ferrochelatase has been examined in erythrocytes with the XLSA/A defects. The mechanism for the neural dysfunction in this disorder remains elusive. As in Friedreich ataxia,\textsuperscript{208} disrupted mitochondrial iron homeostasis in neural cells is likely involved in the pathogenesis.

Among five kindreds so far encountered, the neurologic features are overriding and include delayed motor and cognitive development, incoordination, and nonprogressive cerebellar atrophy with or without atrophy of pons and medulla.\textsuperscript{49,203,204,205,206} The anemia is mild to moderate, and morphologic features are indistinguishable from the isolated heritable forms of sideroblastic anemia, including variable abnormalities in female carriers as observed in XLSA. Both free and zinc-chelated erythrocyte protoporphyrin are increased. Iron overload has not been evident.

Mitochondrial Myopathy, Lactic Acidosis, and Sideroblastic Anemia

This autosomal recessive disorder results from mutations in the genes encoding either pseudouridine synthase (PUS1)\textsuperscript{58,165,210,211} or mitochondrial tyrosyl transferase (YARS2).\textsuperscript{61,212} In the former, missense or nonsense mutations so far described predict an inactive protein. Mitochondrial and cytoplasmic transfer RNAs lack pseudouridine at the expected sites,\textsuperscript{213} likely causing faulty translation of mitochondrial genes of respiratory complexes I and IV. The YARS2 mutations reduce levels of the enzyme and lead to decreased mitochondrial protein synthesis and respiratory chain dysfunction.\textsuperscript{51} How these protein deficiencies lead to mitochondrial iron accumulation and anemia is unclear.

The PUS1 defects have occurred in four families of Jewish Iranian descent, in one family from the Shetland Islands, and in one Italian family;\textsuperscript{57,58,165,210,211} in the Iranian families consanguinity was present, and parents of the Italian brothers were distantly related. The disorder is characterized by muscle weakness, basal lactic academia and normocytic sideroblastic anemia with clinical onset in childhood or around adolescence.\textsuperscript{57} Some cases have exhibited intellectual impairment and/or craniofacial abnormalities. Diminished oxidative phosphorylation is reflected in decreased activity of mitochondrial enzymes of the respiratory chain as well as in the raised blood lactic acid level. The myopathy and the anemia are variably progressive, and transfusions are usually required by the third decade of life if not earlier.

Based on reports of one family and two further unrelated cases with YARS2 mutations,\textsuperscript{61,212} the myopathy and anemia appear of variable severity. While some cases developed a cardiomyopathy, intellectual impairment or developmental abnormalities were not observed.

Congenital Sideroblastic Anemia and B-Cell Immunodeficiency

A novel syndrome of severe microcytic sideroblastic anemia that is associated with B-cell immunodeficiency, periodic fevers and developmental delay and presents in infancy has been described in 12 children.\textsuperscript{213a} In addition, neurologic defects and other multisystem derangements are variably present. Commonly early death was attributed to cardiac or multi-organ failure. The molecular etiology remains to be determined.

Pearson Marrow-Pancreas Syndrome
This progressive, congenital multisystem mitochondrial disorder is associated with sporadic major deletions, rearrangements, or duplications of mitochondrial DNA, leading to the loss of multiple proteins encoded by the mitochondrial genome. About one half of cases are heteroplasmic for a 4,977 bp deletion that involves mitochondrially encoded subunits of respiratory complex I (NADH dehydrogenase), complex IV (cytochrome c oxidase), and complex V (ATP synthase) as well as several mitochondrial tRNA genes. Thus, translation of mitochondrial DNA-encoded proteins may be affected. The spectrum of mitochondrial genomic deletions has also extended to other non-overlapping deletions. The heteroplasmic nature of mitochondrial DNA at the cellular and organ levels is considered to account for the high variability of tissues involved over time.

The disorder generally presents within the first 6 months after birth with anemia, metabolic acidosis, and exocrine pancreatic insufficiency. Also common is development of hepatic and renal failure. Some infants lack the metabolic derangements initially and present only with anemia, resulting in oversight of this syndrome. Usually 25% are anemic in the neonatal period; by 6 months of age, anemia is evident in 75% of cases. Any associated neutropenia and thrombocytopenia are mild. The anemia tends to be severe and is normocytic or macrocytic. In the bone marrow, erythroid precursors are often reduced in number but ring sideroblasts are prominent, in which abnormalities in mitochondrial ultrastructure are pronounced. A distinctive feature is the presence of striking vacuoles in myeloid and erythroid precursors. Erythrocyte protoporphyrin values were increased when measured.

Approximately one half of patients succumb to the metabolic derangements. The anemia may improve or remit in up to one third of cases by 10 years of age. Survivors often develop the Kearns-Sayre syndrome. Thiamine-responsive Megaloblastic Anemia

This autosomal recessive syndrome, also known as Rogers syndrome, is caused by mutations in the SLC19A2 gene, which encodes a 497 amino acid high-affinity thiamine transporter. The protein is predicted to have 12 transmembrane spanning regions. Twenty-eight distinct mutations have been reported to date. Most of these are nonsense or frameshift type; missense mutations result in proteins that are not properly targeted to the cell membrane for their site of function. The dominating megaloblastic feature of the anemia is considered to be due to defective nucleic acid synthesis because limited intracellular thiamine impairs the pentose phosphate pathway and de novo synthesis of ribose-5-P. The unique additional feature of marrow ring sideroblasts may relate to the role of thiamine in the generation of succinyl-CoA, a substrate of ALAS2.

The cardinal clinical characteristic of the syndrome is the triad of megaloblastic anemia, non-type I diabetes mellitus, and sensorineural deafness. Other clinical features have been described in some cases. The disorder has typically manifested between infancy and adolescence. Some patients have a milder phenotype, and a few have presented as adults.

Hematologic findings are macrocytic anemia, variable degrees of neutropenia and thrombocytopenia with megaloblastic changes and fewer marrow ring sideroblasts than in other congenital sideroblastic anemias. Thiamine (vitamin B1) in pharmacologic doses (25 mg/day) usually improves the anemia and the diabetes initially, but it has become ineffective in adulthood.

Animal Models of Sideroblastic Anemia

The first genetically designed animal model of sideroblastic anemia was developed in zebrafish (the sau mutant, sauternes), in which hematopoiesis resembles that of higher vertebrates also at the molecular level, as hematopoietic gene expression and function are conserved. The chemically induced mutant gene encodes the zebrafish ortholog of human ALAS2 and expresses embryonic hypochromic anemia with severe heme deficiency. The two mutation sites, predicting Val249Asp and Leu305Gln substitutions, are in exon 6 and exon 7, respectively, and represent conserved amino acids across large phylogenetic boundaries, including the human. However, the mutants' blood cells did not reveal ring sideroblasts, perhaps because of species differences in cellular iron metabolism.

A second model in zebrafish (the sir mutant, shiraz) has a deficiency of glutaredoxin 5, an essential component of Fe-S cluster assembly, and expresses hypochromic anemia. In the absence of the Fe-S cluster, the iron regulatory protein IRP1 blocks ALAS2 translation by binding to the IRE of the ALAS2 mRNA. As in the ALAS2 zebrafish mutant, ring sideroblasts were not observed and may reflect species differences.

In a transgenic mouse model with homozygous deficiency of ALAS2, erythroid differentiation is arrested, and embryos die by day 11.5. Mice chimeric for ALAS2-null mutant cells or transgenic mice generated with partial ALAS2 expression exhibit the phenotype of human XLSA, with severe anemia and typical ring sideroblasts in the marrow.
In another mouse model, deletion of the Abcb7 gene led to fatal neonatal bone marrow failure, demonstrating that Abcb7 is essential for hematopoiesis. While marrow ring sideroblasts were not observed in these animals or in animals chimeric for the human Abcb7 mutation Glu433Lys, siderocytes were detected in the peripheral blood.

The combination of isoniazid (INH) and cycloserine administered to guinea pigs produces sideroblastic anemia in a few weeks. Blood PLP concentrations become reduced, and bone marrow ALA synthase as well as ferrochelatase activity is diminished. The latter may be secondary to mitochondrial damage by the iron deposits.

The flexed-tail (f/f) mouse has a transient embryonic and neonatal anemia associated with siderotic granules (iron-laden mitochondria) in erythrocytes and reduced heme synthesis, which coincides with the physiologic cessation of hepatic erythropoiesis. The defect is a frameshift mutation in the f gene (sideroflexin, sfxn1) that encodes a protein proposed to facilitate transport of a component required for iron utilization into or out of mitochondria.

**ACQUIRED CLONAL SIDEROBLASTIC ANEMIA**

Since the initial description of acquired idiopathic sideroblastic anemia by Bjorkman, a considerable spectrum of its manifestations has been recognized. The anemia is a component of certain stem cell disorders, namely the myelodysplastic syndromes and the myeloproliferative diseases. Uncommonly, the ring sideroblast abnormality has been observed in acute leukemia and in erythroleukemia at the time of diagnosis. The disorder arises in conjunction with the clonal overgrowth of an altered hematopoietic progenitor cell having a proliferative advantage over the normal cell population and, thus, was included among the myelodysplastic syndromes. Currently three variants are distinguished: refractory anemia with ring sideroblasts (RARS), RARS with thrombocytosis (RARS-T), and refractory cytopenia with multilineage dysplasia and ring sideroblasts (RCMD-RS) (Table 24.1).

**Etiology and Pathogenesis**

Clonality

The clonal nature of the disorder was first suggested by the morphologic and kinetic findings of two populations of red cells, the hypochromic, short-lived cell population being the product of the abnormal clone that bears the characteristic ring sideroblasts. The clonal derivation of the disorder was specifically indicated by the finding of a single glucose-6-phosphate dehydrogenase isoenzyme in hematopoietic cells, but not in fibroblasts, of an individual who was also heterozygous for a glucose-6-phosphate dehydrogenase polymorphism. Further evidence was provided with simultaneous clonality and cytochemical analysis of erythroid progenitors and cytogenetic studies corroborated the clonality of the abnormal hematopoiesis. Chromosomal abnormalities are detectable in bone marrow cells of up to 50% of patients, and deletions in chromosomes 5, 11, and 20 as well as trisomy 8 and loss of Y occur most frequently. Although structurally abnormal X chromosomes are uncommon, Xq13 breakpoints were particularly associated with myelodysplasia and ring sideroblasts in one study. Another recurring cytogenetic abnormality is an isodicentric chromosome Xq13.1 (idicXq13.1) occurring only in females. In a few patients, abnormalities of the long arm of chromosome 3 were associated with thrombocytosis.

More recently it was found that the RARS-T subtype is associated with the V617F mutation in Janus-associated kinase 2 (JAK2), which is common in myeloproliferative disorders, in up to 65% of cases. How the more active mutant JAK2, by dysregulating the JAK-STAT (signal transducer and activator of transcription) signaling pathway, may play a role in the pathogenesis of the ring sideroblast, if it does at all, is not known. A strong correlation has also been found between somatic mutations in splicing factor SF3B1, a core component of the RNA splicing machinery located at the U2snRNP spliceosome catalytic site, and the presence of ring sideroblasts in patients with MDS, ranging from an incidence of 57% to 82%. While mutant SF3B1 thus appears to initiate production of the sideroblastic phenotype, the downstream mechanism(s) leading to the dysregulated iron metabolism in the mitochondrion remains to be identified. It has been suggested that the presence of a SF3B1 mutation imparts a “benign” clinical phenotype and favorable prognosis.

The natural history of this acquired sideroblastic anemia syndrome is commonly characterized by a chronic, stable anemia and, uncommonly, by a progressive marrow failure state or leukemic evolution. An initial genetic change causing expansion of an abnormal hematopoietic clone manifested by defective erythroid cell development is thus insufficient to result in a malignancy, even when persisting for many years. A “second hit” or mutation appears to be necessary for any leukemic evolution that can be reversible, whereas the initial manifested defect expressed in the sideroblastic state persists.
Abnormalities in Heme Synthesis

The defective erythropoiesis is characterized at least in part by impaired hemoglobin synthesis, as reflected in the presence of a hypochromic erythrocyte population. Various studies had indicated that the biosynthesis of heme is impaired at the levels of ALA synthase and ferrochelatase. Reduced activity of ALA synthase in marrow cells was the most consistent abnormality in earlier series of patients and was particularly demonstrable in the youngest erythroblast fraction. In occasional patients, the addition of PLP enhanced the low enzyme activity in vitro, but reported erythropoietic responses to pyridoxine or to PLP administration, as well as restoration of low ALA synthase activity to normal, were unusual and may have reflected an inherited defect of ALAS2. In a later study, the activity of this enzyme was found to be lost in bone marrow cells of patients with ALAS2 deficiency. Thus, impaired iron utilization for heme biosynthesis remained the common denominator in the pathogenesis.

Subsequently, a defect(s) intrinsic to mitochondria, causing diminished heme production in the abnormal clone as well as accounting for the decreased activity of several other mitochondrial enzymes (i.e., cytochrome oxidase, oligomycin-sensitive adenosine triphosphatase, and mitochondrial serine protease) in granulocytes and erythroblasts was sought. Various heteroplasmic point mutations of conserved nucleotides in mitochondrial DNA, as well as in transfer RNAs and mitochondrial ribosomal RNAs, were found in hematopoietic cells of patients with clonal sideroblastic anemia. Many of these affect cytochrome c oxidase and may be implicated in impaired reduction of iron for its incorporation into the heme moiety of this protein. Such mitochondrial defects are consistent with the heterogeneity of hemoglobin content found between individual erythroblasts by scanning microspectrophotometry, as well as with the variable size of hypochromic microcytic erythrocyte and ring sideroblast cell populations in the disorder. A gradual accumulation of affected erythroid precursors and the known higher mutation rate in mitochondrial DNA than in nuclear DNA would provide a basis for the slow progression of the anemia and its expression in later life, respectively.

A uniformly reduced transcript of the ABCB7 transporter was observed in 33 patients with RARS and may indicate one mechanism leading to this ring sideroblast phenotype. In vitro studies also suggested a link between this ABCB7 down-regulation and SF3B1 mutations in association with reduced erythroid development and the aberrant expression of mitochondrial ferritin in CD34+ cells that had previously been observed in low-risk myelodysplastic syndromes.

Nuclear Abnormalities

The principal, often macrocytic, red cell population in the blood may represent the progeny of the normal residual erythroid precursors with a shortened marrow maturation time in response to raised erythropoietin levels. The commonly observed morphologic nuclear abnormalities of erythroid precursors and their defective DNA synthesis and mitosis, however, suggest that more viable precursors of the dysplastic clone produce the macrocytic erythrocytes, whereas a greater proportion of developing cells expressing impaired heme synthesis is destroyed in the bone marrow. By analogy, various other aberrations of erythroid cell metabolism can occur in dysplastic hematopoietic clones, including altered genetic control of globin chain production. Thus, hemoglobin H disease was acquired in association with erythroleukemia, acute leukemia, and myelofibrosis, as well as in sideroblastic anemia with myeloproliferative features and in patients with sideroblastic anemia before leukemia developed.

Iron Overload

Excessive absorption of dietary iron occurs over time in many, if not all, patients with stable disease and can be attributed to the ineffective erythropoiesis, as in congenital sideroblastic anemias and other long-standing disorders with erythroid maturation defects. The consequent iron accumulation closely resembles that of hereditary hemochromatosis. Although...
the presence of at least one allele for this disorder would likely contribute to the iron overload, the incidence of HFE mutations was no greater than in the normal population in most studies. Inadvertent administration of iron for the anemia and red cell transfusions add predictably to the parenchymal iron deposition.

Clinical Features

The disorder usually occurs in middle-aged and older individuals, but younger persons, including children, are not spared. The anemia develops insidiously and may be discovered during a routine examination or in association with an unrelated complaint. The older individual more often experiences symptoms of fatigue and angina if there is coexisting coronary artery disease. Physical examination may reveal no abnormality except for pallor. Hepatosplenomegaly is found in one third to one half of patients. With advanced iron overload, usually after repeated red cell transfusions, symptoms and signs of liver decompensation as well as heart failure and arrhythmia occur.

Laboratory Findings

The anemia is usually moderate and may be normocytic but more often is macrocytic (Fig. 24.6). The mean corpuscular hemoglobin concentration is normal or slightly reduced, and a variable population of hypochromic cells is found on blood smear. A particularly characteristic finding is the presence of occasional basophilic stippling in hypochromic cells that stains positive for iron. Typical Pappenheimer bodies are uncommon unless there is associated hyposplenism or the spleen is absent. Leukocyte and platelet values are usually within the normal range. The presence of the erythroid abnormalities alone constitutes the RARS subtype of the disorder in the World Health Organization (WHO) classification of myelodysplastic syndromes (see Chapter 73). Associated moderate leukopenia, thrombocytopenia, or both tend to be accompanied by other myelodysplastic features, such as morphologically abnormal leukocytes (e.g., the pseudo-Pelger anomaly) or immature forms in the peripheral blood, and define the WHO category RCMD-RS. The presence of leukocytosis, thrombocytosis, or both is indicative of a mixed myelodysplastic/myeloproliferative disease.

Erythroid hyperplasia is found on bone marrow examination. A feature claimed to be helpful in distinguishing idiopathic sideroblastic anemia from erythroleukemia is the lack of periodic acid-Schiff (PAS)-positive material in the erythroblasts. Mild megaloblastic changes are common and may or may not be related to accompanying folate deficiency. Marrow hemosiderin content is increased, and ring sideroblasts constitute up to 100% of the erythroblasts unless masked by concomitant iron deficiency. In contrast to hereditary sideroblastic anemia, ring sideroblasts are evident at all stages of erythroid maturation. Their distinctive expression of mitochondrial ferritin also permits their detection by flow cytometry methods. Because the hematologic phenotype often may be indistinguishable from XLSA in female patients, the analysis of X inactivation status and DNA for ALAS2 defects should be considered.

Serum transferrin saturation is increased in most patients and exceeds 90% in approximately one third of them. Substantially increased deposition of iron is found in the liver, but hepatic dysfunction is rare at presentation. Serum ferritin levels are elevated.

Characteristically, the erythrocyte protoporphyrin is moderately increased, up to 300 µg/dl (normal is 20 to 65 µg/dl). Values ranged from 1,055 to 10,514 µg/dl in the patients with probable acquired deletion of one ferrochelatase allele in the hematopoietic clone, and some had associated dermal photosensitivity.

**Treatment and Prognosis**

Treatment consists of supportive measures. Pyridoxine administration cannot be expected to be beneficial because ALAS2 defects are not involved in the pathogenesis. Administration of large doses of androgen (e.g., 50 to 300 mg of oxymetholone per day) is rarely useful and tends to produce or worsen fluid retention.

and hepatic dysfunction. The effectiveness of erythropoietin has been examined in patients with the myelodysplastic syndromes, including RARS. Most, if not all, patients with uncomplicated sideroblastic anemia have high levels of endogenous erythropoietin, and it would appear unlikely that additional administration of the hormone would be beneficial. However, prolonged administration of recombinant erythropoietin, with or without granulocyte colony-stimulating factor, can lead to gratifying improvement or even correction of the anemia in around 40% of patients, in particular in individuals who have a low or intermediate-1 International Prognostic Scoring System (IPSS) score. A response is also more likely to occur if the endogenous serum erythropoietin level is not commensurate with the degree of the anemia, and large doses may be required.

Many studies evaluating various drug regimens for the myelodysplasias included the RARS subtypes. The drugs used have included the hypomethylating agents 5-azacytidine and decitabine, anti-tumor necrosis factor (TNF) fusion protein (etanercept), antithymocyte globulin (ATG), thalidomide and its derivative lenalidomide, and valproic acid. On average, major responses with improved erythropoiesis or hematopoiesis have been less than 50% (see Chapter 73). Many patients are not significantly incapacitated by the anemia. Without abnormalities of the other hematopoietic cell lines and with minimal iron overload, often no progression occurs for many years. Such individuals frequently succumb to other concurrent diseases, but continued medical follow-up is indicated. Iron status should also be assessed with laboratory studies once per year. Transfusion of packed red cells is necessary for patients with symptomatic anemia, but it should be kept to a minimum because it accelerates the iron overload.

Iron overload, particularly when accentuated by repeated transfusions, can be a significant cause of morbidity and mortality (liver failure or heart failure) and is improved with chelation. When the serum ferritin level is approximately 500 µg/L or higher, along with the increased transferrin saturation, it should be countered. Histologic and chemical determination of iron in the liver biopsy provides the optimal assessment of the degree of iron overload. In mildly or moderately anemic individuals, iron removal can be accomplished with graded phlebotomies. Patients with more severe anemia or who are transfusion-dependent require iron chelation as described for congenital sideroblastic anemias. Because each unit of blood deposits 200 mg of iron, iron overload develops fairly rapidly with regular transfusions, and it is controlled more easily if treatment with an iron chelator is begun after approximately 20 units of blood have been given. In some cases, anemia was improved after iron removal; an independent effect of deferoxamine on erythropoiesis was also implicated.

The survival of patients with isolated anemia who are stable and not transfusion-dependent may not differ from that of healthy individuals. A prospective study of 232 patients, which validated the proposal of the two types of the disorder, provided prognostic information. In pure sideroblastic anemia, with the marrow failure restricted to the erythroid cell lineage and now called RARS, overall survival was the same as in age-matched controls, and leukemic transformation was
not observed. In RARS with features of impaired granulopoiesis, megakaryopoiesis, or both, survival was reduced to 56% at 3 years, and, in approximately 5% of cases, evolution to acute leukemia occurred. Other factors associated with the development of leukemia are the presence of few ring sideroblasts, more severe ineffective erythropoiesis, and impaired bone marrow colony formation. 247,261 The probability of leukemic transformation is also increased in the presence of certain bone marrow karyotype abnormalities (e.g., monosomy 7, deletion 20q, or complex defects). 247,248,306 When sideroblastic anemia followed therapy for various malignant disorders, leukemic evolution tended to be the rule. 307,308

REVERSIBLE SIDEROBLASTIC ANEMIAS

Alcoholism

Anemia associated with alcoholism usually has numerous causes. 309 A ring sideroblast abnormality is never the sole cause but occurs in 25% to 30% of anemic alcoholic patients 310,311 and probably only in the presence of malnutrition and folate deficiency.

The production of heme is impaired by ethanol, as indicated by the ability of heme to restore the concomitantly inhibited globin synthesis in reticulocytes 312 and by the observation that the heme-regulated inhibitor activity of globin translation increases. 313 Inhibitory effects of alcohol have been observed at several steps of the heme biosynthetic pathway. Reduced activity of erythrocyte ALA dehydratase 314 was believed to be related to zinc depletion. 315 Activity levels of erythrocyte uroporphyrinogen decarboxylase, leukocyte coproporphyrinogen oxidase, and ferrochelatase are also decreased in alcoholic patients; those of ALA synthase and PBG deaminase are increased. 314,316 Certain abnormalities of vitamin B₆ metabolism have been observed. Serum levels of PLP are low in chronically ill alcoholic persons 317 but do not correlate with the presence or absence of ring sideroblasts. 311 Acetaldehyde enhanced the degradation of PLP, 317,318 and, in one study, alcohol-induced sideroblastic anemia responded to PLP but not to the combination of folic acid and pyridoxine. 319 The colony formation of early (burst-forming unit-erythroid) and late (colony-forming unit-erythroid) human erythroid progenitor cells is preferentially suppressed by ethanol and acetaldehyde over that of myeloid cell progenitors at concentrations found in vivo and is partially reversed by folinic acid and pyridoxine. 320 Thus, a direct role of vitamin B₆ deficiency in the sideroblastic change is uncertain. Important in the pathogenesis may be the direct effects of ethanol, acetaldehyde, or both on the heme biosynthetic steps or on mitochondrial metabolism, because these agents also inhibit hepatic mitochondrial protein synthesis. 321

Blood hemoglobin values range from 6 to 10 g/dl, and the MCV is normal or increased. The transient sideroblastic change is commonly evident in dimorphic circulating erythrocytes. Siderocytes, present in approximately one third of patients, are a specific finding 309 and provide the most persistent clue for the ethanol-associated ring sideroblast defect. Megaloblastic hematopoiesis resulting from folate deficiency is frequent but is not always present. 320 A striking finding is vacuolization of pronormoblasts. The percentage of marrow ring sideroblasts ranges up to 70%, and they typically represent later stage normoblasts. 41 Marrow iron stores usually are increased, as are the serum transferrin saturation and the serum ferritin level.

Withdrawal of alcohol is followed by disappearance of ring sideroblasts within a few days to 2 weeks 310 (Fig. 24.7). Recovery from the anemia may occur over several weeks and also depends on the presence of other erythroid defects induced by alcohol 310 as well as any associated medical illness that affects erythropoiesis (see Chapter 41). A prompt recovery phase may exhibit reticulocytosis and erythroid hyperplasia in the bone marrow resembling hemolytic anemia. 310

Drugs

Antituberculosis Agents

Reversible sideroblastic anemia occurs in association with the treatment of tuberculosis with INH; in a few patients, pyrazinamide and cycloserine also were implicated. 322 These drugs interfere with vitamin B₆ metabolism, and deprivation of PLP reduces ALA synthesis and, thus, heme production. 322 INH reacts with pyridoxal to form a hydrazone and inhibits pyridoxal phosphokinase. Bone marrow ALA synthase activity is also inhibited by INH in a dose-dependent manner in vitro and is restored by PLP. 138 Cycloserine inhibits PLP-requiring enzyme reactions and directly inactivates pyridoxal. 322 Pyrazinamide appears to have anti-vitamin B₆ properties, but a specific mechanism has not been determined.

P.656

The relative incidence of anemia in relation to the extensive use of these drugs appears to be low, perhaps because of the regular concomitant administration of pyridoxine. Unknown contributory factors or another hematologic disorder may render certain individuals more susceptible to the antipyridoxine effects of the drugs. In one study, ring sideroblasts or increased erythroblast iron was found in 58% of all patients treated for tuberculosis. Anemia has occurred from 1 to 10 months after institution of INH treatment. It is moderately severe (volume of packed red cells, 0.20 to 0.26 L/L), the red cell indices are usually reduced, and the erythrocytes show dimorphic morphologic features with prominent hypochromia and microcytosis. Ring sideroblasts are invariably present in the bone marrow. Serum pyridoxal concentrations were subnormal in most patients studied. Transferrin saturation tends to be increased. The anemia usually is promptly and fully reversed on withdrawal of the drug or by administering large doses of pyridoxine while continuing use of the drug.

Chloramphenicol and Linezolid

In contrast to the sporadic or idiosyncratic and usually fatal aplastic anemia occurring within weeks or months of chloramphenicol use, the dose-dependent and reversible hematologic toxicity of the drug is predictable and is characterized by suppression of erythropoiesis and by the ring sideroblast abnormality. A primary mitochondrial injury by the agent impairs heme synthesis as well as erythroid differentiation and proliferation. Therapeutic concentrations of chloramphenicol (10 µg/ml) inhibit the synthesis of mitochondrial membrane proteins, such as cytochrome a + a3 and b, and, thus, mitochondrial respiration. Impaired heme synthesis is evident in reduced activities of ferrochelatase and ALA synthase, which appear to be secondary effects as these enzymes are synthesized in the cytosol. The greater sensitivity of erythroid cells to chloramphenicol has been demonstrated in vitro, in that therapeutic concentrations of the drug inhibit erythroid colony growth but not granulocyte colony growth.

The anemia may reach moderately severe levels. Bone marrow study reveals variable degrees of hypocellularity and ring sideroblasts as well as prominent vacuolization of early erythroid precursors. Erythrokinetic parameters reflect a hypoproliferative state. Reticulocytopenia, increased serum iron values, and prolonged plasma iron clearance are characteristic. These abnormalities, as well as the ring sideroblasts and anemia, disappear upon withdrawal of the drug. Linezolid causes reversible myelosuppression and the ring sideroblast abnormality has also been observed. Its toxicity resembles that of chloramphenicol in that it inhibits mitochondrial protein synthesis (mRNA translation), although it
blocks assembly of the initiation complex, while chloramphenicol inhibits peptidyl transferases and thus peptide elongation. Vacuolization of erythroid precursors is common, and the hematologic abnormalities disappear upon discontinuation of the drug.

Other Drugs

Several miscellaneous drugs have been implicated in producing sideroblastic anemia in a few patients. These include fusidic acid, busulfan, melphalan, penicillamine and triethylene tetramine dihydrochloride.

Copper Deficiency

Deficiency of copper generally does not occur in humans because requirements are low relative to its wide distribution in food. However, copper deficiency anemia is encountered in various clinical settings and typically leads to sideroblastic anemia and neutropenia. It has developed after prolonged parenteral nutrition and forced enteral feeding if copper was not included in the formulations, and in association with intestinal malabsorption; some patients have had prior gastrointestinal operations, e.g., gastrectomy, bariatric surgery. Copper deficiency also occurs with the use of copper-chelating agents and after prolonged ingestion of zinc, such as in the form of zinc supplements and with the chronic use of denture cream containing zinc. In six instances, the deficiency developed from ingestion of coins and was attributed to their zinc content. A novel syndrome of severe sideroblastic anemia with the neurologic manifestations of central nervous system demyeilination, or peripheral neuropathy with optic neuritis, or myelopathy and profound copper deficiency was recognized only 10 years ago, and was proposed to represent another combined system disorder resembling vitamin B12 deficiency. Subsequently numerous cases with this syndrome were reported. In some, excess zinc ingestion was present and not infrequently remote prior gastric resection was noted. Myeloneuropathy has been the most frequent neurologic abnormality.

The pathogenesis is understood in part from extensive studies of the severe anemia that develops late in the course of dietary copper deficiency in swine. In these animals the anemia is microcytic and hypochromic and is associated with several defects of iron metabolism. Intestinal absorption and mobilization of iron from reticuloendothelial cells and hepatocytes to transferrin are impaired because of the associated lack of ceruloplasmin (ferroxidase). In reticulocytes of deficient animals, protoporphyrin production from glycine and ALA and ferrochelatase activity are not reduced, but iron metabolism in erythroid mitochondria is impaired in that heme synthesis from ferric iron and protoporphyrin is decreased. It was postulated that the reduction of ferric iron to ferrous iron is defective, being somehow linked to the diminished levels of cytochrome oxidase also observed. Low levels of intracellular copper enzymes, such as cytochrome oxidase, may interfere with hematopoiesis in other ways and also account for the neutropenia as well as the neuropathology in humans. The cause of copper deficiency after ingestion of excess zinc has been attributed to induction of the intestinal protein metallothionein by zinc, which preferentially binds copper, prevents its absorption, and enhances its excretion.

The anemia is progressive and may be profound if untreated. The MCV usually is normal or slightly increased at presentation;

P.657

hypochromic microcytic erythrocytes may be detectable on the blood smear. The granulocytes are commonly <1,000/mm³; the platelet count is usually normal. The bone marrow tends to be hypoplastic, with impaired myeloid maturation. Vacuolization of early erythroid and granulocytic precursors is a prominent finding, as are large iron-positive cytoplasmic inclusions in plasma cells. In most instances, moderate numbers of ring sideroblasts are observed, in particular if the anemia is sufficiently severe. The hematologic features have occasionally led to the erroneous diagnosis of a myelodysplastic syndrome before the copper deficiency was recognized.

Serum iron levels and transferrin saturation are normal. The serum copper and ceruloplasmin levels are uniformly low. In cases of zinc-induced copper deficiency, serum zinc levels are increased from two- to threefold above the mean normal value.

With correction of the copper deficit, recovery of the hematologic abnormalities is uniformly prompt and complete. In some cases, recovery followed discontinuation of the excess zinc intake alone. Zinc as a therapeutic agent should thus be prescribed with caution and its use as a stimulus for general well-being should be discouraged. Moreover, the zinc content has been removed from denture cream products. The neurologic abnormalities may improve or only stabilize with
continued copper supplementation. The usual dose of copper may not be sufficient for all patients as relapse has occurred, and longterm follow-up is advised for all patients.

Hypothermia

In 1982, O’Brien et al. described three patients who, during episodic hypothermia, exhibited erythroid hypoplasia and ring sideroblasts as well as thrombocytopenia in the presence of a normal number of megakaryocytes. As the body temperature returned to normal, these changes slowly reversed. The ring sideroblast abnormality might be explained by the well-known inhibition of the translocation of proteins into mitochondria by reduced temperature. Heme synthesis and iron incorporation into hemoglobin by reticulocytes have also been shown to be diminished at lowered temperatures.

ANEMIA FROM DEFECTS IN ERYTHROID HEME SYNTHESIS WITHOUT RING SIDEROBLASTS

Anemia of Lead Poisoning

Lead poisoning has occurred from a wide array of sources, including lodged bullets, inhaled fumes in various industries or lead particles in a firing range, ingested contaminated herbs and food supplements, and beverages containing lead solubilized from glazes of utensils and linings of stills. In children, the primary source was ingestion of lead-based paint chips. Organic lead is acquired by absorption through the skin or by gasoline sniffing. Heterozygotes of hereditary ALA dehydratase deficiency are said to be more susceptible to lower levels of lead exposure, as are persons with one or both genes for the less common allele (ALAD2) of the enzyme. Although lead has been eliminated from various consumer products and occupational exposure is monitored, it may still remain the most common cause of occupational poisoning worldwide.

The anemia that accompanies lead poisoning (plumbism) is in part the result of various inhibitory effects of lead on heme biosynthesis. Most enzymes in the heme biosynthetic pathway are inhibited by lead to varying degrees. Presumably, lead displaces an essential metal or reacts with active-site thiol groups of the enzymes, but the precise mechanism is not worked out in most cases. ALA dehydratase is most sensitive to lead in vitro and in vivo, followed by ferrochelatase, coproporphyrinogen oxidase, and PBG deaminase, respectively. The effects of lead on the production of heme are also interrelated with iron metabolism. In erythroid cells, lead impedes the intracellular delivery of iron to waiting ferrochelatase, and the surrogate metal zinc is inserted into protoporphyrin by ferrochelatase as in iron deficiency so that zinc protoporphyrin accumulates. These events probably account for the usual absence of the ring sideroblast abnormality in persons with lead intoxication. Ferrochelatase may be directly inhibited in acute and more severe lead intoxication, and, only then, nonchelated protoporphyrin accumulates in erythrocytes. Lead also impairs globin synthesis. With prolonged lead exposure, erythroid hypoplasia may occur.

Other effects of lead increase the rate of red cell destruction. Changes in the spatial arrangement of red cell membrane proteins caused by lead are believed to inhibit adenosi triphosphatase, leading to cellular loss of K. If the lead burden is sufficiently severe (i.e., with blood lead concentrations of 200 µg/dl or greater), impaired erythrocyte pyrimidine 5′-nucleotidase activity causes accumulation of nucleotides that inhibit the pentose phosphate shunt and promote hemolysis as in the genetically determined deficiency of the enzyme (see Chapter 28). The typical clinical manifestations are autonomic neuropathy causing abdominal pain and ileus (lead colic) and motor neuropathy (lead palsy). A lead line may be seen on the gums and tonsils. Occasionally, renal dysfunction (lead nephropathy) may prompt the diagnosis. These classic features denote advanced lead toxicity, and more common are insidious, nonspecific musculoskeletal and neuropsychiatric complaints.

The hemolitic changes in lead poisoning are variable and can be attributed to the multiplicity of toxic actions on the erythron. More recently, anemia was present in only 25% of adult patients. Anemia in children is also a late sign of lead poisoning by current standards and frequently is superimposed on pre-existing iron deficiency. The severity of the anemia ranges from mild to moderate, and the red cells tend to be mildly hypochromic and microcytic (Table 24.4). The reticulocyte count may be raised in patients with overt hemolysis. Coarse basophilic stippling may be prominent (Fig. 24.8), representing polysomal aggregates that presumably are retained because RNA degradation is impaired as a result of the pyrimidine 5′-nucleotidase deficiency, but it is not always present and does not correlate with the lead burden. Osmotic fragility of the erythrocytes is decreased; mechanical fragility is increased consequent to the membrane injury. An electrophoretically “fast” hemoglobin similar to hemoglobin A2 may be found. The bone marrow usually reveals erythroid hyperplasia, but it may be hypoplastic. Authentic ring sideroblasts are uncommon, if they occur at all.

The mean red cell life span is reduced with a random pattern of destruction despite problems with the accelerated 51Cr elution from red cells due to lead effects on the red cell membrane. Serum iron levels tend to be normal or slightly
increased unless the patient has associated iron deficiency. The findings of ferrokinetic studies are consistent with ineffective erythropoiesis accompanied by mild hemolysis.  

Parameters of heme biosynthesis reflect the inhibition of the various enzymatic steps and correlate with the lead burden. ALA dehydratase activity in erythrocytes is reduced in proportion to blood lead levels, and, in contrast to the hereditary deficiency of the enzyme, its in vitro activity is restored to normal by reducing agents such as glutathione or dithiothreitol. As a consequence of the reduced activity, urinary ALA is greatly increased, whereas levels of PBG are rarely increased, a combination that distinguishes plumbism from acute porphyrias, in which PBG is excreted in greater excess than ALA. Urinary coproporphyrin, and to a lesser degree uroporphyrin, levels are also increased in lead poisoning. The zinc protoporphyrin level in erythrocytes is increased more than in iron deficiency.

The upper limit of the “normal” level of blood lead, which is mostly contained in erythrocytes, is 30 µg/dl of whole blood. Adults with concentrations of 30 to 75 µg/dl show decreased ALA dehydratase activity, increased urinary excretion of ALA, and an increase in erythrocyte protoporphyrin, and may have nonspecific symptoms of lead poisoning. Clear symptoms usually are associated with concentrations that exceed 75 µg/dl. Concentrations in urine >0.1 mg/24 hours also establish the diagnosis of lead intoxication. When urinary lead excretion is borderline, response to slow intravenous infusion of 25 mg/kg (not to exceed 2 g) of the chelator calcium disodium ethylenediaminetetraacetic acid can confirm the diagnosis; excretion of more than 0.2 mg of lead in 24 hours indicates an increased lead burden.

Treatment consists of removal of the lead source and administration of ethylenediaminetetraacetic acid, 50 mg/kg/day in two divided doses, by slow intravenous infusion with ample fluids for 5 days. This regimen may be repeated in 3 to 4 weeks, depending on the response of blood lead levels. Renal function should be monitored. Recovery usually is prompt. An oral chelating agent, 2,3-dimercaptosuccinic acid, is also available.

Certain Porphyrias

Heme biosynthesis is strikingly perturbed in the various porphyrias that result from heterogeneous molecular defects in each of the enzymes in the pathway (see Chapter 26). Tissue-specific differences of expression and of regulation of these enzymes likely account for the absence of anemia in most porphyrias, as the defective enzymes do not become rate-limiting in the erythroid cell. In a few of them, erythroid heme production may be minimally compromised, as noted for protoporphyria previously; or accumulation of biosynthetic intermediates perturbs erythroid cell development, survival, or both.
FIGURE 24.8. Hypochromia and red cell stippling in lead poisoning.

Congenital Erythropoietic Porphyria

In this rare disorder, expressed as an autosomal recessive trait, erythroid heme biosynthesis is not diminished.\textsuperscript{392,393} Because of the low residual uroporphyrinogen III synthase activity, uroporphyrin I accumulates, mainly in erythroid cells. Variable anemia is associated with dyserythropoiesis and varying degrees of peripheral hemolysis. The porphyrin accumulates in the nuclei of developing erythroblasts and is believed to affect their maturation. Anemia often is not the principal clinical problem. In some patients, the hemolytic process was improved by splenectomy.

Hepatoerythropoietic Porphyria

Hepatoerythropoietic porphyria represents the homozygous deficiency of uroporphyrinogen decarboxylase and is expressed as a variably severe form of porphyria cutanea tarda typically manifesting during infancy or early childhood.\textsuperscript{394} About 40 cases have been reported, and anemia was noted in more than 50% of patients.\textsuperscript{395} Severe anemia or a hemolytic process is the exception. The level of erythrocyte protoporphyrin, primarily as zinc protoporphyrin, is increased and is attributed to a relatively increased conversion of uroporphyrinogen III to protoporphyrin late in erythroid maturation when iron supply may become rate limiting. The anemia has not been characterized.

Harderoporphyria

Anemia has been encountered in this erythropoietic variant of hereditary coproporphyria, in which large amounts of the tricarboxylic harderoporphyrin accumulate.\textsuperscript{396,397,398} Affected individuals carry distinctive homozygous or compound heterozygous mutations in the coproporphyrinogen III oxidase gene, and the mutant enzyme has 18% to 24% residual activity.\textsuperscript{397} Clinically, neonatal hemolytic anemia with hyperbilirubinemia and hepatosplenomegaly is followed by mild microcytic anemia and variable photosensitivity in adulthood. Neurovisceral symptoms of acute porphyria may occur.\textsuperscript{398} Expression of the defect is usually limited to erythroid tissue and is characterized by impaired heme synthesis and dyserythropoiesis with associated iron overload.\textsuperscript{397}
• General Definition of Sideroblastic Anemia (SA)

Sideroblastic anemia comprises a wide spectrum of heritable or acquired erythropoietic disorders. Regardless of clinical and peripheral blood abnormalities, the unifying feature of all forms of SA is the presence of bone marrow ring sideroblasts.

• Prompt Diagnosis of a Sideroblastic Anemia

Consider in all adults and children/infants with unexplained anemia of any severity from history, clinical examination, and basic laboratory data. Certain features are suggestive: history of chronic anemia; exposure to factors causing reversible SA (Table 24.1); family history of anemia; presence of neurologic abnormalities, myopathy, lactic acidosis, immunodeficiency in children or young adults.

Suspect a congenital SA in the presence of microcytosis without evidence of iron deficiency or thalassemia; the MCV and erythrocyte morphology are most accurate before any red cell transfusion (Fig. 24.9).

Establish the diagnosis of SA by performing a Prussian blue stain on the bone marrow aspirate smear.

![Diagram](image)

**FIGURE 24.9. Schema for diagnostic evaluation of patients with a sideroblastic anemia. MCV, mean corpuscular volume; XLSA, X-linked sideroblastic anemia; ARCSA, autosomal recessive sideroblastic anemia; XLSA/A, X-linked sideroblastic anemia with ataxia; Iggs, immunoglobulins; MLASA, myopathy, lactic acidosis, and sideroblastic anemia; mtDNA, mitochondrial DNA; TRMA, thiamine-responsive megaloblastic anemia. *Microcytic hypochromic red cells may be present in the blood smear in many, but not all, of these disorders. **Typically present in infancy or childhood.

• Differential Diagnosis

If ring sideroblasts are evident in the marrow, review the patient’s constellation of clinical findings to narrow the differential diagnosis (Table 24.1, Fig. 24.9).

Where the causative gene is known, mutation analysis provides definitive diagnosis of a congenital SA; some molecular genetic tests are available in several clinical laboratories listed on the [www.genetests.org website](http://www.genetests.org), others may be available in certain research laboratories.

Evaluate for iron overload with serum iron profile and ferritin; assess parenchymal organ involvement as indicated.
• Treatment

Withdraw an identified reversible cause.

Recommend a therapeutic trial of pyridoxine (adult dose 50 to 100 mg/day) in patients with microcytic SA until the genetic cause can be determined; the vitamin is only effective in some cases with XLSA.

For symptomatic anemia, provide supportive treatment with red cell transfusion.

Remove excess body iron by phlebotomy if anemia is mild; by use of iron chelation in patients with severe/transfusion-dependent anemia.

P.660

Prescribe thiamine (25 mg/day) in the TRMA syndrome.

Manage the clinical aberrations associated with the syndromic forms of congenital SA with available supportive measures.

• Follow-up

Educate the patient and family about the disease and relevant inheritance.

Encourage patients to keep records of diagnostic studies and recommended therapy.

In cases with congenital SA, provide for examination of family members and for their genetic testing as indicated.

Iron overload can result from any process that causes iron accumulation in excess of iron loss. Examples of such processes include (a) erythrocyte transfusions in individuals who do not experience blood loss (e.g., patients with hemolytic anemia, aplastic anemia, and sideroblastic anemia); (b) absorption of excessive amounts of normal dietary iron (hemochromatosis types 1 through 4, disorders of ineffective erythropoiesis); and (c) absorption of increased amounts of excessive dietary iron (e.g., high-dose medicinal iron and African iron overload).

**Definition**

The definition of iron overload typically includes a description of an individual's iron phenotype, such as (a) an elevated serum ferritin concentration; (b) excessive iron in the liver or myocardium (estimated histologically or by chemical methods); and (c) the requirement of a greater than normal number of phlebotomies to induce iron-limited erythropoiesis.

**Hemochromatosis**

Hemochromatosis Type 1, HFE Hemochromatosis

The definition of “classical,” autosomal recessive hemochromatosis (type 1) typical of Western European whites once required demonstration of the rare triad of cutaneous hyperpigmentation (“bronzing”), diabetes mellitus, and cirrhosis that was presumed to represent complications of severe iron overload. The eventual ability to measure iron in liver and other tissues, serum, and by phlebotomy to achieve iron depletion revealed that hemochromatosis was more common than previously believed and that the diagnosis could be defined by severity of iron overload. In 1996, it was discovered that most patients with this type of hemochromatosis were homozygous for a common missense mutation (C282Y) of the HFE gene on chromosome 6p21.3. Thus, most current definitions of hemochromatosis in Western European whites include specification of the iron phenotype and HFE genotype. Three important relationships of phenotype and genotype definitions are: (a) HFE C282Y homozygosity is a genetic configuration that markedly increases the risk that iron overload will eventually develop without other readily demonstrable cause; (b) iron phenotypes and organ-specific complications of HFE C282Y homozygotes vary greatly due to genetic and environmental factors; and (c) iron overload, not HFE C282Y homozygosity or abnormal HFE protein, causes tissue injury in target organs.

Hemochromatosis Type 2, Juvenile Hemochromatosis

Hemochromatosis type 2 is characterized by nontransfusion iron overload, often severe, that typically occurs in children or young adults.

Type 2a, Mutations of Hemojuvelin Gene (HJV)
Hemochromatosis type 2a is an autosomal recessive disorder due to pathogenic mutations in the hemojuvelin gene (HJV; chromosome 1q21).\textsuperscript{1, 2} The iron overload phenotype of patients with HJV hemochromatosis is much more severe at the same age than the phenotype of typical patients with hemochromatosis due to HFE C282Y homozygosity and the penetrance of hemochromatosis type 2a genotypes (risk to cause iron overload) is also greater. Hemochromatosis type 2a often causes abdominal pain and hepatomegaly in children, hypogonadotropic hypogonadism in teenagers, arthropathy, and severe heart failure, cardiac arrhythmias, and cirrhosis before the age of 30 years.\textsuperscript{3} Based on the volume of blood removed to achieve iron depletion in some patients, it can be deduced that they absorbed 3.2 to 3.9 mg of dietary iron per day.\textsuperscript{4} In severe HFE hemochromatosis, 2 mg of iron or less is absorbed daily.\textsuperscript{5, 6}

Two pathogenic HJV mutations (either homozygous or compound heterozygous configuration) occur in each patient. The most common HJV mutation causes a change in nucleotide 959G→T, which codes for substitution of the normal glycine by valine in position 320 of the polypeptide sequence of the HJV protein (HJV G320V). This mutation has been detected in patients with juvenile-onset hemochromatosis of diverse European ethnicities.\textsuperscript{7, 8} About 30 pathogenic HJV mutations have been reported. Many are novel (not detected in unrelated patients with hemochromatosis type 2a.)\textsuperscript{7, 8, 9, 10, 11} Some HJV hemochromatosis patients also have an abnormal HFE genotype but the latter does not account for iron overload in most cases.\textsuperscript{12}

Hemojuvelin is involved in the up-regulation of hepcidin synthesis, not in the regulation of HFE function. Decreased hemojuvelin activity decreases hepcidin synthesis, thus decreasing hepcidin binding and inactivation of ferroportin. Consequently, regulation of iron transport out of absorptive enterocytes into the plasma via ferroportin is decreased, even in the presence of increased storage iron.

Type 2b, Mutations of Hemojuvelin Gene (HAMP)

Hemochromatosis type 2b is associated with iron overload of variable severity and age of onset and is also transmitted as an autosomal recessive trait.\textsuperscript{12, 13} This disorder is rare. Hemochromatosis type 2b is due to mutations in the hemojuvelin gene (HAMP, chromosome 19q13). HAMP is an acronym for hepcidin antimicrobial peptide. The word hepcidin is derived from hepatic bactericidal protein.

The first reported HAMP mutation (nucleotide 208T→C) causes substitution of the normal cysteine by arginine at amino acid 70 (C70R).\textsuperscript{14} Approximately 12 other HAMP mutations have been reported.\textsuperscript{15, 16, 17, 18} Mutant hemojuvelin has decreased ability to bind to ferroportin, its only receptor. Consequently, ferroportin is not degraded and thus continues to transport iron across the basolateral membrane of absorptive enterocytes in the presence of excess iron stores.\textsuperscript{19} Some hemojuvelin type 2b patients, usually those heterozygous for pathogenic HAMP promoter or coding region mutations, also have HFE mutations that contribute to the pathogenesis of iron overload (“digenic” hemochromatosis).

Hemochromatosis Type 3, Mutations of Transferrin Receptor-2 Gene (TFR2)

Hemochromatosis type 3 is a rare autosomal recessive disorder reported in persons of European or Asian ancestry caused by mutations of the transferrin receptor-2 gene (TFR2) located on chromosome 7q22.\textsuperscript{20} The clinical phenotype is moderately variable and resembles either that of HFE hemochromatosis or that of juvenile hemochromatosis types 2a and 2b. Fewer than 20 pathogenic TFR2 mutations have been reported.\textsuperscript{20, 21, 22, 23, 24} The penetrance of hemochromatosis type 3 genotypes is relatively great. Consanguinity has been identified in some affected families. TFR2 Y250X and R455Q have been detected in individuals or kindreds who were not closely related.\textsuperscript{25} Pathogenic TFR2 mutations either result in gain-of-function or in decreased quantities of functional transferrin receptor-2. TFR2 protein is thought to modulate the signaling pathway that controls hepcidin expression\textsuperscript{26} with consequent low hepcidin\textsuperscript{27} and increased iron absorption and deposition in hepatocytes.

Hemochromatosis Type 4, Mutations of Ferroportin Gene (SLC40A1)

Hemochromatosis type 4 is an uncommon heterogeneous disorder transmitted as an autosomal dominant trait. It is caused by mutations of a gene of the solute carrier family 40 (member #1) (SLC40A1, chromosome 2q32), which encodes the synthesis of ferroportin, the sole receptor of hepcidin.\textsuperscript{27, 28, 29, 30} There are two distinct ferroportin hemochromatosis phenotypes. Loss-of-function SLC40A1 mutations encode ferroportin that either is not presented normally to the cell surface or has defective iron transport activity. Such mutations decrease iron absorption from the intestine and inhibit iron egress from macrophages. Phenotypes of affected patients include normal or low transferrin saturation, mild anemia, and predominance of iron retention in macrophages. Gain-of-function mutations encode ferroportin that cannot bind hepcidin normally or be internalized after hepcidin binding (hepcidin resistance). This increases iron absorption and
stimulates iron export by macrophages. Affected patients have elevated transferrin saturation and iron deposition in hepatocytes.

Ferroportin mutations are cosmopolitan. Most reported mutations are restricted to single families. SLC40A1 V162del has been reported in persons with iron overload from Australia, Europe, and Asia. SLC40A1 A77D has been reported in persons with iron overload in Italy, Australia, and India. SLC40A1 Q248H occurs as a polymorphism in natives who reside in diverse areas of sub-Saharan Africa and in African Americans, but probably does not cause iron overload.31

HISTORY

Hemochromatosis Type 1, Classical, Hereditary

The first report of a person with hemochromatosis was included in a discussion of diabetes mellitus in 1865.32 The patient was a 28-year-old Parisian man who sold newspapers and who died of a febrile illness that complicated his diabetes. His autopsy revealed hepatomegaly and hypertrophic cirrhosis. The second case of hemochromatosis was reported in 1871 and described a 51-year-old man who lived in Paris.33 He had skin bronzing of his face and hands. His autopsy revealed a chocolate-colored, enlarged liver. Microscopic examination of his liver showed pigment granules inside and outside of hepatocytes. In 1886, the term pigmentation cirrhosis was used to describe the triad of skin bronzing, diabetes mellitus, and hepatic cirrhosis.34 The name hämochromatose was first used by von Recklinghausen in his 1889 description of 12 individuals who had pigmentation of multiple organs.35 He believed that the iron that accumulated in organs came from red blood cells.

ETIOLOGY

Cloning of the HFE Gene

In 1996, the hemochromatosis gene was isolated by positional cloning and two common mutations that account for most cases of hemochromatosis in persons of Western European descent were discovered.36 The gene was named HFE (H = hemochromatosis; Fe = iron).37, 38 The cloning of HFE was reported more than 130 years after the first case description of hemochromatosis at autopsy and confirmed reports during an interval of more than two decades that hemochromatosis was transmitted as an autosomal recessive condition linked to the HLA locus on the short arm of chromosome 6.39, 40

Function of the HFE Gene

The normal HFE gene encodes normal HFE protein which is expressed in duodenal crypt cells and reticuloendothelial cells.48 In a normal individual, HFE protein binds to β2-microglobulin, which decreases the affinity of cell membrane transferrin receptors for transferrin.49-52 This decreases iron absorption. In iron deficiency, HFE protein synthesis is decreased, binding of HFE protein to β2-microglobulin is decreased, the affinity of the transferrin receptor for transferrin is increased, and thus duodenal crypt cells absorb more iron.

Effects of HFE Gene Mutations

The HFE protein binding site for the β2-microglobulin binding site has two cysteine molecules that form a disulfide bridge. In HFE C282Y homozygotes, tyrosine replaces a cysteine molecule at amino acid position 282 in the product of both HFE gene copies (maternal and paternal) and thus the disulfide bridge is absent. This prevents binding of the abnormal HFE protein to β2-microglobulin on the cell surface. Excessive iron is then absorbed through the crypt cells and passed into the circulation.53-58 Despite these observations, the full function and participation of the HFE protein in iron absorption has not been elucidated. Studies of penetrance of hemochromatosis demonstrate that HFE C282Y homozygosity is necessary but probably not sufficient for iron overload to develop.

PATHOPHYSIOLOGY

Normal adults absorb an amount of iron each day that precisely balances daily losses (men ~1 mg, women 1 to 3 mg). In healthy children and infants, daily iron absorption corresponds to the iron requirements of growth and development. In acute blood loss or iron deficiency, daily iron absorption increases until the total body deficit has been replaced. In persons with hemochromatosis, the absorption of dietary iron is inappropriately great in comparison with quantities of total body iron. In some persons with HFE hemochromatosis and iron overload, daily iron absorption may exceed 2 mg at a time when iron absorption should have decreased to nearly zero.59, 60 In some children with juvenile hemochromatosis, average daily iron absorption may exceed 3 mg/day. Phlebotomy therapy to achieve iron depletion in hemochromatosis may increase iron absorption to 10 mg/day and iron absorption may remain inappropriately elevated long after iron deficiency resolves.61-63 Iron loading in hemochromatosis types 1 to 4 is caused either by an abnormality in hepcidin,

Wintrobe's Clinical Hematology 13th Edition
synthesis or a decrease of its activity via decreased function of ferroportin. HFE, HJV, and TFR2 probably all have a contributory role in regulating hepcidin synthesis.

Effects of Hepcidin

Hepcidin, the central regulator of iron absorption, is a low-molecular-weight thionin-like, defensin-like peptide with many cysteine pairs encoded by the HAMP gene. Hepcidin has antimicrobial activity against bacteria and fungi, is present in plasma, and is excreted in urine. Hepcidin is synthesized in hepatocytes in response to anemia, hypoxia, and inflammatory stimuli mediated by interleukin 6, 73, 74, 75 and in the presence of adequate or increased amounts of iron. 72, 73, 74, 75 It is also involved in the abnormalities of iron metabolism that occur in the anemia of chronic disease. 76, 77, 78, 79 Hepcidin levels are inversely related to iron absorption.

P.664

Ferroportin, the sole receptor for hepcidin, occurs as a multimer on the surfaces of cells responsible for gathering and recycling iron: enterocytes (basolateral surfaces), macrophages, hepatocytes, and placental syncytiotrophoblasts. The binding of cell surface ferroportin by hepcidin results in ferroportin tyrosine phosphorylation at the plasma membrane, dephosphorylation, and degradation by ubiquitination. 69, 70, 80 Thus, hepcidin participates in regulation of plasma iron levels and tissue distribution of iron by post-translational regulation of ferroportin.

Hepcidin Effect in Iron Deficiency

In iron deficiency, hepcidin production is down-regulated so the amount of hepcidin available to bind ferroportin is reduced. More iron is exported from absorptive enterocytes by ferroportin than usual, resulting in increased absorption of iron through duodenal enterocytes into the plasma. 81

Hepcidin Effect in Iron Repletion

In normally iron-replete humans, the production of hepcidin is up-regulated. The hepcidin bonds with ferroportin inducing ferroportin internalization and degradation. 19, 69, 80 Consequently, the amount of ferroportin is reduced and iron absorption from duodenal enterocytes into plasma decreases.

Hepcidin Effect in Hemochromatosis

Dysregulation of hepcidin production underlies the pathophysiology of most types of hemochromatosis (types 1, 2a, 2b, and 3). In iron-loaded individuals with HFE hemochromatosis, for example, hepcidin expression by the liver is inappropriately low, 82, 83 and thus iron absorption continues despite increased iron stores. Hepcidin levels are decreased in all types of hemochromatosis except in patients with “classical” ferroportin hemochromatosis (type 4). In those patients, iron overload is caused by a mutation in the ferroportin gene (SLC40A1) that results in diminished or absent functional quantities of ferroportin. 81 In such cases, hepcidin production and regulation are normal.

Molecular Basis of Increased Iron Absorption in Hemochromatosis

Several factors in the duodenum contribute to inappropriately high iron absorption in HFE hemochromatosis. In enterocytes, DMT1 (divalent metal transporter-1) transports iron across the apical microvillous membrane into the cell in the presence of hydrogen ions derived from gastric acid and ferroportin transports iron across the basolateral membrane into the plasma. Untreated C282Y homozygotes have inappropriate up-regulation of DMT1 and ferroportin mRNA expression in proportion to their serum ferritin level. 5, 60 The interaction of transferrin, transferrin receptor, and HFE protein at the basolateral membranes of duodenal absorption cells may play a minor role in regulating iron absorption in persons with HFE hemochromatosis. 19, 69, 80 SLC40A1 mutations that encode ferroportin that either is not presented normally to the cell surface or has defective iron export activity are associated with loss-of-function, normal or low transferrin saturation, and predominance of iron retention in macrophages. Such mutations decrease iron absorption from the intestine and inhibit iron export from macrophages.

The complicated interactions of HFE, DMT1, transferrin, transferrin receptors, hemojuvelin, hepcidin, and ferroportin in regulating iron absorption in normal individuals and in persons with hemochromatosis are a topic of intense and productive research. 75, 80, 86, 87, 88, 89, 90

ORGAN AND CELLULAR INJURY DUE TO IRON OVERLOAD
After many years of increased iron absorption, hepatocyte and Kupffer cell iron storage sites become overloaded and iron accumulates progressively in the myocardium, pancreas, anterior pituitary, spleen, and other organs. Cardiac myocytes, beta-cells of the pancreatic islets, and gonadotroph cells of the anterior pituitary have especially great affinity for otherwise unbound iron. Some individuals with severe iron overload due to hemochromatosis have body iron burdens that are more than 10 times normal. Usually, such individuals do not develop symptoms or signs of illness until after they have had iron overload for three to five decades. Exceptions include the organ damage and death that can occur before the age of 30 years in persons with severe iron overload due to juvenile hemochromatosis.

Iron that is bound to transferrin or stored in modest amounts in ferritin is not toxic. In the presence of excessive iron stores, non-transferrin-bound or non-ferritin iron occurs and generates reactive oxygen species (oxyradicals), especially the hydroxyl radical. It is likely that hydroxyl, alkoxyl, and peroxyl radicals are involved in lipid peroxidation which damages microsomes, mitochondria, and lysosomes. Hydroxyl radicals are also thought to be involved in iron-related damage of enzymes, proteins, nucleic acids, and polysaccharides. Lipid peroxidation then results in disruption of membrane-dependent functions of lysosomes, mitochondria, endoplasmic reticulum, cell membranes, and DNA. Excess iron and iron-induced oxyradicals may also activate stellate cell transformation to fibroblasts in the liver and act as carcinogens in hepatocytes or extrahepatic parenchymal cells.

DIFFERENTIAL DIAGNOSIS OF IRON OVERLOAD

Many heritable or acquired disorders are associated with increased body iron stores. Some of these disorders appear in Table 25.1. Including gene location, mode of heritability, and gene mutation responsible for the disorder. Table 25.1 provides guidance for physicians who are evaluating and managing patients with iron overload.

**HFE HEMOCHROMATOSIS GENE**

**HFE Location**

The HFE gene is located approximately 4 megabases telomeric to the HLA region on the short arm of chromosome 6p(6p). HFE is structurally similar to other HLA class I-like genes. HFE is composed of seven exons, of which the first six encode for the six domains of the HFE protein. The seven exons of HFE result in formation of a messenger RNA transcript of 4.2 kilobases. This in turn results in the synthesis of the HFE product, a protein of 343 amino acids. The most common mutation of HFE (C282Y) associated with iron overload is caused by a mutation of one nucleotide base 845G→A in exon 4 of the HFE gene.

**HFE Mutations**

More than 60 mutations of the HFE gene have been reported. The most common mutation that occurs in people who have hemochromatosis is a change in nucleotide 845 from the normal guanidine to adenine in exon 4 of the HFE gene (referred to as 845G→A). This nucleotide change results in the substitution of tyrosine in place of the normal cysteine in amino acid position 282, referred to as Cysteine282Tyrosine, Cys282Tyr, or C282Y. This mutation causes the majority of iron accumulation in subjects who have hemochromatosis.

- SLC11A2, solute carrier family 11, member 2.
G6PD, glucose-6-phosphate dehydrogenase.

P.666

The second most common HFE gene mutation in hemochromatosis patients is a change in nucleotide 187 from the normal cytidine to guanidine 187C→G in exon 2. This results in substitution of aspartate for the normal histidine at amino acid position 63. Both the C282Y and H63D mutations were identified in the initial report of the isolation and cloning of HFE. Of the reported mutations of the HFE gene, 31 are missense mutations that result in substitution of the normal amino acid by another. There are 27 reported nonsense mutations of HFE, 12 of which are splice errors that are associated with intron sequence variants. Eight mutations involve a nucleotide change that does not result in an amino acid substitution (synonymous mutations). Some important HFE gene mutations are given in Table 25.2. Other mutations occur in noncoding regions of HFE. It is expected that other rare mutations of the HFE gene will be identified in adults with hemochromatosis phenotypes.

HFE Mutations in Hemochromatosis Patients and in Different Populations

In the first report of the HFE gene and its mutations, 83% of subjects with hemochromatosis were C282Y homozygotes. The prevalence of homozygosity for C282Y varies from 33% to 100% among groups of hemochromatosis patients. In the United States, 59% to 89% of hemochromatosis patients are C282Y homozygotes. The percentage of hemochromatosis patients from 14 countries who have the C282Y and H63D genotypes is presented in Table 25.3.

### Table 25.2 Sixty-Seven Mutations of the Hemochromatosis Gene (HFE) in Hemochromatosis Type 1: Nucleotide and Amino-Acid Changes, Type of Mutation, Exon or Intron Involved, and Effect of the Mutation on Iron Loading

The prevalence of HFE mutations is high in some populations, such as those of Central, Western, and Northern Europe, and in countries that were populated predominantly by people who originated in these areas of Europe, including the United States, Canada, and Australia. 241, 277 It is predicted that the prevalence of HFE mutations is very low in parts of the world with little or no ancestry from Central and Western Europe, including sub-Saharan Africa (Native Africans), the Middle East, the Orient, and Native Americans in North, Central, and South America. The frequency of homozygosity for the HFE C282Y mutation in the United States varies from 0% to 1.00% in whites, 0% to 0.22% in Mexican Americans, and 0% to 0.06% in blacks (Table 25.4). The prevalence of C282Y, H63D, and wild-type HFE genotypes from nine studies in the United States is presented in Table 25.4. 231, 242, 244, 278, 279, 280, 281, 282, 283 Extensive data about genotype frequencies in many countries, and from different regions within countries, have been published. 241, 277, 284

Hemochromatosis and Iron Overload Screening Study

The largest study of the prevalence of HFE mutations and of serum iron tests was recently completed and published. It is called the HEIRS Study (Hemochromatosis and Iron Overload Screening Study).136, 285, 286, 287, 288, 289 Tests for the C282Y and H63D mutations of HFE, serum iron concentration, transferrin saturation, and serum ferritin concentration were measured in about 102,000 outpatients in the United States and Canada. Participants were recalled for additional evaluation if they were C282Y homozygotes or if they had elevated results of transferrin saturation (percent saturation >50% in men, >45% in women) or elevated serum ferritin (>300 µg/L in men, >200 µg/L in women).

Wintrobe's Clinical Hematology 13th Edition
Prevalence rates were derived with Hardy-Weinberg proportions within the five ethnic groups who were not C282Y homozygotes.

"Data from participants with complete information on HFE C282Y and H63D mutations, transferrin saturation, and serum ferritin levels, except 1,457 who heard about the study from a participating family member, were included.

The Study centers were Washington DC; Birmingham, Alabama; Irvine, California; Portland, Oregon; Honolulu, Hawaii; and London, Ontario, Canada. Of 99,711 study subjects, 44,082 were Caucasians, 12,772 were Asians, 12,459 were Hispanics, 698 were Pacific Islanders, and 648 were Native Americans. The prevalence of C282Y homozygosity was highest in Caucasians (0.44%, 4.4 per 1,000) and lowest in Asians (0.39 per 1,000,000), followed by Pacific Islanders (0.012%), blacks (0.014%), Hispanics (0.027%), and Native Americans (0.11%). The prevalence of the C282Y/C282Y, C282Y/H63D, and H63D/H63D genotypes in the study participants is presented in Table 25.5.\textsuperscript{287} Among Caucasians, the H63D/H63D and the C282Y/H63D genotypes were about 4 times and 3.5 times as common, respectively, as the C282Y/C282Y genotype.\textsuperscript{287}

Prevalence of HFE Mutations in Other Large Population Studies

In a study of 65,238 Norwegians, 0.68% were C282Y homozygotes.\textsuperscript{290} In a study of 41,038 participants in a Southern California health appraisal clinic, the prevalence of C282Y homozygosity among 30,418 whites was 0.46% (139 homozygotes).\textsuperscript{278}

Association of Iron Loading and HFE Mutations

Some mutations are associated with severe iron loading, such as C282Y, R330M, IVS3 (+1) G→T, E168X, C282S, R74X, and G93fs (Table 25.2). Some mutations are believed to have a modest or moderate effect on iron accumulation, for example, H63D, S65C, G93R, I105T, and E168Q. Other HFE mutations have been identified in individuals without iron overload or in whom the effect of the mutation on iron accumulation could not be determined, such as V53M, V59M, Q127H, E277K, and in several intron sequence variants. Some mutations code for the normal amino acid (synonymous mutations) and do not affect iron absorption. The HFE mutations with severe, mild, or unknown effects on iron accumulation are shown in Table 25.2.

Interaction of Mutations of Hfe and of Other Genes

Interaction of Mutations of HFE and Hepcidin

Mutations of HFE and other genes involved in maintaining iron homeostasis can have a synergistic effect on iron accumulation in hemochromatosis. A striking example of this is the heavy iron loading that occurred in an individual who had C282Y homozygosity and a mutation of the hepcidin gene (a HAMP mutation resulting in deletion of four nucleotides and methionine50 deletion, an intron sequence variant in exon 2 and intron 1, referred to as M50del IVS2+1(-G), a
frameshift deletion). This represents a “digenic” configuration of a mutation in each of two autosomal recessive genes, neither of which alone would likely cause heavy iron accumulation. This digenic genotype caused massive iron overload by age 27 years. The affected man underwent removal of 27 g of iron for 4 years before his serum ferritin concentration became normal (at diagnosis 1,645 µg/L, after treatment 40 µg/L). Mutations of other genes, such as the transferrin receptor-2 or ferroportin, can also result in heavy iron accumulation in individuals who also have HFE mutations.

Some investigators reported that a variant in the D-loop of mitochondrial DNA (mtDNA) where a T→C substitution occurred at nucleotide 16189 (mtDNA 16189T→C) was associated with more severe iron phenotypes in patients with hemochromatosis. Other investigators did not confirm this report. It seems likely that additional mutations in diverse genes will be found to explain increased or decreased rates of iron absorption in C282Y homozygotes.

FREQUENCY OF HEMOCROMATOSIS IN MEN AND WOMEN

Hemochromatosis is transmitted as an autosomal recessive condition and therefore there should be equal numbers of male and female homozygotes. Overt iron overload, organ injury, and illness occur more frequently in men than in women with this disorder. Men with hemochromatosis have approximately two and a half times as much mobilizable body storage iron as women. Most women are protected from severe iron overload by the menstrual loss of 15 to 25 mg of iron each month and by the transfer of approximately 750 mg of iron to the fetus during pregnancy. Regardless, menstrual blood losses and pregnancy do not explain all of the differences in body iron stores between male and female homozygotes. Testosterone suppresses hepcidin production and this could account in part for the tendency of men with hemochromatosis to develop more severe iron overload than women.

CLINICAL FEATURES OF HEMOCHROMATOSIS

Symptoms

The presence or absence of symptoms in persons with hemochromatosis is related to the stage at which the diagnosis is established. Individuals diagnosed to have hemochromatosis during a routine office visit are expected to have no organ injury and many of them are not heavily iron loaded, if at all. This is common among women, young men, children, and the healthy siblings who undergo family screening after a proband is diagnosed. Subjects in whom the diagnosis is established after they seek medical attention due to symptoms are typically ill (Table 25.6). These persons usually have iron overload and evidence of organ injury. The frequency of symptoms, physical signs, and laboratory abnormalities in subjects with hemochromatosis (sick probands) compared with probands who were identified during screening and compared with their homozygous relatives who were identified during family evaluation (clinically unselected homozygotes) are given in Table 25.7. Approximately 90% to 98% of people who are found to have hemochromatosis during screening are asymptomatic.

b p values calculated by chi-square test.

c Scale of 0-4; normal grade 0-1.

The most common symptom in nonscreening hemochromatosis patients at diagnosis is arthralgias, (approximately 40% of homozygotes).³⁴⁵ The joints most commonly involved with typical hemochromatosis arthropathy are metacarpal-phalangeal (MCP) joints, especially the second and third.³⁰⁴ Pain or other manifestations can also occur in knees, hips, shoulders, and other diarthrodial joints. Weakness, fatigue, and lethargy are common but nonspecific symptoms. Weight loss, abdominal pain, loss of libido in men, and palpitations also occur in some iron-loaded homozygotes. The prevalences of arthralgias, abdominal pain, loss of libido or impotence, and palpitations in different study populations are displayed in Tables 25.6 and 25.7.

**Physical Examination Abnormalities**

Gray or bronze pigmentation is the most common physical examination abnormality in hemochromatosis homozygotes diagnosed in nonscreening settings (35% to 84%). Other common findings include arthropathy (13% to 68%), hepatomegaly (54% to 93%), splenomegaly (10% to 55%), irregular heartbeat, congestive heart failure, telangiectases, and loss of midline body hair or testicular atrophy. The frequency of physical abnormalities in hemochromatosis from nine studies is shown in Table 25.6. The prevalence of self-reported illness according to HFE genotype in two very large US and US-Canadian population screening studies is given in Tables 25.8³⁰¹ and 25.9.³⁷⁸

**Laboratory Abnormalities**

The most common laboratory abnormalities in subjects with hemochromatosis are elevations of serum iron concentration, percent transferrin saturation, and serum ferritin concentration.³⁸⁶ ³⁰⁵ Transferrin saturation may be elevated in children or teenage homozygotes before serum ferritin elevation occurs, long before symptoms or physical examination abnormalities develop. This is attributed to the increased release of iron by macrophages via ferroportin in the presence of low hepcidin levels. The typical values of transferrin saturation according to the method of ascertainment
in 291 Utah homozygous probands are presented in Table 25.10.\textsuperscript{245} The results of transferrin saturation and serum ferritin concentration in normal individuals, C282Y heterozygotes, C282Y/H63D compound heterozygotes, and H63D homozygotes according to HFE genotype from a large US population screening study are shown in Table 25.11.\textsuperscript{278}

In untreated C282Y homozygotes, the average hemoglobin concentration is greater than that of control subjects without common HFE mutations.\textsuperscript{306, 307} Likewise, the value of mean corpuscular volume of untreated C282Y homozygotes is elevated, sometimes above the upper reference limit, even in patients without liver disease.\textsuperscript{306} The mean red blood cell count and mean coefficient of variation of mean corpuscular volume (RDW) are lower in C282Y homozygotes.\textsuperscript{308} These erythrocyte-associated characteristics, usually more pronounced in men than women, are due to the ample amounts of iron constantly available to marrow erythroblasts via transferrin, the saturation of which is increased in most C282Y homozygotes. Genome-wide linkage analyses confirm that a locus (loci) on chromosome 6p21 is significantly associated with hemoglobin concentration.\textsuperscript{309} This locus is presumed to be HFE.

Radiographs of hands are often abnormal in homozygotes who have arthralgias. Approximately 50% of homozygotes have radiographic changes. The plain films reveal narrowing of the MCP joint spaces, subperiosteal bone resorption, and periarticular demineralization. Plain films of knees may reveal chondrocalcinosis, linear calcium deposition in the cartilage that is visible across the joint space.

The next most common laboratory abnormality in untreated hemochromatosis patients diagnosed in nonscreening venues is elevation of serum levels of alanine aminotransferase and aspartate aminotransferase (8% to 92%). The prevalence of this abnormality varies markedly according to the method of ascertainment (Tables 25.6 and 25.7). Usually, these enzyme levels are elevated two to five times the upper limit of normal in nonscreening subjects. The significance of elevated serum levels of hepatic transaminases is often different in C282Y homozygotes detected in screening programs than in nonscreening patients. In HEIRS Study participants with hyperferritinemia, mean serum levels of transaminase activities were significantly lower in C282Y homozygotes than nonhomozygotes. The probability of being a C282Y homozygote increased as the transaminase activities decreased. Thus, study participants with hyperferritinemia detected in screening are more likely to be C282Y homozygotes if they have normal liver transaminase activities.\textsuperscript{310} If hepatic failure is present, serum transaminase and bilirubin levels may be very elevated. Other common laboratory abnormalities include elevation of serum glucose concentration (0% to 82%); arrhythmia on electrocardiography; cardiomegaly on chest radiography; decreased ejection fraction on echocardiography; elevated or very low thyroid-stimulating hormone in hypothyroidism or hyperthyroidism, respectively; and blood test evidence of hypogonadism, usually the hypogonadotrophic type with decreased serum concentrations of testosterone, dihydrotestosterone, luteinizing hormone, and follicle-stimulating hormone.\textsuperscript{311} Tables 25.6 and 25.7 show the frequency of lab abnormalities in individuals who have hemochromatosis.

a The homozygous relatives were 164 siblings, 10 parents, 19 offspring, 7 nieces, 6 nephews, 1 aunt, 2 uncles, 1 grandmother, and 4 persons who married into an affected family and had transferrin saturation values similar to those of homozygotes.

b Mean values.

c The \( p \) values calculated by the Kruskal-Wallis nonparametric test for the comparison of ferritin concentrations were as follows: clinically affected probands as compared with probands identified because they had elevated transferrin saturation values: <0.001 for men, 0.002 for women; clinically affected probands as compared with clinically unselected homozygous relatives: <0.001 for men, <0.001 for women; probands identified because of elevated transferrin saturation values compared with clinically unselected homozygous relatives: 0.37 for men, 0.004 for women.

Liver Biopsy Findings

Liver morphology by microscopy is usually normal in homozygotes whose serum ferritin is not elevated. When serum ferritin concentration is elevated, the hepatic parenchymal cell stainable iron is usually increased. The same comments apply to the measured hepatic iron concentration. Many 40- to 50-year-old male homozygotes have hepatic fibrosis when hemochromatosis is diagnosed (2% to 32%) (Table 25.12). A range of 0% to 92% of male homozygotes have cirrhosis at the time of diagnosis, usually the sick individuals (Tables 25.6 and 25.7). Most women with hemochromatosis do not have fibrosis or cirrhosis at diagnosis. Cirrhosis is not expected to occur until the hepatic iron concentration is elevated to approximately 22,000 \( \mu \)g (22 mg) of iron per gram of liver dry weight (normal, approximately 1,000 \( \mu \)g iron per gram dry weight). Hemochromatosis homozygotes who are only identified because they participated in screening studies rarely have heavy liver iron overload or hepatic fibrosis (Tables 25.7 and 25.12).

In hemochromatosis patients, an elevated serum concentration of collagen type IV correlates strongly \((p < 0.0001)\) with hepatic fibrosis or cirrhosis. Serum collagen type IV levels in a group of 42 hemochromatosis patients were compared to those of 19 control subjects. A serum concentration of collagen type IV \( >115 \) ng/ml had a sensitivity of 100% and a specificity of 69% for far-advanced hepatic fibrosis (grade 3) and cirrhosis (grade 4). Among homozygotes who are diagnosed very late, 10% to 29% of those with cirrhosis develop hepatocellular carcinoma. Hepatocellular carcinoma in hemochromatosis may be multifocal rather than focal and may not cause marked elevation of \( \alpha \)-fetoprotein that is common in individuals who have a large nodular hepatoma. Multifocal hepatocellular carcinoma may not be visible by ultrasonography until the diameter of the nodules reaches 1 cm. The frequency of hepatic fibrosis, cirrhosis, and hepatocellular carcinoma in hemochromatosis patients is presented in Tables 25.6, 25.7, and 25.12.
HFE MUTATIONS AND OTHER CONDITIONS

Arthropy

Arthropathy is common in patients diagnosed to have hemochromatosis in nonscreening settings and is a major cause of morbidity in some individuals. The proportion of nonscreening patients who have severe iron overload is relatively high and the prevalence of hemochromatosis arthropathy is significantly greater in patients whose serum ferritin levels are greater than 1,000 µg/L at diagnosis than in those with lower serum ferritin levels.

Hemochromatosis homozygotes with arthropathy usually experience symmetrical arthralgias in the second and third MCP and proximal interphalanegal (PIP) joints. MCP joint swelling, decreased range of motion, and decreased ability to make a fist are typical physical findings. Radiographic findings include hypertrophy and related abnormalities of MCP and PIP joints, subchondral cysts with sclerotic margins at the metacarpal heads, and joint space narrowing, usually with asymmetric cartilage loss. Other degenerative changes that occur in some cases include chondrocalcinosis, involvement of radiocarpal joints, osteophytes at severely affected MCP joints, and generalized osteoporosis of affected hands. Approximately two-thirds of patients with hand arthropathy have or will develop hip or knee arthropathy. Knee radiographs often reveal chondrocalcinosis. Many patients with hip or knee arthropathy eventually require joint replacement. Other diarthrodial joints are affected less frequently (e.g., shoulders, elbows, ankles, and toes).

</tbody>
</table>

In persons diagnosed to have hemochromatosis in screening programs, the proportion who have severe iron overload is relatively low and thus typical hemochromatosis arthropathy is not common. Among the 98,529 participants in the HEIRS screening study (36,474 men and 62,055 women), there was no significant difference in the incidence of self-reported arthritis between groups of C282Y homozygotes and participants without HFE mutations. In another large questionnaire study, there was no significant difference in the prevalence of arthropathy between 45 C282Y homozygotes who were identified by screening and 9,299 control subjects. The results of another screening study were similar.

The prevalence of common HFE mutations did not differ significantly in 1,000 patients who had inflammatory arthritis and in 1,000 normal control subjects. In another study of patients without a diagnosis of hemochromatosis, the prevalence of HFE C282Y was greater in those with radiographic evidence of hand osteoarthritis than in control subjects. Serum ferritin levels were similar in patients with and without hand osteoarthritis. Some HFE C282Y homozygotes develop rheumatoid-factor-positive rheumatoid arthritis, psoriatic arthritis, gouty arthritis, or other types of arthropathy not attributable to iron overload. Osteoporosis defined by decreased bone mineral density was present in 34% of 38 C282Y homozygotes and C282Y/H63D compound heterozygotes who had not undergone iron depletion therapy. Osteopenia was present in 79%. Vitamin D and parathyroid hormone values were normal. Hypogonadism was present in 13%.

Diabetes Mellitus

Diabetes was reported in early accounts of hemochromatosis and for years was considered to be essential for establishing a diagnosis of hemochromatosis. Diabetes remains common in patients with hemochromatosis who have severe iron overload and cirrhosis (Tables 25.6 and 25.7). Siderosis of pancreatic islets, pancreatic fibrosis, and cirrhosis contribute significantly to diabetes pathogenesis in such cases but other factors also influence diabetes risk and expression. Some hemochromatosis homozygotes who have diabetes have elevated body mass index and decreased insulin secretory capacity. Similar abnormalities occur in mouse models of hemochromatosis. Cirrhosis contributes to insulin resistance and hyperglucagonemia. A family history of diabetes in first-degree relatives is a significant predictor of diabetes risk among persons with hemochromatosis, consistent with observations that diabetes and hemochromatosis segregate independently as genetic traits. Diabetes is associated with decreased survival after diagnosis in nonscreening patients with hemochromatosis and C282Y homozygosity.

As hemochromatosis case definition has changed from that of a rare, severe iron overload phenotype to a relatively common disorder defined primarily by HFE C282Y homozygosity, the prevalence of diabetes in hemochromatosis case series has decreased to a level that approaches that of the general age- and sex-matched population. Among the 98,529 participants in the HEIRS Study (36,474 men and 62,055 women), there was no significant difference in the prevalence of self-reported diabetes between groups of C282Y homozygotes and the participants with normal HFE genotypes. In a study of 22,347 control subjects without HFE mutations, 8.4% reported having diabetes, whereas 5.6% of 124 C282Y homozygotes reported having diabetes. Similarly, 7.0% of C282Y/H63D compound heterozygotes had diabetes. The prevalence of HFE C282Y in groups of patients with diabetes is similar to that in corresponding control subjects.

Other Endocrinopathy

Hypogonadism, thyroid disease, and adrenal insufficiency occur in some hemochromatosis patients, usually those who have been heavily iron loaded for decades. Of nondiabetes endocrinopathy in hemochromatosis, the second most common type is hypogonadism (Tables 25.6 and 25.7). This is usually of the hypogonadotrophic type. Iron is deposited selectively in the gonadotroph cells of the anterior pituitary. In a group of 141 ironloaded hemochromatosis patients, 9 patients (6%) had abnormally low testosterone levels. Of these nine patients, eight (89%) also had low values of luteinizing hormone and follicle-stimulating hormone. These findings are characteristic of hypogonadotrophic hypogonadism. Hypothalamic dysfunction occurs in some patients. Other patients with hemochromatosis have primary gonadal failure typically unrelated to iron overload. In a different study of 181 unrelated men who were HFE C282Y homozygotes, none had hypogonadism. It seems reasonable to evaluate for hemochromatosis in individuals who have hypopituitarism of unknown cause. In the HEIRS Study, hypothyroidism was detected in 1.7% of 176 HFE C282Y homozygotes and 1.3% of 312 control subjects who did not have C282Y. None of the C282Y homozygotes and 1% of the controls had hyperthyroidism. These minor differences in prevalence were not statistically significant.
Polycystic ovary syndrome (PCOS) affects approximately 5% of white women and is often associated with decreased serum hepcidin concentration. Homozygosity for the HFE C282Y mutation also is associated with decreased serum hepcidin. In a study of 107 unrelated women who were C282Y homozygotes, a 13-year-old and a 16-year-old had PCOS. Each had elevated serum ferritin concentration and grade 3 to 4 hepatic parenchymal stainable iron. It seems likely that low serum hepcidin concentration due to both PCOS with loss of menses at a very young age and HFE hemochromatosis contributed to early-onset iron overload.

Hepatocellular Carcinoma

The relative risk of hepatocellular carcinoma in patients with hemochromatosis who have cirrhosis is 219-fold higher than in patients with hemochromatosis who do not have cirrhosis. Among patients who have both end-stage hemochromatosis and cirrhosis, 10% to 29% develop hepatoma. About 3% to 4% of patients with hemochromatosis complicated by cirrhosis develop hepatocellular carcinoma per year. There are also reports of hepatoma in hemochromatosis patients who did not have cirrhosis. The histology of primary liver cancer in hemochromatosis is heterogeneous. Although the majority of primary liver cancers in hemochromatosis are of the hepatocellular type, biliary cancers also occur, including cholangiocarcinoma and combined hepatocellular cholangiocarcinoma.

In some reports, the proportion of patients with hepatocellular carcinoma who also have C282Y homozygosity, or C282Y heterozygosity is significantly increased. In another report, the prevalence of HFE mutations in patients with hepatocellular carcinoma was similar to that in control subjects. Positive associations of HFE mutations, chronic viral hepatitis, and hepatocellular carcinoma have been reported. Recent guidelines have been published about the evaluation and management of patients who have hepatocellular carcinoma.

Colorectal Polyps and Colorectal Cancer

In the Prostate, Lung, Colorectal and Ovarian Cancer Screening Trial, a study of 679 persons with advanced distal adenoma and 697 control persons revealed no significant relationship of C282Y and H63D or dietary iron intake on the risk of advanced distal adenomatous colorectal polyps. In a study of 475 case patients and 833 control subjects, C282Y and H63D mutations were associated with an increased risk of colon cancer. In a cohort study of 28,509 participants, C282Y homozygotes had twofold increased risk for colorectal cancer and female C282Y homozygotes were at twofold increased risk for breast cancer.

Other Types of Cancer

Iron can be carcinogenic. Possible mechanisms of carcinogenesis include redox cycling of iron, that produces reactive oxygen species and free radicals, which in turn cause lipid peroxidation and damage to proteins and DNA. Iron may facilitate tumor cell growth and modify immune system responses. The results of some studies suggested that HFE mutations were associated with colorectal or breast or other carcinomas, whereas results of some studies did not identify HFE mutations as a risk factor for cancer. In the cohort study of 28,509 participants cited above, male C282Y homozygotes did not have increased risk for prostate cancer. C282Y/H63D compound heterozygotes and C282Y heterozygotes did not have increased risk for colorectal, breast, prostate, or other cancers. In a meta-analysis of the risk of 66,263 people with HFE mutations to develop 31 different disorders, compared with 226,515 control subjects without HFE mutations, there was no identifiable risk for the development of cancers other than hepatocellular carcinoma.

Porphyria Cutanea Tarda

The most common type of porphyria is sporadic porphyria cutanea tarda. An elevated amount of storage iron is characteristic of this disorder. The interaction of iron and porphyria cutanea tarda has been reviewed. In addition, the presence of one or two HFE C282Y or H63D mutations is common in subjects with sporadic porphyria cutanea tarda and increased storage iron. Some patients with porphyria cutanea tarda (either sporadic or familial) and heavy iron loading are homozygous for HFE mutations.

Porphyria cutanea tarda occurs in individuals who have decreased activity of uroporphyrinogen decarboxylase which results in the accumulation of uroporphyrinogen I. In the presence of excess iron, accumulated uroporphyrinogen undergoes iron-mediated oxidation, resulting in production of uroporphophene. Uroporphophene then further inhibits the already decreased activity of uroporphyrinogen decarboxylase.
decarboxylase gene on chromosome 1q and hemochromatosis alleles on chromosome 6p was first reported in 1989.\textsuperscript{109} This was substantiated after HFE was cloned and sequenced and HFE mutations were identified.\textsuperscript{111, 112, 396} In a study of 108 subjects in Utah who had porphyria cutanea tarda, 19% were C282Y homozygotes and 7% were C282Y/H63D compound heterozygotes.\textsuperscript{111} The HFE mutation(s) causes increased iron absorption which further depresses the already decreased activity of the enzyme uroporphyrinogen decarboxylase. This results in the accumulation of uroporphyrin I in organs. Deposition of porphyrin in skin causes photosensitivity, blistering, and scarring.

Risk factors for the expression of porphyria cutanea tarda include common HFE mutations,\textsuperscript{396, 397, 398, 399, 400, 401, 402, 403} hepatitis C, alcoholism, oral estrogen therapy (but possibly not transdermal estrogen),\textsuperscript{113, 398, 399, 387} and tamoxifen.\textsuperscript{399} Hepatitis C infection, a potent risk factor, occurs in 28% to 74% of individuals with porphyria cutanea tarda. A 2002 study from Galveston was performed to assess the factors involved in the expression of porphyria cutanea tarda.\textsuperscript{399} In 39 consecutive patients with porphyria cutanea tarda, 9% had HFE genotype C282Y/C282Y, 9% had C282Y/wt, 12% had C282Y/H63D, 9% had H63D/H63D, and 26% had H63D/wt. None had the S65C mutation. Among these patients, 79% drank alcohol, 73% of 11 women took estrogens, 86% were smokers, and 74% were positive for the hepatitis C antibody. The authors concluded that HFE mutations were common and that the expression of porphyria cutanea tarda was multifactorial. Three or more risk factors for expression of porphyria cutanea tarda were detected in 92% of the 39 patients.\textsuperscript{399}

The prevalence of the C282Y, H63D, and S65C mutations of HFE and antibody to the hepatitis C virus was compared in 65 patients with sporadic porphyria cutanea tarda and in 108 control subjects.\textsuperscript{400} Of the porphyria patients, 17% had the C282Y mutation (4% of controls). There was no significant difference in the prevalence of the H63D and S65C mutations or compound C282Y/H63D heterozygosity between groups. Hepatitis C antibodies were detected in 28% of the patients with porphyria cutanea tarda. In another study of porphyria cutanea tarda patients in France, hepatitis C was identified as the major risk factor for porphyria.\textsuperscript{401}

In a study of 190 German patients with sporadic porphyria cutanea tarda and 115 age-matched healthy blood donors, 39% of patients with porphyria had HFE C282Y (3% of control subjects) and 12% were C282Y homozygotes (0% of controls).\textsuperscript{402} The H63D mutation was present in 45% of patients with porphyria (10% of controls) and 9% of patients with porphyria were C282Y/H63D compound heterozygotes. In studies among the Basque population in Spain, patients with porphyria cutanea tarda did not have increased frequency of HFE C282Y, H63D, or S65C mutations. Hepatitis C was present in 35% of the porphyria patients.\textsuperscript{403}

Tamoxifen therapy in patients with breast cancer has been associated with the occurrence of porphyria cutanea tarda.\textsuperscript{397, 404, 405} A woman with porphyria cutanea tarda that was caused by oral contraceptives only experienced full remission of porphyria while undergoing anastrazole therapy for metastatic adenocarcinoma of the breast.\textsuperscript{404}

Steatohepatitis

Many reports of the prevalence of HFE gene mutations and/or hyperferritinemia in subjects with nonalcoholic steatohepatitis were reviewed recently.\textsuperscript{406, 407, 408, 409, 410, 411, 412, 413, 414, 415, 416, 417, 418, 419, 420, 421, 422, 423, 424, 425, 426, 427, 428, 429, 430, 431, 432, 433, 434, 435, 436, 437} In 36 men in Massachusetts who had nonalcoholic steatohepatitis, 2.8% were C282Y homozygotes, 17.0% were C282Y heterozygotes, 5.6% were H63D homozygotes, and 44.0% were H63D heterozygotes.\textsuperscript{419} In 348 control subjects, none was a C282Y homozygote, 11.0% were C282Y heterozygotes, 2.9% were H63D homozygotes, and 26.0% were heterozygous for the H63D mutation. Individuals with nonalcoholic steatohepatitis who had a HFE mutation had higher levels of transferrin saturation and serum ferritin, and those with C282Y had significantly higher levels of alanine aminotransferase and a greater level of hepatic fibrosis than those without C282Y.\textsuperscript{419} Insulin resistance syndrome is common in people who have nonalcoholic steatohepatitis, with or without mutations of HFE.\textsuperscript{415, 417, 420, 421, 422}

Hereditary Spherocytosis

Individuals who have hereditary spherocytosis may develop severe iron overload and hepatic cirrhosis if they are HFE C282Y homozygotes or heterozygotes.\textsuperscript{393, 423, 424, 425, 426, 427, 428, 429, 430, 431, 432, 433} Iron overload can also occur in patients with hereditary spherocytosis who do not have common HFE mutations.\textsuperscript{434, 435} In a Utah family, for example, two brothers with C282Y homozygosity had iron overload.\textsuperscript{424} Iron overload in the propositus with both hemochromatosis and hereditary spherocytosis was much more severe than that of his brother who had hemochromatosis without hereditary spherocytosis. The son of the propositus was a C282Y heterozygote who also had hereditary spherocytosis. His serum ferritin concentration and liver iron stores were modestly elevated.

\(\beta\)-Thalassemia Minor
β-Thalassemia minor and hemochromatosis sometimes occur in the same person. In one family, an index patient with β-thalassemia minor and hemochromatosis had a brother with β-thalassemia minor who was a C282Y homozygote. The proband’s wife was also a C282Y homozygote. One of their children had β-thalassemia minor and hemochromatosis, whereas the other had hemochromatosis alone. The proband’s brother married a woman who was a C282Y/wt heterozygote. Both of their children were C282Y homozygotes. Some persons with β-thalassemia minor who have common HFE mutations develop iron load. In a study of 22 iron-loaded Italian patients with β-thalassemia minor and 62 relatives, β-thalassemia trait appears to worsen the iron-related complications of C282Y homozygosity. It is believed that the mild ineffective erythropoiesis of

P.677

β-thalassemia trait exaggerates the amount of iron absorbed by the duodenum. C282Y heterozygotes and H63D heterozygotes with β-thalassemia trait did not develop iron overload. In some other populations, heterozygosity for common HFE mutations appeared to be unassociated with development of iron overload in persons who also had thalassemia minor.

On the island of Sardinia, an area not reached by Celtic migrations, HFE C282Y is very rare. The H63D mutation prevalence is similar to that of other populations, and the prevalence of β-thalassemia minor is 13%. Among 152 Sardinian men who had β-thalassemia minor, approximately 2.6% were H63D homozygotes, 29.5% were H63D/wt heterozygotes, and 68% were wt/wt (normal HFE genotype). Concurrent control subjects were not studied.

In a study from Turin, 71 subjects with transfusion-dependent β-thalassemia major and 200 control subjects were tested for C282Y and H63D. None of the patients (or controls) was a C282Y homozygote. One patient (1.4%) was a C282Y/H63D compound heterozygote (similar to 0% among controls); 21.0% of patients (20.0% of controls) were H63D heterozygotes; and one patient (1.4%) was a H63D homozygote (1.0% in controls). The latter patient had greater iron overload than expected. The authors concluded that H63D homozygosity caused the heavy hepatic iron accumulation and advanced hepatic fibrosis. Individuals with either HFE H63D or C282Y were more heavily iron loaded than could be explained by transfusion-dependent homozygous β-thalassemia alone.

Refractory Anemia with Ringed Sideroblasts

Iron accumulation varies in this myelodysplastic disorder. In 40 patients from Switzerland, Greece, and France who had refractory anemia with ringed sideroblasts and nontransfusion iron overload, 1.25% had C282Y. This prevalence was similar to that in 200 normal control subjects (2.50%). The prevalence of the H63D mutation was also similar in patients and controls (19% and 13%, respectively). Ineffective erythropoiesis alone may account for the increased intestinal absorption of iron in most nontransfused patients with refractory anemia with ringed sideroblasts.

X-Linked Sideroblastic Anemia

Some men with X-linked sideroblastic anemia (mutations of the aminolevulinate synthase gene, ALAS2) with ringed sideroblasts and heavy iron overload also have HFE mutations. Coinheritance of X-linked sideroblastic anemia and HFE gene mutations was first described in a 59 year-old French man who had hepatic iron overload and C282Y/H63D compound heterozygosity. His iron overload was much more severe than that of his 61 year-old brother who had X-linked sideroblastic anemia but no HFE mutation.

Among 18 unrelated patients with X-linked sideroblastic anemia, 17.0% had HFE C282Y (5.5% in white controls) and 23.0% had H63D (15.0% in controls). Prevalence of the C282Y mutation was significantly greater in the patients with sideroblastic anemia than in controls, but prevalence of H63D was similar in both groups. After iron depletion, the responsiveness of anemia to pyridoxine supplementation increased in some patients. Coinheritance of one or more HFE mutations and a mild mutation of ALAS2 can result in heavy iron overload. The iron status of patients with mutations of ALAS2, with or without HFE mutations, has been reviewed.

Infections in Hemochromatosis Patients

Individuals who have hemochromatosis, especially those with cirrhosis, are susceptible to infection by organisms that rarely cause illness in people with normal body iron stores, including Vibrio vulnificus and Yersinia enterocolitica. Escherichia coli, Listeria, and zygomycosis may also cause severe and sometimes unusual infections in hemochromatosis patients.

Vibrio vulnificus
V. vulnificus is a motile free-living, Gram-negative bacillus that grows as normal flora in warm coastal saline waters worldwide. It usually does not cause infection in humans except in persons who have iron overload, cirrhosis, compromised immunity, or renal insufficiency. When ingested with raw shellfish (especially oysters), it can cause gastroenteritis, septic arthritis, or fatal septicemia. Invasive organisms are encapsulated. The organism thrives in blood that has elevated iron content but can also derive iron for its own metabolism from erythrocytes or hemoglobin. Most infections in patients with hemochromatosis have been reported from states adjacent to the Gulf of Mexico and from Northern Australia. In both areas, HFE hemochromatosis is common in whites and V. vulnificus is abundant in coastal waters.

Yersinia enterocolitica

Y. enterocolitica belongs to the family Enterobacteriaceae. It can cause transfusion-associated sepsis, gastroenteritis, septic arthritis, hepatic abscesses, osteomyelitis, or bloody diarrhea. It is usually ingested in contaminated water, pork, milk, bean sprouts, or chocolate. Unlike V. vulnificus, Yersinia is often present in colder climates or occurs as a contaminant in any climate. In patients with hemochromatosis, Yersinia can cause severe infections including bacteremia and multiple hepatic abscesses.

IgG Deficiency

Some patients with hemochromatosis and HFE C282Y homozygosity have frequent, severe, or unusual infections and common variable immunodeficiency or immunoglobulin (Ig) G subclass deficiency. Approximately 30% of probands have selective IgG isotype deficiency, especially that of subclasses IgG1 or IgG3. Deficiency of IgA or IgM is uncommon. Mean values of age, transferrin saturation, and serum ferritin at diagnosis and phlebotomy units required to induce iron depletion were similar in probands with or without CVID or IgGSD; phlebotomy had no effect on IgG levels. There was concordance of Ig and hemochromatosis phenotypes in probands and respective human leukocyte antigen (HLA)-identical siblings and a significant positive association of selective IgG deficiency to C282Y-bearing chromosome 6p HLA haplotypes that included HLA-A*03, B*07. This suggests that a gene that modulates IgG subclass levels occurs on these hemochromatosis-associated chromosomes.

Coronary Artery Disease

Hemochromatosis can cause cardiac arrhythmias or congestive heart failure due to siderosis of conducting fibers and cardiac myocytes. This complication is much more prevalent in juvenile hemochromatosis than in HFE hemochromatosis. It was estimated that German adults with hemochromatosis had a 300-fold increased risk of developing cardiomyopathy. In a more recent Swedish study of nationwide, population-based health and census registers, the risk of cardiomyopathy in persons with hemochromatosis was significantly elevated (hazard ratio 3.2 [95% CI 2.15 to 4.81]), but the risk of ischemic heart disease was barely elevated. Neither cardiomyopathy nor ischemic heart disease risk was increased in first-degree relatives of persons with hemochromatosis. Most studies have revealed no association between coronary artery disease and HFE mutations. Other studies suggest that an association exists. Total mean serum cholesterol and low-density lipoprotein levels were lower in C282Y homozygotes than in HFE wild-type participants in the HEIRS Study. Whether these differences influence manifestations of coronary or peripheral atherosclerosis in C282Y homozygotes is unknown.

DIAGNOSIS

History and Physical Examination Findings

Recent guidelines and reviews have been published about screening and about the evaluation and management of individuals in whom hemochromatosis is suspected, and for relatives of a person who has HFE hemochromatosis. A large percentage of HFE C282Y homozygotes who are identified during screening studies do not have symptoms of illness and do not have persistently elevated serum ferritin concentration. Currently, screening of the general population for hemochromatosis is not recommended.

Hemochromatosis with iron overload may be suspected in an individual who has some combination of the following: arthralgias, right upper quadrant abdominal pain, impotence, palpitations, unexplained fatigue or weight loss, gray-bronze skin, hepatomegaly, stigmata of portal hypertension, diabetes, or hypogonadism. Most hemochromatosis homozygotes do not have these findings. Individuals in whom the diagnosis is established during routine screening are nearly always
asympomatic and have no physical examination abnormalities. People in whom the diagnosis is established after seeking evaluation due to illness usually have several of the symptoms and physical examination abnormalities stated above. Only heavily iron-loaded patients with far-advanced organ injury have all of the above symptoms and physical examination abnormalities. The wide variation in the frequency of symptoms and signs of hemochromatosis from 12 reports appears in Tables 25.6, Tables 25.7, Tables 25.8 and 25.9.

Laboratory Findings
Transferrin saturation is the first blood test to become elevated in hemochromatosis homozygotes and usually is greater than 60% in symptomatic men and greater than 50% in symptomatic women.\(^{245, 302, 303, 517}\) Unbound iron-binding capacity is usually decreased in untreated homozygotes.\(^{518, 519, 520, 521}\) In iron-loaded patients, serum ferritin concentration is elevated. Liver stainable iron and the hepatic iron index are also elevated in iron-loaded homozygotes. The sensitivity of elevated transferrin saturation to identify a patient with hemochromatosis is 94% to 98%, and its specificity is 70% to 98%.\(^{303, 517}\) Typical results of transferrin saturation and serum ferritin concentration in different groups of hemochromatosis homozygotes are displayed in Tables 25.10 and 25.11. HFE C282Y homozygosity was present in 89% of hemochromatosis patients in the Utah studies, whether or not iron overload was present.\(^{245}\)

Evaluation of Relatives
After the diagnosis of hemochromatosis is established in an index patient (proband), it is important to study his or her siblings. Test selection is the same as for the index patient: transferrin saturation; serum ferritin concentration; and HFE mutation analysis to identify C282Y, H63D, and S65C alleles. Young homozygous siblings of a hemochromatosis proband may have a normal serum ferritin concentration.\(^{246}\) Serum ferritin levels should be measured at 2- or 3-year intervals. When serum ferritin becomes elevated, it is reasonable to begin intermittent phlebotomy therapy to prevent accumulation of excess iron in the liver and other organs.

HFE homozygous relatives who have marked elevation of serum ferritin concentration greater than 700 µg/L\(^{522}\) or greater than 1,000 µg/L\(^{523, 524}\) and elevated serum concentrations of hepatic transaminases may have hepatic cirrhosis. Liver biopsy in such individuals is usually necessary to determine the presence or absence of hepatic fibrosis or cirrhosis and allows measurement of hepatic iron stores. Typical liver biopsy findings in iron-loaded homozygotes appear in Figure 25.1 and Table 25.12. The great majority of homozygous relatives identified during family screening are less iron loaded and have fewer complications than their corresponding probands. Authors of a recent article made recommendations about when and for whom to advise liver biopsy in these settings.\(^{525}\)

Heterozygous Relatives
HFE heterozygotes do not become iron loaded unless they have an additional disorder that increases iron accumulation.\(^{526}\) There was no difference in the amount of heme iron or non-heme-iron absorption in C282Y heterozygotes and normal control subjects. Similarly, differences in non-transferrin-bound iron, transferrin saturation, or serum ferritin levels did not differ significantly between C282Y heterozygotes and normal controls.\(^{527}\) Transferrin saturation and serum ferritin concentration measurements in large numbers of C282Y heterozygotes and normal individuals are displayed in Table 25.11.\(^{278}\)

Because approximately 10% of whites of Central, Western, and Northern European ancestry are C282Y heterozygotes, the occurrence of hemochromatosis in whites in consecutive generations is common. It seems reasonable to measure transferrin saturation or unbound iron-binding capacity in the interested parents and adult children of homozygotes, in addition to all siblings of the proband.

Homozygous Relatives
In a study of the relatives of 291 hemochromatosis probands, 214 homozygous relatives were identified.\(^{245}\) When these 214 clinically unselected individuals were stratified by age and sex, it became apparent that 90% of the homozygous male relatives were iron loaded by age 40 years, and 52% had iron-related organ injury. Clinically unselected female homozygous relatives became iron loaded on average approximately one decade later than men. After age 50, 88% of clinically unselected female homozygous relatives became iron loaded and 16% of them had iron-related organ injury.\(^{245}\) The results of transferrin saturation and serum ferritin concentration tests in 291 probands and their 214 clinically unselected homozygous relatives in the Utah studies are displayed in Table 25.10.
FIGURE 25.1. Grade 4 hepatic parenchymal cell stainable iron in a 30-year-old asymptomatic HFE C282Y homozygous woman who was evaluated after her sick brother was found to have hemochromatosis.

MANAGEMENT

Phlebotomy Therapy

Detailed discussions of phlebotomy therapy for hemochromatosis patients have been published. Overall, men require approximately twice as many units of phlebotomy to induce iron depletion as women. Complications of hemochromatosis that respond to and complications that do not improve after phlebotomy therapy are displayed in Table 25.13. Treatment for specific problems usually should be managed as in patients who do not have hemochromatosis.

Initial Weekly Phlebotomy Schedule

The main treatment of iron-loaded hemochromatosis patients is phlebotomy therapy. In a phlebotomy of 500 ml of whole blood with a hematocrit of 40%, 200 ml of packed red blood cells are removed. Because each 1 ml of packed red cells contains about 1 mg of iron, each 500-ml phlebotomy removes about 200 mg of iron. When the diagnosis of iron overload due to hemochromatosis is established, it is important to start the first phase of phlebotomy therapy. Serum ferritin level, not serum iron or transferrin saturation levels, should be used to monitor levels of storage iron during phlebotomy.

TABLE 25.13 CLINICAL CHANGES EXPECTED FOLLOWING PHLEBOTOMY THERAPY

<table>
<thead>
<tr>
<th>Observed Complications of Iron Overload</th>
<th>Expected Treatment Outcome</th>
</tr>
</thead>
<tbody>
<tr>
<td>No complications</td>
<td>Prevention of complications of iron overload; normal life expectancy.</td>
</tr>
<tr>
<td>Weakness, fatigue, lethargy</td>
<td>May resolve if only due to iron overload.</td>
</tr>
<tr>
<td>Elevated hepatic transaminases in serum</td>
<td>Resolution or marked improvement.</td>
</tr>
</tbody>
</table>
Hepatomegaly
Resolution often occurs.

Hepatic cirrhosis\(^d\)
Usually no change.

Increased risk for primary liver cancer\(^b\)
May persist in presence of cirrhosis.

Right upper quadrant pain\(^c\)
Resolution if only due to iron overload.

Arthropathy
Arthralgias may improve; joint deformity not expected to resolve; worsening sometimes occurs.

Hypogonadotrophic hypogonadism
May resolve if pituitary injury is not extensive.

Diabetes mellitus
Occasional improvement, often temporary.

Hyperthyroidism, hypothyroidism
Resolution is rare.

Cardiomyopathy
Resolution sometimes occurs.

Hyperpigmentation
Resolution usually occurs.

Hyperferritinemia\(^d\)
Resolution.

Hyperferremia
Usually decreases, then rises again after cessation of phlebotomies.

Excess absorption and storage of nonferrous metals\(^e\)
Little or no change.

Infection with *Vibrio vulnificus* or other bacteria
Little or no change.

\(^d\) Regression was reported in some patients. Falize L, Guillygomarch A, Perrin M, Laine F, Guyader D, Brissot P, Turlin B, Deugnier Y. Hepatology 2006;44:472-477.\(^446\)

\(^b\) Increased risk is usually only in those who have hepatic cirrhosis.

\(^c\) Right upper quadrant pain that is only due to iron overload usually improves, but not if the pain is due to hepatocellular carcinoma, portal vein thrombosis, gallbladder disease, or other non-iron causes.

\(^d\) Serum iron levels may be normal or subnormal in persons with hemochromatosis due to severe iron deficiency, chronic inflammatory or infectious disease, vitamin C deficiency, or prolonged fasting.

\(^e\) Cobalt, manganese, zinc, and lead.

Most iron-loaded homozygotes tolerate removal of 500 ml of whole blood each week. Some women, small individuals, or elderly patients may only tolerate removal of 250 ml of whole blood each week. Twice-weekly phlebotomy may be performed for very heavily iron-loaded patients who have cardiac arrhythmias or hepatic failure in an effort to improve cardiac and hepatic function quickly. Phlebotomy therapy should be continued until the hemoglobin drops by approximately 1 to 2 g/dl below baseline, the mean corpuscular volume drops by approximately 3 to 5 fl below baseline, and serum ferritin concentration drops to 20 to 50 µg/L. These findings provide evidence of iron-limited erythropoiesis, which concludes the initial rapid sequence phase of phlebotomy therapy. The patient then enters the second, life-long maintenance phase of phlebotomy therapy.\(^503\), \(^528\), \(^529\), \(^530\), \(^531\), \(^532\)

Life-long Maintenance Phlebotomy Schedule
After the initial iron depletion is accomplished, the patient enters the life-long maintenance phase of phlebotomy therapy. Removal of 500 ml of whole blood every 2 to 4 months (every 3 to 6 months in women) prevents re-accumulation of
excessive organ storage iron. The goals of life-long maintenance phlebotomy therapy include maintenance of a normal hemoglobin level and main-tenance of the serum ferritin concentration less than 300 µg/L in men and less than 200 µg/L in women. A very low serum ferritin and the presence of anemia indicate that the frequency of phlebotomy therapy can be decreased to 4- or 6-month intervals.

Patients and physicians often want to estimate the duration of weekly phlebotomy therapy to achieve iron depletion. Based on a study of the correlation of serum ferritin to the number of grams of iron removed by phlebotomy therapy, 1 µg/L of pretreatment serum ferritin corresponded to ~8 mg of mobilizable iron. A person whose pretreatment serum ferritin concentration is 600 µg/L is likely to have ~4,800 mg (8 × 600 mg) of mobilizable storage iron. Each ml of centrifuged red blood contains about 1 mg of iron and each 500-ml unit of blood with a hematocrit of 40% contains approximately 200 mg of iron. Therefore, a patient whose serum ferritin is 600 µg/L is predicted to undergo ~24 units of phlebotomy to achieve iron depletion ([8 × 600 mg] = 4,800 mg/200 mg/unit = 24 units). This simple estimate holds reasonably well except in patients whose serum ferritin is elevated out of proportion to storage iron due to hepatic necrosis or another source of inflammation that causes hyperferritinemia. After patients achieve iron depletion by phlebotomy, the number of units of whole blood removed, multiplied by 200 mg iron per phlebotomy, provides a reliable calculation of the number of grams of iron that were removed.

Hemochromatosis Homozygotes as Blood Donors

Experts in the Department of Transfusion Medicine at the National Institutes of Health in Bethesda studied hemochromatosis patients as blood donors for patients treated at the National Institutes of Health. They evaluated 1,402 units of blood from hemochromatosis donors and concluded that if such individuals do not have serologic results necessitating deferral, they do not pose a health risk for recipients. The authors also noted that these donors could significantly augment the blood supply at the Institutes. After 27 months of study, blood from hemochromatosis donors represented 14% of all blood donations. In another report, an ethicist at the Centre for Environmental Philosophy and Bioethics of the University of Ghent, Belgium concluded that hemochromatosis patients can be free, voluntary, altruistic blood donors if they do not request any benefit other than blood removal. When phlebotomy therapy is performed in a setting other than a blood bank, the blood cannot be collected and processed properly for future transfusion.

Clinical Changes after Iron Depletion

If hepatic cirrhosis and arthropathy were not present before iron depletion therapy, these complications of hemochromatosis may be preventable by initial iron depletion followed by life-long maintenance phlebotomy therapy. An important question is whether hepatic fibrosis or cirrhosis can diminish following iron depletion. Regression of hepatic fibrosis was studied in 36 hemochromatosis patients who underwent two liver biopsies, the first one before and the second after iron depletion, with an interval of at least 2 years between biopsies. Regression of fibrosis occurred in 9 of 13 patients whose initial fibrosis was far advanced (grade 3), and in 8 of 23 whose initial biopsy showed cirrhosis (grade 4). The clinical changes that may occur following iron depletion appear in Table 25.13.

Dietary Recommendations

Persons with hemochromatosis have increased risk to develop a life-threatening infection with V. vulnificus from raw shellfish (see the section, “Infections”). It is prudent to advise these individuals not to consume raw shellfish, although consumption of cooked shellfish is safe. Much more iron can be removed in each 500-ml whole blood phlebotomy each week than can be absorbed during that week. For this reason, it is not necessary to impose severe dietary restrictions in an attempt to avoid all foods that contain iron. Regardless, heme iron of meat, especially red meat, is readily absorbed. It is reasonable to advise patients to eat red meat in moderation, to decrease dietary intake of saturated fat and animal protein, and to increase consumption of fresh vegetables and fruit, as for anyone else who follows a prudent cardiovascular diet.

Alcohol Intake

Alcohol can be hepatotoxic. Individuals with hepatic damage from iron overload may benefit from avoiding drinks containing alcohol. It is estimated that 30 g or greater than 60 g of alcohol per day can worsen iron-related liver damage. Consumption of these amounts of alcohol by a person with cirrhosis may also increase the risk of hepatocellular carcinoma.
Vitamins

It is reasonable to advise hemochromatosis patients to avoid medicinal intake of vitamin C (ascorbic acid) because it can increase the absorption of dietary iron, mobilization of storage iron, or production of free radicals. Vitamin C also may cause oxidative damage of the myocardium and cardiac conduction system, resulting in rare fatal arrhythmias in ironloaded patients who have hemochromatosis or thalassemia major. It seems reasonable for hemochromatosis patients to not take multiple vitamins that contain iron.

PROGNOSIS

The outlook for an iron-loaded hemochromatosis patient is related to whether the patient undergoes iron depletion therapy before the development of cirrhosis or diabetes mellitus. In a study of 111 hemochromatosis patients in England, the average survival of 85 people who underwent phlebotomy therapy was 63 months, compared with 18 months in the 26 subjects who did not become iron depleted. In a study of survival among 251 hemochromatosis patients in Germany, survival of those who became iron depleted was similar to that of the background population. Hemochromatosis patients with diabetes had a 10-year survival of 65%; in patients without diabetes, the survival was 90%. The 10-year survival of hemochromatosis patients with cirrhosis was 72%, whereas survival of patients without cirrhosis was 82%. Iron overload that could not be depleted within 18 months from the onset of phlebotomy therapy was also associated with decreased survival. In 422 hemochromatosis probands homozygous for HFE C282Y, serum levels of ferritin greater than 1,000 µg/L at diagnosis were positively associated with male sex and cirrhosis. Even with treatment, the relative risk of death from iron overload was fivefold greater in probands with serum levels of ferritin greater than 1,000 µg/L.

Additional reports of survival and prognosis of hemochromatosis patients have been published.

IMAGING OF THE LIVER

Computed Tomographic Scanning of the Liver

Single-energy computed tomographic (CT) scanning is not adequately sensitive to distinguish hepatic iron overload from a fatty liver. CT scanning also has very limited value in the assessment of sources of hepatic inhomogeneity, including edema, regenerative nodules, perfusion abnormalities, iron, fibrosis, or cirrhosis. Similarly, density histogram analysis of unenhanced hepatic CT does not distinguish among most diffuse liver diseases.

P. 681

Dual-energy CT scanning is able to distinguish hepatic iron from fat. In a dual-energy CT scan, an iron-loaded liver appears brighter than paraspinous muscles.

Magnetic Resonance Imaging of the Liver

Magnetic resonance (MR) imaging has largely replaced CT scanning in the evaluation of livers that are presumed to be cirrhotic. Some of the advantages of MR scanning include superior contrast resolution, multiplanar capability, greater sensitivity and specificity in the detection and characterization of abnormalities, and no use of ionizing radiation. MR imaging can be used to identify hepatic cirrhosis, regenerating nodules, increased iron, and hepatocellular carcinoma in subjects who have hemochromatosis.

Iron is a paramagnetic element that becomes magnetized in a magnetic field. The result is that the transverse (T2) relaxation time of iron becomes shortened compared with the longitudinal (T1) relaxation time. In an iron-loaded liver, the shortened T2 relaxation time causes a decrease in signal intensity. The result is that an iron-loaded liver appears darker than paraspinous muscles on T2-weighted MR images. The proton transverse relaxation rate (R2) is related to the presence of iron. For this reason, the R2 value is expected to allow measurement of a wide range of liver iron concentrations on MRI machines that have a magnetic field strength of 1.5 Tesla. Comparison of both MR imaging and biomagnetic liver susceptometry in 23 patients yielded a high correlation over a wide range of hepatic iron concentration.

Gradient-echo MR scanning after gadolinium is considered to provide the most useful information about iron stores, using both T1- and T2-weighted images. An MR magnet strength of 1.5 tesla provides better predictive ability than a 0.5-tesla magnet. The intensity of the signal in liver is often compared to signal intensity in paraspinous muscles. Iron causes increased attenuation of the gradient-echo signal in hepatocytes, which means that iron-loaded liver tissue appears darker than paraspinous muscle. Whereas CT cannot quantify iron stores less than five times normal, gradient-echo MR allows quantification of iron stores that are minimally increased.

1555
Gradient-echo sequences allow quantification of storage iron that correlates well with chemical measurement of iron in a liver biopsy sample. Thus, MR scanning can provide credible estimation of the hepatic iron concentration in patients who, for any reason, do not undergo liver biopsy. After iron depletion, there is a decreased amount of attenuation of the gradient-echo signal, so the liver appears lighter than before. Conventional T1-weighted and T2-weighted spin-echo MR or MR T2-star (T2*) imaging can identify increased amounts of iron in myocardium and liver. Organs that are iron loaded have low signal intensity, so they appear dark on T2* MR images.

The porphyrias are diverse disorders that arise from various inherited enzyme defects in the heme biosynthesis pathway (Fig. 26.1). The first authentic cases of porphyria were described in 1874. Since that time, eight genetically distinct forms of porphyria have been characterized (Fig. 26.1; Table 26.1), each caused by a partial deficiency, and in one type by activation, of a different enzyme within the pathway (Table 26.2). The genes encoding these enzymes have been cloned, their chromosomal location is defined, and DNA analyses have revealed many heterogeneous molecular defects in all the porphyrias. The biosynthetic blocks resulting from the defective enzymes are expressed either in the liver or in the bone marrow, the sites where most of body heme is produced. The clinical and pathologic phenotype of each porphyria is dictated by effects of the associated enzyme defect and the mode of inheritance (Table 26.2) and is often influenced by...
certain metabolic and environmental factors that affect the tightly regulated heme pathway. In some “late-onset porphyrias,” acquired clonal hematopoietic disorders may harbor a somatic mutation involving a heme synthesis enzyme that contributes to the expression of the porphyria.

Although the pathophysiologic mechanisms of the clinical manifestations of the porphyrias are only partly understood, two cardinal features prevail: cutaneous photosensitivity and neurologic symptoms of intermittent autonomic neuropathy, motor nerve palsies, and central nervous system disturbances. The cutaneous photosensitivity is a manifestation of the unique fluorescent properties of the porphyrins (the oxidized forms of the natural porphyrinogens in the heme synthesis pathway) that accumulate in those porphyrias in which the enzyme defects cause porphyrin accumulation (Fig. 26.1). The neurologic manifestations are associated with increased production of the porphyrin precursors 5-aminolevulinic acid (ALA) and porphobilinogen (PBG), which characterize the acute or inducible porphyrias. Among some of these, however, photosensitivity occurs as well if the enzyme defect also leads to accumulation of porphyrins. The distinguishing clinical manifestations of the porphyrias form the basis for the classification in Table 26.1. The diagnosis of a specific porphyria is ascertained by its characteristic profile of accumulated and excreted metabolic intermediates of the heme synthesis pathway (Table 26.2). It can be further confirmed by the activity of the affected enzyme but best by identification of the molecular defect causing the porphyria.

**FIGURE 26.1.** The heme biosynthetic pathway, its enzymes, and the eight forms of human porphyria associated with genetic defects of these enzymes. The major compound accumulated and excreted in excess in the seven porphyrias beyond the ALA synthase step is the substrate of the respective deficient enzyme; genetic defects in the erythroid ALA synthase (ALAS2) causing increased enzyme activity lead to increased flux of intermediates through the pathway and accumulated protoporphyrins. In the acute or inducible porphyrias (*), increased hepatic ALA production results from release of the normal negative feedback on ALA synthase exerted by heme, indicated by the trail of arrows. ALA, 5-aminolevulinic acid; Fe²⁺, ferrous iron.

**TABLE 26.1 CLASSIFICATION OF THE PORPHYRIAS**

I. Porphyrias with only cutaneous photosensitivity
Congenital erythropoietic porphyria (CEP)
Porphyria cutanea tarda (PCT); hepatoerythropoietic porphyria (HEP)
Erythropoietic protoporphyria (EPP)
X-linked protoporphyria (XLPP)

II. Acute porphyrias with only neurologic manifestations
Acute intermittent porphyria (AIP)
ALA dehydratase porphyria (ADP)

III. Acute porphyrias with both neurologic manifestations and cutaneous photosensitivity
Variegate porphyria (VP)
Hereditary coproporphyria (HCP)

IV. Dual porphyrias

**PORPHYRIAS WITH CUTANEOUS PHOTOSENSITIVITY**

**CONGENITAL ERYTHROPOIETIC PORPHYRIA**

Congenital erythropoietic porphyria (CEP; Gunther porphyria), the second least common of the porphyrias, is characterized by a marked accumulation in erythroid precursors of uroporphyrin and coproporphyrin, which are predominantly of the isomer I type because defects reside in the gene for the enzyme uroporphyrinogen III synthase (UROS; Fig. 26.1). Many marrow erythroblasts and immature circulating erythrocytes exhibit intense red fluorescence in ultraviolet light. The large amounts of porphyrins released from these cells cause the most intense photosensitivity of all the porphyrias.

ALA, 5-aminolevulinic acid; PBG, porphobilinogen; HMB, hydroxymethylbilane.

\(^a\) Gene symbol and chromosomal location as listed in the Human Gene Mutation Database, located at http://www.hgmd.org.

\(^b\) Percentage of normal.

\(^c\) Often a compound heterozygote.

\(^d\) The major metabolite and route are shown in boldface. The route of porphyrin...
excretion is determined by the number of carboxyl groups on the porphyrin and hence by its water solubility.

In harderoporphyria the activity is 18% to 24% of normal (see text).

Increased in urine during acute attack; in VP urine coproporphyrin is increased when symptoms are only cutaneous.

One allele is mutant and the other allele is usually underexpressed (see text).

Probably first recognized by Schultz and Baumstark in 1874, CEP was described comprehensively and distinguished from other porphyrias by Gunther in 1911. It is a very rare disease, with less than 200 cases reported. It occurs with equal frequency in males and females and in a wide variety of racial groups. Usually, the illness is first detected in infancy but, in a number of instances, was not apparent until later in life. All evidence is consistent with transmission of the disorder as an autosomal recessive trait.

Molecular Basis and Pathogenesis

The pattern of porphyrin accumulation in CEP reflects a defect in the conversion of PBG to uroporphyrinogen III. This conversion requires two enzymes: PBG-deaminase (PBGD) and UROS (Fig. 26.1). Affected individuals are homozygotes or compound heterozygotes for mutations in the UROS gene that result in markedly reduced activity of UROS (1% to 20% of normal), leading to the overproduction of uroporphyrinogen I through nonenzymatic cyclization of the substrate hydroxymethylbilane in erythroid precursors. In heterozygotes (parents and some siblings of
patients with the disease), the activity of the synthase is intermediate (approximately 50%) between that found in affected individuals and that in normal subjects.8 The UROS gene resides on chromosome 10 (10q25.2-q26.3)9 and has alternative promoters that generate identical housekeeping and erythroid-specific transcripts.7 Forty-six distinct mutant alleles have been identified and molecular defects include point mutations, deletions, insertions, splicing defects, intron branch chain mutations, and erythroid-specific promoter mutations.5, 7, 10 Approximately one third are homoallelic and about 20% of alleles remain undefined. The most common mutation (Cys73Arg) has occurred in one third of alleles (and in nearly one half of homoallelic cases) and correlates with the most severe phenotype of nonimmune hydrops fetalis, transfusion-dependent anemia from birth, or both, particularly in homoallelic cases.5 In most instances, mild forms of the disease have been heteroallelic or only one mutant allele could be identified. Residual enzyme activity of the mutant proteins expressed in prokaryotic systems, or gene promoter-reporter activities in cases of promoter mutations, have provided more precise genotype/phenotype correlations.5, 7, 11 However, in two instances marked divergence of phenotypic expression among siblings suggested undefined modifying factors.12, 13 In another family it was demonstrated that the clinical phenotype is markedly affected by co-inheritance of an activating (gain-of-function) mutation in the erythroid-specific 5-aminolevulinate synthase (ALAS2) gene.14

In addition, variant genetic forms of the CEP phenotype are described. (1) In two patients porphyrin patterns and enzyme assays were consistent with a uroporphyrin decarboxylase (UROD) rather than a UROS defect, and the presence of a second dyserythropoietic defect was suggested to account for the clinical severity.15, 16 (2) A variant caused by a mutation in the X-linked erythroid transcription factor GATA binding protein 1 (GATA1) demonstrated that CEP can result from a genetic defect in a transacting factor.17 (3) CEP has occurred as a milder form in later life.6, 18 Of 16 such cases, 8 were associated with a myelodysplastic syndrome; the pattern of excess porphyrins was characteristic of childhood-onset CEP but at lower concentrations and erythrocyte UROS activity was normal.18 Presumably UROS mutations could not be identified if only a minor clone of uroporphyrinocytes harbors a somatic mutation; alternatively another gene that determines UROS activity remains a possibility. This late-onset form of CEP has been termed “erythropoietic uroporphyria secondary to myeloid malignancy.”18

Although defective UROS operating in the erythron characterizes the primary inherited abnormality, no overall deficiency of heme production is evident, perhaps because normal UROS activity appears to be the highest relative to all other heme biosynthetic enzymes in erythroid cells. It is more than 1,000 times greater than the activity of ALA synthase,19 the rate limiting enzyme, so that even very low residual enzyme activity seems to be sufficient to support normal or even increased rates of heme synthesis. Uroporphyrin I is the predominant urinary porphyrin, but increased excretion of uroporphyrin III also invariably occurs, implying up-regulation of the UROS or of enzymes higher up in the pathway. These findings are consistent with the idea that the pathophysiology of CEP is a result of the accumulation of uroporphyrin I rather than of subnormal production of uroporphyrinogen III and heme.20 However, it is unclear why uroporphyrin I, not coproporphyrin I, is the main porphyrin excreted, which may relate to the relative UROD activity in normal erythroid cells being on the order of one tenth of that of UROS.19

The large amounts of porphyrins released from erythroid cells and deposited in multiple tissues21 exert the principal damage in the skin and subcutaneous regions through oxygen-dependent phototoxic reactions on excitation by light (see section “Porphyria Cutanea Tarda”).22, 23 This relentless process leads in varying degrees to the formation of subepidermal bullae, secondary infection, scarring, epidermal atrophy, and resorption of acral structures. Laboratory parameters of hemolysis correlate with severity of anemia. Associated splenic sequestration leads to splenomegaly and variable leukopenia and thrombocytopenia. Whether photolysis of the porphyrin-laden erythrocytes occurs in vivo is not known.

Clinical Description

The first sign of this affliction is often discoloration of the infant’s diapers by the urine, which ranges in color from pink to deep burgundy and fluoresces under Wood’s light.24 The most prominent manifestation is pronounced cutaneous photosensitivity. Exposure to visible light is followed by the development of vesicular or bullous lesions containing a porphyrin-rich, fluorescent fluid. The lesions tend to heal slowly, leaving pigmented scars (Fig. 26.2A). Often, they become infected, ulcerated, and necrotic. Over a period of years, patients develop progressive mutilation and disfigurement with loss of portions of the fingers, nose, eyelids, or ears (Fig. 26.2B). Corneal scarring can lead to blindness.2 Skin not exposed to light is unaffected. Hypertrichosis is prominent and fine hair growth may cover much of the face and extremities. The patients often adopt extreme precautions to avoid the sun. Deposition of porphyrin in the dentin of the teeth causes them to appear red (erythrodontia), brown, or yellowish. Even if discoloration is not apparent in ordinary light, the teeth exhibit
red fluorescence in ultraviolet light. At necropsy, the entire skeleton has this red fluorescence. Osteopenia and osteolytic lesions can occur.

Anemia, the result of both hemolysis and ineffective erythropoiesis, is detected in most patients, and usually the spleen is enlarged. The most severe phenotypes are transfusion-dependent.

Laboratory Findings

The anemia is normocytic, normochromic, and of variable severity. Detailed morphologic descriptions of the blood and bone marrow have been reported in a few patients. Anisocytosis, poikilocytosis, polychromasia, basophilic stippling, and nucleated erythrocytes are fairly common features of the peripheral blood. Following splenectomy, needlelike fluorescent red cell inclusions that may represent precipitated porphyrin have been observed. Morphologic abnormalities of the bone marrow range from erythroid hyperplasia to striking dyserythropoiesis. Nuclear inclusions containing hemoglobin may be present. Results of studies of the marrow with light and fluorescence microscopy suggest the coexistence of normal and abnormal erythropoietic cells. Fluorescence is restricted to the morphologically abnormal cells and is most marked in cell nuclei. Evidence of a dual nature of the erythroid precursors has been supported by ultrastructural studies in two cases. Kinetically, the anemia is characterized by both a shortened red cell survival and ineffective erythropoiesis. Its morphologic and kinetic features closely resemble those of congenital dyserythropoietic anemia type I (Chapter 40).

The most characteristic metabolic abnormality is greatly increased urinary excretion of uroporphyrin I, a biologically useless isomer that cannot be converted to heme. Urinary excretion of uroporphyrin III and coproporphyrins I and III is also increased but to a lesser extent than uroporphyrin I. Total urinary porphyrin excretion may exceed 100,000 µg daily (normal is <300 µg), and the urine usually fluoresces on exposure to ultraviolet light. Fecal excretion of porphyrins, especially coproporphyrin I, is greatly increased. The concentration of uroporphyrin I is increased in erythrocytes and plasma, but the marrow porphyrin content exceeds that of the peripheral blood or other tissues.

Treatment

Splenectomy may partially or completely relieve the hemolytic anemia and may also lead to reduced porphyrinuria and photosensitivity. However, this operation is not always beneficial and is not always warranted by the degree of anemia. Suppression of erythropoiesis by transfusion decreases porphyrin excretion. A young boy with CEP was successfully treated with chronic hypertransfusion; transfusion-induced iron overload was avoided by means of concomitant iron chelation therapy. After puberty, his relapse on this regimen was controlled with the addition of hydroxyurea.
Another patient was treated successfully with long-term orally administered charcoal at a dose of 60 g three times daily. Oral charcoal appeared to act by binding porphyrins excreted in bile and serving as a sump that diverted circulating and skin porphyrins to a fecal route of elimination in two cases but had no effect in others. In two patients, severe anemia improved with administration of the antioxidants α-tocopherol and ascorbic acid. Hematopoietic stem cell transplantation (HSCT) remains the only known curative treatment and to date was successful in 17 of 21 patients.

In theory, the most definitive method to control the disease would be transfer of the normal gene into hematopoietic stem cells of the affected patient. After in vitro correction of the enzyme defect by viral transfer of the normal gene into deficient cells, long-term correction of the disease in CEP mice had provided support for hematopoietic stem cell gene therapy clinical trials, and gene correction of CEP-derived iPSCs (induced pluripotential stem cells) was recently achieved to circumvent potential proviral insertional leukemogenesis. In another approach, the function of the common mutant protein Cys73Arg could be rescued with a proteasome inhibitor in cultured cells. Prenatal diagnosis or exclusion of the disorder is possible with enzyme assay or DNA analysis of amniotic fluid cells.

Most patients must rely on avoidance of exposure to sunlight. They should be instructed to wear photoprotective clothing, including gloves and broad-brimmed hats. Conventional sunscreen agents are ineffective because they do not screen out the wavelengths in the Soret band of the nearly visible spectrum (around 400 nm) that are responsible for inducing porphyrin-mediated photosensitivity. To be effective, a local agent must be visible on the skin. Reflective materials, such as zinc oxide and titanium oxide, are useful, as is ordinary pigmented theatrical makeup. Preparations containing substituted quinones (such as 2-hydrox-1,4 napthoquinone, also known as hemotannic acid or Lawsone) and dihydroxyacetone turn the skin a cosmetically acceptable brownish-tan and may be effective. Therapy with β-carotene beadlets may also offer some protection from the deleterious effects of light (see section “Erythropoietic Protoporphyria”). A single-observer clinical study of 29 CEP cases together with a proposal for a management algorithm derived from the patient cohort has recently been presented.

Congenital Erythropoietic Porphyria in Animals

CEP (pink tooth) in cattle appears to be milder than the human disorder. The disease is inherited as an autosomal recessive trait, and heterozygous animals are clinically and biochemically normal, although an increased ratio of
Porphyria cutanea tarda (PCT) is the most commonly encountered porphyric disorder. It results from reduced activity of UROD (Fig. 26.1) in the liver, leading to accumulation of uroporphyrins (oxidized uroporphyrinogens), their release into plasma, and excretion in the urine. Clinical manifestations are limited to the skin in the form of a photosensitive bullous dermatosis as a consequence of the circulating uroporphyrins. Neurovisceral symptoms never occur. Symptoms usually arise in mid- or later life (hence the name tarda) and are nearly always brought on by genetic and environmental factors, most often hepatic siderosis, alcohol abuse, hepatitis C virus, and estrogen therapy. Since the first comprehensive description of the disease in 1937, three variant forms of the illness have been recognized: familial, sporadic, and toxic.

Molecular Basis and Pathogenesis

Among the variants of the disorder, a genetic basis has been established for one, designated familial PCT (type II), but it accounts on average for only 20% to 30% of cases. Studies of patients with subnormal UROD activity in both hepatic and extrahepatic tissues, and their relatives, revealed that the enzyme defect is inherited as an autosomal dominant trait. Enzyme activity is one-half normal in all tissues, as is the amount of UROD protein detected with antibodies. In the rare homozygous form, designated heptaoerythropoietic porphyria (HEP), residual enzyme activity ranges from 3% to 27% of normal, but immunoreactive enzyme is variable. Since the cloning of the human UROD gene, located on chromosome 1 (1p34), at least 113 different mutations in the gene have been identified. Usually, a given mutation is found in one or in a few kindreds only. The majority are various point mutations in the coding region of the gene or splice site mutations, resulting in changes of amino acids, frameshifts, or deletions; in some instances, large nucleotide deletions were detected. The defects usually result in the production of an unstable or inactive enzyme from the mutant allele. Functional consequences of many of the mutations have been defined or predicted on the crystal structure of the enzyme. In the homozygous version among about 40 cases reported, 15 different mutations have been identified. The mutations are homoallelic or heteroallelic, causing instability or impaired catalytic activity of the enzyme, and survival hinges on residual enzyme activity encoded by the alleles.

When reduced UROD activity is restricted to the liver and a genetic basis for the disorder is not evident, it is called sporadic PCT (type I). Both the catalytic activity and the immunoreactivity of erythrocyte UROD are normal in this variant. In the liver, catalytic activity of UROD is subnormal, but immunoreactive enzyme is present in normal or increased amounts. After prolonged remission is induced by phlebotomy therapy, both catalytic activity and immunoreactivity become normal. These findings, coupled with lack of a family history in most cases of sporadic PCT, have implied that this form of the disease is acquired and not inherited. At the molecular level, no mutations could be found in the UROD gene or its promoter region. However, in a few families, clinically manifest PCT was associated with decreased UROD activity in liver and normal activity in erythrocytes and other tissues. These cases were called type III PCT; molecular studies have not identified UROD mutations in them.

The cutaneous damage produced by the accumulated uroporphyrins in plasma and skin of patients with PCT is the consequence of the fundamental properties of the porphyrins. As they absorb light at 400 to 410 nm (Soret band), not only does their photoexcitation yield energy as fluorescence, but in the aerobic environment of tissues, reactive oxygen species (superoxide anion and other reactive metabolites) are produced that are damaging to cells. In vivo, superoxide
anions are generated by activation of xanthine oxidase. The complement system is light activated in vitro in sera containing porphyrins and in vivo in the skin of porphyric patients, promoting release of proteases from dermal mast cells. M Chemotactic activity is also generated under these conditions, and the peroxides produced by photoexcitation of the porphyrin and those arising from polymorphonuclear leukocytes with activation of the complement system may act synergistically to contribute to the development of the cutaneous lesions. As a consequence of these events, the dermal-epidermal junction becomes disrupted and leads to skin fragility and the formation of vesicles and bullae that easily rupture. Sclerodermoid changes of the skin result from a light-independent effect (the “dark effect”) of the uroporphyrin on collagen synthesis by skin fibroblasts. The pathogenesis of the hyperpigmentation, hypopigmentation, and hypertrichosis is not understood.

Most family members carrying a defective gene of familial PCT do not have clinically apparent disease but a significant number have increased excretion of porphyrins; in occasional pedigrees, overt manifestations of the disease were noted in several generations. Clinical expression of both familial and sporadic PCT is nearly always associated with prevalent confounding factors that cause hepatic injury, so the disorder remains silent without these. In large series of PCT, most patients had more than one of four cardinal hepatotoxic risk factors, namely hepatic iron excess, excessive alcohol use, viral infection (hepatitis C), and medicinal estrogens, although these are far more common than the estimated frequency of PCT (approximately 1 per 25,000).

**Hepatic Iron**

The central role of iron in the clinical expression of PCT has been recognized for 52 years. Numerous studies documented hepatocellular siderosis in most patients with significant uroporphyrinuria. The iron deposits generally are moderate in amount, 1.5 to 4 times normal, but are usually greater with co-inheritance of hemochromatosis susceptibility alleles (Chapter 25). Except for the geographic variation in the frequency of the hemochromatosis HFE alleles, on average, 35% of patients with PCT are heterozygous for the Cys282Tyr mutation, and 15% are homozygous or double heterozygotes with the His63Asp mutation. The cause of excess hepatic iron in the remaining cases appears to result from down-regulation of hepcidin expression regardless of iron status and consequent to the oxidative stress associated with the other risk factors for PCT. However, in another study serum hepcidin levels were found increased. Transfusional iron overload also promotes clinical expression of PCT.

Depletion of iron by repetitive phlebotomy or by administration of deferoxamine uniformly induces both clinical and biochemical remissions. Replenishment of iron stores promptly reignites symptoms in patients in whom a remission has been induced by phlebotomy. The explanation for the provoking influence of iron is based on studies in mouse models, which indicate that the hepatic UROD activity of 50% in UROD-deficient animals must be reduced to 20% or less of normal in order for PCT to be manifest and is achieved by concomitant iron overload. An inhibitor of the enzyme was found in liver cytosol of these animals, as well as of PCT patients, and is a porphomethene that is generated by iron-dependent partial oxidation of uroporphyrinogen via catalysis by cytochrome P4501A2 (CYP1A2) or another enzyme. This is consistent with the diminished hepatic UROD activity without reduction in enzyme protein in symptomatic PCT patients and the restoration of hepatic UROD activity to its genetically determined level after iron depletion. The mechanism for the generation of sufficient inhibitor in patients with sporadic PCT that does not occur in iron overload states in general remains to be defined. The oxidative environment in the hepatocyte generated by the common environmental risk factors accompanying clinical expression of the disorder, as well as other traits such as the allele variants of CYP1A2 and G51M1A, probably play an important role.

**Alcohol**

Ethanol exacerbates PCT. Heavy alcohol intake was found in 25% to 100% of patients in many studies, and hepatic cirrhosis is not uncommon. Yet the porphyria is an uncommon complication of alcoholic liver disease, occurring in only approximately 2% of cases. The association of clinically expressed PCT with alcoholism would relate to its hepatotoxicity and its effect of stimulating iron absorption. In this regard, PCT is particularly common among the Bantu population of South Africa, where it is associated with excessive consumption of alcoholic beverages brewed in iron containers, thus providing a double threat to susceptible people. Studies have suggested that an undefined hemochromatosis gene plays a role in the iron overload of this population when iron intake is excessive (Chapter 25).

**Hepatitis C**

Wintrobe's Clinical Hematology 13th Edition
A striking association between symptomatic PCT, familial and sporadic, and hepatitis C is well recognized but is variable around the world. Although most patients with hepatitis C infection do not have the porphyria, as many as 80% of PCT patients are chronically infected with the virus in some locations. This infection elicits oxidative stress in hepatocytes as well as down-regulation of hepcidin expression and would explain, at least in part, the liver damage often found in PCT. Association of PCT with human immunodeficiency virus (HIV) infection also occurs, and such patients may be infected with both HIV and the hepatitis C virus. Dual infection causes more severe hepatic disease; whether the HIV virus per se plays a role in the expression of PCT is not known. Thus, patients should be evaluated for the presence of hepatitis C and HIV at the time of diagnosis.

Estrogens

The association of estrogen ingestion and expression of PCT has been reported numerous times but occurs only in a very small percentage of patients who ingest estrogens, consistent with an underlying predisposition to the disease. The cutaneous symptoms have occurred with the use of estrogen as a post-menopausal supplement, and for prostatic carcinoma. Uncommonly, patients present with the disorder during pregnancy, but pregnancy has also not exacerbated PCT. The mechanism of the estrogen effect is thought to relate to its adverse effects on the liver such as steatosis and steatohepatitis. It is generally a lesser factor, as venesection alone has brought about full recovery. Most women needing estrogen supplements at the usual dose can probably use them, provided that storage iron is removed and maintained at a low level.

Other Susceptibility Factors

Additional susceptibility factors that are positively associated with PCT are smoking, allele variants of CYP1A2 and GSTM, and ascorbic acid deficiency. Several diverse drugs and radiation have also been implicated in precipitating PCT in a few cases.

Renal Failure

PCT occurs in patients with renal failure undergoing hemodialysis. Symptoms may first arise in this setting for several reasons. Iron overload is not uncommon in such patients, and intravenous iron used in conjunction with erythropoietin for the anemia may precipitate clinical PCT. Hemodialysis or peritoneal dialysis does not effectively clear circulating plasma uroporphyrins, presumably because porphyrins are bound to proteins. The uremic state may also contribute to an inhibited UROD and uroporphyrin accumulation independent of an underlying enzyme defect or inhibition. In most reported cases, the lack of family or molecular studies makes it difficult to classify the porphyria.

Clinical Description

Cutaneous changes represent the clinical manifestations of PCT. Skin lesions are found predominantly on light-exposed areas such as the face and hands and, in women, on the legs and feet as well. There is little discomfort with sun exposure per se, and blue (visible) light triggers only an insidious cutaneous damage. The most common complaint is marked skin fragility in areas subjected to repeated minor trauma, such as the hands and forearms (Fig. 26.3). Vesicles and bullae form primarily on the dorsa of the hands and may erode, leaving atrophic scars that often display zones of both hyperpigmentation and hypopigmentation. Small, 1- to 2-mm, firm, whitish papules (milia) are commonly noted on the hands and, at times, on the face.

Facial hypertrichosis occurs in most patients, is generally more noticeable in women, and may be an isolated presenting feature. Hypertrichosis, sometimes striking, is occasionally observed on areas of the skin that are rarely exposed to the sun, such as the trunk and legs. Other findings include hyperpigmentation of facial skin, alopecia, and scleroderma-like changes on the skin of the face, neck, and hands. The histologic appearance of the scleroderma-like lesions is identical to that seen in patients with systemic scleroderma. Occasionally, patients have overt signs and symptoms of underlying liver disease, but no good correlation exists between the degree of liver disease and the occurrence or severity of the porphyria.

In the homozygous form of familial PCT, or HEP, the skin changes just described usually occur before the age of 5 years and photosensitivity may be severe, resembling CEP and including disfigurement. Developmental delay and seizures have also been reported. Other features are pink urine, dental fluorescence, and occasionally hepatosplenomegaly. Severity of clinical manifestations can vary in affected children within a family; in some instances the clinical phenotype is unusually mild.

Laboratory Findings
Patients with symptomatic PCT excrete greatly increased amounts of porphyrins in the urine. Uroporphyrin and heptacarboxylic porphyrin predominate, with lesser amounts of coproporphyrin and small amounts of 5- and 6-carboxylate porphyrins. Usually, the daily urinary excretion of uroporphyrin is approximately 3,000 µg (normal, <50 µg), but considerably higher values may be found. Uroporphyrin in the urine is predominantly isomer I, whereas the heptacarboxylic porphyrin is predominantly isomer III.

Photosensitive cutaneous symptoms rarely occur when the daily urinary excretion of uroporphyrin is <1,000 µg. Urinary coproporphyrin rarely exceeds 600 µg daily. An unusual and distinctive tetracarboxylic porphyrin, isocoproporphyrin, is excreted in feces, and a slight increase may be noted in total fecal porphyrin excretion. Plasma porphyrin level is typically increased, with a fluorescence peak at neutral pH near 619 nm. Homozygotes for the defect have mild anemia; it was severe in three cases. The erythrocyte protoporphyrin was found to be moderately increased when measured and is primarily zinc protoporphyrin.

FIGURE 26.3. Porphyria cutanea tarda in a 60-year-old man. Note denuded skin areas over the fingers, an erosion, blisters, and milia.

The serum iron concentration and, hence, transferrin saturation are commonly increased as is the serum ferritin level. Values for liver function tests vary considerably from one case to another. Some patients have mild degrees of jaundice and slight to moderate elevations in serum transaminase levels. Liver biopsy specimens display characteristic reddish-pink fluorescence. On microscopic examination, siderosis, periportal inflammation, focal necrosis, fatty infiltration, and some evidence of fibrosis are common findings. Often, fluorescent and birefringent needle inclusions are noted. Electron microscopic studies reveal needlelike lucent areas, which appear to be in lysosomes. Microscopic examinations of skin biopsy specimens show bullae formed by the separation of the epidermis from the dermis; periodic acid-Schiff-positive, diastase-resistant material around vessel walls in the upper dermis; and a sparse inflammatory cell infiltrate. Immunofluorescence studies display deposition of immunoglobulin G (and less often immunoglobulin M) or complement around upper dermal vessels and at the dermal-epidermal junction.

Treatment
Exposure to alcohol and excessive estrogen supplements in women, as well as smoking, should be avoided. Abstinence from alcohol can lead to remissions in some patients with the porphyria associated with alcoholic liver disease, but removal of iron by phlebotomy can induce remissions even if alcohol intake continues. It is of interest that occasionally remission has been achieved in patients with PCT and hepatitis C after antiviral treatment alone. Conversely, poor response to interferon-α is common in patients with hepatitis C and PCT. Transdermal administration of estrogen was found to be safe in a small number of patients and avoids any possible first-pass effects of the hormone on the liver.

The definitive treatment of both sporadic and familial PCT is the removal of iron stores by phlebotomy, which leads to clinical and biochemical remission in virtually every case and may improve concomitant hepatitis C virus infection. It is recommended that any antiviral therapy be deferred until a de-ironed state is reached. If there are no contraindications, 500 ml of blood is removed every 1 to 2 weeks. Initial serum transferrin saturation and ferritin values are obtained to estimate the iron burden. Liver biopsy must also be considered to assess the disease status of associated viral hepatitis and hemochromatosis. Clinical remissions often occur after the removal of approximately 3 L of blood; patients who also have hemochromatosis usually require considerably more therapy and indefinite regular maintenance phlebotomies. The optimal approach is to achieve mild iron deficiency, defined by onset of iron-limited erythropoiesis in which the mean corpuscular volume is decreased to low normal, the serum transferrin saturation is low normal, and the serum ferritin is near 20 µg/L or lower. Although further overproduction of uroporphyrins is halted thereafter, the chronically accumulated, relatively hydrophilic porphyrins are released slowly from the liver. Patients should be advised that formation of new skin lesions ceases gradually, and full recovery often extends over several months to a year or more.

Remissions for years are the rule and are permanent when the known precipitating factors are avoided or removed; any clinical and biochemical relapse responds to another course of phlebotomies.

Hydroxychloroquine and chloroquine have also been used in the treatment of PCT. After the administration of chloroquine (0.5 to 1.0 g/day) for several days, a large amount of the porphyrins stored in the liver was mobilized and excreted in the urine. This purging effect results from the formation of an easily excreted water-soluble complex between uroporphyrin and the drug. The chloroquine effect was often accompanied by malaise, anorexia, fever, and signs of hepatocellular damage. Subsequent use of lower doses made it possible to avoid the toxic response without impairing efficacy, but this maneuver does not always preclude toxicity. Because of the potential danger of the hepatic reaction to antimalarials and because phlebotomy is usually safe and effective, administration of low doses of hydroxychloroquine or chloroquine should be reserved for patients for whom phlebotomy is unsuitable. Moreover, patients with HFE hemochromatosis appear not to respond to this therapy.

The use of sunscreen agents effective in the Soret band of the spectrum and avoidance of sunlight through protective clothing can be useful until the beneficial effects of phlebotomy are achieved. These measures are the principal means to help patients with the homozygous form of PCT in whom phlebotomy is not effective. The antimalarials may be beneficial in these individuals. Severe anemia and cutaneous symptoms responded to erythropoietin in one case. Efforts toward somatic gene therapy were initiated by demonstrating correction of the enzyme defect with retroviral gene transfer in vitro in transformed B-cell lines and may become a prospect in vivo as noted for CEP. Prenatal exclusion of HEP has been possible.

Treatment of patients with PCT and renal failure presents special challenges. The disorder may be particularly severe because such patients lack the renal excretory pathway for porphyrins, leading to higher porphyrin levels in plasma and tissues. Chloroquine-porphyrin complexes are not filtered out by standard hemodialysis. High-flux hemodialysis appears to remove porphyrins from plasma better and may be of some benefit. The treatment of choice is administration of recombinant erythropoietin to mobilize stored iron and relieve the anemia so that phlebotomies can be performed as necessary to induce remission. This method is preferable to the alternative of depleting iron stores with iron chelation. In patients refractory to these treatment methods, the porphyria fully resolved after renal transplantation.

Toxic Porphyrria Cutanea Tarda

In Turkey between 1956 and 1961, an epidemic of acquired porphyria affecting more than 3,000 people occurred as the result of exposure to flour contaminated with a seed-wheat fungicide, hexachlorobenzene. Members of both sexes were affected, and many of the subjects were children. Affected people developed hepatomegaly, hyperpigmentation, uroporphyrinuria, and a photosensitive dermatosis. Uroporphyrinuria and a variety of other signs and symptoms persisted in some individuals for more than 25 years, and no effective therapy has been devised for this toxic porphyria. Studies in animals demonstrated that hexachlorobenzene, or one of its metabolites, is a potent inhibitor of hepatic UROD. Iron magnifies this inhibitory effect, and clear genetic susceptibility to this type of acquired porphyria has been shown in mice.
Other polyhalogenated aromatic hydrocarbons also have produced a toxic porphyria in humans. 2,3,7,8-Tetrachlorodibenzo-p-dioxin, a by-product in the manufacture of the herbicides 2,4-dichlorophenoxyacetic acid, 2,4,5-trichlorophenoxyacetic acid, and some polychlorinated biphenyls have proved porphyrinogenic for humans. Animal studies indicate that compounds of this class inhibit hepatic UROD activity. As in the case of hexachlorobenzene-induced porphyria, iron magnifies the inhibition of UROD, and iron depletion minimizes the inhibitory effect of these agents. The parallel between the permissive effects of iron in these toxic porphyrria models and the role of iron in the pathogenesis of both familial and sporadic PCT is striking.

Hepatocellular Carcinoma

An increased frequency of hepatocellular carcinomas is recognized in patients with PCT, and such tumors are associated with a long symptomatic period before the start of treatment as well as with the presence of cirrhosis or chronic active hepatitis. The body iron status is not known in these cases, but iron overload could also play a role. Thus, in the presence of hepatitis or cirrhosis, surveillance for hepatocellular carcinoma with regular hepatic imaging is indicated.

In contrast, documented evidence supports a PCT-like illness as a manifestation of porphyrin-producing hepatoma in an otherwise normal liver (paraneoplastic PCT) in several cases. When the tumor could be surgically removed, the cutaneous symptoms and biochemical abnormalities remitted.

Animal Models of Porphyria Cutanea Tarda

The first genetically designed animal model of PCT and HEP was developed in zebrafish, designated yquem. Heterozygous and homozygous mutants have 67% and 36% of wild-type UROD activity, respectively. The enzyme deficiency was linked to a missense mutation in the UROD gene, predicting a Met38Arg substitution that involves a conserved amino acid across all species examined, including humans. The mutant phenotype could be rescued by transient and germline expression of the wild-type allele.

Transgenic mice with one disrupted UROD allele (UROD−/−) have half the wild-type hepatic UROD protein and enzyme activity but no accumulation of porphyrins. However, in response to iron loading, hepatic porphyrins accumulate, and UROD activity declines to 20%. When bred to HFE+/− mice, UROD+/−/HFE−/− animals developed a porphyric phenotype with further reduction of UROD activity to 14%, resembling the human condition.

HFE−/− mice that are fed ethanol also develop uroporphyria and reduced hepatic UROD activity, seemingly mediated by effects of ethanol on hepatic iron metabolism. Additional mouse models have been informative for understanding the susceptibility factors in PCT. CYP1A2 knockout mice are highly resistant to developing uroporphyria induced by chemicals. In mice that are genetically unable to synthesize ascorbic acid, a threshold of body iron was demonstrated at which a biphenyl-induced uroporphyrin accumulation occurs despite ascorbate repletion. Extensive study of such animal models of hepatic uroporphyria has provided a paradigm of the complex interactions among genetic factors, chemicals, drugs, and endogenous factors including iron homeostasis.

PCT was identified in a flock of German Blackface sheep with clinical features similar to human PCT. It is associated with a point mutation in the ovine gene, predicting the amino acid substitution Leu131Pro, which is located in the active site cleft of the UROD protein.
entirely, in erythroid cells, whose contribution to heme production far exceeds that of all other tissues. Although the normal relative activity of FECH in erythroid tissue, in contrast to liver, is the second lowest among the enzymes of the heme biosynthetic pathway and is only three times higher than 5-aminolevulinate synthase, defective FECH in EPP does not appear to be rate limiting until late in erythroid development. Patients often exhibit a mild hypochromic-microcytic anemia as a consequence of the FECH deficiency that in turn appears to limit iron assimilation. Protoporphyrin begins to accumulate in bone marrow erythroblasts just before the nucleus is lost, and reticulocytes and young erythrocytes probably are the major source of protoporphyrin in plasma on its rapid release from these cells. Because of its low water solubility, the protoporphyrin is not excreted in urine but is taken up by the liver and excreted exclusively through the biliary tract.

Based on clinical features and FECH activity in many pedigrees, inheritance of this porphyria was first believed to most often follow an autosomal dominant pattern with incomplete penetrance. In a few families, autosomal recessive inheritance was evident. However, FECH activity in tissue lysates from patients with clinical EPP is always only 20% to 30% of normal, not the 50% value expected for an autosomal-dominant enzyme deficiency. Neither levels of FECH activity nor levels of erythrocyte and fecal protoporphyrin consistently correlate with severity of symptoms. Moreover, most obligate carriers of the disorder have no symptoms. Their erythrocyte and fecal protoporphyrin levels are usually normal, and tissue FECH activity is approximately 50% of normal. To explain these findings, it was proposed that more than one allele is involved in the full expression of the disease.

Upon the cloning and characterization of the human FECH gene, which is located on chromosome 18 (18q21.3), at least 187 different molecular defects have been identified and are highly heterogeneous, commonly as missense/nonsense mutations, nucleotide deletions and insertions, and intronic point mutations near intron/exon splice sites in one FECH allele. Most often, the defects lead to frameshifts or deletions, resulting in a truncated protein (“null allele”). The entire FECH gene was absent in one patient as a result of a chromosome 18q deletion. Two types of regulatory defects in the gene have also been reported, impairing transcription due to hypermethylation of the promoter region or a point mutation affecting transcription factor binding in the promoter. In about 4% of cases a mutation is present on each allele, defining recessive inheritance, where the majority are missense mutations. Although these few double heterozygotes clarify the phenotypic differences between symptomatic and asymptomatic family members, all other manifesting cases usually coinherit a “low-expression” normal FECH allele trans to a deleterious mutant allele. The low-expression allele is highly associated with a specific ancestral haplotype involving a single nucleotide polymorphism site in the FECH gene (IVS3-48T/C) that influences the use of a constitutive aberrant acceptor splice site in the gene. The aberrantly spliced RNA fraction is degraded, decreasing the steady-state level of FECH mRNA expressed by the allele by ≥20%. Hence the term

P.690

“pseudodominant EPP” came into use for patients with a FECH mutation trans to a hypomorphic IVS3-48C allele, to distinguish them from those with autosomal recessive EPP who are hetero- or homoallelic for FECH mutations. The frequency of the hypomorphic IVS3-48C allele differs widely between ethnic groups, ranging from 67.8% in Japanese to <1% in West Africans, and in general correlates with prevalence of clinical EPP among individuals with a mutant FECH allele in the different populations. When a low-expression allele is not found, a dominant-negative effect of FECH mutants may be operative. Because the enzyme activity is restricted to its homodimers, a mutant monomer may generate nonfunctional homodimers and impaired or unstable heterodimers, resulting in residual enzyme activity of <50% of normal. Thus, the ultimate effect of a specific mutation in the FECH gene depends on how it affects the integrity of the protein and whether the nonmutated allele is expressed at a lower level to reduce FECH activity to below a threshold of around 30% of normal as found in clinically overt EPP.

More recently a third pattern of inheritance of EPP that is X-linked was described and is referred to as X-linked protoporphyrinaemia (XLPP). In the United Kingdom and in the US, the disorder accounts for 2% and 10% of unrelated EPP patients, respectively. FECH enzyme activity is normal but erythrocyte protoporphyrin concentrations are higher than in EPP due to FECH deficiency. Around 40% is zinc protoporphyrin, indicating that the supply of the iron substrate as well as ferrochelatase activity becomes rate limiting. To date, five distinct mutations have been identified in exon 11 of the erythroid-specific 5-aminolevulinic acid synthase gene (ALAS2) (Fig. 26.1), which resides on the X chromosome, and lead to predicted amino acid sequence disruption or deletion of up to 40 C-terminal amino acids of the enzyme. The recombinant mutants have two- to three-fold increased activity, explaining the protoporphyrin overproduction. This gain-of-function in the enzyme contrasts with all other previously described ALAS2 mutations that decrease enzyme
activity and cause X-linked sideroblastic anemia (Chapter 24). It also reflects a critical role of the C-terminal structure of ALAS2 for its activity and thus erythroid heme synthesis.

About 5% of EPP families in a large cohort were mutation-negative for FECH and ALAS2. However, in these the disease was strongly associated with inheritance of the IVS3-48C allele and decreased FECH activity, suggesting that most may have mutations in regions of the FECH gene that are not included in current strategies for mutation detection. In one case mild photosensitivity was ascribed to the IVS3-48CC genotype alone.

The pathophysiology of EPP is mediated by the accumulated protoporphyrin. As it leaks out of erythroid cells into plasma, it gains entry into tissues. It is extracted solely by the liver and secreted unchanged into the bile. The liver is capable of clearing large amounts of protoporphyrin, but its secretion across the canalicular membrane and into the bile appears to be rate limiting. Yet despite microscopic evidence of hepatobiliary changes in many EPP patients, cholestasis leads to cirrhosis and hepatic failure in only a few (<5%). This complication tends to be an abrupt event, is unrelenting, and is not predictable from prior biochemical features or the clinical course of the patient. However, it occurs more commonly in compound heterozygotes for two mutations and in XLPP than in heterozygotes. Profoundly reduced ferrochelatase activity predisposes to liver failure. In an analysis of 112 EPP patients, all 18 who developed liver disease carried a null allele mutation, whereas none of 20 patients having missense mutations had liver disease as yet. Undetected molecular derangements or undefined hepatic factors, including a greater hepatic source of the excess protoporphyrin related to the defect, can be postulated. Excess alcohol intake and viral hepatitis, as well as hyperthyroidism, also accentuate the genetic disorder.

In the skin, the hydrophobic protoporphyrin transfers to endothelial cells of capillaries to produce the light-induced skin damage in patients with EPP. Porphyrin-sensitized, oxygen-dependent histochemical reactions and the activation of complement eliciting an inflammatory response are involved in the pathogenesis. The extensive double-bond structure of the protoporphyrin renders it particularly photoactive, resulting in the unique acute epidermal phototoxicity, in contrast to the porphyrins that accumulate in the other porphyrias with cutaneous photosensitivity. The activated porphyrin also stimulates fibroblast proliferation, accounting for a characteristic waxy thickening of the sun-exposed skin.

Variant Erythropoietic Protoporphyria

The presence of an abnormal transcript of mitoferrin 1 (MFRN1) associated with reduced FECH activity was identified in a series of 7 patients with the EPP phenotype but without genetic defects in FECH in 6 of them, although no cause for the aberrant splicing of MFRN1 mRNA was found in the MFRN1 sequence. Four patients also had a previously reported C-terminal deletional ALAS2 mutation, and 4 cases had advanced liver disease. MFRN1, which transports iron into mitochondria, is highly expressed and regulated in erythroid cells. A molecular complex of FECH protein, MFRN1 and ABCB10 (a MFRN1 stabilizer) integrates mitochondrial iron import with heme synthesis. Thus, aberrant MFRN1 can contribute to the EPP phenotype in some patients, apparently by reducing FECH activity.

Late-onset Erythropoietic Protoporphyria Variant

EPP that is clinically indistinguishable from the inherited forms has developed in later years in the setting of a myelodysplastic syndrome, including the sideroblastic anemia subtype (Chapter 24), or a myeloproliferative disorder. Two cases were associated with severe cholestatic liver disease. In several instances acquired deletion of one FECH gene was demonstrated. An associated low-expression allele or a mutation in the other FECH allele, or altered erythroid heme biosynthesis in the dysplastic clone, likely contributes to the clinical expression in such cases. One case with late-onset XLPP has also been reported.

Clinical Description

EPP typically first manifests in childhood or early adolescence. The cutaneous features of photosensitivity are unlike those seen in patients with other porphyrias; bullae, scarring, sensitivity to trauma, hypertrichosis, and hyperpigmentation are extremely unusual. In some cases, the symptoms are only subjective. Exposure to the sun (or to UV light) for periods of a few minutes up to several hours induces diffuse, intensely unpleasant sensations of pricking, itching, or burning (photoparesthesias) followed by the development of erythema, urticaria, and edema. Less commonly, solar urticaria, a confluent, hivelike rash, occurs within minutes of exposure and lasts approximately 30 minutes. In general, the signs and symptoms involve only the uncovered areas of the body and subside in the course of hours or days without significant sequelae.

Occasionally, these early reactions are followed within a day or two by vesicular eczematous lesions (solar eczema) that become crusted, last for several weeks, and heal with scar formation. Chronic skin changes may include shallow pitted
scars or pseudovesicles over the cheeks and nose and thickened leathery skin (pachydermia) over the dorsa of the hands (Fig. 26.4A and B). Many cutaneous manifestations of EPP do not differ greatly from those found in patients with photosensitivity of unknown cause (so-called polymorphic light eruptions), which is common and is not associated with abnormal porphyrin metabolism. In one study of over 600 light-sensitive patients, only 8% were found to have laboratory evidence of EPP.

A number of EPP patients have been identified with palmar keratoderma. They represent a subtype of EPP, which is characterized by seasonal palmar keratoderma, relatively low erythrocyte protoporphyrin concentrations, and recessive inheritance with different hetero- or homoallelic FECH mutations. These individuals appear to carry a lower risk of liver disease than other patients with recessive EPP.
FIGURE 26.4. Erythropoietic Protoporphyria. A, B: In a 29-year-old man. Note cobblestonelike, flesh-colored, lichenoid papules over the nose and dorsum of the hand joints. C: Dilute suspension of erythrocytes under the fluorescence microscope. Note a fraction of fluorescing cells. (Courtesy of Dr. Maureen Poh-Fitzpatrick, Columbia University, New York.) D, E: Needle biopsy section of liver. Note deposits of protoporphyrin pigment in the parenchyma and a portal triad (D), and birefringence of the deposits, including a dark Maltese cross figure near the left center (E).

Cholelithiasis tends to develop early in life 183 and ultimately occurs in approximately 10% of patients. The gallstones fluoresce and consist, in part, of precipitated protoporphyrin. 20, 227

Although EPP is generally a benign disorder with clinical manifestations limited to the skin, as noted above a small subset of patients (<5%) develops progressive liver disease, leading to a fatal cirrhosis in the second to fourth decades of life. 207, 209 At autopsy, massive hepatic deposits of protoporphyrin are found. 207, 228 Associated with the fulminant liver failure are rising blood protoporphyrin levels with progressive cholestasis, hemolysis, increasing photosensitivity, and neurologic crises resembling those of the acute porphyrias. 207, 229, 230 The neurologic dysfunction was best correlated with a markedly increased level of plasma protoporphyrin and was believed to cause neurotoxicity, leading to axonal degeneration. 230

Laboratory Findings

The free erythrocyte protoporphyrin (FEP) concentration is greatly increased in symptomatic patients. Reported values range from 600 to 4,500 µg/dl (normal, <50 µg/dl). 20, 183 However, in the XLPP form of EPP about 40% of the protoporphyrin is in the form of zinc-protoporphyrin and total erythrocyte protoporphyrin values ranged from 1,130 to 11,000 µg/dl. 204 Increased levels of erythrocyte protoporphyrin are observed in certain other conditions, especially iron deficiency anemia and in lead poisoning, but only rarely do they exceed 300 µg/dl; the excess protoporphyrin is present as the zinc chelate 231 and is distinguished spectrally from the nonchelated FEP that is found in EPP and XLPP. 232 Plasma protoporphyrin is usually increased as well, and a normal plasma porphyrin in a patient with increased erythrocyte protoporphyrin may exclude EPP. In asymptomatic carriers, the FEP ranges from normal values to 200 µg/dl. 20 The life-threatening liver disease may be predicted by increasing FEP and plasma protoporphyrin levels along with altered liver function tests. In patients with severe protoporphyric liver disease, the FEP concentration generally exceeds 2,000 µg/dl, and values >8,000 µg/dl have been reported. 207

Fluorescence microscopy of a dilute suspension of freshly obtained blood reveals fluorescence in a variable proportion of erythrocytes (Fig. 26.4C). 179 Protoporphyrin is increased chiefly in young erythrocytes 186 but is heterogeneous, and a population of reticulocytes without protoporphyrin is also present, reflecting a nonuniform expression of the genetic defect at the cellular level. 187 In asymptomatic carriers, a small population of such fluorocytes may be detected even when the FEP concentration is normal. 174

Most patients with EPP have mild, slightly hypochromic anemia and reduced iron stores. 182, 183, 184, 225 Studies of red cell survival and iron kinetics have failed to detect a characteristic abnormality, 20, 225 but hemolysis was occasionally reported. 233 Severe hemolytic anemia may occur with advanced hepatic disease that is exacerbated by photo-oxidative stress occurring during the prolonged operative procedure of liver transplantation. 234 Why some cases exhibit the ring sideroblast abnormality in erythroblasts (Chapter 24) 235, 236 but others do not 177 is not clear and may relate to the nature of the defect. This feature has not been systematically studied.

Fecal protoporphyrin excretion usually is increased in symptomatic patients. 183 Values may be as high as 1,400 µg/g (dry weight; normal, <100 µg/g) and vary widely from patient to patient, although variations in a given patient are not great. 237 In some carriers, fecal protoporphyrin is increased even when the FEP is normal. An increasing ratio of FEP to fecal protoporphyrin and an increasing ratio of biliary protoporphyrin to biliary bile acids may also suggest impending hepatic decompensation. 207, 237, 238 Urinary porphyrin and porphyrin precursor concentrations are normal.

The majority of patients with EPP have no clinical evidence of liver disease, although 20% to 30% have slight elevations of liver enzymes; in the eight families with XLPP a higher percentage of liver dysfunction was noted. 204 However, in most if not all cases, the liver contains dark brown pigment deposits (Fig. 26.4D) in hepatocytes, Kupffer cells, and portal macrophages as well as within the lumens of ductules and interlobular ducts that exhibit the characteristic red fluorescence of protoporphyrin when transilluminated with light of wavelength 380 to 500 nm. 239 These deposits are crystalline in nature on electron microscopy. They also exhibit a distinctive type of birefringence, not shared by any other pigment known to occur in the liver, that is demonstrable in routinely fixed and stained paraffin-embedded sections and is
as sensitive as the red fluorescence (Fig. 26.4E). Not infrequently, the pigmentation is accompanied by bile stasis and varying degrees of portal inflammation, fibrosis, and ductular proliferation. In patients who have developed the protoporphyric liver disease, liver histology shows micronodular or macronodular cirrhosis and massive deposits of the pigment throughout.

DNA analysis with amplification of exons and flanking intronic sequences has detected FECH or ALAS2 mutations in about 95% of patients with EPP. As large intragenic deletions in FECH are not uncommon their identification requires the use of a gene dosage analysis method. EPP patients are at risk of vitamin D deficiency and monitoring 25-hydroxyvitamin D is advised.

Treatment

Therapy is directed at reducing the consequences of sun exposure and minimizing the hepatotoxic effects of protoporphyrin. Topical sunscreens must be effective in the 400-nm portion of the spectrum to be useful. The only readily available effective topical preparations are opaque formulations containing oxidizes of zinc or titanium. Most proprietary sunscreens contain compounds that reduce transmission only of the sun-burning portion of the spectrum between 290 and 320 nm. The induction of carotenemia (serum carotene levels above 400 µg/dl) can be effective in reducing photosensitivity, although some studies suggested lack of efficacy. Carotenemia is best induced by the administration of synthetic β-carotene beadlets (Lumitene, Tishcon Corporation, Westbury, NY) in adults at a dose of 120 to 180 mg/day, but doses up to 300 mg/day may be needed. The ability of carotene to quench photoexcited oxygen and to scavenge highly reactive free radicals probably explains its action. Increased tolerance to sunlight occurs after 3 to 4 weeks of treatment, and the protective effect may last 4 to 8 weeks after cessation of the drug. In northern climates, this therapy may be required only in spring and summer, but winter sports enthusiasts may benefit from more prolonged therapy. To date, no significant side effects have been reported in patients using β-carotene.

In patients unresponsive to β-carotene, narrow-band ultraviolet B (TL-01) phototherapy and psoralen and ultraviolet A light treatment have been effective. Two patients experienced marked reduction in photosensitivity with administration of pyridoxine. Oral cysteine also appears to be effective as a free radical quencher, and, in a preliminary report, a flavonoid mixture (hydroxethyluratosides) was effective as an antioxidant.

An α-melanocyte-stimulating-hormone analog, afamelanotide (Scenesse, Clinuvel, Melbourne, Australia), is probably the most effective agent for alleviating the photosensitivity of EPP by promoting melanin synthesis and increasing skin pigmentation. It has become available in some European countries and is currently in a Phase 3 clinical trial in the United States. The preparation is a 16-mg sustained-release resorbable implant (grain of rice size) formulation of afamelanotide that is inserted subcutaneously. Studies to date showed that this prophylactic treatment significantly increased sunlight tolerance and improved quality of life.

Multiple attempts to minimize the hepatotoxic effects of protoporphyrin have been directed at both reducing the amount of protoporphyrin presented to the liver for excretion and depleting hepatic protoporphyrin stores. Suppression of erythropoiesis and the erythrocyte protoporphyrin accumulation can be achieved with transfusion therapy, but the hazards of transfusion-induced iron overload and the risk of transfusion-related infectious disorders make this form of therapy undesirable. Administration of iron with the rationale of enhancing porphyrin conversion to heme was followed by decreases in stool and erythrocyte porphyrins and improved liver function, but the disease was aggravated by oral iron therapy in others. The use of nonabsorbable porphyrin binders, namely cholestyramine and activated charcoal, aimed at reducing enterohepatic recirculation of porphyrin, and/or bile acids, to promote fecal porphyrin excretion have benefited selected patients. None of these approaches is well established, owing to inconsistent or uncertain efficacy and experience in relatively few cases.

In some patients with liver failure, the circulating protoporphyrin burden could be reduced by hemin infusion, plasma exchange, red cell exchange, or by extracorporeal albumin dialysis; parenteral and oral n-acetyl cysteine was beneficial in one case. Once severe liver damage has occurred, usually no form of medical therapy is effective. Thus, liver transplantation was undertaken as a life-saving measure. The results have been favorable in part, with patient and graft survival rates up to 66% at 5 years. However, the protoporphyrin burden from erythroid tissue remains and recurrence of protoporphyrin hepatopathy is common, supporting most evidence that the primary if not the only contribution of the excess protoporphyrin is from bone marrow. Moreover, in a case with EPP due to heteroallelic FECH mutations and coincidental acute leukemia, a successful marrow transplant from a sibling carrying one FECH mutation
cured the patient’s manifestations of the porphyria. HSCT has also been performed in four EPP patients with a prior liver transplant to treat or prevent disease recurrence in the graft. Although in three of the four cases successful engraftment led to clinical and biochemical resolution, two succumbed to infectious complications. In a fifth patient bone marrow transplantation following medical control of severe progressive protoporphyrin cholestasis was curative. Apart from its inherent risks, HSCT would appear to be the ideal treatment in EPP patients prone to severe liver disease before liver transplantation becomes necessary. Identification of patients at risk of severe liver disease remains the principal challenge.

The most definitive treatment for the disease would be replacement of the defective gene in affected tissues. Targeting the hematopoietic stem cells with gene therapy will probably suffice once it is technically feasible. In vitro studies have demonstrated effective transfer of normal FECH complementary DNA into cultured fibroblasts from patients with EPP with correction of the biochemical defect. Genetic analysis of EPP patients’ spouses for carrier status of a FECH mutation and a low-output FECH allele allows assessment for the probability of clinical disease in offspring as well as prenatal testing or pre-implantation genetic diagnosis.

Erythropoietic Protoporphyria in Animals

Bovine EPP was described in 1977 and is transmitted as an autosomal recessive trait. Affected calves have acute photosensitization during the first few weeks of life, the erythrocyte and fecal protoporphyrin is greatly increased, and FECH is reduced to 10% in all tissues examined. The animals do not develop anemia or hepatobiliary disease. Carrier dams have approximately half the normal FECH activity. DNA analysis revealed a novel stop codon mutation (X417L).

A protoporphyric disorder occurs in mice that are fed a diet containing 2.5% by weight of griseofulvin and exhibits a pronounced hepatic component. It is similar in many respects to the human disease, and the hepatic histopathologic abnormalities are indistinguishable by light or electron microscopy. Another murine EPP (fch) is produced by chemical mutagenesis with ethylnitrosourea. It is characterized by photosensitivity, severe hepatobiliary dysfunction in early life, and microcytic hypochromic anemia as well as a redistribution of storage iron to the spleen. FECH activity in various tissues is 2.7% to 6.3% of normal in homozygotes and approximately 50% in heterozygotes. A point mutation has been identified in the FECH gene (Fechm1Pas), and prokaryotic expression studies have substantiated it as the basis for the porphyria. Bone marrow transplantation is effective in this mouse model. Moreover, reversal of the phenotype and restoration of normal hepatic porphyrinemia have been achieved with pre-selective gene therapy as well as with the use of a dual gene therapy technology. A third mouse model exhibiting a protoporphyria is produced by targeted deletion of iron-regulatory protein 2 (IRP2). The phenotype is manifested by iron-limited erythropoiesis, marked overexpression of ALAS2 from loss of IRP-dependent translational repression, and markedly increased levels of free and zinc protoporphyrin. These features closely resemble those of XLDPD.

A genetically designed model of EPP was developed in zebrafish named dracula. Protoporphyrin IX accumulates in the mutant embryos, and the phenotype shows light-dependent hemolysis and liver disease. The mutation is a G to T transversion at a splice donor site in the FECH gene and creates a stop codon.

ACUTE OR INDUCIBLE PORPHYRIAS WITH NEUROLOGIC MANIFESTATIONS

Porphyrias manifesting neurologic and psychiatric illness are called acute porphyrias to reflect the often abrupt onset of symptoms. They are also referred to as inducible porphyrinas because symptoms are usually brought on by endogenous or exogenous factors that stimulate heme biosynthesis through certain biochemical mechanisms. These disorders are deficiencies of the remaining four enzymes of the heme synthetic pathway that restrict the capacity for the production of heme in the liver and lead to derepression of ALA synthase: PBGD, ALA dehydratase (ALAD), coproporphyrinogen oxidase (CPOX), and protoporphyrinogen oxidase (PPOX) (Fig. 26.1). During acute attacks, hepatic ALA synthase is markedly induced, and the porphyrin precursors ALA and PBG accumulate because PBGD becomes rate limiting, normally having the second lowest relative activity among the enzymes of the hepatic heme synthetic pathway. These events are best understood in the liver, and they may occur in neural tissue. Deficiencies of CPOX and PPOX also result in accumulation of their respective porphyrin substrates and therefore can be accompanied by photosensitivity, whereas only the precursors accumulate with deficient PBGD and ALAD, and photosensitivity does not occur.

Acute Intermittent Porphyria

Patients with acute intermittent porphyria (AIP; pyrroloporphyria, Swedish porphyria) were probably reported by Gunther. The extensive family studies in Sweden by Waldenström provided the first comprehensive description of the disorder. It is transmitted in an autosomal dominant manner with low penetrance and results from mutations in the gene encoding PBGD (hydroxymethylbilane synthase, uroporphyrinogen I synthase) (Fig. 26.1). The prevalence of the trait in most countries had been estimated at 1 to 2 per 100,000. More recent population screening studies in northern
Europe with enzyme assays and DNA analysis indicate a much higher prevalence of carriers, ranging from 1 to 2 per 10,000, and an even higher prevalence in Sweden and France. A study of psychiatric patients in the United States showed a higher prevalence of AIP than in the general population (approximately 0.21%).

Molecular Basis and Pathogenesis

A decreased conversion of PBG to porphyrins observed in liver tissue from patients with AIP provided the first evidence that the enzyme PBGD is defective. Decreased catalytic activity of PBGD to approximately half of normal was subsequently demonstrated in all tissues examined, including liver, erythrocytes, cultured skin fibroblasts, cultured amniotic cells, and mitogen-stimulated lymphocytes. Considerable heterogeneity of the defect became evident from biochemical and immunologic studies of the enzyme in erythrocytes from patients with AIP. Up to 10% of unrelated and clinically affected individuals had either normal or indeterminate levels of erythrocyte PBG-D activity. Overlapping enzyme activity levels could be resolved with internal family reference values, consistent with apparent genetic regulation of the enzyme activity. Patients with normal erythrocyte PBGD activity responded to an ALA loading test with increased excretion of PBG and reduced excretion of fecal protoporphyrin, just like patients with low PBGD activity in erythrocytes, suggesting that the defect is expressed in the liver but not in erythrocytes. Approximately 80% of patients with half-normal PBGD catalytic activity were found to have half-normal PBGD protein concentration, referred to as cross-reacting immunologic material negative, and approximately 20% of pedigrees were cross-reacting immunologic material positive (i.e., the PBGD catalytic activity was half-normal, but the PBGD protein was normal or even increased). In addition, molecular heterogeneity was indicated by detection of differing restriction haplotypes for the PBGD gene locus.

After the cloning and sequencing of the PBGD gene, the molecular basis for two isoforms of the enzyme was established, and genetic defects responsible for AIP could be identified. A single PBGD gene, located in the chromosomal region 11q23.3, under the control of two independently regulated promoters, produces two transcripts through alternative splicing. In the mRNA of the enzyme produced in all cells (ubiquitous mRNA), exon 1 is spliced to exon 3, whereas exon 1 is excluded in the transcript in erythroid cells, and translation begins in exon 3 (Fig. 26.5). Thus, the erythroid-specific protein lacks the 17 amino acids that are encoded by exon 1 for the ubiquitous enzyme.

Close to 400 different mutations have been identified in the PBGD gene, most of which were found in single pedigrees. High frequencies of a few mutations in restricted geographic areas (e.g., Sweden, The Netherlands, Switzerland, Canada, Argentina) are believed to represent founder effects. On the other hand, approximately 3% of all index cases with AIP may have de novo mutations. Approximately two thirds of mutations are singlebase substitutions, and the remaining mutations consist of insertions or deletions, resulting in a spectrum of splice defects of transcripts, frameshifts, stop codons, unstable proteins, or reduced catalytic activities of the enzyme; a few are in the promoter region of the gene. The least common mutations (i.e., involving the exon 1-intron 1 junction or exon 1) restrict the PBGD defect to nonerythroid tissues and account for the normal activity of the enzyme in erythrocytes observed in such cases. In four families, double heterozygotes or homozygotes for point mutations had severe PBGD deficiency. Although, in general, no correlation between the genotypes and phenotypes has been found, some prevalent mutations exhibit higher penetrance. Using the knowledge of the three-dimensional structure of PBGD, structural and functional outcomes of the mutations can be predicted. For instance, many mutations change amino acids in the vicinity of the active site of the enzyme, and a number of these are involved in binding the primer or substrate of the enzyme; others perturb conformation of the protein.
