At first, the disease was considered a distinct entity. It has been suggested that the disease is an exaggeration of the process of acclimatization and aging, because patients with chronic mountain sickness had Hb concentrations within the normally distributed values for large groups of native residents. Support for this suggestion comes from the observation that chronic lung disease increases the likelihood of chronic mountain sickness.111 Chronic mountain sickness has not been reported to occur in natives of the Himalayas.112 This may reflect in part occupational differences, namely mining, and a consequently high incidence of chronic lung disease in the Andes as compared with the pastoral occupation of the Sherpas. Investigation of selective gene expression in populations in whom chronic mountain sickness is prevalent, may further enhance understanding of this syndrome.113, 114, 115

Differentiation of chronic mountain sickness from other causes of hypoxic polycythemia should not be difficult. Cases of congenital or acquired cyanotic heart disease can be distinguished by the cardiac findings. Polycythemia vera is not altered by increased ambient oxygen tension, whereas in Monge disease, descent to sea level produces complete relief of symptoms, together with a pronounced reduction in the blood volume and restoration of normal blood counts.116

Pulmonary Disease

A variety of diseases, such as chronic obstructive pulmonary disease, diffuse pulmonary infiltrates (fibrous or granulomatous), kyphoscoliosis, and multiple pulmonary emboli, leads to erythrocytosis as the result of inadequate oxygenation of the blood circulating through the lungs. Not all patients with lung disease and decreased arterial oxygen saturation, however, have elevated Hb or hematocrit levels,117, 118 and only in approximately 50% is an increase in red cell mass noted.119 The reason for this suboptimal response to hypoxia is not clear, but it does not appear to result from a decrease in erythropoietin production or the presence of chronic infection.117, 118, 120 When polycythemia occurs, it usually is associated with increased MCV, reduced MCHC,119 and normal MCH values. The red cell morphology changes have been attributed to increased water uptake by the cell, which in turn may result from carbon dioxide retention.117 If polycythemia is present, it is corrected by chronic oxygen administration.121

Vascular malformations in the lung may also be associated with erythrocytosis.122, 123 Pulmonary arteriovenous fistulae should be suspected when a murmur is heard in a lung field in association with erythrocytosis.

Chronic Cor Pulmonale

The clinical picture of chronic cor pulmonale varies, but oxygen deficiency with arterial desaturation and elevated pulmonary artery pressure is of central importance.124, 125 Polycythemia with its associated increase in blood viscosity and volume appears to be the physiologic price of a compensatory mechanism progressively extended to the point at which it is more injurious than beneficial.126 As in less severe pulmonary disease, the MCV of the red cells tends to be elevated, whereas the MCHC generally is decreased.127

Cyanotic Heart Disease

Marked degrees of polycythemia may be seen in patients with a partial shunt of the blood from the pulmonary circuit. Hematocrit levels greater than 0.60 are not uncommon. The most frequent defects producing such polycythemia are pulmonary stenosis (usually with defective ventricular or atrial septum, patent foramen ovale, or patent ductus arteriosus), persistent truncus arteriosus, complete transposition of the great vessels, and the tetralogy of Fallot (pulmonary stenosis, defective ventricular septum, dextroposition of the aorta, right ventricular hypertrophy). Individuals
with such defects exhibit evidence of disturbed cardiorespiratory function, marked cyanosis, clubbing of the fingers and toes, and sometimes stunted growth.

The total plasma volume may be reduced to below normal levels, but the increase in the size of the red cell mass is so great that the total blood volume usually is higher than normal.\textsuperscript{128} Erythroid hyperplasia is observed in the marrow.\textsuperscript{129, 130} The general consensus is that low oxygen tension resulting from shunting of unoxygenated blood through or around the lungs with consequent desaturation of the arterial blood stimulates erythropoietin production. With successful operative intervention, this value may be significantly corrected, with resolution of polycythemia.

Acquired Heart Disease

In 1901, Abel Ayerza described a syndrome characterized clinically by slowly developing asthma, bronchitis, dyspnea, right-sided heart failure, and severe cyanosis with associated polycythemia.\textsuperscript{131} The striking degree of cyanosis led Ayerza to describe these patients as “black cardinals.” It was subsequently demonstrated that the unifying feature of these patients was not pulmonary disease but rather pulmonary arterial hyperplasia, leading to pulmonary hypertension and consequent right-sided heart failure.\textsuperscript{132} In all forms of acquired heart disease, any erythrocytosis that may develop is correlated to some extent with the degree of cardiopulmonary decompensation. It is typically minimal. Polycythemia is reportedly accompanied by evidence of intensified erythropoiesis in the bone marrow, an increase in red cell mass, and some macrocytosis.\textsuperscript{131}

P.1039

Hypoventilation Syndromes

Polycythemia is found occasionally in patients who exhibit no evidence of pulmonary disease or cardiovascular shunts. The primary defect in at least some of these patients appears to be an inadequate ventilatory drive from the respiratory center in the brain.\textsuperscript{126, 133} A similar defect has been reported in patients with the Pickwickian syndrome, so called because of the description of Joe, the hypersomnolent fat boy, in Dickens's The Pickwick Papers.\textsuperscript{134} In the setting of extreme obesity, these patients exhibit somnolence, cyanosis, and hypercapnia and may develop periodic respiration, ultimately with right ventricular failure. Voluntary hyperventilation alleviates the hypercapnia, and in many patients, loss of weight restores normal alveolar ventilation and reverses the syndrome.\textsuperscript{135, 136} Alveolar hypoventilation and erythrocytosis, however, do not develop in all obese individuals; it appears that only in the presence of an insensitive respiratory center does a massive panniculus limit respiratory function and result in alveolar hypoventilation, hypoxemia, and hypercapnia.\textsuperscript{137} In some patients, the decreased ventilatory drive is of unknown cause or is a result of idiopathic disease of the medullary respiratory center (Ondine curse)\textsuperscript{133, 136}; other etiologies include bulbar poliomyelitis, vascular thrombosis, or previous encephalitis.\textsuperscript{126, 137} In any case, the consequent hypoxemia results in elevated levels of erythropoietin and erythrocytosis, with hematocrits reported as high as 0.75.\textsuperscript{8}

Patients with polycythemia and positional arterial oxygen desaturation have also been reported.\textsuperscript{139} Whether this results from alveolar hyperventilation while supine or from shunting through an arteriovenous malformation while upright is unclear.\textsuperscript{140} Obstructive sleep apnea has been associated with polycythemia (presumably due to episodic erythropoietin secretion during apneic episodes) in some\textsuperscript{141} but not all\textsuperscript{142} reports.

Abnormal Hemoglobins

Inherited Abnormalities of Hemoglobin

Certain mutant Hbs are characterized by increased oxygen, and patients who carry such Hbs tend to develop erythrocytosis.\textsuperscript{143, 144, 145, 146} More than 200 high-affinity Hbs have been characterized, of which roughly half produce significant erythrocytosis.\textsuperscript{147} Oxygen-Hb dissociation curves are shifted dramatically to the left in individuals carrying these abnormal Hbs. The degree of left shift can be quantified by determining the P\textsubscript{50} (i.e., the oxygen pressure at which Hb is half-saturated). The normal value in whole blood is 23 to 29 mm Hg at standard pH, temperature, CO\textsubscript{2} content, and barometric pressure. The whole-blood P\textsubscript{50} is almost invariably decreased in patients with a high-affinity Hb; most values fall between 9 and 21 mm Hg. In a few instances, the P\textsubscript{50} has been normal, or nearly so, in whole blood (e.g., HbG Norfolk\textsuperscript{148}), necessitating the measurement of the oxygen dissociation curve of the purified Hb to demonstrate the defect. The approach to the diagnosis of high-affinity Hb variants, the characteristics of patients with representative mutations, and the molecular pathology are discussed in Chapter 35.
The most important physiologic consequence of increased oxygen affinity is that release of oxygen is impaired at partial pressure of oxygen values normally found in tissues. Uptake of oxygen in the lungs is enhanced, but this effect is relatively unimportant, because normal Hb is nearly completely saturated in the lungs under the usual physiologic circumstances. As previously noted, however, the increased affinity may confer some advantages when environmental oxygen is low, such as at high altitudes.

Individuals with high-affinity Hbs are not at a disadvantage under hypoxic conditions. They tolerate ascent to high altitudes as well as or better than normal subjects and thus appear to be preadapted to hypoxic stresses. Under such conditions, the enhanced oxygen loading seems more important than the impaired delivery. Similarly, exercise tolerance appears unimpaired. There is no evidence that oxygen delivery to the heart is defective in patients with high-affinity Hbs. Although myocardial infarctions and other findings of atherosclerotic cardiovascular disease are reported in these patients, it is unclear whether this is an actual association or simply reflects the high frequency of atherosclerosis in the general population.

High-affinity Hbs appear to exert no adverse effects on fetal development in utero. Theoretically, oxygen delivery to a developing noncarrier fetus might be impaired when the mother is a carrier, because the normal differential in oxygen affinity between fetal and adult Hb (which is in favor of the developing fetus) would be narrowed. However, only in the family with Hb Yakima was there a suggestion that spontaneous abortions occurred at an increased rate. In contrast, normal pregnancy outcomes were recorded for mothers carrying the severe high-affinity variants Hb Bethesda, Hb Osler, and Hb Little Rock. Evidently, maternal and fetal polycythemia and increased uterine and fetal blood flow compensate for the theoretic deficit in placental oxygen transport. There are no data addressing whether carrier fetuses have a developmental advantage over noncarriers born to these mothers; however, in dizygotic twins born to a mother with Hb Osler, the carrier twin developed more fully than the noncarrier as measured by the ponderal index (weight/length^3).

It has been suggested that the homozygous state for high-affinity Hbs would be incompatible with life because of insufficient oxygen release to tissue. This may be true; however, at least four patients with abnormal Hb levels approximating those that would be observed in homozygotes have been described with no apparent ill effects (Hb Abruzzo, Hb Crete, and Hb Headlington). The unusually high proportion of abnormal Hb was clearly due to concurrent β-thalassemia in two cases and probably in the others as well.

No treatment is indicated for most patients with high-affinity Hbs. Their erythrocytosis is a compensation for a physiologic state and should be regarded as “normal for them.” In the rare patient with erythrocytosis and associated symptoms, phlebotomy may be used, but caution must be used to avoid lowering the hematocrit to a point at which oxygen delivery is impaired. A reasonable approach is probably to phlebotomize the individual patient to the highest hematocrit at which he or she is no longer symptomatic rather than to a specific number. Certainly, reducing blood Hb concentrations to normal levels would be undesirable. Cytoreductive agents should not be used for treatment.

Acquired Abnormalities of Hemoglobin

Moderate elevations of carboxyhemoglobin in erythrocytes shift the oxygen dissociation curve. In heavy smokers, carboxyhemoglobin concentration may reach sufficiently high levels (4.0% to 6.8%) to produce polycythemia. In the older literature, polycythemia in association with phosphorus poisoning has been described, although it may have been merely relative erythrocytosis resulting from acute liver damage. Although certain drugs and chemicals (e.g., nitrates, aniline dyes, sulfonamides, and nitrobenzene) produce toxic levels of methemoglobin, sulfhemoglobin, or both in the blood of even normal persons, their erythrocytosis apparently has not been described in patients with toxic methemoglobinemia.

Familial Polycythemia (Physiologically Appropriate)

Familial defects in 2,3-BPG metabolism (e.g., BPG mutase deficiency or elevated erythrocyte adenosine triphosphatase), which would have the effect of shifting the oxygen dissociation curve to the left, provide other physiologically appropriate (tissue hypoxia) reasons for polycythemia. A specific pyruvate kinase mutation resulting in higher than normal enzyme activity and decreased 2,3-BPG causing erythrocytosis has been described as well in association with erythrocytosis.

Secondary Polycythemia (Physiologically Inappropriate [Normoxic])
Unlike patients with physiologically appropriate secondary polycythemia, individuals with inappropriate polycythemia receive no benefit from the higher red cell concentrations. Treatment should be aimed at correcting the underlying disease; phlebotomy can be considered in the symptomatic.

Aberrant Erythropoietin Secretion

Erythrocytosis has been described in association with a variety of neoplasms, cysts, vascular abnormalities, and endocrinologic disorders. In the syndromes discussed in the preceding section, erythrocytosis was secondary (i.e., driven by increased erythropoietin); however, this erythropoietin secretion and the consequent erythrocytosis were physiologic responses to tissue hypoxia. In this section, disorders in which erythropoietin-driven erythrocytosis bears no relation to physiologic requirements are reviewed (Table 44.4).

Renal Disorders

Renal cell carcinoma (hypernephroma) is one of the disorders most frequently associated with erythrocytosis. Erythrocytosis is observed in 0.9% to 1.6% of patients with renal cell carcinoma (approximately one fourth as frequent a finding as anemia). Elevated serum erythropoietin levels, however, are observed in more than 60% of patients. Erythrocytosis also has been reported in patients with renal sarcoma, hemangioma, adenoma, Wilms tumor, renal cysts, hydronephrosis, horseshoe kidney, and polycystic kidneys. Renal artery stenosis has also been reported in association with erythrocytosis.

Erythrocytosis in renal cell carcinoma is attributed to constitutive erythropoietin production by the tumor. Erythropoietin messenger RNA can be demonstrated in renal carcinoma cells. It is assumed that this is also the mechanism by which other parenchymal renal diseases produce erythrocytosis. Hydronephrosis and anatomic abnormalities probably produce erythrocytosis by increasing pressure on erythropoietin-producing cells in the renal parenchyma. Significant and measurable concentrations of erythropoietin (sometimes >100 mU/ml) can be detected in fluid aspirated from renal cysts associated with polycythemia. Production of erythropoietin in renal cell carcinoma is said to predict a good response to therapy. Management of erythrocytosis in these patients should be directed at treatment of the responsible renal lesion with phlebotomy as an adjunct, when necessary.

Erythrocytosis is also observed in patients after renal transplantation. This phenomenon is associated with elevated serum erythropoietin; the source of erythropoietin is presumed to be the transplant recipient’s native kidneys. Effective therapeutic modalities include phlebotomy, angiotensin-converting enzyme inhibitors, and theophylline.

Liver Diseases

During fetal development, the liver contributes to erythropoietin production (Chapter 6); hepatic disease, like renal disease, may be associated with erythropoietin production and polycythemia. Erythrocytosis has been identified in persons with hepatocellular carcinoma with incidence 2.5% to 10.0%. When measured, red cell mass has been shown to be increased, and elevated serum erythropoietin levels have also been described. As with renal cell carcinoma, erythropoietin production by the tumor has been demonstrated. Remission of erythrocytosis may be observed after successful tumor treatment.

Human immunodeficiency virus infection

Polycythemia infrequently reported.

Erythrocytosis has also been reported with hepatic hamartomas and tumors metastatic to liver, as well as hepatic angiomas and hemangiosarcomas. Polycythemia has been reported in the early stages of viral hepatitis. Cirrhosis is occasionally listed in texts as associated with erythrocytosis, but this apparently does not occur except in the setting of another disease, such as cirrhosis with hepatocellular carcinoma.

Cerebellar Vascular Tumors
The association of erythrocytosis with vascular tumors of the cerebellum is well established. Elevated serum erythropoietin levels and tumor production of erythropoietin have been demonstrated, but abnormalities in Von Hippel-Lindau
protein are observed as well.\textsuperscript{203} 204 205 Correction of erythrocytosis may be observed after effective therapy and erythrocytosis may return with recurrence of the tumor.\textsuperscript{171}

Leiomyoma and Fibroid Tumors of the Uterus

Several cases in which large leiomyomas and fibroid tumors of the uterus were associated with erythrocytosis have been reported.\textsuperscript{206} 207 Erythrocytosis tends to subside after effective therapy and is also associated with production of erythropoietin by tumor.\textsuperscript{207} 208 Cutaneous leiomyomata have also been associated with erythrocytosis.\textsuperscript{209}

Other Neoplasms

Rare instances of erythrocytosis in association with a variety of other tumors have been reported, but some of these associations may be coincidental.\textsuperscript{210} However, erythropoietin synthesis by tumor cells has been clearly demonstrated in a patient with meningioma.\textsuperscript{210} Erythrocytosis has also been reported in rare patients with chronic lymphocytic leukemia,\textsuperscript{211} systemic amyloidosis,\textsuperscript{212} placental trophoblastic tumors,\textsuperscript{213} and atrial myxomas.\textsuperscript{214}

Endocrinologic and Other Disorders

Erythrocytosis has been reported in association with a number of endocrinologic disorders, including Cushing syndrome, primary aldosteronism,\textsuperscript{215} virilizing ovarian tumors,\textsuperscript{216} Barter syndrome,\textsuperscript{217} and pheochromocytoma.\textsuperscript{218} 219 In the latter disorder, tumor erythropoietin production has been reported.\textsuperscript{220}

There have been a number of reports describing small numbers of patients with human immunodeficiency virus infection and polycythemia.\textsuperscript{221} 222 223 224 225 226 It is unclear if there is an actual pathophysiologic association or if this is coincidental.

Drug-induced Erythrocytosis

Anabolic and androgenic steroids may be abused by both recreational and professional athletes for purposes of improving performance.\textsuperscript{227} A consequence of androgen administration, either medicinal or extralegal, may be erythrocytosis.\textsuperscript{228} 229 230 In some cases, the degree of erythrocytosis may be severe.

Recombinant human erythropoietin has also been abused by athletes (particularly those in endurance sports) to increase the red cell mass and thus oxygen-carrying capacity.\textsuperscript{231} 232 233 As indicated earlier in Figure 44.2, this may backfire if the athlete becomes hypovolemic as a result of exertion. Cases of surreptitious erythropoietin self-administration resulting in accelerated hypertension and unstable angina have been reported.\textsuperscript{234} A perceived advantage of erythropoietin over androgens for this purpose is the inability to distinguish endogenous from exogenous erythropoietin as well as the lack of hepatic toxicity. Newer approaches that allow discrimination between exogenous recombinant erythropoietin and endogenous erythropoietin may make this practice less frequent.\textsuperscript{235} 236 237 238

Familial Polycythemia (Physiologically Inappropriate)

Kindreds that exhibit an autosomal recessive erythrocytosis associated with increased erythropoietin production have been described.\textsuperscript{239}

Idiopathic Polycythemia

The term idiopathic polycythemia (or erythrocytosis) refers to patients who have an elevated red cell mass of unknown etiology after appropriate investigation. It would include most of the patients formerly categorized as “benign erythrocytosis.” The existence of this group, which is estimated to contain 20% to 30% of patients evaluated for polycythemia,\textsuperscript{141} essentially represents a failure to categorize all polycythemic patients correctly.

Of 25 patients reported in one series, 12 were found to have elevated erythropoietin levels and were therefore assumed to represent patients with secondary polycythemia; these patients tended to be younger than the patients with normal erythropoietin levels.\textsuperscript{139} Progenitor culture studies were not helpful in subcategorizing the group in this particular study.\textsuperscript{139} Some studies have reported endogenous colony-formation studies to be useful and serum erythropoietin levels not helpful,\textsuperscript{50} whereas others have reported the opposite.\textsuperscript{240}

Kiladjian et al. treated 39 patients with idiopathic erythrocytosis with pipobroman and compared their clinical course to 140 concurrently treated polycythemia vera patients.\textsuperscript{241} The risk of leukemia, thrombosis, and myelofibrosis was the same in the two groups. This study confirms that the idiopathic erythrocytosis group contains a certain number of polycythemia vera patients; however, it does not provide a way to identify individuals who do not have a myeloproliferative disorder and therefore should not be exposed to leukemogenic agents.\textsuperscript{241}
Because this category probably represents a mixed bag, including early polycythemia vera, mild secondary polycythemia, and normal individuals at the higher end of the bell-shaped curve for red cell mass, a cautious approach is warranted. Observation may be the most reasonable intervention; this may be the patient subset in which otherwise low-yield studies, such as erythroid progenitor studies, are likely to be useful. Periodic retesting for the JAK2 V617F mutation or other JAK2 mutations may also be useful, although a study that addressed this question found that less than 2% of idiopathic erythrocytosis patients studied exhibited the mutation.

Part V - Disorders of Hemostasis and Coagulation

Section 1 - Introduction

Chapter 45 Diagnostic Approach to the Bleeding Disorders

Except for that which occurs during menstruation, spontaneous bleeding is abnormal. Surprisingly, little blood is lost, even after large injuries, because of the efficiency with which vascular integrity is normally maintained and the rapidity with which it is restored after injury. In general, these phenomena reflect the functional effectiveness of normal hemostasis (see Chapters 17, 18, and 19). It must be recognized, however, that the adequacy of hemostasis is only relative, and despite the presence of normal vessels, platelets, and coagulation factors, bleeding can occur as the result of localized pathologic processes.

The 11 chapters in Part V deal with disorders that result from abnormalities of the hemostatic process. This chapter is a summary of the diagnostic approach to these disorders and includes a brief discussion of laboratory methods for their study. In subsequent chapters, individual disorders are considered in six categories: thrombocytopenia (Chapters 46, 47, 48, and 49), bleeding disorders caused by vascular abnormalities (Chapter 50), thrombocytosis (Chapter 51), disorders of
platelet function (Chapter 52), inherited coagulation disorders (Chapter 53), and acquired coagulation disorders (Chapter 54). The pathophysiology of thrombosis and the principles of antithrombotic therapy are summarized in Chapter 55.

**CLINICAL EVALUATION OF THE BLEEDING PATIENT**

A careful evaluation of the patient presenting with a bleeding disorder can often provide valuable clues as to whether the abnormality resides in the vessels, platelets, or the process of blood coagulation; a carefully obtained history can usually establish whether the disorder is inherited or acquired; and the physical examination may reveal findings such as the characteristic skin lesions of hereditary hemorrhagic telangiectasia, which alone may provide the diagnosis of a previously perplexing bleeding problem. Results of the clinical evaluation should lead to a rational and efficient laboratory investigation.

It is important to ask specific questions about bleeding because people with normal hemostasis may believe they bleed excessively. Certain questions may discriminate between those with normal and abnormal hemostasis, including whether excessive bleeding occurs after tooth extraction or small cuts, whether spontaneous bruising or muscle bleeding occurs, or whether the patient has ever been transfused or treated with blood products.

**MANIFESTATIONS OF DISORDERED HEMOSTASIS**

Certain signs and symptoms are virtually diagnostic of disordered hemostasis. They can be divided arbitrarily into two groups: those seen more often in disorders of blood coagulation and those most commonly noted in disorders of the vessels and platelets. The latter group is often called purpuric disorders because cutaneous and mucosal bleeding usually are prominent. The clinical findings that are most valuable in distinguishing between these two broad categories are summarized in Table 45.1. Although these criteria are relative, they provide valuable clues to the probable diagnosis if they are applied to the predominant clinical features in a given patient.

Bleeding into Skin and Soft Tissues

Petechiae are characteristic of an abnormality of the vessels or the platelets, such as thrombocytopenia, and are exceedingly rare in the coagulation disorders. These lesions are small capillary hemorrhages ranging from the size of a pinhead to much larger (Fig. 45.1). They characteristically develop and regress in crops and are most conspicuous in areas of increased venous pressure, such as the dependent parts of the body and areas subjected to pressure or constriction from girdles or stockings. In patients with scurvy, petechiae may be distributed around hair follicles in the “saddle area” of
Petechiae must be distinguished from small telangiectasias and angiomas. Vascular structures such as telangiectasias or angiomas blanch with pressure, whereas petechiae do not.

In the purpuric disorders, petechiae commonly are associated with multiple superficial ecchymoses, which usually develop without perceptible trauma but seldom spread into deeper tissues. Small isolated ecchymoses are commonly noted in apparently normal women, especially on the legs, and in small children.

Although large superficial ecchymoses may be seen in association with the coagulation disorders, the most characteristic lesion is the large spreading hematoma (Fig. 45.2). Such hematomas may arise spontaneously or after trivial trauma and often spread to involve an entire limb by dissecting within muscles and deep fascial spaces, often with minimal discoloration of the overlying skin.

Hemarthrosis

Hemorrhage into synovial joints is virtually diagnostic of a severe inherited coagulation disorder, most commonly hemophilia A or hemophilia B, and is rare in disorders of the vessels and platelets or in acquired coagulation disorders. This disabling problem often develops with pain and swelling as chief symptoms but without discoloration or other external evidence of bleeding (see Fig. 53.3). Subperiosteal hemorrhages in children with scurvy and swollen painful joints that may develop in some patients with allergic purpura occasionally may be confused with hemarthrosis.
FIGURE 45.1. Diffuse petechial rash induced by a tourniquet in a patient with chronic idiopathic thrombocytopenic purpura (platelet count = 40 × 10^9/L).
Traumatic Bleeding

The unavoidable traumas of daily life and even minor surgical procedures are a greater challenge to hemostasis than any test yet developed in the laboratory. In contrast to “spontaneous” bleeding manifestations, bleeding after trauma in a person with a hemorrhagic diathesis differs in a quantitative way from that which would normally be expected in terms of the amount, duration, and magnitude of the inciting trauma. Such variables are extremely difficult to assess accurately by taking the patient’s history. The amount of blood lost may be exaggerated by the patient. The need for transfusions and the number administered may serve as a rough guide. The patient’s statement concerning the duration of bleeding is
more reliable. Detailed inquiry as to past injuries and operations must be made because the patient is likely to forget procedures or injuries that were uncomplicated and to dwell on those in which bleeding was a problem. Whether reoperation was required for prolonged bleeding after tooth extraction or other minor surgical procedures may be helpful in identifying a patient with abnormal hemostasis.

In individuals with a coagulation disorder, the onset of bleeding after trauma often is delayed. For example, bleeding after a tooth extraction may stop completely, only to recur in a matter of hours and to persist despite the use of styptics, vasoconstrictors, and packing. The temporary hemostatic adequacy of the platelet plug despite defective blood coagulation may explain this phenomenon of delayed bleeding, as well as the fact that patients with coagulation disorders seldom bleed abnormally from small superficial cuts such as razor nicks. In contrast, posttraumatic or postoperative surgical bleeding in thrombocytopenic patients usually is immediate in onset, as a rule responds to local measures, and rarely is as rapid or voluminous as that encountered.

Valuable information often is obtained from a careful review of dental procedures, because most patients have had one or more teeth extracted at some time during their lives. The amount of bleeding normally encountered varies greatly, but as a rough guide, uncomplicated extraction of a single molar tooth may result in brisk bleeding for up to 1 hour and slight oozing for up to 2 days in normal persons. Typically, bleeding is more profuse from upper than from lower sockets and is more extensive after extraction of molar teeth, particularly impacted third molars, than after removal of other teeth. In patients with inherited coagulation disorders, the shedding of deciduous teeth often is uncomplicated.

The response to trauma is an excellent screening test for the presence of an inherited hemorrhagic disorder, and a history of surgical procedures or significant injury without abnormal bleeding is equally good evidence against the presence of such a disorder. The removal of molar teeth is a major challenge to hemostasis, as is a tonsillectomy, and it is a rare hemophiliac, however mildly affected, who can withstand these procedures without excessive bleeding.

Miscellaneous Bleeding Manifestations

Despite the fact that structural causes for bleeding (such as polyps, varices, and tumors) are commonly seen in patients with hematuria, hematemesis, and melena, bleeding from these sites may also be associated with both purpuric and coagulation disorders. Severe menorrhagia may be the sole symptom of women with von Willebrand disease (vWD), mild thrombocytopenia, or autosomally inherited coagulation disorders. Recurrent gastrointestinal bleeding or epistaxis in the absence of other bleeding manifestations is common in hereditary hemorrhagic telangiectasia. A coagulation disorder or a disorder of platelet function should be considered if protracted hematuria is the only symptom.

Bleeding into serous cavities and internal fascial spaces often occurs in patients with inherited coagulation disorders and may create serious diagnostic problems. In hemophilia, retroperitoneal hemorrhage or bleeding into the psoas sheath may mimic appendicitis, and hemorrhage into the bowel wall may be confused with intestinal obstruction. Signs and symptoms simulating a variety of acute intra-abdominal disorders also may be seen in association with allergic purpura. Bleeding into the central nervous system may complicate thrombocytopenia and may occur after minor trauma in patients with coagulation disorders. Multiple small retinal hemorrhages are common in patients with thrombocytopenia and other purpuric disorders but are uncommon in those with inherited coagulation disorders; large hematomas of the orbit may be seen in the latter group. The coexistence of bleeding and thromboembolic phenomena or bleeding from previously intact venipuncture sites is suggestive of diffuse intravascular coagulation (DIC). Protracted wound healing, wound dehiscence, and abnormal scar formation have been described in inherited afibrinogenemia, the dysfibrinogenemias, and in factor XIII deficiency. Hemoptysis rarely is associated with hemorrhagic disorders.

CLINICAL FEATURES OF INHERITED BLEEDING DISORDERS

An inherited bleeding disorder is suggested by the onset of bleeding symptoms in infancy and childhood, a positive family history (particularly if it reveals a consistent genetic pattern), and laboratory evidence of a single or isolated abnormality, most commonly the deficiency of a single coagulation factor.

Age at Onset: Bleeding in the Neonate

Birth and the neonatal period provide unique challenges to the hemostatic mechanism, and bleeding during the first month of life often is the first evidence of an inherited disorder of hemostasis. Small cephalohematomas and petechiae are common in the newborn as a result of the trauma of delivery. Large cephalohematomas that progressively increase in
size may result from hemophilia but are more common in association with acquired bleeding disorders such as hemorrhagic disease of the newborn (see Chapter 54). Bleeding from the umbilical stump and after circumcision is common in the acquired coagulation disorders, and it also occurs in the inherited coagulation disorders, with the exception of hypofibrinogenemia, dysfibrinogenemia, and factor XIII deficiency. The onset of bleeding from the umbilical cord may be delayed in these latter disorders. In the evaluation of bleeding in the neonate, the clinician should remember that hematochezia and hematemesis may originate from swallowed blood of maternal origin. Simple tests to distinguish such maternal blood from fetal blood have been described. Many infants with inherited coagulation disorders do not bleed significantly in the neonatal period. Less than one-third of patients with hemophilia A and B and only 10% of those with other inherited coagulation disorders have hemorrhagic symptoms during the first week of life. In such patients, the disorder may become clinically silent for a time. Hematomas may first be seen only when the child becomes active. Hemarthrosis commonly does not develop until a child is 3 or 4 years of age.

A mild inherited hemorrhagic disorder may be difficult to distinguish from the insidious onset of an acquired defect. Patients with mild inherited coagulation disorders may enter adult life before characteristic bleeding manifestations occur. These patients and those with some forms of inherited thrombocytopenia and disordered platelet function often describe a history of posttraumatic bruising and hematoma formation that they have come to accept as normal. In hereditary hemorrhagic telangiectasia, the lesions become more prominent with advancing age and may not be symptomatic until middle age. Similarly, in patients with Ehlers-Danlos syndrome, bleeding may not be a problem until adult life.

Family History

The family history is of great importance in the evaluation of bleeding disorders. In disorders inherited as autosomal dominant traits with characteristic symptoms and high penetrance, such as hereditary hemorrhagic telangiectasia, an accurate pedigree spanning several generations can often be obtained. The presence of typical bleeding manifestations in male siblings and maternal uncles is virtually diagnostic of X-linked recessive inheritance, which characterizes hemophilia A and hemophilia B. In such X-linked traits, the family history also may be helpful in a negative sense—that is, it may clearly exclude the disorder in certain offspring, such as the sons of a known hemophiliac. Details of the various genetic patterns that may be encountered are discussed in the chapters that deal with these conditions.

The limitations of the family history, however, are greater than is commonly realized. Hearsay history is difficult to evaluate, and it is often impossible to assess the significance of easy bruising or to differentiate between manifestations of a generalized bleeding disorder and more common localized lesions, such as peptic ulcer and uterine leiomyomas. A negative family history is of no value in excluding an inherited coagulation disorder in an individual patient. As many as 30% to 40% of patients with hemophilia A have a negative family history. The family history usually is negative in the autosomal recessive traits, and consanguinity, which is commonly present in these kindreds, is notoriously difficult to document or exclude.

P.1046

CLINICAL FEATURES OF ACQUIRED BLEEDING DISORDERS

Generalized bleeding may be a prominent feature of a wide variety of acquired disorders that encompass virtually the entire field of medicine. Bleeding manifestations usually are less severe than in the inherited forms, and the clinical picture often is dominated by evidence of the underlying disorder rather than by bleeding alone. In the neonate, for example, DIC usually is associated with significant complications such as sepsis, hypoxia, acidosis, or problems related to prematurity. The physician should suspect sepsis or occult thrombosis in any sick neonate with unexplained thrombocytopenia. Multiple hemostatic defects commonly are present in patients with acquired hemorrhagic diseases, which often include thrombocytopenia and significant coagulation abnormalities. In contrast, a single abnormality usually is found in patients with inherited hemorrhagic disorders.

In general, the emphasis of the study of the acquired bleeding disorders should be on the patient, not on the laboratory. A thorough history and the physical examination often reveal the cause of thrombocytopenia, such as a drug or acute leukemia. In most vascular disorders, including senile purpura, allergic purpura, scurvy, and amyloidosis, the history and physical examination are of primary diagnostic importance, and the laboratory has little to offer.

Drug History
The importance of exhaustive interrogation regarding drug use and chemical exposure cannot be overemphasized. The list of drugs associated with thrombocytopenia (see Table 47.6) or vascular purpura grows longer each year. Less common but more serious is drug-induced aplastic anemia, which may present initially with bleeding. Many commonly used drugs, notably aspirin, impair platelet function and produce abnormal findings on laboratory tests that often lead to expensive and unnecessary additional laboratory studies. The same drugs may provoke bleeding when administered to patients with pre-existing hemostatic defects such as hemophilia A. Drug ingestion also may produce coagulation abnormalities, and drugs that potentiate or antagonize the anticoagulant effects of coumarin derivatives may lead to bleeding or erratic laboratory control. The surreptitious ingestion of such agents is not uncommon.

\(^a\) Normal range in the University of Utah coagulation laboratory.

\(^b\) Tests affected by heparin.
Significant variations depending on reagents and technique.

Results of various coagulation tests may be abnormal in a surprisingly large percentage of hospitalized patients because of heparin that is administered therapeutically or is used in small amounts to maintain the patency of indwelling venous catheters, venous pressure lines, arteriovenous shunts, and various pumps and infusion machines. The partial thromboplastin time (PTT), in particular, may be greatly prolonged in patients who have received even a minute amount of this anticoagulant. Such coagulation abnormalities often are confused with DIC, inhibitors of factor VIII, and other serious coagulation disorders, and they commonly lead to repeated, and usually useless, coagulation studies. A thorough bedside inventory often is required to find out that heparin is indeed responsible. Prolongation of the thrombin time associated with a normal reptilase time or direct assay of heparin provides laboratory evidence of heparin contamination.

LABORATORY METHODS FOR STUDY OF HEMOSTASIS AND BLOOD COAGULATION

No single test is suitable for the laboratory evaluation of the overall process of hemostasis and blood coagulation, but methods of varying complexity and use are available for assessing various components and functions individually. The emphasis of the following discussion is on methods that are simple and widely available in most laboratories. The interpretation of the most commonly used tests and the range of values obtained in normal subjects with representative techniques are summarized in Table 45.2. Definitive coagulation methods usually require a specially equipped laboratory and trained personnel, and are discussed here from a general standpoint only. Additional comments concerning the use and limitations of the various methods are included in chapters dealing with individual disorders.

Tests of Vascular and Platelet Phases

Bleeding Time

Hemostasis in a small superficial wound, such as that produced when measuring the bleeding time, depends on the rate at which a stable platelet plug is formed and, thus, provides a measure of the efficiency of the vascular and platelet phases. However, it does not discriminate between vascular defects, thrombocytopenia, and platelet dysfunction. The bleeding time leaves much to be desired in terms of reproducibility, because no two skin areas are exactly the same and it is impossible to produce a truly standard wound.

Older studies using the bleeding time test supported the view that this test might be helpful in predicting bleeding in individual patients. More recent studies suggest that a bleeding time result is determined not only by platelet number and function, but also by hematocrit, certain components of the coagulation mechanism, skin quality, and technique. A careful analysis of this literature indicates that there is no correlation between a skin template bleeding time and certain visceral bleeding times, and that no correlation exists between preoperative bleeding time results and surgical blood loss or transfusion requirements.

A clinical outcomes study reported that discontinuation of the bleeding time in a major academic medical center had no detectable adverse clinical impact. A position paper of the College of American Pathologists and the American Society of Clinical Pathologists concluded that the bleeding time was not effective as a screening test, and that a normal bleeding time does not exclude a bleeding disorder. Patients thought to have a platelet-type bleeding disorder based on their personal or family history (or both) should be evaluated for vWD and the inherited qualitative platelet disorders, using assays discussed in the section Platelet Function Assays. Newer assays that may be useful in screening patients for platelet dysfunction are also discussed in the section New Assays of Platelet Function.

Platelet Enumeration

Platelets are considerably more difficult to count than erythrocytes or leukocytes. This difficulty is to be expected in view of the small size of these cells and their tendency to adhere to foreign surfaces and to aggregate when activated.

In general, techniques for platelet counting may be classified into two groups: hemacytometer or direct methods, in which whole blood is diluted and the platelets are counted in much the same way as leukocytes or erythrocytes, and fully automated electronic methods. Virtually identical values for the normal range of the platelet count have been obtained with modern methods, as summarized in Table 45.2.

An estimate of platelet numbers in a well-prepared blood smear by an experienced observer is a valuable check on the platelet count as determined by any method. In general, when a blood smear is examined at 100× power, each platelet

P.1047
counted/field represents approximately 10,000 platelets × 10^9/L. Consequently, a normal blood smear should demonstrate, on average, at least 14 platelets/high-power field.

Instruments for totally automated platelet counting are widely used. Details of automated cell counters are discussed in Chapter 1. When automated methods are used, various nontechnical factors may produce falsely low platelet counts. These factors include platelet agglutinins, abnormal amounts of plasma proteins in various paraproteinemias, previous contact of platelets with foreign surfaces such as dialysis membranes, large or giant platelets, platelet satellitism, lipemia, and ethylenediaminetetra-acetic acid (EDTA)-induced platelet clumping, a phenomenon that may produce platelet clumps of sufficient size to artifactually increase the leukocyte count. Spuriously high platelet counts may result from the presence of microspherocytes, fragments of leukemic or red blood cells, and Pappenheimer bodies. Special technical modifications and the use of careful manual counting methods may be required to eliminate these artifacts and to obtain accurate platelet counts.

Platelet Volume Measurements

The widespread availability of particle counters in the clinical laboratory permits the accurate measurement of platelet volume on a routine basis. Mean platelet volume (MPV) is increased in disorders associated with accelerated platelet turnover as the result of large numbers of megathrombocytes or in patients with Bernard-Soulier syndrome. Normal or decreased values for MPV usually are obtained in patients with disorders associated with deficient platelet production, in some patients with sepsis, and in people with certain big-spleen syndromes.

Some authors suggest that increased MPV provides evidence of accelerated platelet production and may be interpreted in the same way as the reticulocyte count. The method is difficult to standardize, however, and when determined on routinely collected specimens by automated counters, it is affected by numerous variables pertaining to specimen collection, anticoagulant, temperature, and duration of storage. In view of these problems and the difficulty in interpreting platelet size heterogeneity under normal and abnormal conditions, these measurements should be interpreted with caution.

The presence of microcytic platelets in patients with some inherited thrombocytopenias such as Wiskott-Aldrich syndrome is reliably reflected by MPV measurements. On the other hand, giant platelets associated with Bernard-Soulier syndrome may be counted as leukocytes or erythrocytes and may not be reflected in the MPV.

Platelet Function Assays

Since the 1960s, platelet aggregation using platelet-rich plasma has been the standard method to assess platelet function. This method uses aggregometers, which are modified nephelometers that permit measurement of changes in optical density of a platelet suspension under conditions of constant temperature and continuous agitation (Fig. 45.3). Most instruments measure a combination of light scatter and absorption. Instruments have been developed that permit both nephelometric and photometric measurements and the simultaneous measurement of aggregation and nucleotide release.
FIGURE 45.3. The interpretation of aggregometer tracings. Tracing of platelet aggregation produced by a low concentration of adenosine diphosphate (ADP), illustrating normal changes in optical density (OD)—that is, (1) a slight decrease caused by dilution with aggregating agent; (2) a transient increase caused by initial platelet swelling or shape change; (3) a rapid progressive decrease as platelet aggregates form, the size of which is roughly proportional to the amplitude of the oscillations in the tracing (4). The OD then reaches a nadir (5) from which maximal aggregation as a percentage of the initial OD may be calculated as follows: maximal aggregation (%) = OD at T0 — minimum OD/OD at T0. After this (6), a slow increase in OD caused by disaggregation occurs under some conditions.

Platelet aggregation usually is studied in suspensions of citrated platelet-rich plasma, in which the size and dimensions of the stirring bar, variations in plasma citrate concentration attributable to variations in hematocrit, the pH, and the nature of the buffers are important variables. Platelet suspensions usually are prepared by differential centrifugation, but methods that use albumin density gradient centrifugation and gel filtration have also been described. Although harvesting platelets from the blood of thrombocytopenic patients is difficult, testing such platelets in the aggregometer is reproducible in suspensions containing as few as 50,000 platelets/µl. Methods for the study of platelet aggregation in whole blood also have been described. Interfaced computer systems have been developed for calculating and expressing platelet function data.

Adenosine diphosphate (ADP) in concentrations of 5 µmol/L or higher produces platelet aggregation directly that is independent of the release of platelet-contained ADP. Various other aggregating agents act mainly by inducing the release reaction, such as a suspension of connective tissue particles (collagen), epinephrine and norepinephrine, and thrombin. With epinephrine (5 µmol/L), a weak primary aggregating effect usually can be clearly distinguished from the subsequent release reaction, which produces a secondary wave of aggregation. Such primary and secondary waves of aggregation also may be seen with carefully titrated amounts of ADP (0.2 to 1.5 µmol/L).

Ristocetin is an antibiotic that induces platelet agglutination (platelet metabolic activity not required) in the presence of von Willebrand factor (vWF). Patients deficient in vWF (vWD) or in the receptor for vWF (Bernard-Soulier syndrome) have an abnormal ristocetin response. Ristocetin is tested in concentrations of 0.6 to 1.2 mg/ml; the lower concentrations are helpful in identifying specific variants of vWD, type 2B and platelet-type vWD (see Chapters 52 and 53).
The release reaction is measured only indirectly by routine aggregometry—that is, the aggregation associated with the release of ADP from the platelets (release-induced aggregation or secondary aggregation). Methods for the quantitation of various substances released from platelets have been described. For example, the amounts of ADP or serotonin released/unit of time serve as indices of dense body release; the amount of various hydrolytic enzymes or platelet factor 4 released is a measure of the extent of α-granule release. Suggested guidelines for standardization of platelet aggregation methods have been proposed.

Sensitive methods have been developed for the determination of platelet-derived substances in plasma that may serve as markers of intravascular platelet activation, including platelet factor 4, β-thromboglobulin, stable prostaglandins (6-keto prostaglandin F1α and thromboxane A2), and leukotrienes. These measurements may have diagnostic value in thromboembolic disorders and syndromes characterized by intravascular platelet aggregation.

New Assays of Platelet Function

An appreciation of the limitations of the bleeding time test has led to the development of newer assays to evaluate platelet function. Some of these are point-of-care tests. The clinical use and predictive value of these tests to identify patients with hemostatic disorders remain to be established. One assay, the platelet function analyzer (PFA-100), has been investigated for several years, and many published reports using this assay are available. In this method, citrated blood samples are exposed to high shear rates in a capillary flowing through an aperture within a membrane coated with collagen and either ADP or epinephrine. The closure time to hemostatic plug formation within the aperture is the endpoint of the test. A large study using the PFA-100 found that prolonged closure times could be attributed to specific quantitative or qualitative abnormalities in platelet function or vWF (or both) in 93% of patients tested. However, the International Society on Thrombosis and Haemostasis has taken the position that the PFA-100 is insufficiently sensitive and specific to be used as a screening device for platelet disorders. It has been suggested that optimal use of the PFA-100 in evaluation of hemostasis would use an algorithmic approach, evaluating not only PFA-100 closure times, but also a complete blood count, blood smear, and assays for vWD and platelet aggregation to further evaluate abnormal closure times. A recent addition to the PFA repertoire is the INNOVANCE PFA P2Y test designed to assess P2Y12-receptor blockade.

Several additional platelet function analyzers are available on the market, though they are not as well studied as the PFA-100. The ICHOR II-Plateletronics system (Helena Laboratories, Beaumont, TX) compares impedance-derived platelet counts in samples with and without added platelet agonists to assess platelet function. This system has historically been used to evaluate cardiopulmonary bypass patients, but more recently has been applied to patients undergoing coronary stent placement. The Impact-R (Matis Medical, Beersel, Belgium) is an automated cone-and-plate research analyzer that assesses platelet adhesion and aggregation on a polystyrene surface under laminar flow conditions. The VerifyNow system analyzes platelet agonist-induced aggregation of fibrinogen-coated microparticles to assess platelet function. Agonist cartridges are designed to evaluate the effects of aspirin, clopidogrel, and GPIIb/IIIa platelet receptor inhibitor administration on platelet function. Platelet mapping, a modification of thromboelastography, measures the platelet contribution to clot strength in the presence of specific agonists. To date, no platelet function analyzer assay has been sufficiently studied or validated to warrant routine clinical use.

Tests of Coagulation Phase

In general, meticulous performance of coagulation tests is more important than the exact technique chosen. Blood samples obtained by traumatic venipunctures or from indwelling catheters often are inadequate for coagulation studies. A poorly collected blood sample is a far more common cause of inaccurate results than is technical error.

With the exception of one assay for fibrin degradation products (FDPs), all coagulation tests are performed on citrated plasma, most commonly obtained using blue-top vacuum blood collection tubes that pull in nine parts of blood to one part citrate. The International Society for Thrombosis and Haemostasis recommends the routine use of 3.2% sodium citrate. A pool of freshly frozen citrated plasma from several normal donors is a suitable control for screening procedures in most laboratories. Lyophilized control plasma and borderline abnormal control plasmas are available commercially to standardize coagulation assays and to provide reference standards.

The citrate ion does not enter the erythrocyte. Consequently, the plasma citrate concentration is abnormally high when blood with a high hematocrit (>55%) is collected in usual concentrations of this anticoagulant. This may produce artifactual prolongation of one-stage screening tests of coagulation, such as the PTT. To obtain interpretable data on such samples, tubes containing citrate concentrations appropriate for the hematocrit must be prepared by removing an aliquot of the citrate anticoagulant contained in standard blue-top tubes.

Activated Partial Thromboplastin Time
The activated partial thromboplastin time (PTT) is a simple test of the intrinsic and common pathways of coagulation. When a mixture of plasma and a phospholipid platelet substitute is recalcified, fibrin forms at a normal rate only if the factors involved in the intrinsic pathway (prekallikrein, high-molecular-weight kininogen, and factors XII, XI, IX, and VIII) and in the common pathway (factors X and V, prothrombin, and fibrinogen) are present in normal amounts (Fig. 45.4). Platelet substitutes of various kinds may be used, such as chloroform extract of brain and other crude cephalin fractions as well as soybean phosphatides (inosithin). In the PTT, such platelet substitutes are provided in excess, and the test is unaffected by the number of platelets remaining in the plasma (unless the sample contains antiphospholipid antibodies). Platelet substitutes are only partial thromboplastins, however, and they are incapable of activating the extrinsic pathway, which requires complete tissue thromboplastin (tissue factor). Thus, the PTT bypasses the extrinsic pathway and is unaffected by a deficiency of factor VII. The PTT assay is used to detect factor deficiency, screen for the lupus anticoagulant, and monitor heparin anticoagulation.

FIGURE 45.4. The interpretation of common screening tests of blood coagulation. Coagulation factors are indicated within arrow-shaped blocks, which represent the major pathways of coagulation. Screening tests are indicated at the side of these blocks in relation to pathways and coagulation factors measured by each. HMWK, high-molecular-weight kininogen; PL, phospholipid; Pre-K, prekallikrein.
The PTT is somewhat more sensitive to deficiencies of factors VIII and IX than to deficiencies of factors XI and XII or factors involved in the common pathway, but with most techniques, the test usually yields abnormal results if the plasma level of any of the essential factors is <15% to 30% of the normal value. The PTT thus detects some mild coagulation disorders. However, the ability to detect mild factor deficiency is reagent-dependent, and certain PTT reagents may not detect factor deficiency as low as 5% to 10%. As is the case with all one-stage tests, the PTT may be shortened by high levels of a single factor, most commonly factor VIII. Thus, a short PTT may signify any of the various hypercoagulable states (see Chapter 55), and high levels of any of the factors involved in the intrinsic or common pathways of coagulation may mask deficiencies of other factors.

In the original method, contact activation was provided by the glass tube, but the addition of activators, such as ellagic acid, or particulate silicates, such as Celite or kaolin, provides more optimal and standardized contact activation and represents a significant improvement over the original nonactivated test. The PTT is the routine assay currently used to evaluate intrinsic coagulation. The PTT of plasma deficient in prekallikrein (Fletcher factor) is abnormal when it is determined by standard methods using particulate activators such as Celite or kaolin. This abnormality is minimized or abolished by protracted contact activation (15 minutes), as compared with 2 to 3 minutes used in the standard technique. The PTT may yield normal results in prekallikrein deficiency when soluble activators such as ellagic acid are used. A large recent pediatric reference interval study found no significant differences between adult PTT values and those of children ages 7 to 17 years. Whereas increased PTT values may suggest a bleeding disorder, shortened PTT values have been found to be independent predictors of an increased risk of death, thrombosis, bleeding, and morbidity. The use of the PTT in the control of heparin therapy and in detection of the lupus anticoagulant is discussed in Chapters 55 and 54, respectively.

Prothrombin Time

The production of fibrin by means of the extrinsic and common pathways (Fig. 45.4) requires tissue factor and factor VII, in addition to factors X and V, prothrombin, and fibrinogen. These pathways are measured by the prothrombin time (PT), in which plasma is recalcified in the presence of excess tissue factor. This test does not require contact activation and bypasses the intrinsic pathway and the factors involved therein. Because tissue thrombo-plastins contain phospholipids that act as platelet substitutes, the test is unaffected by platelet numbers. Of the five coagulation factors measured by the PT (factors V, VII, and X, prothrombin, and fibrinogen), three (prothrombin and factors VII and X) are vitamin K-dependent and are decreased by coumarin-like drugs. As a result, the PT is the test used most widely for controlling oral anticoagulant therapy. The PT usually is prolonged if the plasma levels of any of the requisite factors are <10% of normal, and it is more sensitive to deficiencies of factors VII and X than to deficiencies of fibrinogen and prothrombin. The PT also is prolonged by inhibitors of any of the essential factors and by heparin (unless heparin neutralizers are present in the PT reagent), but it is less sensitive to the anticoagulant action of heparin than is the PTT. A large pediatric reference interval study found that children ages 7 to 17 years have PT values 1 second longer than normal adults.

Various modified techniques and thromboplastins, including recombinant human thromboplastins, have been developed to improve the use of the PT in the control of coumarin anticoagulant therapy (see Chapter 55). Use of the international normalized ratio in monitoring oral anticoagulation therapy is the recommended format (discussed in Chapter 55). The PT performed with bovine brain thromboplastin is abnormal in patients with certain genetic variants of factor IX deficiency but is normal in patients with the more common form of this disorder. The venom of the Russell viper contains an enzyme that initiates coagulation by the direct activation of factor X and does not require factor VII. The one-stage “prothrombin time” performed with this venom (the Stypven time) thus distinguishes between deficiency of factor VII and deficiency of factor X (Fig. 45.4).

Assay of Plasma Fibrinogen

Several accurate methods are available for the quantitative assay of plasma fibrinogen, a measurement of great clinical importance that should be available in all laboratories. Fibrinogen may be converted into fibrin, which is quantitated by gravimetric, nephelometric, or chemical methods. An immunologic method has also been described. Kinetic techniques based on the thrombin time, however, are simple to perform, and they have been widely adopted. Both gravimetric methods and those based on the thrombin time underestimate fibrinogen in the presence of high concentrations of FDPs; technical modifications designed to avoid these problems have been proposed. Some nephelometric methods appear to be minimally affected by FDP. Modified methods that eliminate interference by heparin, as well as
automated techniques, have been described. Marked differences in fibrinogen levels obtained by gravimetric and immunologic methods and those obtained by functional techniques are found in patients with the inherited dysfibrinogenemias. Reference values to identify patients with dysfibrinogenemia have been reported. 75

Thrombin Time and Related Techniques

When thrombin is added to plasma, the time required for clot formation is a measure of the rate at which fibrin forms (Fig. 45.4). This test (thrombin time) yields abnormal results when the fibrinogen level is <70 to 100 mg/dl, but it is unaffected by the levels of any of the other coagulation factors 76; it is greatly prolonged by heparin. The thrombin time may also be prolonged by a qualitatively abnormal fibrinogen (dysfibrinogen), elevated levels of fibrin (fibrinogen)-degradation products, certain paraproteins, and hyperfibrinogenemia. The thrombin time and modifications thereof are technically simple, can be performed quickly, and are valuable, particularly in the diagnosis of DIC. The reptilase clotting time is similar to the thrombin time in principle, but coagulation induced by this enzyme, which is prepared from snake venom, is unaffected by the presence of heparin.

Tests for Fibrin (Fibrinogen)-degradation Products and D-Dimer

Fibrin (fibrinogen)-degradation products (FDPs) are protein fragments of varying sizes that result from the proteolytic action of plasmin on fibrin or fibrinogen (see Chapter 18). 77 Plasma levels of these fragments are commonly increased in association with DIC and fibrinogenolysis, disorders in which their presence is of considerable diagnostic significance. Quantitative assays for FDP are based on several principles, such as the agglutination of latex particles coated with antifibrinogen antibody, 78 immunodiffusion, 79 and red cell hemagglutination inhibition. 80 Serum containing rheumatoid factor 79 or residual fibrinogen may yield false-positive results in some assays. 81

None of the aforementioned methods distinguishes between fibrin degradation products and fibrinogen degradation products; to make this distinction, measurement of the DD-dimer or even more sophisticated methods are required. 82 Extremely sensitive methods for the measurement of fibrinopeptides and specific FDP, such as the DD-dimer, 83 DDE-trimer, or B-β 15-42-related peptide, are useful as indices of DIC and as markers of subtle activation of coagulation in vivo (see Chapter 54).

Unpolymerized fibrin monomer is commonly present in the blood of patients with DIC. Various techniques (paracoagulation techniques) for demonstrating such monomers have been described; these range from the ethanol gelation test, 84 which is insensitive, to various protamine gelation techniques, 85 which are highly sensitive but nonspecific. Cryofibrinogen, which may be demonstrated in some cases of DIC, also may signify the presence of fibrin monomers. All of these assays to diagnose DIC have been supplanted by the D-dimer test. 86 The use of D-dimer tests to exclude venous thromboembolism is discussed in Chapter 55.

Tests for Factor XIII Activity

The principle of the factor XIII screening test is that clots crosslinked by factor XIII resist denaturation by high concentrations of urea or acid. Deficiency of factor XIII results in premature clot lysis. 87 Patient plasma is recalcified to induce a clot; the clot is then suspended in 5 mol/L urea (or 1% monochloroacetic acid) for 24 hours. Clot stability is examined visually after 24 hours of incubation. Because this assay is a screening test, abnormal results should be repeated and confirmed using a quantitative factor XIII method, such as measuring factor XIII-dependent incorporation of labeled amines into substances such as fibrinogen or casein. 86

Tests for Fibrinolysis

The plasma euglobulin fraction contains plasminogen activators and fibrinogen. Most of the major antiplasmins are removed in the pseudoglobulin supernatant fluid. The rate of lysis of a fibrin clot prepared from the euglobulin fraction (the euglobulin clot lysis time) thus provides a measure of fibrinolysis in the absence of major inhibitors and is a measure of the activity of plasminogen activators. 87

Tests for fibrinogenolysis and assays for individual components of the fibrinolytic enzyme system, including plasminogen, 88 free plasmin, 89 and antiplasmins, are available. Routine coagulation assays for plasminogen activators and plasminogen activator inhibitors typically involve enzyme-linked immunosorbent assay (ELISA) methods. 90, 91 Blood collection methods, timing, processing, and determination of assay-specific reference ranges are critically important in accurate evaluation of fibrinolysis parameters. 77

Moderate concentrations of ε-aminocaproic acid (4 × 10^{-4} mol/L) inhibit plasminogen activators but not free plasmin. Thus, a shortened euglobulin lysis time in the presence of such concentrations of ε-aminocaproic acid indicates the
presence of free plasmin, as in association with fibrinogenolysis (see Chapter 54). Fibrinolysis in heated fibrin plates also measures free plasmin because plasminogen activators are thermolabile.

Bioassays for Coagulation Factors

Bioassays for coagulation factors are usually based on the familiar screening tests, such as the PT and PTT. In principle, the extent to which an unknown sample corrects the abnormality in plasma with a known deficiency is assumed to be proportional to the content of the deficient factor in the sample. The results of coagulation assays may be expressed in terms of units, which equal the amount of a given factor that is present in 1 ml of normal pooled or reference plasma. Alternatively, plasma levels of various factors may be expressed as a percentage of normal. Thus, plasma levels of various coagulation factors typically range from 50 to 150 U/dl, or 50% to 150% of normal.

One-stage methods for factors VIII and IX, which are based on the PTT and use substrate plasma from patients with severe inherited deficiencies (<1% of normal) of these factors, are somewhat simpler to perform than comparable two-stage methods. However, two-stage methods are more specific than one-stage methods, particularly in patients with intravascular coagulation and liver disease, presumably because the two-stage methods are less affected by the presence of activated coagulation factors or traces of thrombin that increase the activity of factors V and VIII. One study found that for detecting low factor VIII levels, the clot-based assay was better than the chromogenic assay, while for elevated factor VIII levels, the chromogenic assay was preferred. Plasmas deficient in specific factors are available commercially. Modifications that do not depend on natural substrates have been developed, including techniques for the assay of prothrombin, factors V, VII, and X combined; and factors VIII, IX, X, and XI. Details of coagulation assay methodology have been summarized.

Tests for Inhibitors of Coagulation

Abnormalities in any test of coagulation, if caused by deficiency of an essential factor, are corrected by the addition of small amounts of normal plasma. If the abnormality is caused by the presence of one of the various inhibitors of coagulation rather than a deficiency of an essential factor, the opposite is true: Small amounts of the patient’s plasma impair coagulation in normal samples. These tests are called mixing studies or inhibitor screens. This phenomenon is the essence of all screening tests for inhibitors, most of which are based on one-stage coagulation techniques, such as the PT and PTT. The presence of heparin may be confirmed in various ways, including use of thrombin time and reptilase time assays, correction by protamine sulfate, or direct assays for activity of heparin or low-molecular-weight heparin.

Tests for Physiologic Inhibitors of Coagulation

Several methods have been described for the assay of physiologic inhibitors of coagulation, such as antithrombin, heparin cofactor II, protein C, and protein S. Both immunologic and functional assays are available for many of these components. Quantitative assays of such physiologic inhibitors may yield valuable information in patients with certain thromboembolic disorders (see Chapter 55).

Automated Coagulation Methods

Numerous instruments are available to detect automatically the endpoint of blood coagulation. These devices operate on a variety of principles: mechanical detection of the onset of fibrin formation, photometric recording of clot opacity, or the rate of fibrin polymerization. Such instruments are helpful in the performance of one-stage screening tests, such as the PT and PTT, especially if a large number of tests must be done daily.

Totally automated methods for performing coagulation tests are widely used. Automated instrument platforms have been developed to perform a large variety of coagulation methods with significant cost savings, permitting more laboratories to do comprehensive coagulation testing. A College of American Pathologists Web site has summarized coagulation instrumentation (www.cap.org; see vendor surveys at the CAP Today link).

The thromboelastograph, an instrument that demonstrates changes occurring during blood coagulation and fibrinolysis, has been used by some investigators. Different coagulograms are described in association with various bleeding disorders and hypercoagulable states. However, this is not a commonly used method to diagnose coagulation abnormalities in most laboratories. Its primary use is as a point-of-care instrument in the surgical setting.

The activated clotting time (ACT) is a whole blood clotting assay now used primarily as a point-of-care test. The ACT measures the clotting time for a whole blood sample after addition of particulate (contact) activators such as kaolin or
factor VIIIc (see P.1052 of von Willebrand disease is the result of an abnormality in primary hemostasis combined with mild to moderate deficiency.

Other point-of-care coagulation instruments are being used in the setting of outpatient or home-based oral anticoagulation monitoring. Numerous studies have found that these instruments are at least as effective in providing safe and efficacious anticoagulation as is provided by physicians with standard laboratory anticoagulation testing.

Chromogenic and Fluorometric Techniques

Artificial peptides release chromogenic substances or fluorophores when they are enzymatically cleaved. The hydrolysis of such peptides by activated coagulation factors provides a novel means for assessing various coagulation reactions. Such chromogenic and fluorometric techniques have been developed for the assay of prothrombin and factors VII, IX, and X; antithrombin; α2-antiplasmin; heparin; urokinase; kallikrein; plasmin; and other components of the fibrinolytic enzyme system. Assays also have been developed for coagulants that do not have enzymatic activity, such as cellulose sandwich fluoroimmunoassays for vWF antigen and solid-phase front-surface fluorescence detection methods for factors VIIIc and IX. These methods appear to be intrinsically more precise and may be less time-consuming than traditional coagulation methods, and instruments designed specifically for their performance are available. Chromogenic and fluorometric assays are expensive, however, and at present are used mainly in research and in large reference coagulation laboratories.

INITIAL LABORATORY EVALUATION

Primary Screening Tests

The initial laboratory study of the bleeding patient should be guided by the information obtained from the clinical evaluation. In many cases, however, the routine use of a small battery of screening tests has merit because it usually saves time, and the results direct the course of further study. It is generally agreed that the most essential information usually can be obtained from the three tests summarized in Table 45.3, which, in view of their availability, simplicity, and low cost, are well suited to serve as primary screening tests. The platelet count provides the most reliable and reproducible test of primary hemostasis. The PTT measures all of the coagulation factors involved in the intrinsic and common pathways (Fig. 45.4) and generally is accepted as the best single screening test for disorders of blood coagulation. When supplemented with the PT, which assesses the extrinsic as well as the common pathway, the abnormality usually can be localized to one of the three pathways and the factors involved therein (Fig. 45.4 and Table 45.3). The results of these three tests thus provide a presumptive diagnosis, which can then be clarified further by the confirmatory methods summarized in the next section. The bleeding time test has been omitted from this evaluation because of its nonspecificity in the general clinical setting. The definitive laboratory diagnosis of individual bleeding disorders is discussed in Chapters 46, 47, 48, 49, 50, 51, 52, 53, and 54.

It is important to realize that patients with mild bleeding disorders (factor VIII, IX, or XI deficiency) may have normal PTT values, because most PTT reagents do not detect mild deficiency states (factor levels of 20% to 30%). Consequently, if the clinical suspicion is high, specific factor assays for these disorders should be performed, even if the initial evaluation suggested in Table 45.3 is not productive.

CONFIRMATORY TESTS

Thrombocytopenia

Thrombocytopenia, like anemia, is a symptom, not a diagnosis. It is the most common of the acquired bleeding disorders. Additional laboratory tests usually are not indicated merely to confirm the presence of thrombocytopenia (Table 45.3), but are helpful in establishing the mechanism for thrombocytopenia. It is useful, however, to examine the thrombocytopenic patient’s blood smear to exclude pseudothrombocytopenia that may be seen in a small number of patients. The differential diagnosis of thrombocytopenia is discussed at length in Chapters 46, 47, 48, and 49. One approach to evaluating thrombocytopenia is shown in Figure 45.5.

von Willebrand Disease

von Willebrand disease is the result of an abnormality in primary hemostasis combined with mild to moderate deficiency of factor VIIIc (see Chapter 53). In the classic case, the results of screening tests reveal a normal platelet count and a
prolonged PTT (Table 45.3). In many patients, however, the PTT will be normal. Furthermore, the results of all of the laboratory tests tend to fluctuate from time to time. If the clinical suspicion is high, initial laboratory studies directed at excluding vWD should be performed, because vWD is more common than the inherited disorders of platelet function (Fig. 45.6). Useful tests include bioassay of factor VIII (VIIIc), immunoassay of vWF antigen, and measurement of ristocetin cofactor activity. In many cases, the diagnosis of vWD requires repeated testing.

| Table 45.3 Profiles of Hemostasis Screening Tests in Patients with Bleeding Disorders |
|---------------------------------|---------------------------------|---------------------------------|---------------------------------|---------------------------------|
| Prothrombin Time | Activated Partial Thromboplastin Time | Platelet Count | Differential Diagnosis |
| ↑ | — | — | Common |
| Acquired factor VII deficiency (early liver disease; early vitamin K deficiency; early warfarin therapy) |
| Rare |
| Factor VII inhibitor; dysfibrinogenemia; some cases of DIC; inherited factor VII deficiency; certain factor X variants |
| — | ↑ | — | Common |
| Deficiency or inhibitor of factors VIII, IX, or XI; vWD; heparin |
| Rare |
| Lupus inhibitor with qualitative platelet defect; certain factor X variants |
| ↑ | ↑ | — | Common |
| Vitamin K deficiency; liver disease; warfarin; heparin; superwarfarin |
| Rare |
| Deficiency or inhibitor of factors X or V, prothrombin, or fibrinogen; lupus inhibitor with hypoprothrombinemia; DIC; dysfibrinogenemia; primary fibrinolysis |
| ↑ | ↑ | ↓ | Common |
| DIC; liver disease |
| Rare |
| Heparin therapy with associated thrombocytopenia |
| — | — | ↓ | Common |
| Increased platelet destruction; decreased platelet production; hypersplenism; hemodilution |
| Rare |
| Certain inherited platelet disorders (Wiskott-Aldrich syndrome, Bernard-Soulier syndrome) |
| — | — | ↑ | Myeloproliferative disorders |
Common
Mild vWD; acquired qualitative platelet disorders (uremia, antiplatelet medications)

Rare
Inherited qualitative platelet disorders; vascular disorders; fibrinolytic disorders; factor XIII deficiency; autoerythrocyte sensitization; dysfibrinogenemia; mild factor deficiency (VIII, IX, XI); disorders of platelet procoagulant activity

↑, increased; ↓, decreased; —, normal; DIC, disseminated intravascular coagulation; vWD, von Willebrand disease. Note: The differential diagnosis of bleeding disorders suggested by results of the prothrombin time, partial thromboplastin time, and platelet count is listed for each profile. This table includes the differential diagnosis of hemostasis screening test results in patients with a history of bleeding. Consideration of patients with abnormal coagulation tests and negative bleeding histories is not included in this table.

Another available test to evaluate patients for vWD is multimeric analysis of vWF. Patient plasma is separated by agarose electrophoresis, and vWF is identified by immunologic methods. The patient's multimeric pattern is compared to that of normal plasma. A more detailed description of this test is given in Chapter 53.

Qualitative Platelet Disorders

Symptoms of mucocutaneous bleeding in the presence of a normal number of platelets and normal results of coagulation tests (Table 45.3) are presumptive evidence of a disorder of platelet function (see Chapter 52). Inherited forms are uncommon, but bleeding caused by platelet dysfunction may be an important complication in patients with various acquired disorders, such as uremia. Commonly available confirmatory tests occasionally provide useful information regarding platelet dysfunction. Various morphologic abnormalities of the platelets may be seen on the blood smear. Strikingly large platelets are characteristic of certain inherited disorders, such as Bernard-Soulier syndrome. A markedly elevated platelet count is present in the myeloproliferative disorder, essential thrombocytosis.

Definitive methods for the study of platelet dysfunction are time-consuming and technically difficult. The absence of platelet aggregation by ADP, collagen, and epinephrine is characteristic of Glanzmann thrombasthenia. Deficient secondary wave aggregation is associated with various disorders of the release reaction, such as inherited deficiency of storage nucleotides, uremia, and aspirin ingestion. Abnormal responses to ristocetin indicate vWD or Bernard-Soulier syndrome.

P.1053
FIGURE 45.5. An approach for evaluation of thrombocytopenia. The necessity to do a bone marrow examination in the evaluation of idiopathic thrombocytopenic purpura (ITP) is controversial. ITP is a diagnosis of exclusion. DIC, disseminated...

Disorders of the Intrinsic Pathway of Coagulation

Disorders of the intrinsic pathway of coagulation are characterized by a prolonged PTT and a normal PT (Table 45.3). Inherited forms include deficiencies of factor VIII or IX (hemophilia A and B), prekallikrein, high-molecular-weight kininogen, factor XI, or factor XII (Fig. 45.7). Factor XII (Hageman factor) deficiency and deficiencies of prekallikrein or high-molecular-weight kininogen can be excluded readily, because they are not associated with excessive clinical bleeding. Distinguishing between deficiencies of factors VIII, IX, and XI is done by performing specific assays for these factors. Screens (mixing studies) should also be performed to exclude antibodies to the intrinsic factor under study. If a factor VIII inhibitor is identified, the titer should be quantitated (see Chapter 54). An algorithm approach for evaluating bleeding patients with an isolated, prolonged PTT is shown in Figure 45.8.

Acquired coagulation disorders associated with a prolonged PTT and a normal PT include the lupus inhibitor and antibodies to factor VIII. Prolongation of the PTT is commonly the result of heparin administration or poorly collected blood samples.

Disorders of the Common Pathway of Coagulation

Prolongation of the PTT and PT in a patient with an inherited bleeding disorder indicates a deficiency of one of the factors in the common pathway—factor X, factor V, prothrombin, or fibrinogen, or a dysfibrinogen (Table 45.3 and Fig. 45.7). Such isolated deficiencies are exceedingly rare. On the other hand, deficiency of one or more of these factors is associated with additional abnormalities in the intrinsic and extrinsic pathways in many of the common acquired coagulation disorders, such as vitamin K deficiency, liver disease, and DIC. A prolonged PT usually suggests an acquired disorder.
(excluding the rare cases of inherited factor VII deficiency) and usually is associated with a complex abnormality involving multiple pathways, such as DIC.

When confronted with this combination of findings, the first step should be to exclude or to identify an abnormality of fibrinogen. This may be accomplished by determination of the plasma fibrinogen level and tests for increased amounts of D-dimer or FDP. The most helpful ancillary procedures are the platelet count and examination of the blood smear for schistocytes. The laboratory findings characteristic of DIC are summarized in Chapter 54.

Inherited disorders associated with a low fibrinogen level include afibrinogenemia, hypofibrinogenemia, and dysfibrinogenemia (see Chapter 53). In certain dysfibrinogenemias, large amounts of unclotted fibrinogen remain in the serum and are detected by tests for FDP.

Inherited deficiencies of factor V, factor X, and prothrombin can be diagnosed by specific factor assays.

Disorders of the Extrinsic Pathway of Coagulation

A prolonged PT and a normal PTT (Table 45.3) suggest an isolated deficiency of factor VII, which is rare and may be the result of an inherited or an acquired abnormality (Figs. 45.7 and 45.9). Less commonly, inhibitors of factor VII have been reported (see Chapter 54). Additionally, certain cases of DIC or dysfibrinogenemia may present with isolated prolonged PT values. Because factor VII is essential only in the tissue factor-activated extrinsic pathway of coagulation, the Stypven time is normal in patients with factor VII deficiency.
FIGURE 45.8. Evaluation of a patient with bleeding and an isolated, prolonged partial thromboplastin time (PTT). Asterisk indicates that patients with clinical bleeding but normal studies should be evaluated further for lupus anticoagulants associated with either platelet dysfunction or thrombocytopenia. PT, prothrombin time; PTT, activated partial thromboplastin time; vWD, von Willebrand disease; vWF, von Willebrand factor. (Redrawn from Kjeldsberg CR, Perkins SL, eds. Practical diagnosis of hematologic disorders, 5th ed. Chicago: ASCP Press, 2010:349.)

Disorders in Which Results of Primary Screening Tests Are Normal

Screening tests usually yield normal results in patients with bleeding disorders related to vascular abnormalities (Tables 45.3 and 45.4). The diagnosis is usually made from the associated clinical findings that are often characteristic, such as the skin lesions of hereditary hemorrhagic telangiectasia, allergic purpura, scurvy, and senile purpura. The results of screening tests also are normal in factor XIII (fibrin-stabilizing factor) deficiency, a disorder in which the diagnosis is made by the demonstration of characteristic clot solubility in urea or monochloroacetic acid.
FIGURE 45.9. Laboratory diagnosis of acquired coagulation disorders. Results of primary screening tests of coagulation (partial thromboplastin time [PTT], prothrombin time [PT]) are summarized in the left-side block. Additional tests (right-side block) and a suggested sequence for their performance are presented as a flow diagram. Because of the complexity of acquired coagulation disorders and great variations in the results of laboratory tests that may be encountered in the various disorders and in individual patients, this diagram should be regarded as a general guide only. A more complete list of the differential diagnosis of bleeding disorders is presented in Table 45.3. A, abnormal; FDP, fibrin degradation products; N, normal.

### TABLE 45.4 BLEEDING DISORDERS IN WHICH THE RESULTS OF PRIMARY SCREENING TESTS MAY BE NORMAL

- von Willebrand disease
- Mild inherited coagulation disorders, particularly factor XI deficiency
- Heterozygous carriers of inherited coagulation disorders
- Factor XIII (fibrin-stabilizing factor) deficiency
- Some forms of dysfibrinogenemia
- Disordered platelet function, particularly deficient release reaction; Scott syndrome
- Hereditary hemorrhagic telangiectasia
- Allergic and other vascular purpuras
α₂-Plasmin inhibitor deficiency

Elevated levels of plasminogen activator

Although abnormal in the typical case, the results of screening tests may be normal or equivocal in patients with mild coagulation disorders (including heterozygous carriers), certain disorders of platelet function, mild forms of vWD, and dysfibrinogeneremia or abnormal fibrinolysis. More definitive tests are required to establish the diagnosis in these patients (Table 45.4). An increasing number of reports have indicated that many bleeding patients with normal screening studies have disorders of platelet procoagulant activity, such as Scott syndrome.

There are patients with a significant bleeding history in whom the results of detailed studies of hemostasis and blood coagulation are normal. Some have disorders of hemostasis that cannot be detected by methods currently available. The clinical management of these cases requires great care, and the fact that a clear-cut history of bleeding is always more significant than negative laboratory data cannot be overemphasized. Trauma may be denied in physically abused patients and may be self-inflicted in psychotic or neurotic patients.

PREOPERATIVE HEMOSTASIS EVALUATION

The value of obtaining routine screening tests before surgical procedures has been debated for years. The screening tests for hemostasis are not totally satisfactory in detecting all mild hemostatic defects. Nevertheless, routine preoperative laboratory screening is of great value in certain high-risk patients who have disorders that predispose them to unexpected postsurgical bleeding, even from limited biopsy procedures. Important in this category are patients with liver disease, biliary obstruction, renal disease (particularly if complicated by azotemia), myelofibrosis, polycythemia vera, and other myeloproliferative disorders, particularly those associated with thrombocytosis and those with paraproteinemias. Included in this list should be all patients scheduled to undergo procedures involving the use of extracorporeal circulatory devices.

One approach to the question of preoperative hemostasis screening tests is to balance the financial costs of laboratory testing with the extent of surgery to be performed and with the amount of bleeding that can be safely tolerated. This approach makes the patient’s hemostasis history particularly important. Patients scheduled for minor surgical procedures (dental, skin biopsy) do not need routine hemostasis screening tests if they have a negative history. In contrast, patients undergoing neurosurgery or other procedures that may induce a hemostatic defect (use of a bypass pump) or patients with a positive bleeding history need a hemostasis evaluation by the laboratory. Table 45.5 summarizes the recommendations of Rapaport in evaluating preoperative patients.

</table>

PT, prothrombin time; PTT, activated partial thromboplastin time.

Note: Information in this table is a revision based on the suggested preoperative guidelines for hemostasis testing by Rapaport. The bleeding time is omitted as a hemostasis test because of more recent appreciation of its weakness as a useful test. Comprehensive testing should be performed on level IV patients.

Modified from Rodgers GM. Preoperative hemostasis screening. In: Kjeldsberg CR, Perkins SL, eds.
EVALUATION OF THE NEONATE

Laboratory investigation of hemostasis and blood coagulation in the neonate and infant differs from that just outlined in several respects. First, the quantity of blood that can be obtained is limited, and often, the venipuncture is difficult. Various microtechniques and modifications of standard coagulation techniques that involve the use of capillary blood have been developed to circumvent this problem. Second, in terms of adult norms, the results of some tests are abnormal, even in healthy full-term infants (Table 45.6). Such physiologic abnormalities presumably are the result of deficiencies of the vitamin K-dependent factors and of additional abnormalities in the contact phase of coagulation and in the thrombin-fibrinogen reaction.

The PT may be prolonged but often is normal if vitamin K is administered to the infant or mother. Abnormalities of the thrombin time and the PTT are present in many normal neonates. These findings usually disappear within 2 to 6 months. These abnormalities and moderate deficiencies of the vitamin K-dependent factors (prothrombin; factors VII, IX, and X; and proteins C and S) are more pronounced in the premature than in the full-term infant, and they are inversely proportional to gestational age and birth weight. Levels of factors VIII and V as well as antithrombin may be low in extremely premature infants. Factor VIII levels and the ratio of vWF-Ag to VIlc are higher in term infants than in adults or older children.

Levels of factor V are normal in both neonates and thriving premature infants. Levels of antithrombin and other physiologic inhibitors of coagulation and of factor XIII are below adult norms in term neonates. Significant abnormalities of platelet aggregation and of the results of other platelet function tests may be seen in normal neonates. The newborn also is abnormally susceptible to drugs that impair platelet function, including those transferred placentally from the mother. The platelet count in term infants, as well as in thriving premature infants, is within the range found in adults and older children. Table 45.6 summarizes coagulation reference ranges in newborns, children, and adults.

59. Edson JR, Krivit W, White JG. Kaolin partial thromboplastin time: high levels of procoagulants producing short clotting times or masking deficiencies of other procoagulants or low concentrations of anticoagulants. J Lab Clin Med 1967;70:463-470.

Thrombocytopenia may be defined as a subnormal number of platelets in the circulating blood. It is the most common cause of abnormal bleeding. Despite the number and diversity of disorders that may be associated etiologically, thrombocytopenia results from only four processes: artifactual thrombocytopenia, deficient platelet production, accelerated platelet destruction, and abnormal distribution or pooling of the platelets within the body (Fig. 46.1). The changes in the basic parameters of thrombopoiesis that are characteristic of each of these processes are summarized in Table 46.1.

### Artifactual Thrombocytopenia

Artifactual thrombocytopenia, or falsely low platelet counts, occurs ex vivo when platelets are not counted accurately. This mechanism should be considered in patients who have thrombocytopenia but no petechiae or ecchymoses. Although inaccurate counting may occur in the presence of giant platelets or with platelet satellitism, the most common cause of artifactual thrombocytopenia is platelet clumping (pseudothrombocytopenia). Platelet clumping in pseudothrombocytopenia appears to be caused by anticoagulant-dependent platelet agglutinins that are immunoglobulins (Igs) of IgG, IgA, or IgM subtypes. Although clumping is most commonly seen when blood is collected into ethylenediaminetetraacetic acid anticoagulant, other anticoagulants may cause clumping, even hirudin or Phe-Pro-Arg chloromethyl ketone. Platelet clumping is also time-dependent and varies with the type of instrumentation used for automatic counting. There is evidence that the autoantibodies bind to glycoprotein IIb/IIIa, and in one study, there was over 80% concordance between the presence of anticardiolipin antibody and platelet agglutinins in individual patient plasmas. These autoantibodies have no known associations with disease or drugs and have been noted in some patients for over 10 years.

### Accelerated Platelet Destruction

Accelerated platelet destruction is the most common cause of thrombocytopenia. It leads to stimulation of thrombopoiesis and, consequently, to an increase in the number, size, and rate of maturation of the precursor megakaryocytes (Fig. 46.1). When the rate of platelet destruction exceeds this compensatory increase in platelet production, thrombocytopenia develops. “Compensated” platelet destruction without thrombocytopenia also may occur in patients with prosthetic heart valves and in patients with idiopathic thrombocytopenic purpura after splenectomy.

Platelet destruction may result from both intracorpuscular defects and extracorpuscular abnormalities. Intracorpuscular defects are rare but have been demonstrated in certain forms of hereditary thrombocytopenia, such as Wiskott-Aldrich syndrome (see Chapter 49). In such disorders, the survival of affected platelets is shortened in the circulation of both the patient and normal recipients. Platelets injured by either intracorpuscular or extracorpuscular processes usually are removed from the circulation by the spleen, liver, and reticuloendothelial system. Platelet destruction most often is the result of extracorpuscular factors; various immunologic phenomena are the most common. Immunologic platelet destruction is discussed in Chapter 47.

Platelet consumption in intravascular thrombi or on damaged endothelial surfaces is another cause of thrombocytopenia. This occurs in disseminated intra vascular coagulation (see Chapter 54) and in thrombotic thrombocytopenic purpura (see
Deficient Platelet Production

Deficient platelet production may result from any of a number of processes. Those that depopulate the stem cell or megakaryocyte compartments are the most common, such as marrow injury by myelosuppressive drugs or irradiation and aplastic anemia. Deficient platelet production also may be the consequence of disordered proliferation within a precursor compartment of normal or even increased size. For example, in disorders characterized by megaloblastic hematopoiesis, hypertrophy of the precursor compartment occurs in response to thrombopoietic stimuli, but thrombopoiesis is ineffective and platelet production is insufficient. Rarely, abnormalities of the processes that normally regulate thrombopoiesis appear to underlie deficient platelet production, such as deficiency of thrombopoietin and cyclic thrombocytopenia.

Minor component of ineffective thrombopoiesis present in some cases.

Equated to total thrombopoiesis.

Equated to effective thrombopoiesis.

*Not representative of sequestered antibody-sensitized platelets.

### Abnormal Pooling

Abnormal pooling or abnormal in vivo distribution of an essentially normal total platelet mass may produce thrombocytopenia. This type of thrombocytopenia is seen in the various disorders associated with splenomegaly (see Chapter 49), in which platelet production is normal or even increased, but most of the platelets are sequestered in the vastly enlarged extravascular splenic pool. Thrombocytopenia may also be caused by dilution of platelets when patients are massively transfused during blood loss. A discussion of various forms of thrombocytopenia attributable to deficient or ineffective thrombopoiesis or abnormal platelet pooling is included in Chapter 49.

### CLASSIFICATION

A classification of thrombocytopenia based on pathophysiologic criteria is presented in Table 46.2. It should be recognized that multiple pathogenetic factors may simultaneously or sequentially play a role in the production of thrombocytopenia. Methods for the measurement of serum thrombopoietin concentrations or reticulated platelets have been reported. These techniques may both elucidate the pathophysiology of thrombocytopenia in various disease states and determine
the mechanism of thrombocytopenia in individual patients. Reticulated platelets can be identified with fluorescent dyes that bind to nucleic acids,

P.1060

especially RNA. Measurement of the percentage of reticulated platelets identifies platelets that have recently been released from the bone marrow. There is an increased percentage of reticulated platelets in patients with thrombocytopenia caused by increased destruction and a normal to reduced percentage of reticulated platelets in patients with deficient production.\textsuperscript{13}, \textsuperscript{14} The sensitivity and specificity of this method of distinguishing between these categories are reported to be more than 95%.\textsuperscript{15}

Chapter 47 Thrombocytopenia Caused by Immunologic Platelet Destruction

Immune thrombocytopenia (ITP) occurs when platelets undergo premature destruction as a result of autoantibody or immune complex deposition on their membranes. Although this disorder was previously known as idiopathic thrombocytopenic purpura, it is now correctly termed ITP because this nomenclature more clearly reflects the immune-
mediated mechanism of the disease. In this chapter, both primary and secondary types of ITP are discussed (Table 47.1). Human immunodeficiency virus-related autoimmune thrombocytopenia, which is also in major part a result of the deposition of autoantibody or immune complexes, or both, on the platelet surface, is discussed in Chapter 64.

The diagnosis of ITP is primarily a diagnosis of exclusion, because currently available clinical assays for platelet-associated antibodies or serum antiplatelet antibodies/immune complexes are neither specific nor sensitive enough for routine clinical use. These disorders are characterized by peripheral thrombocytopenia (confirmed by examination of the peripheral smear), with a normal or increased number of megakaryocytes present on bone marrow examination, and absence of splenomegaly. Those patients who have no identifiable underlying cause, which might include infections, collagen vascular diseases, lymphoproliferative disorders (chronic lymphocytic leukemia or lymphoma), or drugs, are diagnosed as primary ITP. In some instances, ITP may be the presenting manifestation of an underlying disease, and additional manifestations appear weeks to months later.

**PRIMARY IMMUNE THROMBOCYTOPENIA**

Primary ITP refers to thrombocytopenia in which apparent exogenous etiologic factors are lacking and in which diseases known to be associated with secondary thrombocytopenia have been excluded. This syndrome has been recently reviewed.

Acute ITP and chronic ITP differ in incidence, prognosis, and therapy (Table 47.2). These differences illustrate the wide spectrum of disorders that by definition are included in the syndrome, but many clinicians have long believed that acute ITP and chronic ITP are fundamentally different disorders.

**Incidence**

The annual incidence of ITP in the United States is estimated to be 1.6/10,000. Acute ITP, defined as thrombocytopenia occurring for <6 months and usually resolving spontaneously, most often affects children and young adults. The incidence peaks in the winter and spring, following the incidence of viral infections. Acute ITP is most common between 2 and 6 years of age. Approximately 7% to 28% of children with acute ITP develop the chronic variety. Chronic ITP, lasting >6 months and requiring therapy to improve the thrombocytopenia, occurs most commonly in adults. In chronic ITP in adults, the median age is usually 40 to 45 years, although in one large series of patients, 74% of 934 cases were younger than age 40 (range, 16 to 87 years of age). The ratio of females to males is nearly 1:1 in acute ITP and 2 to 3:1 in chronic ITP.

**Pathophysiology**

The syndrome of ITP is caused by platelet-specific autoantibodies that bind to autologous platelets, which are then rapidly cleared from the circulation by the mononuclear phagocyte system via macrophage Fcγ receptors predominantly in the spleen and liver (Fig. 47.1). The ITP antibody does not fix complement in vitro when tested by the usual techniques, but activation of components of complement on the platelet surface may be demonstrated.

A compensatory increase in platelet production takes place in most patients in response to the autoantibody-mediated platelet destruction described above. In others, however, platelet production appears to be impaired as a result of either intramedullary destruction of antibody-coated platelets by marrow macrophages or the inhibition of megakaryopoiesis. Autoantibodies from ITP patients have been shown to inhibit production of megakaryocytes in vitro, and megakaryocyte apoptosis has also been observed in this setting. Turnover studies have shown platelet production to be reduced or inappropriately normal in around two thirds of ITP patients. In one study, megakaryocytes were small in patients...

FIGURE 47.1. Antiplatelet antibody-induced destruction of platelets (P) in chronic immune thrombocytopenia. Immunoglobulin binds to platelet-associated antigen, resulting in phagocytosis by macrophages (M). Antiplatelet antibody-coated platelets bind to macrophages through macrophage Fc receptors (FcR). \(\bullet\), platelet membrane antigen; \(\gamma\), platelet autoantibody.

Consistent with findings of inappropriately low platelet production in ITP, plasma levels of endogenous thrombopoietin have not been found to be elevated in ITP.\textsuperscript{29, 30} This differs from impaired platelet production settings such as following chemotherapy.\textsuperscript{29, 30, 31} This may be a result of clearance of thrombopoietin by the megakaryocyte and platelet mass.\textsuperscript{32}

Platelet Antibodies
In 1951, Harrington and colleagues first reported that the infusion of plasma from patients with ITP predictably induced thrombocytopenia in normal recipients. Shulman and colleagues then demonstrated that the responsible factor was an immunoglobulin (Ig) of the IgG class that was species-specific and could be removed from serum by absorption to and elution from normal human platelets. In addition, the platelet-depressing factor produced effects in vivo that were quantitatively and qualitatively similar to those produced by known platelet antibodies. In 1982, van Leeuwen first identified platelet membrane glycoprotein IIb/IIIa as a dominant antigen by demonstrating that the autoantibodies eluted from ITP platelets bound to normal platelets but not to platelets from patients with Glanzmann thrombasthenia. Increased quantities of IgG have been demonstrated on the platelet surface in ITP, and the rate of platelet destruction is proportional to levels of such platelet-associated Ig. Autoantibodies are readily found in plasma or platelet eluate in patients with active disease, but are infrequently found in patients in remission. Disappearance of the antibodies correlates with the appearance of normal platelet counts.

The antiplatelet antibodies and platelet antigens involved in ITP have been extensively studied (Table 47.3). The presence of antibodies against multiple antigens is seen in most patients. Although two studies identified antiphospholipid antibodies (lupus anticoagulant activity or anticardiolipin antibodies) in 46% and 38%, respectively, of ITP patients at diagnosis, there was little clinical evidence that they played a role in the pathogenesis of the disease or affected outcome.

The presence of antibodies against multiple antigens is seen in most patients. Once destruction of platelets within antigen-presenting cells occurs, this generates a series of neoantigens that in turn results in sufficient antibody to cause thrombocytopenia. This phenomenon is termed epitope spread.
platelets in the same patient may have slight differences in antigen specificities within a membrane glycoprotein complex. There is evidence from two studies that the specific $\beta_3$ antigen epitope in any given patient to which anti-gpIIa autoantibodies are directed may influence the clinical presentation and course of the disease. Whether these findings can be generalized to other ITP autoantibody epitopes is unknown.

Autoantibodies bind to platelets and cause thrombocytopenia primarily by shortening platelet survival. However, rare autoantibodies have also been reported that bind to glycoproteins and activate platelets. Additionally, one patient with an anti-gpIIa antibody was reported to have developed an antibody-related defect in aggregation and adhesion.

The incidence of serum autoantibodies to platelet gpIIb/IIIa is the same in the acute and chronic forms of childhood ITP (68% vs. 62%, respectively). The presence of anti-gpIIb/IIIa, therefore, does not predict which children will develop the chronic form of the disease, and, in fact, these data provide evidence that the mechanism may be the same in both acute and chronic forms of ITP.

The role of cell-mediated immunity in ITP remains uncertain, although data from patients with ITP suggest that T lymphocytes demonstrate phenotypic and functional abnormalities. Platelet reactive T-cell clones can be identified from the peripheral blood of adults and peripheral blood and spleens of children with chronic ITP, suggesting that autoreactive peripheral T lymphocytes may mediate or participate in disease pathophysiology. Adults with ITP often have increased numbers of HLA-DR$^+$ T cells, increased numbers of soluble interleukin-2 receptors, and a cytokine profile suggesting the activation of precursor and mature helper T-cells. $CD^+$ T cells from ITP patients in one DNA microarray study had increased expression of genes involved in cell-mediated cytotoxicity and, in addition, cytotoxic cell-mediated lysis of autologous platelets was shown in active ITP.
FIGURE 47.2. Types of antibody-mediated platelet destruction. A: Platelet autoantibodies bind to variable external and internal platelet epitopes. B: Quinine/quinidine-dependent antibodies. The antibody target is a complex of drug and glycoprotein (GP) (usually gpIb/V/IX or gpIb/IIia). C: Heparin-dependent antibodies. The antigen-antibody complex
Platelet Survival

Platelet survival, measured using $^{51}$chromium- or $^{111}$indium-labeled platelets, is shortened in ITP, and the survival time can range from 2 to 3 days to a matter of minutes.22 23 24 80 81 82 83 84 85 86 87 88 89 Using $^{111}$indium-labeled autologous platelets, some investigators found an inverse correlation between venous platelet count and platelet survival,86 whereas others have not.87 These study differences may relate to the types of patients included, as patients with mild to moderate thrombocytopenia have a longer measured platelet survival than patients with severe thrombocytopenia.

P. 1064

Splenic sequestration and destruction account for the shortened survival in most patients,90 91 but the liver and the reticuloendothelial cells of the bone marrow can play a major role in the sequestration of antibody-coated platelets, especially in patients with very low platelet counts or continued thrombocytopenia after splenectomy.92 93 Patients with severe thrombocytopenia have been found to have elevated levels of macrophage colony-stimulating factor92 and increased in vitro monocyte-platelet rosette formation.94 95 In a pathologic study of 83 spleens that had been removed after patients did not respond to steroid therapy, investigators found splenic weights of <300 g, prominent secondary lymphoid follicles (28%), foamy macrophages (67%), and megakaryocytic extramedullary hematopoiesis (60%).96 These pathologic changes reflect the two major pathogenic roles of the spleen: Antiplatelet antibody production and macrophage-mediated platelet destruction.

Clinical Picture

Immune Thrombocytopenia in Children

In children with acute ITP, the onset of the disorder usually is sudden (Table 47.2). A history of infection preceding the onset of bleeding has been documented repeatedly.97 98 In one series, such infections were noted within 3 weeks of the onset of ITP in 84% of cases.8 9 Varicella zoster virus and Epstein-Barr virus are the most frequently identifiable viruses, although nonspecific unidentified viral infections predominate.99 Acute ITP may also occur after vaccination.100 Although it is most common between 2 and 5 years of age, ITP occurs in all pediatric age groups.101 The severity of ITP in infants is similar to that in older children, but compared to older children, a relatively small percentage of infants develop chronic ITP. A male preponderance was observed in the infant population in two studies.101 102 Even though thrombocytopenia is likely to be severe, the bleeding manifestations of acute ITP in children usually are mild,103 and intracranial hemorrhage occurs in <1% of patients. The rare adult with the acute form of the disorder, however, may suffer hemorrhage and a more fulminant course. Acute ITP in children usually is self-limited; spontaneous remissions occur in as many as 90% of patients.8 9 The duration of the disease ranges from a few days to a few months, with an average of 4 to 6 weeks.104 The favorable prognosis of ITP in children reflects the preponderance of the acute form of the disease in this age group. Children with thrombocytopenia of >6 months duration are classified as chronic ITP, although spontaneous remissions may still occur in an occasional child after 6 months.105 106 Fever of mild degree has been reported, and the spleen tip may be palpable in up to 10% of patients, but this is believed to be the same incidence as is seen in normal children.107 The spleen is usually of normal weight in those patients who proceed to splenectomy.97

Immune Thrombocytopenia in Adults

In adults, the onset of the chronic form of the disorder usually is insidious (Table 47.2). A long history of hemorrhagic symptoms of mild to moderate severity is often described by the patient, but antecedent infections or fever are uncommon. Patients with chronic ITP usually have a fluctuating clinical course. Episodes of bleeding may last days or weeks and may be intermittent or even cyclic. Spontaneous remissions are very uncommon in adults, with an estimated occurrence of <5%.13 14 108 109 110 Most spontaneous remissions occur early; however, remissions have been described after 6 months in a small number of patients.13 Relapses in some cases are associated with vaccination.111 Often the clinical course is surprisingly benign.

Bleeding Manifestations

The hemorrhagic manifestations of ITP are of the purpuric type. Patients with only ecchymoses and petechiae have “dry” purpura; those with mucous membrane bleeding in addition to skin manifestations have “wet” purpura.112 Platelet counts
are usually lower and the complication rates higher in those with wet purpura. In a series of 712 patients reported by the Israeli ITP study group, 82% of all patients had bleeding limited to the skin, although 43% of adult women reported menometrorrhagia.

In general, the severity and frequency of hemorrhagic manifestations correlate with the platelet count (Fig. 47.3).\(^{113}\) Bleeding after trauma without spontaneous hemorrhage is usual in mildly affected patients with platelet counts >50,000/µl. Thrombocytopenia associated with counts between 10,000 and 50,000/µl results in spontaneous hemorrhagic manifestations of varying severity, such as ecchymoses and petechiae. Patients with platelet counts <10,000/µl are at risk for serious morbidity and mortality from bleeding, although the mortality rate is actually quite low.\(^{114}\) Patients who have an increased risk of bleeding include those with a history of bleeding, those with additional bleeding diatheses, and patients >60 years of age.\(^{112,114}\) Older patients have also been reported to have an increased incidence of major, life-threatening bleeding.\(^{112,115,116}\)

Skin and Mucous Membranes

Spontaneous bleeding into the skin in the form of petechiae is characteristic. These lesions are minute, red to purple hemorrhages that range in size from that of a pinpoint to that of a pinhead (Fig. 47.4). They are flat, do not blanch with pressure, and appear and regress, often in crops, over a period of days. They are most conspicuous in areas of vascular stasis, such as the areas below tourniquet sites, the dependent portions of the body (especially around the ankles), and areas subjected to constriction from belts or stockings, as well as on skin surfaces over bony prominences. The presence of petechiae on the face and neck is unusual, except as the result of coughing.

Ecchymoses may develop on any skin surface. In ITP, they are seldom associated with subcutaneous hematomas and infrequently spread or dissect into deeper or adjacent structures. Large, purple, superficial ecchymoses may be seen, particularly on the back and thighs. Circular ecchymoses often surround even atraumatic venipuncture sites, but external bleeding from such sites is uncommon. Hemorrhagic vesicles or bullae may be seen inside the mouth and on other mucous surfaces. The bullae probably are the result of severe acute thrombocytopenia rather than a specific feature of any particular pathogenetic form.

FIGURE 47.3. Bleeding manifestations in relation to platelet count in patients with primary immune thrombocytopenia. Bleeding manifestations (or duration) are graded from 0 to 4, as follows: 0, no bleeding; 1, minimal, resulting from trauma; 2, spontaneous, but self-limited; 3, spontaneous, requiring special attention (e.g., nasal packs); and 4, massive uncontrolled or poorly controlled. (From Lacey and Penner, reference 113.)

P.1065
FIGURE 47.4. Petechiae. Pinpoint, nonblanching erythematous capillary bleeding sites are most common in dependent body areas or pressure points.

Gingival bleeding and epistaxis are common. The latter usually responds for a time to conservative measures, such as nasal packing or tamponade, often to recur intermittently. Epistaxis may originate from lesions resembling petechiae in the nasal mucosa. Such lesions also may be found in the mucous membranes of the throat and mouth, sometimes in the absence of cutaneous hemorrhage. In many patients, discrete bleeding points cannot be identified.

The genitourinary tract is a frequent site of bleeding. Menorrhagia may be the only symptom of ITP and may appear for the first time at puberty. Hematuria also is a common symptom, the blood coming from the kidneys, the bladder, or the urethra, although bleeding into the kidney parenchyma is rare. Gastrointestinal bleeding is usually manifested by melena or, less often, by hematemesis.

Central Nervous System

Intracranial hemorrhage is the most serious complication of ITP. Fortunately, it is rare, affecting 1% to 2% or less of patients with severe thrombocytopenia. The hemorrhages usually are subarachnoid, often are multiple, and vary in size from petechiae to large extravasations of blood. Numerous small hemorrhages often are seen in the retina; subconjunctival hemorrhage may also occur.

Bleeding after Trauma

Excessive bleeding often follows tooth extractions, tonsillectomy, or other operations or injuries and may first suggest the diagnosis of ITP. In contrast to the hereditary coagulation disorders, such traumatic bleeding is seldom voluminous or rapid. Slow persistent oozing may occur after trivial cuts, razor nicks, and scratches. Delayed bleeding and spontaneous hemarthrosis, which are characteristic of the hereditary coagulation disorders, are extremely rare in ITP.

Laboratory Findings

Blood

The mean platelet count of patients at the time of diagnosis of ITP is 25 to 30,000 and severe thrombocytopenia (<10,000) is frequently seen. Abnormalities in platelet size and morphologic appearance are common. The platelets often are
were quite cumbersome and therefore never became available for routine testing. These tests measured different types antiplatelet antibodies have been developed and reported through the years.

Primary ITP is a diagnosis of exclusion and relies on clinical impression. A number of different types of antiplatelet antibody tests have been developed and reported through the years. Most of these tests were quite cumbersome and therefore never became available for routine testing. These tests measured different types
of Ig, including serum antiplatelet antibodies, platelet-associated surface Ig, or total platelet Ig and are now generally regarded as unreliable. The platelet Ig is released, along with other α-granule proteins, such as platelet factor 4 and β-thromboglobulin, during platelet activation and secretion. It is presumed that some of these released proteins bind to the platelet surface. These observations make it difficult to use either the platelet-associated IgG assays or the total platelet Ig assays for the diagnosis of ITP.

In a more recent generation of antiplatelet antibody assays, monoclonal antibodies for the specific platelet membrane glycoproteins that are implicated in ITP are used in antigen-capture-type assays (also called glycoprotein immobilization assays). Studies have identified a specificity of 78% to 93%. However, the sensitivity (49% to 66%) is not high enough to exclude the presence of ITP if the test is negative. None of these tests is in routine clinical use, and experts disagree on their role in the diagnosis of ITP. Future direction might include the use of flow cytometry in the diagnosis and follow-up of autoimmune thrombocytopenia.

Differential Diagnosis

The initial step in the evaluation of a thrombocytopenic patient is inspection of the peripheral blood smear to confirm the decreased platelet count. Thrombocytopenia may be produced artifactually by clumping of the platelets in the blood sample caused by ethylenediaminetetra-acetic acid-associated platelet agglutinins (pseudothrombocytopenia), or the platelets may be unavailable for counting because they are bound in rosette formation to the surface of white blood cells in the venous blood sample ("platelet satellitism").

The diagnosis of ITP is usually a diagnosis of exclusion based on a demonstration of peripheral thrombocytopenia, with a history, physical examination, and complete blood count that do not suggest another cause for the thrombocytopenia. Splenomegaly suggests that the thrombocytopenia may be a result of hypersplenism related to the presence of a separate underlying disease associated with splenic enlargement.

The initial manifestations of acute leukemia, myelodysplastic syndrome, myelophthisic processes, and aplastic anemia may mimic ITP. These other types of underlying hematologic disorders are suggested by anemia out of proportion to blood loss and by changes in the leukocytes not attributable to either he

The presence of schistocytes in the blood smear suggests that thrombocytopenia may be associated with a microangiopathic process (see Chapter 48). In thrombotic thrombocytopenic purpura (TTP) or hemolytic-uremic syndrome (HUS), thrombocytopenia is associated with laboratory manifestations of hemolysis, including elevated levels of lactate dehydrogenase and indirect bilirubin. Patients may also have transient, multifocal neurologic signs or symptoms, renal insufficiency, and/or fever in TTP, or renal insufficiency alone in HUS. After a diagnosis of ITP, the next essential step is to distinguish between primary ITP purpura and secondary forms of ITP purpura, such as human immunodeficiency virus, hepatitis C, or Helicobacter pylori infections; collagen vascular diseases such as systemic lupus erythematosus (SLE); lymphoproliferative disorders such as chronic lymphocytic leukemia; and drug ingestion. The ASH guidelines recommend considering testing all adults with a new diagnosis of ITP for hepatitis C and HIV as treatment plans differ in these settings. The importance of careful inquiry regarding drug ingestion or exposure to toxic substances cannot be overemphasized, because thrombocytopenia attributable to drugs or toxins often is indistinguishable from ITP. The development of thrombocytopenia in an adult, in particular, should arouse suspicion of a pharmacologic etiology, because many of the drugs associated with thrombocytopenia are used more often by adults than by children. It is also essential to eliminate the possibility that the thrombocytopenia is secondary to heparin administration. ITP may be produced by heparin administered in any dose and by any route of administration, including heparin-bonded catheters. Finally, the antiphospholipid antibody syndrome is a disorder that may be associated with thrombocytopenia. In the usual case, this presentation may be associated with thromboembolic manifestations, anticardiolipin antibodies, and coagulation inhibitors of the lupus type (see Chapter 54).

Treatment of Primary Immune Thrombocytopenia

Many of the treatment recommendations for ITP are based on expert opinion rather than high-level evidence from randomized controlled trials. The ASH has published a practice guideline on ITP. The reader is referred to this practice guideline for specific questions regarding the treatment of patients with ITP.

Children

Childhood ITP is usually benign and self-limited. Therefore, treatment is not required for most patients. Treatment is reserved for patients with severe thrombocytopenia (<20,000/µl) and bleeding, or patients who remain thrombocytopenic...
for >6 months, that is, those with chronic ITP (Table 47.4). Treatment guidelines recommend observation for all children with no or mild bleeding, regardless of platelet count. Although the greatest fear in the acute form is intracranial hemorrhage, several large studies show that even with low platelet counts (<30,000/µl) life-threatening bleeding and intracranial hemorrhage are rare (<0.5%).

TABLE 47.4 RECOMMENDATIONS FOR INITIAL TREATMENT OF IMMUNE THROMBOCYTOPENIA (IVIG) PATIENTS WITH PLATELET COUNTS <20,000-30,000/µl

The current ASH guidelines recommend treatment for adults with platelet counts of <30,000/µl.

Treatment guidelines for pediatric ITP recommend first-line treatment with either a single dose of intravenous immunoglobulin (IVIG) (0.8 to 1 g/kg) or a short course of steroids. Several multicenter randomized trials have been performed in high-risk patients with acute ITP to define whether treatment is associated with a prompt increase in platelet counts. These clinical trials demonstrated that treatment with either oral prednisone or IVIG was associated with a more rapid rise in platelet count to >20,000/µl than either no therapy or treatment with anti-D. Only IVIG shortened the time to reach a platelet count >50,000/µl. More recently, children with platelet counts <10,000/µl or counts of 10,000 to 29,000/µl and mucosal bleeding were studied in a prospective randomized clinical trial, and IVIG raised platelet counts faster than three corticosteroid regimens. Therefore, IVIG should be preferentially used if a rapid rise in platelet count is desired.

Treatment of children who develop persistent ITP or are unresponsive to initial treatment is evolving. Splenectomy remains a standard given high response rates; however, many experts recommend delaying splenectomy for at least 12 months given the frequency of spontaneous remission. Rituximab treatment has been used in children and adolescents in a small study comprised of 36 patients with chronic ITP. In contrast to observations in adults, the median time to response was 1 week (range 1 to 7 weeks), and the overall response rate was 31%. Outcome was not associated with age, prior pharmacologic response, prior splenectomy, duration of disease, screening platelet count, refractoriness, or IgM reduction. Therefore, rituximab may be considered as an alternative to splenectomy in children with chronic ITP or in patients with persistent bleeding despite first-line treatments. High-dose dexamethasone (0.6 mg/kg/day) may also be considered in patients who are unresponsive to initial therapy based on small studies showing a 25% response rate in refractory patients.
FIGURE 47.5. Therapy of adult immune thrombocytopenia (ITP). 

(1) Minimal emergency therapy includes intravenous (IV) methylprednisolone and intravenous immunoglobulin (IVIG). Intravenous anti-D and platelet transfusions may be given as needed. All three modalities given prior to transfusions may help preserve platelet longevity in the circulation and repeated or continuous platelet transfusions may be required in urgent situations. 

(2) Initial treatment of ITP typically consists of steroids (prednisone or dexamethasone) with the goal of attaining a platelet count of >30,000/μl and cessation of bleeding. IVIG or anti-D may be used if steroids are contraindicated or the patient has persistent thrombocytopenia despite steroids. 

(3) Thrombocytopenia recurs in most adults as corticosteroids are tapered. Treatment options for refractory ITP include splenectomy, thrombopoietin mimetics, and rituximab. (Modified from Cines and Bussel, reference 459.)

Adults

Patients with chronic ITP may have mild thrombocytopenia that can be followed without treatment. The incidence of bleeding is correlated with the platelet count; therefore, patients with platelet counts >50,000/μl rarely have spontaneous bleeding and may require treatment only if extensive operative procedures are planned. Patients with platelet counts <20,000 to 30,000/μl or significant mucosal membrane bleeding with platelet counts <50,000/μl are usually treated\(^5\) (Table 47.4 and Fig. 47.5). 

No prospective studies on long-term prognosis of ITP after treatment are reported. However, it has been reported that most adult patients have a good response to treatment (without necessarily returning to normal platelet counts) and have no excess mortality when compared to the general population.\(^{173}\) A small group of patients who had severe thrombocytopenia after 2 years of primary and secondary therapies had a mortality risk of 4.2 (95% confidence interval, 1.7 to 10.0) resulting from both bleeding and infectious complications related to therapy.

ITP is uncommon in elderly patients; only 30% of patients in reported series are >45 years of age.\(^{133,174}\) However, these patients may be more refractory to therapy\(^{115}\) and appear to have a higher incidence of hemorrhagic complications than younger patients.\(^12\) Guthrie and colleagues reported a 52% incidence of life-threatening or fatal bleeding in their series of 40 patients.

P.1068

older than age 45 years.\(^{115}\) This risk of fatal bleeding in patients with platelet counts that are chronically <30,000/μl is estimated at 0.4% per year for patients <40 years of age and 13.0% per year for patients >60 years of age.\(^{175}\)
First-line Treatment

Initial treatment for adult patients with newly diagnosed ITP is typically steroids. Other options that increase the platelet count rapidly include IVIG and anti-D. The most recent ASH guideline recommends use of these alternative first-line therapies in patients with contraindications to steroids. Patients with life-threatening bleeding may require parenteral glucocorticoids and IVIG followed by platelet transfusions, plasmapheresis, or even emergency splenectomy as first-line treatment. Standard ITP treatments and their dosing schedules are shown in Table 47.5.

Steroids

Steroids are the conventional first-line therapy for adult ITP. Dameshek first reported his experience with prednisone therapy in 1958, when 30 consecutive patients with acute (N = 11) or chronic (N = 19) ITP were treated with 20 to 150 mg/day of prednisone. Twenty-two of the patients demonstrated an increase in platelet count to normal after an average interval of 22 days and then were maintained on 2.5 to 15.0 mg/day of prednisone. In eight patients, prednisone was discontinued without relapse.

Numerous retrospective studies of steroid treatment in both children and adults with ITP have been reported. The criteria for inclusion of patients in the individual studies and the criteria for response to treatment vary significantly among the reports; therefore, it is difficult to combine the data accurately. However, some useful observations can be made. Complete (CR) and partial (>50,000/µl) responses (PR) in patients treated with prednisone (usually, 1 mg/kg/day as starting dose) average 65% to 85%, but sustained responses after discontinuation of the drug occur in only 25% or less of patients. Platelet counts usually increase within 1 week in responding patients and have usually reached peak values by 2 to 4 weeks. Patients who have not had any response by 4 weeks are unlikely to respond to prednisone and therefore should be considered for other forms of treatment. No pretreatment patient characteristics have predicted a patient’s response to steroids.

Modified from Narang et al.

Several prospective randomized steroid treatment trials in patients with ITP have been reported. Bellucci and colleagues randomized patients between low (0.25 mg/kg/day) or high (1.0 mg/kg/day) prednisone for 3 weeks, with taper and discontinuation by the end of the fourth week. If bleeding continued, patients could be increased from low dose to high dose, or a second 4-week course could be given. CR, defined as a platelet count >100,000/µl for at least 6 months, was seen in 74% of children and 41% of adults. CRs or PRs occurred in 83% of children and 59% of adults. No significant differences were seen between low- and high-dose regimens in either age group. Mazzucconi and colleagues randomized...
patients between prednisone 0.5 mg/kg/day and 1.5 mg/kg/day. The response rates in adults were not significantly different between patients treated with low- versus high-dose steroids: 30% and 34% CR, respectively. In children, however, the rates were 64% for low-dose versus 81% for high-dose prednisone. Therefore, there is evidence to support the use of lower doses of steroids in adults than have conventionally been used at the beginning of treatment. However, based on the opinion of an expert panel convened by the ASH, high-dose prednisone (1 mg/kg/day) is recommended as an appropriate initial treatment in ITP patients with platelets <30,000/µl, including asymptomatic patients.

Another prospective randomized, controlled trial compared prednisone (1 mg/kg/day) to IVIG (400 mg/kg/day for 4 days), or to both in a small number of patients. A platelet count >50,000/µl was achieved in 82%, 54%, and 92% of patients, respectively. The median times to peak platelet counts were 8.5, 7.0, and 7.0 days. These authors concluded that there was no advantage for IVIG over conventional corticosteroid treatment. In another recent randomized control trial, platelet counts >50,000/µl were achieved more quickly in patients receiving IVIG than in those receiving intravenous methylprednisolone, but long-term outcomes were the same.

There are also several studies that have evaluated the role of high-dose dexamethasone in the initial treatment of ITP. This protocol was initially developed because of concern regarding long-term side effects of daily prednisone use. Initial trials showed that using 40 mg of dexamethasone daily for 4 consecutive days results in an initial response in 85% of patients. Additional work has shown that repeating dexamethasone bursts may provide long-term disease control in some patients. Mazzucconi and colleagues treated newly diagnosed patients with ITP with dexamethasone 40 mg daily for 4 days, repeating these cycles every 14 days for 4 cycles. A total of 85% of patients responded with 65% achieving a CR. Relapse-free survival at 15 months was 81% indicating that many of these patients may be long-term responders.

There are conflicting opinions regarding the choice of prednisone versus dexamethasone for first-line treatment of ITP. The writers of the 2011 ASH guidelines favor longer-term prednisone over dexamethasone but other experts in the field think that either is reasonable.

The mechanism of action of steroids in ITP involves both direct and indirect effects on thrombocytopenia. Steroids ameliorate thrombocytopenia directly by several mechanisms. Steroids may (a) decrease consumption of antibody-coated platelets by the spleen, or bone marrow, (b) reduce antibody production by the spleen, (c) decrease antibody production by the bone marrow, and/or (d) increase marrow platelet production by undetermined mechanisms.

There is little doubt that corticosteroids in high doses ameliorate splenic sequestration of antibody-coated platelets. Corticosteroids decrease antibody-coated red blood cell sequestration in guinea pigs spleens by decreasing Fcy receptor proteins on macrophages, and in vivo and in vitro data support a similar action of steroids in humans. Corticosteroids also decrease monocyte Fc receptors in autoimmune hemolytic anemia. This down-regulation of monocyte/macrophage Fc receptors may account for the early effects of steroid treatment on platelet counts. Chronic corticosteroid treatment is associated with a decrease in antibody production, but this usually occurs after several weeks of high-dose steroids. Steroid treatment also results in increased platelet production in some ITP patients, an effect that may be secondary to reduction of the antiplatelet Ig effect on thrombopoiesis, reduction in intramedullary destruction of antibody-coated platelets before their release into the circulation, or decreased antibody synthesis by bone marrow lymphocytes.

In addition to these direct effects on thrombocytopenia, steroids also act on endothelial cells to reduce bleeding. Experimental evidence indicates that thinning of the endothelium with development of endothelial fenestrations occurs in both animal models and humans with ITP, suggesting that platelets play a role in normal endothelial homeostasis.

Clinically, steroids are known to ameliorate the purpuric bleeding in ITP patients before the platelet count actually increases. Experimentally, investigators have demonstrated that 3 days after steroid therapy in rabbits and 4 days after steroid therapy in patients, the endothelial thinning reverts toward normal, providing a scientific explanation for this clinical observation. This endothelial effect may in part be explained by the observation that when endothelial cells are cultured with steroids, cell morphology is altered, with greater confluence and increased protein synthesis and content.

Intravenous Immunoglobulin

The intravenous administration of polyvalent Ig (IVIG), first used in 1981, may induce remissions in patients with life-threatening bleeding or in patients with refractory ITP. IVIG therapy has proved most effective in infants and small
children, an age group in which the response is difficult to evaluate because of the frequency of spontaneous remissions. In adults this regimen has produced relatively less impressive long-term results, although an occasional patient enters complete remission after the initial treatment and a series of booster doses. In a review of 28 published reports of IVIG in 282 adults, 64% of patients had a peak platelet count >100,000/µL, and 83% had peak platelet counts >50,000/µL after the initial infusion. Platelets may begin to rise after 2 days and usually reach peak levels by 1 week after treatment.

Regimens of 400 mg/kg/day for 5 days versus 1,000 mg/kg/day for either 1 or 2 days, have been equally effective in randomized trials, and doses of 0.5 g/kg are as effective as 1.0 g/kg for maintenance therapy. These doses produce significant increases in serum and platelet levels of IgG. In a randomized controlled trial, one dose of 1,000 mg/kg was superior to 500 mg/kg in raising platelet counts to >80,000/µL by day 4. Most of these patients were being prepared for splenectomy or delivery.

Several mechanisms are thought to be involved in the beneficial effects of IVIG. They include Fc receptor blockade of reticuloendothelial cells, effects on B cells and antibodies, and anti-inflammatory effects. No evidence exists that reduction of antiplatelet antibodies accounts for the acute effects of therapy.

Therapy with IVIG remains expensive. The rapid nature of the response to treatment makes it an ideal agent for treatment of patients for life-threatening bleeding or before surgery; however, the role of IVIG in long-term therapy remains uncertain. The major side effect of treatment is headache, although some patients also develop fever, myalgias, and skin rashes. There are also reports of acute renal failure occurring in up to 7% of patients, especially older patients and those with diabetes, or baseline increases in creatinine (or both). The patients may be oliguric, and most demonstrate peak creatinine levels by day 5 after the IVIG infusion. Hemodialysis may be required acutely, and several patients required chronic dialysis. The volume of fluid required for IVIG administration can also be a major problem in some older patients with co-morbidities such as congestive heart failure.

Anti-D

Intravenous Rho (D) immune globulin (anti-D) has been studied in children and adult ITP as an alternative to IVIG. The mechanism of action is unknown; however, it is believed that the antibody coats the red blood cells of Rh-positive patients and either blocks the reticuloendothelial clearance of platelets or modulates the immune system, resulting in an increase in the platelet count. Although infusion of both IVIG and anti-D slow the Fcy-receptor-mediated destruction of antibody-coated platelets, responses to anti-D appear to uniquely correlate with polymorphisms specific to the FcyRIIa and FcyRIIIa receptors. This is characterized by increases in the plasma levels of IL-6, tumor necrosis factor-α, monocyte-chemoattractant protein-1, and IL-10 that are specific to IV anti-D infusions compared with IVIG.

Children respond better than adults, and nonsplenectomized patients respond better than splenectomized patients to anti-D. The platelet count does not begin to increase for 48 to 72 hours, so it may not be as effective for the treatment of life-threatening bleeding compared with IVIG. The effect lasts for several weeks to a month, and patients respond well to retreatment. They may respond to intramuscular injections given weekly as maintenance. Occasionally, patients have a sustained remission. Most patients exhibit a modest decrease in hemoglobin, and most have subclinical signs of mild hemolysis, with decreased haptoglobin, increased lactate dehydrogenase, and increased indirect bilirubin. Red cell survival is only modestly reduced. No correlation has been found between the amount of hemolysis and the platelet response, leading some investigators to question the proposed effect on reticuloendothelial blockade. Reinfusion of autologous red blood cells that have been opsonized with anti-D has produced both complete and partial remissions in a small number of patients, even after splenectomy. With respect to anti-D dosing, early studies in adults receiving 25 to 50 µg/kg/day showed an increase in platelet count of >20,000/µL in 79% of patients. However, the platelet count did not increase for >72 hours, which made this treatment approach less efficient for bleeding patients. More recent studies have shown a more rapid increase of the platelet count within 24 hours and a longer duration of the increase when using a higher dose of 75 µg/kg compared with 50 µg/kg. Anti-D therapy now carries a black box warning that requires observation of the patient for 8 hours after administration due to the risk of intravascular hemolysis and disseminated intravascular coagulation.

Treatment of Chronic Primary Immune Thrombocytopenia

Many adult patients with ITP, even if they initially respond to steroids, will develop chronic ITP. Chronic ITP is defined as ITP lasting longer than 12 months. Patients who are asymptomatic and have platelet counts between 30,000 and 50,000/µL may be managed with careful observation. Symptomatic patients with platelet counts <30,000/µL who had an initial response to steroids can be retreated with prednisone and then tapered to find the minimum dose that can
Splenectomy. The majority of studies have demonstrated a 73% excellent therapeutic response and a 27% moderate response to accessory splenectomy.

Most patients who do not respond to splenectomy or who relapse after an initial response to splenectomy should be studied for the presence of accessory spleens. The incidence of accessory spleens found at the time of the original splenectomy ranges from 15% to 20%. The incidence of accessory spleens in patients who relapse after splenectomy may be as high as 50%, and surprisingly, the majority of these patients demonstrate post-splenectomy changes (i.e., Howell-Jolly bodies) on their peripheral blood smears. Relapse secondary to an accessory spleen may occur weeks to years after the initial splenectomy. Scanning methods have varying sensitivities; conventional technetium scans, technetium scans using heat-denatured red blood cells, or computed tomography scans can be used. Accessory spleens as small as 0.5 cm have been found when indium scans were performed preoperatively and isotope detector probes were used intraoperatively to detect all accessory splenic tissue. A review of 56 published cases demonstrated a 73% excellent therapeutic response and a 27% moderate response to accessory splenectomy.

The effectiveness of splenectomy in the therapy for ITP is attributed to removal of the organ that is primarily responsible for the destruction of antibody-sensitized platelets. The increase in platelet count correlates with an increase in platelet survival, whereas platelet production remains unchanged. The removal of the spleen may also result in a reduction of antibody production, but this effect is probably of minimal significance in view of the immediate favorable responses to splenectomy. No factors have consistently predicted a response to splenectomy; age, concentration of platelet-associated IgG, the time between diagnosis and splenectomy, the patient's response to steroids, IVIG or intravenous anti-D, and the peak postoperative platelet count have all been studied. The site of platelet sequestration, based on preoperative chromium- and indium-labeled platelet survival studies, may be predictive of response, but these techniques are seldom used.

Rituximab

Rituximab, an anti-CD20 monoclonal antibody, has produced CRs or PRs in approximately 60% of patients. Rituximab causes selective B-cell lysis in vitro and B-cell depletion in vivo. Involved mechanisms of action include apoptosis, antibody-dependent cell-mediated cytotoxicity, and/or complement-dependent cytotoxicity. Recovery of B-cell counts usually occurs by 6 to 12 months after completion of treatment.

Most of the patients in the studies of rituximab in ITP had relapsed or refractory disease, and some had undergone splenectomy. The majority of studies have used the standard treatment dose of 375 mg/m² weekly for four weekly doses; however, published reports have shown that lower doses are effective as well. The side effects were mild and
seen most commonly after the first infusion. The long-term safety profile of rituximab is felt to be favorable. Only one case of progressive multifocal leukoencephalopathy, a rare but fatal consequence of rituximab administration, has been reported in a patient with ITP. There are two different response patterns, early versus late. Patients with an early response to four weekly infusions had an increasing platelet count after the first or second infusion and peaked between weeks 6 and 10. Late responders had no rise of their platelet count during treatment but increased their platelet count between weeks 6 and 8, with the peak occurring shortly thereafter. In one study, the B-cell count in patients who responded was lower than in patients who did not have a response.

A recent meta-analysis of studies employing rituximab in the treatment of refractory/relapsed patients consisted of 299 patients described in 15 reports. The overall response rate was 55%, of which 38% of patients achieved a CR, which was defined as a platelet count of at least 100,000 to 150,000/µl. In addition, 17% of the patients achieved a PR, which was defined as a platelet count of >50,000 and <100,000/µl. The median duration of response was 74 weeks (24 to 120 weeks) and in PR patients was 55 weeks (12 to 160 weeks). CR in splenectomized patients (62%) was higher than in nonsplenectomized patients (available from five studies, n = 126). Another recent meta-analysis showed similar results with 43.6% of patients achieving a CR (>150,000/µl) and 62.5% of patients achieving a PR (>50,000/µl).

Longer-term studies have shown that prolonged disease responses are less common. Patel et al. reported that with 2.5 years of follow-up 1 in 6 patients remained in remission. Most patients with relapse can be retreated with rituximab with success. The role of rituximab as part of first-line therapy for ITP is currently under investigation but is not considered a standard of care.

Thrombopoiesis-stimulating Agents

Thrombopoiesis-stimulating agents (thrombopoetin mimetics) are another, recently approved treatment option for management of refractory ITP. There are two currently available thrombopoiesis-stimulating agents, eltrombopag and romiplostim. They have both been the subject of randomized controlled trials in refractory ITP.

Eltrombopag, an oral agent, is a peptide that interacts with the transmembrane domain of the thrombopoietin receptor thereby stimulating differentiation and proliferation of megakaryocytes in the bone marrow. The most common side effects are mild elevation in liver enzymes and nausea/vomiting. In a study published in 2009, 114 patients with refractory ITP were randomized to eltrombopag versus placebo in a 2:1 randomization. After 6 weeks of follow-up, 59% of patients in the eltrombopag arm versus 16% in the placebo arm had achieved a platelet count >50,000 and less bleeding was observed in the eltrombopag arm.

Platelet counts dropped again within 2 weeks of discontinuing therapy. A phase III study (RAISE) in patients with chronic ITP published in 2011 showed similar results. After two weeks of therapy, median platelet counts in the eltrombopag group were 53,000 to 73,500 versus 17,500 to 23,000 in the placebo arm. Patients in the eltrombopag arm had less bleeding and were more successfully tapered off their other ITP treatments.

Similar results have been seen with romiplostim. Romiplostim is an injectable thrombopoetin mimetic that is given once per week. It is a thrombopoietin mimetic peptide (peptibody) which binds to the thrombopoietin receptor. In a randomized study published in 2008, patients with ITP were randomized in a 2:1 fashion to romiplostim versus placebo. In splenectomized and nonsplenectomized patients, 79% and 88% of patients receiving romiplostim achieved a platelet count >50,000. Only a very low number of patients in the placebo arm achieved this threshold (14% of nonsplenectomized patients, 0% of splenectomized patients). This correlated with decreased use of other ITP therapies. The most common side effects are arthralgias, fatigue, and nausea. Serious adverse events are rare. Additional trials have shown that romiplostim is safe and effective for prolonged use and that decreased bleeding is observed in patients receiving romiplostim due to higher platelet counts. With prolonged use patients do still require regular platelet monitoring as the dose required may vary over time. As with eltrombopag, indefinite treatment is required as platelet counts fall quickly when treatment is discontinued.

There has been some concern regarding increased marrow fibrosis in patients receiving eltrombopag or romiplostim. Preclinical data showed increased fibrosis in the marrow of rats treated with romiplostim. This appeared to be dose dependent and decreased after the treatment was discontinued. In the same paper, a retrospective review of clinical trials using romiplostim was performed. Reticulin deposition was noted in 10 of 271 patients; however, most patients did not have bone marrow biopsies performed. In 5 patients who had pretreatment bone marrow biopsies, reticulin deposition increased in 4 patients. In all patients, reticulin staining decreased when romiplostim was discontinued. In 10 patients
followed prospectively with serial bone marrow biopsies, only 1 of 10 patients treated developed new reticulin fibrosis on treatment. Similar findings are seen with eltrombopag. The clinical significance of this finding is unclear.

Although the thrombopoietin mimetics are effective in both splenectomized and nonsplenectomized patients, expert panels recommend that they be reserved for patients with refractory ITP after splenectomy and patients with contraindications to splenectomy. This recommendation is based on concerns regarding the requirement for indefinite treatment which is accompanied by significant cost and risk of long-term toxicities that have not yet been identified.

Immunosuppressive Drugs

Immunosuppressive therapy for ITP has yet to be evaluated thoroughly; the overall effectiveness of these potent drugs is variable, and remissions achieved have been short-lived. Poor results were reported in children. Favorable results are nevertheless noteworthy, because they were obtained in refractory patients who had not responded to splenectomy or steroids.

Preliminary reports of successful treatment in refractory patients have been published using high-dose methylprednisolone and cyclophosphamide-based combination chemotherapy. Cyclophosphamide alone, either daily oral or pulse intravenous therapy, induced remissions in 16% to 55% of patients. However, this drug must be administered for several weeks before the platelet count rises and often must be continued for an indefinite period to maintain the remission, and side effects such as leukopenia and alopecia are often significant. Azathioprine, cyclosporin A, mycophenolate mofetil, actinomycin, and other immunosuppressive agents, either alone or in combination with corticosteroids, have variable success.

Vincristine and vinblastine, administered intravenously at weekly intervals, may be as effective as cyclophosphamide but act more rapidly, often increasing the platelet count within 7 days. In addition to their suppressive effects on cellular and humoral immune responses, these agents increase platelet production in both animals and normal human subjects. In ITP, their mechanism of action has been postulated to be inhibition of microtubule-dependent events required for monocyte-macrophage function.

Other Proposed Therapies

A number of other therapies have been reported to be successful in single case reports or in small series of patients. Danazol, an attenuated androgen, has been effective in increasing platelet counts in patients with ITP in doses ranging from 50 mg/day to 800 mg/day. The mechanism of action is postulated to be a danazol-induced reduction of Fc receptors on phagocytic cells. Long-term results indicate a final response rate of >40% at a median follow-up of 10 years with a reasonable safety profile. Recombinant α-interferon can increase platelet counts in up to 50% of patients when injected subcutaneously three times a week, and some responses were durable after stopping treatment.

Supportive Measures

Physical activity should be restricted to minimize the hazards of trauma, particularly head injury. Drugs, such as nonsteroidal anti-inflammatory drugs, that impair platelet function should be avoided. Blood loss should be treated as indicated, and platelet concentrates should be administered in the presence of significant bleeding. However, transfusions typically produce only a slight and transient increase in the platelet count, no doubt because of the rapidity with which they are destroyed in vivo. Platelet transfusions, nevertheless, may produce some increase in platelet numbers in many patients, often diminish bleeding for a time, and can be effective in the management of serious complications such as subarachnoid hemorrhage. They should be reserved for such life-threatening emergencies or for the immediate preoperative treatment of patients with serious hemorrhage before splenectomy. A single large dose of IVIG followed by a platelet transfusion can be effective in arresting hemorrhage in some critically ill patients. In most patients with platelet counts >50,000/µl, preoperative platelet transfusions are not indicated. Platelet transfusions should be avoided in patients with chronic ITP because of subsequent development of alloantibodies. Exchange plasmapheresis may be valuable in critically ill patients and may be particularly effective in children. Anovulatory hormones are useful when menorrhagia is a major complaint. Because of the risk of septicaemia, polyvalent pneumococcal vaccine, Haemophilus influenzae B vaccine, and quadrivalent meningococcal polysaccharide vaccine should be administered at least 2 weeks before elective splenectomy in both adults and children.

Immune Thrombocytopenia in Pregnancy

Both ITP and non-ITP may occur during pregnancy. Thrombocytopenia was present in 7% of women when they were admitted to hospital for a full-term delivery in a prospective 7-year study of 15,741 mothers and 15,932 newborns. Most platelet counts were between 100,000 and 150,000/µl, and 1% of women had platelet counts <100,000/µl. Thrombocytopenia was detected incidentally in the majority of women, and only 0.01% of their infants had fetal platelet
counts <50,000/µl. None of the infants had hemostatic impairment, and most mothers had normal or near-normal platelet counts by discharge. If the mothers had an obstetric or medical complication, the incidence of thrombocytopenia (<50,000/µl) in the infants was 0.35%. It is unclear when the incidental thrombocytopenia (called gestational thrombocytopenia) developed during pregnancy, and the etiology of this mild abnormality is likewise unknown. Antiplatelet antibody testing was not sufficiently specific to differentiate patients with gestational thrombocytopenia from those with ITP. Among those with maternal thrombocytopenia, 74% have incidental thrombocytopenia, and only 4% have ITP. It is therefore recommended that healthy women who have a platelet count of 70,000 to 150,000/µl at delivery require no specific treatment, and the mode of delivery should be determined only by obstetric indications.

A recent retrospective 11-year analysis of obstetric patients with ITP examined 92 women with ITP during 119 pregnancies. For most women, the pregnancy was uneventful, although women had moderate to severe bleeding in 25 pregnancies (21.5%). Women in 37 pregnancies received treatment to increase platelet counts. During delivery, 44 women received epidural analgesia without complications, with most having a platelet count between 50,000 and 149,000/µl. Most deliveries were vaginal (82.4%). Bleeding was uncommon at delivery. In most settings epidural analgesia is held if platelets are less than 80 to 90,000/µl.

Platelet autoantibodies in pregnant patients with ITP cross the placenta and can produce thrombocytopenia and clinical bleeding in the infant. During pregnancy, both maternal and infant health must be considered, and management of women with ITP diagnosed before or during the pregnancy is therefore more difficult and still controversial. Women with severe thrombocytopenia should be treated with IVIG or the lowest dose of steroids needed to maintain a platelet count >50,000 to 60,000/µl; it must be noted, however, that when mothers have been treated during pregnancy, changes in their platelet counts do not correlate with the fetal platelet counts when these have been sampled before and after treatment. When betamethasone or placebo was given for 4 weeks before delivery in a randomized trial, no differences were seen in either the maternal or infant platelet counts or the incidence of bleeding at delivery. Splenectomy during pregnancy may have higher complication rates, but it is not contraindicated. IVIG can be used before delivery to increase the platelet count rapidly. The safety of other forms of therapy used in nonpregnant ITP patients is uncertain.

At the time of delivery, it must be decided whether to deliver the infant by cesarean section or by vaginal delivery. When 474 infants were analyzed from series reported over a 20-year period, 10% of infants had platelet counts between 50,000 and 100,000/µl, and 15% had platelet counts <50,000/µl. Intracranial hemorrhage occurred in 3%, but no significant association existed between intracranial hemorrhage and mode of delivery. More recent data indicate that morbidity and mortality in infants with neonatal thrombocytopenia is lower than originally reported. Burrows and Kelton published a systematic review of pregnancy in patients with ITP, selecting only those series with more than 10 patients and those that included fetal platelet counts and infant outcome. They reported 288 live births and an incidence of fetal thrombocytopenia of 10% with platelet counts <50,000/µl and 4% with platelet counts <20,000/µl. There were no deaths and no cases of intracranial hemorrhage, and there was no difference in morbidity between cesarean sections and vaginal births. During the decade from 1990 to 2000, these cumulative totals from 13 prospective studies were 9% and 4%. Minor bleeding complications occurred in 3% of infants, and 2% had major bleeding complications.

Many studies have been done to determine maternal characteristics that may correlate with severe thrombocytopenia in the newborn and to help with decisions regarding method of delivery. To date, only the birth of a previously affected infant correlates with the incidence of neonatal thrombocytopenia. Other variables that were analyzed, such as the mother’s platelet count or prior splenectomy, were predictive in some studies but not in others. Fetal platelet counts might be able to predict newborn risks of bleeding, but scalp-vein platelet counts can be artificially low, and the incidence of complications associated with percutaneous umbilical blood sampling is higher than the incidence of postnatal major bleeding. In all these reports, it was also noted that the infant platelet count could fall for several days after delivery. It is therefore currently recommended that the mode of delivery should be determined solely by obstetric indications.

SECONDARY AUTOIMMUNE THROMBOCYTOPENIC PURPURA

Autoimmune thrombocytopenia can be associated with drugs and with several common diseases (i.e., collagen vascular disease, infections, lymphoproliferative disorders, and Graves disease). Secondary ITPs are discussed separately because of their unique features and the issues of diagnosis and management. ITP associated with human immunodeficiency virus infection is discussed in Chapter 64.
Autoimmune Thrombocytopenic Purpura Secondary to Drugs

Numerous drugs have been associated with ITP. In some cases, the evidence associating a given drug to ITP is circumstantial. However, a systematic review is available in which specific criteria were established to determine the likelihood of drug-induced ITP due to specific drugs (Table 47.6). The most common drugs with level 1 evidence are quinidine, quinine, rifampin, trimethoprim-sulfamethoxazole, danazol, methyl dopa (Aldomet), acetyaminophen, and digoxin. The most common drugs with level 2 evidence are gold, procainamide, carbamazepine, hydrochlorothiazide, ranitidine, and chlorpropamide. Heparin, which causes ITP in as many as 1% of patients, is discussed in Chapter 55.

Pathophysiology

Drug-induced platelet antibodies are the result of an idiosyncratic reaction that develops in only a small percentage of persons exposed to a drug. This ranges from an estimated 38 cases per 1 million exposures for trimethoprim-sulfamethoxazole to as many as 1 in 100 patients for gold salts, and 3 in 100 patients for true immune-mediated heparin-induced thrombocytopenia. It is not clear whether there are predisposing risk factors for most of the drugs that cause ITP, although evidence suggests that the risk of developing antibodies to gold salts depends on host HLA type, with the majority of patients studied expressing HLA-DR3 antigen.

Drug-induced antibodies may be complement- or noncomplement-activating antibodies that react with platelets, in either the absence (autoantibodies) or presence of drugs. The most completely studied antibodies are those that develop in response to quinidine/quinine and heparin. Most nonheparin drug-induced antibodies bind specifically to platelet membrane glycoproteins in the IIb/IIIa or the Ib/V/IX complex through the Fab portion of the antibody molecule (Fig. 47.2B). In contrast, antibodies to heparin bind to a heparin-platelet factor 4 complex, and the immune complex then binds to the platelet membrane via the Fc portion of the antibody molecule (Fig. 47.2C).

Most of the drug-induced antibodies are developed in response to the parent drug, and drug-dependent antibodies can be demonstrated in a variety of in vitro tests. In some cases, however, these tests are negative when the parent compound is present but positive if known metabolites are used instead of the parent compound. Antibodies against drug metabolites have been reported with acetyaminophen, para-aminosalicylic acid, naproxen, and trimethoprim-sulfamethoxazole.

Interferon-α             Vancomycin

Criteria\(^a,b\)

1. The candidate drug preceded thrombocytopenia, and recovery from thrombocytopenia was complete and sustained after the drug was discontinued.
2. The candidate drug was the only drug used before the onset of thrombocytopenia, or other drugs were continued or reintroduced after discontinuation of the candidate drug with a sustained normal platelet count.
3. Other etiologies for thrombocytopenia were excluded.
4. Re-exposure to the candidate drug resulted in recurrent thrombocytopenia.

\(^a\) Level 1 evidence met criteria 1-4.

\(^b\) Level 2 evidence met criteria 1-3.

Modified from publications by George et al. (references 162, 352-354).

Clinical Features

Drug-induced thrombocytopenia is associated with a heterogeneous clinical picture and varying degrees of bleeding. Thrombocytopenia and bleeding usually appear abruptly and may be severe. Mucosal membrane bleeding from all sites and oral hemorrhagic bullae may occur, and patients often develop fever, chills, nausea, vomiting, and fatigue as part of a prodrome to the bleeding.

Severe thrombocytopenia usually develops within hours in sensitized patients ingesting quinidine or quinine; however, a minimum of 6 to 7 days is required to initiate a primary immune response in individuals taking the drug for the first time. Some patients do not develop thrombocytopenia for months or years, a characteristic that seems to be more dependent on the host than the type of drug. The amount of drug that is required to cause thrombocytopenia is quite variable; however, even the amount of quinine present in a gin and tonic (15 mg) is sufficient to produce severe thrombocytopenia and bleeding in a patient who has been previously sensitized to quinine (“cocktail purpura”). After the drug is stopped,
platelet counts return to normal within days and usually are normal by 1 week. Thrombocytopenia induced by gold salts resolves more slowly, usually over weeks or months, because gold remains in the tissues.

Diagnosis

It is often difficult to make a definite diagnosis of drug-associated ITP because either the patient has taken the medication intermittently or a hospitalized patient is receiving more than one drug that may cause thrombocytopenia. Although it may be possible to demonstrate drug-dependent antibodies against the parent drug or its metabolites, this type of testing is beyond the scope of hospital laboratories. The readministration of the suspected drug in an attempt to confirm an etiologic relationship is not recommended as a routine diagnostic measure. Most of the level 1 drugs listed in Table 47.6 were demonstrated to cause immune-mediated thrombocytopenia because of patient response to an inadvertent in vivo challenge.

A detailed history, including all prescribed drugs, over-the-counter medications, and any herbal supplements, is of great benefit. Complete data from all English-language articles describing patients with assumed drug-induced thrombocytopenia have been catalogued on the Internet (http://www.ouhsc.edu/platelets/ditp.html).

Treatment

Ordinarily, no therapy is needed, because withdrawal of the offending drug is followed by recovery. IVIG and plasmapheresis may be helpful if life-threatening bleeding occurs. Many patients are treated with corticosteroids, and a normal platelet count is usually restored within 1 week. The major exception is gold-induced thrombocytopenia, which may persist for weeks or even months. British anti-Lewisite (dimercaprol) may accelerate the excretion of gold and speed recovery.

Autoimmune Thrombocytopenia in Systemic Lupus Erythematosus

Thrombocytopenia may complicate collagen vascular diseases and other disorders associated with disordered immunologic responses such as thymoma and myasthenia gravis. In most instances, the ITP in SLE appears to result from immunologic platelet injury and is identical to primary ITP in most respects.

From 5% to 15% of patients with ITP fulfill the criteria for diagnosis of SLE at the time of presentation. Other patients have a positive antinuclear antibody test when they are first diagnosed with ITP, and a small number of them may develop SLE within several years. Patients with high-titer antinuclear antibody in a speckled pattern and antibodies against native DNA and other nuclear antigens are the patients most likely to develop SLE. SLE is a chronic and debilitating disease, so it is important to identify such patients so therapy can be directed at all aspects of the autoimmune disease.

ITP in SLE patients may be the result of either specific platelet autoantibodies or immune complex deposition on platelets. Only a few studies have been reported in which the newest platelet antigen-capture autoantibody tests have been used, and in these patients, platelet autoantibodies to platelet membrane glycoproteins have been detected. Thrombocytopenia correlates with SLE disease activity but not the presence of antiphospholipid antibodies. These antibodies, which may be present in SLE or in otherwise healthy patients, also bind to platelet membrane glycoproteins or cross-reactive. Patients with ITP and SLE should be treated the same as patients with primary ITP, even though there are conflicting reports on the success rate of splenectomy in this population.

Immune Thrombocytopenia in Other Disorders

ITP has been reported in association with a number of other medical conditions, including infections, neoplasms, and thyroid disease, and it is unknown whether this increased platelet destruction involves antibody binding, immune complex deposition, and/or antibody-mediated complement activation.

ITP has been documented in patients with infectious mononucleosis, cytomegalovirus, varicella or zoster, hepatitis C, tuberculosis, and human immunodeficiency virus infections (discussed in Chapter 64). During the last several years, ITP was also reported in patients with H. pylori, particularly in Europe and Japan. Platelet counts may or may not normalize with treatment directed only at Helicobacter. The ASH guidelines
recommend that H. pylori infection be considered in all adults with ITP for whom eradication therapy would be undertaken if testing were positive.\textsuperscript{5}

ITP is a well-known complication of chronic lymphocytic leukemia,\textsuperscript{396} although it is not as frequent as autoimmune hemolytic anemia in these patients. It has also been reported in patients with other lymphoproliferative disorders including Hodgkin disease.\textsuperscript{397, 398, 399, 400} Thrombocytopenia in patients with a variety of solid tumors has also been thought to most likely be immune-mediated.\textsuperscript{401, 402}

Thrombocytopenia may accompany Graves disease and Hashimoto thyroiditis,\textsuperscript{403, 404, 405, 406} but it is not certain that it is immunologically mediated. Platelet-associated IgG has been increased when studied,\textsuperscript{406} but there may also be an element of enhanced reticuloendothelial phagocytosis.

**ALLOIMMUNE THROMBOCYTOPENIA**

Platelets express membrane-associated epitopes as a result of polymorphisms in discrete regions of the platelet membrane surface glycoproteins.\textsuperscript{407} No natural antibodies to human platelet antigens are known. Acquired platelet alloantibodies are of clinical importance in three circumstances: (a) Neonatal alloimmune thrombocytopenia (NAIT), which is the result of the placental transfer of alloantibodies formed by the mother to incompatible fetal platelet antigens,\textsuperscript{408} (b) posttransfusion purpura (PTP), a rare disorder in which the transfusion of platelet-containing blood products provokes the formation of alloantibodies that act as autoantibodies,\textsuperscript{409} and (c) passive transfer of platelet alloantibodies after transfusion from a multiparous or multiply transfused donor.\textsuperscript{410, 411, 412, 413}

Neonatal Alloimmune Thrombocytopenia

**Pathophysiology**

Immunologic thrombocytopenia in the newborn may result from the placental transfer of platelet antibodies formed as the result of active immunization of the mother by fetal platelet antigens. Pathophysiologically, such NAIT is similar to erythroblastosis fetalis. Thus, as a consequence of the inheritance by the fetus of platelet antigens lacking in the mother, alloantibodies are formed in the maternal circulation and cross the placenta, producing thrombocytopenia in the fetus. Antibodies can be detected as early as the 19th week, and thrombocytopenia has been found in utero by 20 weeks' gestation.\textsuperscript{414} Immunization to human platelet alloantigen (HPA)-1a (PlA\textsuperscript{A}, Zw\textsuperscript{A})\textsuperscript{415, 416, 417}, or HPA-5b (Br\textsuperscript{A}, Zav, Hc)\textsuperscript{418, 419}, is most common; however, other antigens have been detected and found to be responsible for occasional cases of NAIT (Fig. 47.2D).\textsuperscript{415, 416, 417, 418, 419, 420, 421, 422, 423, 424, 425, 426} One of the largest studies to date examined maternal sera for platelet-reactive antibodies in mothers of infants suspected of NAIT. Maternal HPA-1a (PlA\textsuperscript{A}) alloimmunization accounted for 79% of confirmed NAIT cases.\textsuperscript{427} The overwhelming majority of platelet polymorphisms found to date are caused by a single base-pair mutation leading to a single amino acid substitution in the polypeptide chain of the specific glycoprotein.\textsuperscript{428} Rarely, HLA antibodies are responsible.\textsuperscript{415, 418}

Alloimmunization to platelet antigens commonly develops during the first pregnancy and then recurs in >80% of patients during subsequent pregnancies. However, not all mothers who are missing the antigens presented by the fetus develop antibodies, and not all fetuses and neonates develop thrombocytopenia in spite of antibody development.\textsuperscript{418} HPA-1 mismatch is present in 1 in 50 births, yet NAIT occurs in only 1 in 1,000 to 2,000 births.\textsuperscript{414, 416, 417, 429} Maternal HLA Class II determinants appear to be important. A high incidence of maternal allotypes HLA-DR3 and HLA-DRw52a has been demonstrated in mothers isoimmunized to fetal alloantigen HPA-1\textsuperscript{A},\textsuperscript{417, 420} and a high incidence of HLA-DR6 has been reported in mothers sensitized to PLA-5b.\textsuperscript{418}

**Clinical Features**

Infants with NAIT are born with signs of purpura and severe thrombocytopenia. Thrombocytopenia usually is present at birth, but the platelet count may fall further during the postpartum period. Intracranial hemorrhage occurs in 20% to 30%, with one half of the episodes occurring in utero.\textsuperscript{431} An overall mortality rate of 6% to 14% has been reported.\textsuperscript{416, 419, 420} Thrombocytopenia usually resolves after 10 to 14 days. Platelet antibody titers during the second half of the pregnancy appear to correlate with the risk of thrombocytopenia or bleeding, or both, in NAIT.\textsuperscript{432, 433}

**Laboratory Diagnosis**

When infants are born with platelet counts <20,000 µl, NAIT must be suspected. Maternal plasma should be studied with paternal or neonatal platelets as targets; maternal (antigen-negative) platelets and paternal plasma are appropriate negative controls. NAIT is diagnosed when platelet antigen incompatibility is found between the parents, maternal antipaternal platelet antibodies are present, and the antibody detected corresponds to the incompatibility of platelet antigens that have been noted.
Posttransfusion Purpura

Alloantibodies that develop as a result of transfusion of incompatible platelets are responsible for the destruction of the transfused platelets. This is a frequently encountered problem in patients who have received multiple platelet transfusions. Rarely, however, severe thrombocytopenia in the recipient—that is, destruction of host platelets—is produced by the transfusion of incompatible platelets, and this potentially fatal reaction is known as PTP. PTP is characterized by abrupt onset of thrombocytopenia and bleeding that occurs 1 week after the transfusion of packed red blood cells. PTP has also been described after the transfusion of other blood components, including plasma.

The syndrome occurs most commonly in multiparous women who have been sensitized by pregnancy; however, previously transfused patients may also develop PTP. The antibody most commonly develops against PL	extsuperscript{A1} (HPA-1a) in PL	extsuperscript{A1} (HPA-1b) homozygous recipients, but the Bak (HPA-3a/HPA-3b), Pen (HPA-4a/HPA-4b), Br (HPA-5a/HPA-5b), and Nak	extsuperscript{A} polymorphisms have been implicated as well. The diagnosis of PTP is a clinical one, and physicians must therefore consider this diagnosis in any patient who develops thrombocytopenia within 3 to 14 days after transfusion of any blood product.

Prevention of NAIT In women with no personal or family history of NAIT, screening by platelet typing is currently not recommended. Maternal platelet antigen typing has been recommended for those with a sister whose pregnancy was complicated by NAIT or if personal or family history is suggestive of NAIT.

(e.g., neonatal thrombocytopenia of undetermined origin or fetal or neonatal intracranial hemorrhage of undetermined origin). In these cases, maternal and paternal platelet typing is performed simultaneously in order to look for incompatibility in the PHA-1 antigen system. Screening studies to detect neonatal thrombocytopenia during the first pregnancy have been limited to patients with known PL	extsuperscript{A1} incompatibility and an HLA allotype associated with an increased incidence of antibody formation. However, after the birth of one child with NAIT, subsequent pregnancies should be evaluated antenatally.

When maternal and paternal platelet typing document a risk of NAIT, after the index case, over 85% of that couple's subsequent fetuses will be at risk for NAIT. In the absence of any intervention, thrombocytopenia in the second affected fetus is always as or more severe than in the previous fetus/infant. Because of the high risk of in utero bleeding, the majority of which include intracranial hemorrhage, initiating therapy antenatally, rather than waiting until birth, has become standard. Previously, it was recommended that fetal platelet typing and platelet counts should be obtained at 20 weeks' gestation. If platelet incompatibility is noted and the infant is thrombocytopenic, in utero platelet transfusions or maternal treatment with IVIG should be instituted and maintained during the pregnancy.

In the United States, the most common therapies include infusion of IVIG and/or oral prednisone. Combination therapy with IVIG plus steroids may lead to higher platelet counts in women with a previous child with intracranial hemorrhage or a current fetus with platelet counts <20,000/µl. Fetal platelet transfusions have been advocated. However, because of the risk of fetal mortality, this has become a therapy of last resort, to be used only if IVIG or prednisone are ineffective. There is no consensus on whether fetuses affected by NAIT or at risk for NAIT should be delivered by cesarean section.

Because the use of serial fetal blood sampling procedures is clearly associated with an increased risk of fetal morbidity and mortality, some practitioners prefer to avoid performing fetal blood sampling and choose to treat empirically. The precise role of this invasive procedure remains to be determined. Studies of the cost-effectiveness of empiric treatment versus treatment directed by fetal blood sampling favored empiric treatment, decreasing perinatal deaths, although increasing the number of infants with long-term neurologic deficits. Follow-up studies of children after antenatal treatment for alloimmune thrombocytopenia show that general health and neurodevelopmental outcome is comparable to that of the general population. However, significantly more infections and hearing problems were observed in children who were not exposed to maternal IVIG treatment in comparison to children who were exposed to IVIG treatment or the normal population.

Posttransfusion Purpura

Severely thrombocytopenic children should be treated aggressively with IVIG and platelet transfusions of compatible irradiated platelets. Maternal platelets are usually obtained by pheresis, concentrated, irradiated, and transfused. Interestingly, a recent retrospective study reported that transfusion of platelet concentrates from random donors is an appropriate strategy in the management of unexpected severe NAIT predominantly in first pregnancies, pending the availability of compatible platelets. Prevention of NAIT In women with no personal or family history of NAIT, screening by platelet typing is currently not recommended. Maternal platelet antigen typing has been recommended for those with a sister whose pregnancy was complicated by NAIT or if personal or family history is suggestive of NAIT.

gp, glycoprotein; HPA, human platelet alloantigen.

^a Antigen appears to be distinct from PL^A1 (HPA-1a).

Modified from McCrae and Herman.\(^{409}\)

The pathophysiology of this rare but severe thrombocytopenia is still uncertain, but several hypotheses have been proposed: (a) Autologous platelets are destroyed because of binding of immune complexes to their surface; (b) recipient platelets acquire the phenotype of the donor's platelets because they bind soluble antigens from the transfused blood product, and the platelets are then destroyed by alloantibodies; and (c) exposure to foreign platelets in transfused products induces the formation of autoantibodies to the recipient's platelets.\(^{409}, 451, 452\)

PTP is self-limited, resolving within 1 to 3 weeks in most patients. Treatment with steroids, plasmapheresis, or IVIG may shorten the period of thrombocytopenia. Plasmapheresis is effective in 80% of patients,\(^{446}, 453, 454, 455\) but IVIG, in doses of 2 g/kg over 2 days, may be preferable because plasmapheresis requires central venous access with large-bore catheters and places the patient in danger of significant bleeding.\(^{456}, 457, 458\) Platelet transfusions should be reserved for life-threatening hemorrhage, because patients often develop a febrile reaction and an increase in platelet count is infrequent.

Chapter 48 Thrombotic Thrombocytopenic Purpura, Hemolytic-Uremic Syndrome, and Related Disorders

The various forms of thrombocytopenia discussed in this chapter share the common features of thrombocytopenia and hemolysis with characteristic schistocytes on blood smears (microangiopathic hemolytic anemia, MAHA) (Fig. 48.1). It is believed that thrombocytopenia results from consumption of platelets, whereas erythrocyte fragmentation and hemolysis are due to mechanical injury of the red blood cells by abnormal levels of shear stress.

Fragmentation of the red blood cells occurs in two types of clinical conditions: vascular devices such as prosthetic heart valves, ventricular assist devices, and extracorporeal oxygenator and microvascular stenosis.
In the absence of mechanical devices, fragmentation of the red blood cells signifies stenosis in the arteriolar microvasculature. This is because wall shear stress, determined by blood viscosity, flow rate, and the inverse of the luminal diameter to the third order, is at its highest in the arterioles and may be further increased to exceed the threshold level of red cell fragmentation when the lumen is narrowed. Furthermore, the red cells are likely to be entrapped in the presence of microvascular stenosis. The combination of abnormal shear stress and cell entrapment accounts for red cell fragmentation in patients with arteriolar stenosis. Due to their lower shear stress profile, it is unusual that stenosis in the venules, veins, or arteries is sufficient to cause red cell fragmentation.1

Arteriolar stenosis may result from one of five different types of pathology (Fig. 48.1): (1) von Willebrand factor (vWF)-platelet thrombosis, as typically observed in patients with thrombotic thrombocytopenic purpura (TTP) due to severe ADAMTS13 (a disintegrin and metalloprotease with thrombospondin type 1 motif, member 13) deficiency; (2) platelet fibrin thrombosis, as exemplified in patients with disseminated intravascular coagulopathy (DIC) but also may occur in a variety of other conditions; (3) tumor cell invasion of the microvasculature in patients with metastatic neoplasm; (4) microvascular vasculitis, as occasionally observed in patients with systemic lupus erythematosus and related autoimmune disorders or certain types of infections such as Rocky Mountain spotted fever and anthrax; and (5) thrombotic microangiopathy (TMA), as observed in patients with the typical shiga toxin-associated hemolytic-uremic syndrome (stx-HUS) following Escherichia coli infection, pneumococcal HUS, or atypical hemolytic-uremic syndrome (aHUS) due to defective regulation of the alternative complement pathway.

FIGURE 48.1. A scheme depicting how different types of pathology may lead to microvascular stenosis and the syndrome of thrombocytopenia and microangiopathic hemolysis (MAHA). Thrombotic microangiopathy may also lead to tissue edema and organ dysfunction by increasing vascular permeability. DIC, disseminated intravascular coagulopathy; CAPS, catastrophic antiphospholipid antibody syndrome; HELLP, hemolysis with elevated liver enzymes and low platelets; HIT, heparin-induced thrombocytopenia; HUS, hemolytic-uremic syndrome; PNH, paroxysmal nocturnal hemoglobinuria; Stx-HUS, shiga toxin-associated hemolytic-uremic syndrome; TTP, thrombotic thrombocytopenic purpura.

A comprehensive classification of microangiopathic disorders is listed in Table 48.1. This classification includes four groups: TTP, TMA due to defective complement regulation (aHUS), TMA due to other mechanisms, and MAHA due to other types of pathology. In TMA, organ dysfunction may result from thrombotic stenosis, which causes thrombocytopenia and MAHA; non-thrombotic stenosis, which causes MAHA but not thrombocytopenia; and/or abnormal vascular permeability, which causes tissue edema and cavitary effusions but not thrombocytopenia or MAHA. Due to multiple pathogenetic pathways, organ dysfunction or clinical disease severity in patients with aHUS or other types of TMA does not always closely correlate with thrombocytopenia or MAHA. TTP, stx-HUS, and aHUS are further discussed in this chapter.
TABLE 48.1 CLASSIFICATION OF MICROANGIOPATHIC DISORDERS

I. TTP: a disease with propensity to microvascular thrombosis due to ADAMTS13 deficiency
   - Acquired: autoimmune inhibitors of ADAMTS13
   - Hereditary: mutations of ADAMTS13

II. aHUS: a disease with propensity to TMA due to defective complement regulation
    A: Idiopathic aHUS
    - Mutations or genetic variants of CHF, MCP, CFI, CFB, C3, THBD, etc.
    - Autoantibodies to CFH, with or without CFHR1 genomic deletion
    B: Co-morbidity as a trigger of aHUS presentation in patients with the disease
    - Pregnancy, IV contrast, pancreatitis, infection, inflammation, surgery, trauma, etc.
    C: Co-morbidity causing defective complement regulation (e.g., CFH autoantibodies)
    - Hematopoietic stem cell therapy
    - Suspected, but not yet proven: HIV infection, systemic autoimmune diseases, drugs, etc.

III. TMA via other mechanisms
    - Shiga toxin-associated HUS: Shiga toxin-producing E. coli or Shigella dysenteriae
    - Microbial neuraminidases causing T-antigen activation (e.g., Streptococcus pneumoniae or influenza virus)
    - Angiogenesis inhibitor: e.g., bevacizumab
    - Undefined mechanisms: hematopoietic stem cell therapy, HIV infection, systemic autoimmune diseases, drugs (e.g., gemcitabine, mitomycin, quinine, calcineurin inhibitors*, cocaine, etc.) , severe hypertension**

IV. Other types of pathology
    - Microvascular thrombosis comprised of fibrin and platelets
    - DIC, CAPS, HELLP syndrome, HIT, PNH, etc.
    - Vasculitis:
    - Infectious diseases (e.g., Rocky Mountain spotted fever, anthrax)
    - Intravascular clusters of neoplastic cells
    - Intravascular devices:
    - Ventricular assist device, extracorporeal membrane oxygenator, prosthetic heart valves, etc.

ADAMTS13, a disintegrin and metalloprotease with thrombospondin type 1 motif, member 13; aHUS, atypical hemolytic-uremic syndrome; CAPS, catastrophic antiphospholipid antibody syndrome; CFB, complement factor B; CHF, complement factor H; CFHR1, complement factor H-related protein 1; CFI, complement factor I; DIC, disseminated intravascular coagulopathy; HELLP, hemolysis with elevated liver enzymes and low platelet count; HUS, hemolytic-uremic syndrome; HIT, heparin-induced thrombocytopenia; MCP, membrane cofactor protein (CD46); PNH, paroxysmal nocturnal
hemoglobinuria; THBD, thrombomodulin; TMA, thrombotic microangiopathy; TTP, thrombotic thrombocytopenic purpura; vWF, von Willebrand factor.

* Some patients are found to have aHUS with defective complement regulation.

** Severe hypertension may be a consequence of aHUS rather than cause of thrombotic microangiopathy

ACQUIRED THROMBOTIC THROMBOCYTOPENIC PURPURA

The current definition of TTP is based on the demonstration of autoimmune inhibitor for acquired TTP and genetic mutation of the ADAMTS13 gene for hereditary TTP. By this definition, TTP is a disease that is prone to, but does not always have, microvascular thrombosis, thrombocytopenia, microangiopathic hemolysis, or organ dysfunction.

This definition is different from the conventional diagnosis of TTP as a clinical syndrome. It requires the demonstration of ADAMTS13 inhibitors or mutations and encompasses patients who are asymptomatic and patients who do not have thrombocytopenia or microangiopathic hemolysis.

The problem of conventional TTP diagnosis based solely on clinical features is most clearly illustrated by the vast difference in the prevalence of severe ADAMTS13 deficiency among the patients in the Canadian Apheresis Group trial on the efficacy of plasma therapy and the patients in the Oklahoma TTP registry. Severe ADAMTS13 deficiency was detectable in more than 76% of the patients in the Canadian Apheresis Group trial, yet in less than 15% of the patients in the Oklahoma registry. Indeed, many clinical series of ‘TTP’ or ‘TTP/HUS’ included patients with atypical HUS or other causes of microangiopathic hemolysis, resulting in confusion in the diagnosis and management of patients presenting with microangiopathic hemolysis and thrombocytopenia.

Pathology

The pathology of TTP, as first described by Moschcowitz in 1925, is quite distinctive: widespread hyaline thrombi in the terminal arterioles and capillaries, accompanied by no or little endothelial injury or inflammation (i.e., microangiopathy) (Fig. 48.2A). The thrombi are present most extensively in the heart, pancreas, spleen, kidney, adrenal gland, and brain (mainly cerebral cortex) and are composed primarily of platelets and vWF (Fig. 48.2B). Small amounts of fibrin may be present surrounding or sometimes penetrating the amorphous or granular material. Glomerular microthrombi are usually spotty, and cortical necrosis of the kidney is uncommon in TTP. Fibrinoid necrosis and vascular or perivascular inflammatory cell infiltration are characteristically absent or minimal.
In chronic cases, the thrombi may be infiltrated by fibroblasts or converted to subendothelial deposits by proliferating endothelial cell lesions. Pseudoaneurysmal dilatation may also be present upstream of the stenosis or occlusion.

In the literature, some investigators have suggested that endothelial cell injury is prominent in TTP. A review of the clinical features in those reports suggests that those patients likely had shiga toxin-associated or atypical HUS rather than TTP.

Pathophysiology

Historically two schemes have been proposed to account for the microvascular thrombosis in TTP: endothelial cell injury and uncontrolled platelet aggregation. The scheme of endothelial cell injury is not consistent with the absence or paucity
of microangiopathy in TTP patients. The predominance of vWF and platelets in the thrombi and the integrity of vascular endothelial cells suggest that thrombosis results from dysregulation of vWF-platelet interaction in TTP.

vWF, a plasma glycoprotein derived primarily from vascular endothelial cells, supports platelet adhesion and aggregation at sites of microvascular injury under high shear stress conditions. Deficiency in vWF causes defective microvascular hemostasis and a bleeding diathesis in patients with von Willebrand disease.

vWF is synthesized in vascular endothelial cells as a disulfide-bonded polymer that is converted to a series of multimers in the circulation (Fig. 48.3). This conversion is mediated by repetitive cleavage at the Tyr1605-Met1606 bond by ADAMTS13.
polymer is cleaved by ADAMTS13. A repetition of this process converts a vWF polymer to a series of multimers in normal plasma. vWF is separated by SDS-agarose gel electrophoresis and visualized with a radio-labeled antibody to vWF. Lower panel: a scheme of vWF biosynthesis and proteolysis. A: Pre-pro-vWF with 2,813 amino acid residues. B: A dimer of pro-vWF with disulfide bonds near the C-terminus. C: In the Weibel-Palade bodies, a vWF polymer is formed through disulfide bonding near the N-terminus of vWF dimers and cleavage of the propeptide. D: Under the high shear stress conditions of the microcirculation, vWF is cleaved at the Tyr1605-Met1606 bond, generating dimers of the 140 kD and 176 kD fragments and a series of progressively smaller multimers.

vWF exists in a compact form with its cleavage sites and platelet binding sites cryptic. This explains why in a test tube vWF is not susceptible to cleavage by ADAMTS13 and is inactive in aggregating platelets. High levels of shear stress induce a conformational change of vWF, exposing its binding sites for platelet receptors (Fig. 48.4A). Due to its large molecular size and responsiveness to shear stress, vWF is uniquely capable of supporting platelet adhesion and aggregation under high shear stress conditions.

In the circulation, the activation of vWF by shear stress is prevented by ADAMTS13, which cleaves vWF whenever its cleavage sites are exposed by shear stress. The process of proteolysis is repeated during each cycle of circulation through the microvasculature, thereby converting vWF from a large polymer to a series of multimers while maintaining vWF in its compact inactive configuration (Fig. 48.4B).

A disruption in this proteolytic regulation of vWF occurs in TTP, in which ADAMTS13 deficiency, due to genetic mutation or autoimmune inhibitors, leads to incessant unfolding and activation of vWF by shear stress, resulting in vWF-platelet binding and microvascular thrombosis (Fig. 48.4C). This explains why a severe deficiency of ADAMTS13 can lead to microvascular thrombosis characteristic of TTP.

P.1080
circulation, vWF-platelet aggregation is prevented by ADAMTS13, which cleaves vWF whenever its cleavage sites are exposed by shear stress. This process maintains vWF in its compact inactive configuration while its size becomes progressively smaller. C. In the absence of ADAMTS13, vWF is relentlessly activated by shear stress, leading to vWF-platelet aggregation and microvascular thrombosis of TTP. Thrombosis increases the shear stress in the microcirculation, leading to further cycles of vWF-platelet aggregation.

Observations in patients with TTP reveal that vWF-platelet aggregation and thrombosis does not occur when the plasma ADAMTS13 activity level is greater than 10% of normal. On the other hand, a patient with ADAMTS13 activity less than 10% may be asymptomatic and may have a normal platelet count. This is because other factors such as platelet number, vWF level, shear stress profile in the circulation, and modifiers of vWF response to shear stress such as thrombospondin may affect the propensity to vWF-platelet aggregation when ADAMTS13 is deficient.

Distinction between Thrombotic Thrombocytopenic Purpura Disease and Its Complications

A patient with autoimmune inhibitors or genetic mutations of ADAMTS13 may be completely asymptomatic and have normal blood counts. Such asymptomatic individuals are considered to have TTP, the disease, and are prone to the development of microvascular thrombosis causing clinical features such as thrombocytopenia, microangiopathic hemolysis, neurologic deficits, and injury of other organs.

Animal Models of ADAMTS13 Deficiency

Animal models of severe ADAMTS13 deficiency have been created in mice by inactivation of the ADAMTS13 gene and in baboons by infusion of an inhibitory ADAMTS13 antibody. In both models, thrombi comprising vWF and platelets ensue in the arterioles. The findings in these animal models support the role of ADAMTS13 deficiency in causing microvascular thrombosis of TTP. Nevertheless, some mouse strains are phenotypically free of thrombosis. The difference in phenotypic severity among the mouse strains highlights the principle of epistasis in which the composition of other genes modifies the expression of a molecularly defined disease.

Interactions between von Willebrand factor and ADAMTS13

The vWF polypeptide comprises a series of homologous domains. The cleavage site of vWF, Tyr1605-Met1606, is located in the A2 domain, sandwiched between the A1 domain, which contains epitopes interacting with the platelet glycoprotein Ib, and the A3 domain, where a collagen-binding epitope is located (Fig. 48.5). This topographic arrangement facilitates the regulation of platelet thrombus formation, as cleavage of vWF at the A2 domain disengages the platelet from the vessel wall.

Structural studies confirm that shear stress induces vWF cleavage by altering the conformation of vWF. Narrow-angle neutron scattering studies of vWF in guanidine hydrochloride, which also promotes vWF cleavage by ADAMTS13, or after exposure to shear stress, shows that conformational change at the subdomain level is sufficient for proteolysis to occur. Unfolding of vWF to extended configurations at the multimeric level is not necessary for proteolysis.

ADAMTS13, comprising 1,427 amino acid residues, is a member of the ADAMTS metalloprotease family, which shares a conserved domain structure of metalloprotease (MP)-disintegrin (Dis)-thrombospondin type 1 repeat (TSR)-cysteine rich region (Cys) and spacer (Spa) domains. ADAMTS13 contains 7 additional TSR downstream of the Spa domain, followed by two unique CUB (complement C1r/C1s, Uegf, Bmp1) domains (Fig. 48.5).

ADAMTS13 is synthesized primarily in the stellate cells of the liver. ADAMTS13 may also be expressed, albeit at much lower levels by at least one to two orders, in the spleen and other organs. The localization of its biosynthesis to the stellate cells instead of hepatocytes may be instrumental in maintaining the ADAMTS13 activity in patients with hepatic insufficiency, as the stellate cells react to liver injury by activation and proliferation. The expression of ADAMTS13 in hepatic stellate cells and endothelial cells may be down-regulated by cytokines such as IFN-γ, TNF-α, and IL-4.
FIGURE 48.5. A scheme depicting the domain structures of von Willebrand factor (vWF) and ADAMTS13 and their interactions. The cleavage of vWF by ADAMTS13 involves exosite and catalytic interactions. It is believed that the exosite binding 1 occurs constitutively, whereas exosite binding 2 occurs only when the sequence in the A2 domain downstream of the scissile bond Tyr1605-Met1606 is exposed by shear stress. The exosite bindings orient the catalytic site of ADAMTS13 to attack the scissile bond of vWF (double-arrowhead red line). The inhibitors of thrombotic thrombocytopenic purpura (TTP) patients target the exosites of ADAMTS13 downstream of the metalloprotease domain. Expression of ADAMTS13 has been described in the renal glomerular podocytes and endothelial cells and vascular endothelial cells in culture. The ADAMTS13 expressed in renal glomeruli may cleave vWF before it is neutralized by autoantibodies, accounting for the generally milder renal injury observed in acquired versus hereditary TTP.

The metalloprotease domain of ADAMTS13 contains a catalytic 224-HEIGSFGLEHD-235 module characteristic of the ADAMTS proteases (conserved residues are underlined). Structural analysis has identified three surface exosites of ADAMTS13 in the Dis, Cys, and Spa domains that react with discrete epitopes of the vWF A2 sequence around and downstream of the Tyr1605-Met1606 scissile bond. The exosite bindings greatly enhance the efficiency of catalytic reaction between ADAMTS13 and vWF. The vWF scissile bond and the exosite binding sites of the vWF A2 domain are normally cryptic, only exposed by tensile force to initiate interaction with ADAMTS13. Another exosite in the TSR5-CUB region of ADAMTS13 may interact with a constitutively exposed epitope in the N-terminal D4-CK region of vWF. This C-terminal binding may facilitate the interaction of the exosites upstream.

Alteration of von Willebrand Factor Multimers in Thrombotic Thrombocytopenic Purpura

The involvement of vWF in the pathophysiology of TTP was first suggested by the intriguing observation that large multimers disappear during acute crisis of chronic relapsing TTP and yet ultra-large multimers are present during remission. The complexity of vWF multimers in TTP is due to two opposing processes acting upon plasma vWF in patients with ADAMTS13 deficiency: deficiency of ADAMTS13 leading to the presence of ultra-large multimers; and the activation of vWF by shear stress leading to the consumption and depletion of ultra-large and large multimers.

Three types of vWF multimer abnormalities are observed in TTP (Fig. 48.6). A shift of vWF to ultra-large forms occurs when ADAMTS13 activity is <20% to 30%; at this stage, no platelet thrombosis occurs (lane 1). The ultra-large and large multimers are partially depleted when ADAMTS13 is <10% and vWF-platelet aggregation begins to occur (lane 2). The ultra-large multimers are depleted and the large multimers are further decreased or depleted in patients presenting with extensive thrombosis and severe thrombocytopenia (lane 3).

The vWF changes in TTP are a dynamic process, as the multimers in a plasma sample represent a snapshot of the balance of the two changes acting in opposite directions. Transition from one multimer pattern to another occurs swiftly during the course of the disease, reflecting the changes in ADAMTS13 level and the process of vWF-platelet aggregation.
von Willebrand factor (vWF) abnormalities in thrombotic thrombocytopenic purpura (TTP) reflect the balance of underlying ADAMTS13 deficiency and vWF-platelet thrombosis. Three types of vWF abnormalities are detected in TTP during its course: Lane 1: A shift of vWF to ultra-large forms occurs when ADAMTS13 activity is <20-30%. Lane 2: The ultra-large and large multimers are decreased when ADAMTS13 is <10%, and vWF-platelet aggregation begins to occur. Lane 3: The ultra-large multimers are depleted and the large multimers are further decreased in patients presenting with extensive thrombosis and severe thrombocytopenia.

In other types of microangiopathic hemolysis such as shiga toxin-associated or atypical HUS, depletion of the large vWF multimers also occurs. In these conditions, the loss of large multimers is due to excessive cleavage of vWF by ADAMTS13 under abnormal shear stress conditions.

Other Pathogenic Mechanisms in Thrombotic Thrombocytopenic Purpura
Various hypotheses have been proposed to explain the thrombosis of TTP, including defects in fibrinolytic activity or prostacyclin homeostasis, increased circulating thrombomodulin, abnormal tissue plasminogen activator or plasminogen activator inhibitor-1 levels, antiendothelial cell antibodies, immune complexes, platelet aggregating proteins, anti-CD36 antibodies, calcium-dependent cysteine proteases, endothelial cell apoptotic factors, and activation of the complement system. These observations are preliminary, represent secondary changes, or are not specific for TTP. Immune complexes and activation of the complement system detected in patients with TTP may result from ADAMTS13 binding with its antibodies.

Causes of ADAMTS13 Deficiency
Severe ADAMTS13 deficiency results primarily from autoimmune inhibitors of the protease, although in a small number of patients the deficiency is the consequence of homozygous or, more commonly, compound heterozygous mutations of the ADAMTS13 gene.
The ADAMTS13 activity level is also decreased in various pathologic conditions such as sepsis, malarial infection, multiorgan failure, major surgery, DIC, metastatic neoplasm, and pregnancy. In these conditions, the decrease in ADAMTS13 levels is mild to moderate, and generally not sufficient to cause platelet aggregation. Yet the decrease induced by infection, surgery, or pregnancy may be sufficient to precipitate vWF-platelet aggregation and thrombosis in patients with pre-existing ADAMTS13 mutations or inhibitors, giving rise to the suspicion that these conditions cause TTP.

The ADAMTS13 activity is also less stable in pathologic samples, yielding falsely low ADAMTS13 levels if the samples are not properly handled.

Autoimmune Inhibitors of ADAMTS13

In patients with acquired TTP, which accounts for >95% of TTP cases, deficiency of ADAMTS13 results from autoimmune inhibitors of the ADAMTS13 protease. In most cases of acquired TTP the causes of the autoimmunity are unknown. It is speculated that an otherwise innocuous infection may induce autoimmune reaction to ADAMTS13 in genetically susceptible individuals. Indeed 10% to 40% of TTP patients exhibit positive autoimmune reactions to other antigens, suggesting they have defective immune regulation. Deranged immune regulation is consistent with the finding that the HLADRB1*11 allele is overrepresented among patients with acquired TTP.

Ticlopidine therapy increases the risk of developing ADAMTS13 antibodies by 50- to 300-fold. The antibodies occur between 2 to 8 weeks after institution of ticlopidine therapy, respond to plasma exchange and discontinuation of the culprit drug, and generally do not recur. Although another anti-platelet thienopyridine, clopidogrel, has also been implicated, an association between clopidogrel and TTP has not been confirmed.

HIV infection has been associated with TTP. It is estimated that the risk is increased by 35-fold among patients not being treated with antiretroviral therapy. This higher risk may be related to the predisposition of HIV-infected individuals to autoimmunity.

An ADAMTS13 polymorphism (R1060W) is reportedly more prevalent in acquired TTP patients than in the population, raising the speculation that certain ADAMTS13 polymorphisms may predispose the affected individuals to develop ADAMTS13 inhibitors. The validity of this association remains to be confirmed.

ADAMTS13 Mutations

DNA sequence analysis reveals that hereditary TTP patients have compound heterozygous or, less commonly, homozygous mutations of the ADAMTS13 gene on chromosome 9q34. More than 80 mutations, including nonsense, missense, frame-shifting insertion or deletion, and splicing mutations, have been detected in patients with hereditary TTP. Only a few mutations have been detected in seemingly unrelated families. One mutation, 4143insA, has been detected in at least 15 patients in central-northern Europe, Turkey, and Australia that appear to share a common haplotype.

More than 25 polymorphisms have also been detected in the coding sequence of ADAMTS13. One polymorphism, P475S, common among Japanese (5%), Koreans (4%), and Chinese (1%), makes the ADAMTS13 variant more susceptible to inhibition by urea, which is used in some ADAMTS13 assays. It yields falsely low ADAMTS13 activity levels if urea-based assays are used. Certain cis-combinations of polymorphisms or mutationpolymorphism may result in severe ADAMTS13 deficiency.

Characteristics of the Inhibitors

In most patients the levels of the ADAMTS13 inhibitors are low (<10 U/ml), and often further decrease to undetectable levels after a few weeks or months. Occasionally the inhibitor level may surge to very high levels.

The ADAMTS13 inhibitors of TTP are primarily IgG, with IgA and IgM antibodies detectable infrequently. The VH1-69 germline heavy chain gene appears to be used most frequently in producing the ADAMTS13 antibodies. All four subclasses of IgG have been detected, although IgG4 appears to be the most prevalent, detectable in ≥90% of the patients according to one study.

Targets of the ADAMTS13 Inhibitors

The cysteine-rich region and spacer domain are an integral part of the epitopes of ADAMTS13 reacting with the inhibitors of TTP patients. ADAMTS13 variants truncated upstream of the cysteine-spacer domain, but not those truncated downstream, exhibit markedly decreased but detectable vWF cleaving activity that is not suppressible by the inhibitors of patients with TTP. This decreased activity is consistent with the existence of critical exosites in the deleted domains.
Such nonsuppressible ADAMTS13 species may be exploited to overcome the therapeutic difficulty posed by ADAMTS13 inhibitors.

Further mapping studies show that residues R660, Y661, and Y665 in the spacer domain are critical for binding with vWF A2 domain sequences. They are also the target of TTP inhibitors. Substitution of residues Arg660, Tyr661, or Tyr665 in ADAMTS13 with Ala abolishes the binding targets of ADAMTS13 inhibitors. Intriguingly, two vWF variants with substitutions of these three residues exhibit increased vWF cleaving activity by several fold. Such “super” variants of ADAMTS13 may be potential candidates as a replacement therapy for patients with TTP, although immune responses to these foreign proteins may be a concern.

Some studies found that TTP antibodies may also target other epitopes downstream of the spacer domain. However, it remains unclear whether these antibodies contribute to ADAMTS13 deficiency in TTP patients. 

Clinical Presentation
The incidence of TTP is estimated to be 2 to 15 cases per 1 \times 10^6 person-years. The broad range of the observed incidence rates is likely due to differences in demographics, particularly the prevalence rate of HIV infection in the population.

![FIGURE 48.7. Progression of thrombotic complications in thrombotic thrombocytopenic purpura (TTP). When ADAMTS13 decreases below the threshold level, microvascular thrombosis begins to occur. In most patients, TTP evolves progressively from ADAMTS13 deficiency to thrombocytopenia, microangiopathic hemolytic anemia (MAHA), fleeting neurologic deficits (TIA), stroke, altered mental status, seizures, and death if it is not treated. Occasionally, a patient may be detected at the thrombocytopenia stage when a CBC is ordered for other reasons. TTP may also present in forme fruste, with microvascular thrombosis causing TIA or stroke before thrombocytopenia or MAHA occurs. ΔMS, altered mental status.](image)
the plasma ADAMTS13 level, eventually leading to microvascular thrombosis, thrombocytopenia, microangiopathic hemolysis, and organ dysfunction (Fig. 48.7).

The duration of asymptomatic ADAMTS13 deficiency is quite variable, ranging from a few days to years. Serial monitoring of patients with a history of acquired TTP suggests that the plasma ADAMTS13 activity level may fluctuate for weeks to months before decreasing to less than 10% of normal and causing thrombosis.

Thrombocytopenia is detectable when platelet consumption exceeds compensatory platelet production. The stage of thrombocytopenia without overt hemolytic anemia may last for days to months, and the course of TTP at this stage is not invariably downhill; some patients may spontaneously revert to a normal platelet count. The patients at this stage may be given the incorrect diagnosis of immune thrombocytopenic purpura (ITP). On the other hand, infection, surgery, or pregnancy may worsen microvascular thrombosis in patients with subclinical ADAMTS13 deficiency, giving rise to the clinical impression that TTP is triggered by these events. Neurologic complications typically, albeit not invariably, present later, when thrombocytopenia is profound and microangiopathic hemolysis is evident.

Most of the patients have no other significant medical history and begin to notice ill-defined symptoms such as headache, dizziness, and fatigue that are often considered insignificant until more serious complications such as profound fatigue, focal neurologic deficits, syncope, mental status changes, or seizures ensue. Less frequently, a patient may present with abdominal pain, nausea, and vomiting, with or without pancreatitis, or chest pain due to myocardial infarction, or even sudden death.

Advanced renal failure causing oliguria, anuria, fluid retention, electrolyte abnormalities, or uremia is rare in acquired TTP. The creatinine generally increases only minimally. When advanced renal failure occurs in a patient with acquired TTP, it is likely due to other causes.

Thrombotic Thrombocytopenic Purpura without Microangiopathic Hemolysis or Thrombocytopenia

Thrombocytopenia and microangiopathic hemolysis are not invariably present at the time of acute presentation (Fig. 48.7). Relapse of TTP is also increasingly diagnosed before microangiopathic hemolysis ensues.

Until recently, TTP presenting with acute stroke or transient ischemic attack without overt microangiopathic hemolysis was diagnosed only in retrospect after the patients went on to develop thrombocytopenia and microangiopathic hemolysis. ADAMTS13 assays greatly facilitate the diagnosis of atypical TTP.

Hereditary Thrombotic Thrombocytopenic Purpura

Also known as Schulman-Upshaw syndrome or chronic relapsing TTP, hereditary TTP is rare, accounting for <5% of all TTP cases. Because the diagnosis is not recognized in milder cases, the incidence is likely higher than presently appreciated.

Hereditary TTP typically has its initial manifestations during the neonatal period, but historically is often not recognized until later in life. Some of these patients have siblings who died before birth presumably due to TTP complications. Milder cases may present with thrombotic complications or have their disease recognized later in their life.

In a typical case, the affected neonate is born with meconium stain or presents within a few hours after birth with neonatal distress, jaundice, and thrombocytopenia. Hemolysis may not be severe and schistocytes on blood smears may be overlooked. Occasionally, serious complications such as seizures and mental obtundation may occur.

The symptoms typically improve immediately after blood transfusion or exchange transfusion performed unknowingly for thrombocytopenia or hyperbilirubinemia. Consequently, the neonates may be discharged from the hospital without a correct diagnosis, only to present with complications of the disease weeks or years later.

Like most genetic disorders, hereditary TTP varies in its severity. Many patients with hereditary TTP invariably develop hematologic or other complications if not treated regularly with plasma infusion every 2 to 4 weeks. Others have no or only subtle symptoms and maintain normal or mildly subnormal platelet counts and develop more serious complications only intermittently. The severity may also vary during the lifetime of individual cases, with or without apparent exacerbating conditions such as pregnancy.

The thrombotic process may cause focal neurologic deficits, seizures, pancreatitis, or renal failure. Of the patients not receiving regular plasma infusion, 10%-20% of the cases develop at least one episode of acute renal failure requiring dialysis during their course. The renal failure is reversible if the patients promptly receive plasma infusion. Chronic renal failure occurs in approximately 10% of the patients not being regularly treated with plasma infusion, likely a result of cumulative microinfarcts in the kidney.
The propensity to acute and chronic renal disease in hereditary TTP is quite different from its rarity in acquired TTP. It is speculated that local expression of ADAMTS13 in renal glomerular podocytes and endothelial cells\(^\text{20}\) may provide protection against vWF-platelet aggregation before its activity is suppressed by the inhibitors. Such protection is not present in patients with genetic ADAMTS13 mutations. Rarely renal failure may occur because the patient also has concurrent atypical HUS.\(^\text{81}\)

**Laboratory Findings**

In de novo TTP cases presenting at the emergency service, the diagnosis is typically raised by the laboratory findings of severe thrombocytopenia and hemolysis with the presence of schistocytes on blood smears. The haptoglobin level is decreased or undetectable. Other common laboratory tests for assessment of hemolysis, including reticulocyte count, LDH, and indirect bilirubin are often but not invariably abnormal. In chronic cases, hemolytic anemia may predominate, as active platelet consumption is masked by compensatory thrombopoiesis.

As mentioned above, a patient with TTP may have no symptoms or may present with acute focal neurologic deficits without thrombocytopenia and/or microangiopathic hemolysis. Therefore, absence of thrombocytopenia or microangiopathic hemolysis in laboratory tests does not exclude the diagnosis of TTP.

Hematuria and proteinuria reflect renal glomerular thrombosis. The increase in the creatinine level is minimal in most cases. This is consistent with the pathologic findings that the kidney is minimally affected and its architecture is well preserved in TTP patients at autopsy.

Overt renal failure causing hypertension, fluid retention, electrolyte derangement, oliguria, or anuria favors the diagnosis of typical or atypical HUS over autoimmune TTP, unless there is a concurrent renal disorder. As mentioned above, acute and chronic renal failure may occur in patients with hereditary TTP.

Imaging studies such as CT or MRI are often requested for neurologic dysfunction. In most cases, the studies yield negative results or reveal only subtle ischemic changes, although occasionally a TTP patient may present with macrovascular ischemic strokes detectable by conventional imaging studies. It is speculated that in such cases the macrovascular thrombosis may result from thrombotic injury of the vasa vasorum.

The literature includes reports of “TTP” case series with a high percentage showing abnormal CT or MRI findings. However, a review of cases in these reports reveals that most of these patients likely had typical or atypical HUS rather than TTP.

Abnormal electrocardiograms with nonspecific ST-T wave changes and elevated CPK or troponin levels are common. Occasionally thrombosis may affect large coronary arteries leading to myocardial infarction. Cardiac arrhythmia is uncommon. Electromechanical dissociation, heart failure, or pulmonary infiltrates or hemorrhage occur in advanced, pre-terminal cases.

The amylase and lipase levels may be elevated. Abnormal liver function is rare. Abdominal CT scans may detect focal pancreatitis, intestinal wall or mesenteric thickening, or stranding due to ischemia or infarction.
FIGURE 48.8. Plasma ADAMTS13 activity is undetectable in patients with thrombotic thrombocytopenic purpura (TTP). Patients (338 cases) presenting with thrombocytopenia and microangiopathic hemolysis segregate in two nonoverlapping groups based on their plasma ADAMTS13 activity levels. Severe ADAMTS13 deficiency defines the diagnosis of TTP in 219 patients (65%), of which 191 had autoimmune ADAMTS13 inhibitors and 28 had genetic mutation as the cause of the deficiency. ADAMTS13 activity is detectable in some patients after receiving plasma or blood transfusion (TTP tx). During remission, (TTP rem) most patients continue to have decreased ADAMTS13 activity levels, consistent with the chronic nature of their disease. The two upper dashed lines encompass the normal range of plasma ADAMTS13 activity. The lowest line marks the detection limit of the assay at 10%.

ADAMTS13 Activity Levels

Among patients presenting with thrombocytopenia and microangiopathic hemolysis, only TTP patients have severe ADAMTS13 deficiency (less than 10%), whereas patients with other disorders have detectable ADAMTS13 levels (Fig. 48.8). ADAMTS13 may be detectable if the assay is performed after the patients receive plasma or blood transfusions. The ADAMTS13 activity level remains decreased in most patients during their remission, suggesting that the autoimmunity is active. Severe ADAMTS13 deficiency provides the diagnosis of TTP in the patients with co-morbidities in whom the diagnosis would otherwise be difficult to make.

The assay used to obtain the data presented in Figure 48.8 uses purified vWF as the substrate and SDS-PAGE to detect the proteolytic products. This assay is technically demanding and not practical for use in clinical laboratories. Various assays using vWF peptides spanning the scissile bond have been developed for analysis of ADAMTS13 activity in clinical laboratories. The assays differ in their performance and reliability and may not provide a definitive diagnosis or exclusion of TTP.82, 83, 84, 85, 86, 87, 88

Because some clinical assays may yield falsely high or low values of ADAMTS13, the diagnosis of TTP requires corroboration of the ADAMTS13 test results with clinical and other laboratory data.

ADAMTS13 Inhibitors

Inhibitors of ADAMTS13, measured by mixing patient and normal plasma samples, are detectable in 80% to 90% of the acquired TTP patients. A negative test for ADAMTS13 inhibitors does not exclude the presence of ADAMTS13 inhibitors. In such patients, the presence of inhibitors may be inferred if the increase of the ADAMTS13 activity level is less than expected after plasma therapy, or if the ADAMTS13 activity recovered to >10% during remission.

ADAMTS13 Antibody and Antigen Assays

Assays have been developed to measure ADAMTS13 antigen and antibody levels in enzyme-linked assay formats. These solid-phase microtiter plate-based assays have limited utility in practice. The antigenic assay detects free ADAMTS13 as well as ADAMTS13/inhibitor complex, yielding low ADAMTS13 antigen levels in <50% of TTP patients.89 The ADAMTS13 antibody assay is highly
sensitive (>90%) for acquired TTP but may yield false-positive results in 5% to 10% of individuals without ADAMTS13 antibodies.\textsuperscript{90, 91}

ADAMTS13 Activity Levels during Plasma Therapy and Remission

ADAMTS13 activity assays are used not only for initial diagnosis of TTP, but are also used to assist management during plasma therapy and clinical remission.\textsuperscript{43}

In general, vWF-platelet aggregation does not occur when ADAMTS13 activity is >10% of normal. Thus, in a patient with persistent thrombocytopenia or declining platelet counts, an ADAMTS13 activity >10% of normal, either at initial presentation or during plasma therapy, precludes TTP as the cause of the low platelet count, and requires a search for other causes.

At the end of plasma therapy and during remission, persistently low (<10%) or steadily declining ADAMTS13 levels connote a high risk of immediate or impending relapse.

Hereditary Thrombotic Thrombocytopenic Purpura

The ADAMTS13 activity level should be ≤10% and the inhibitor and antibody tests should be negative in patients with hereditary TTP. Falsely-positive antibody results may cause confusion. Improvement of the ADAMTS13 level to greater than 10% during remission excludes the diagnosis of acquired TTP.

Familial studies may be performed to show that the parents have partial ADAMTS13 deficiency.\textsuperscript{59} In practice, familial studies may be limited in the power to distinguish carriers from normal individuals.

Differential Diagnosis

Although the diagnosis of TTP depends on the demonstration of severe ADAMTS13 deficiency, it is essential to exclude other causes of microangiopathic hemolysis as listed in Table 48.1. On the other hand, the presence of a co-morbidity does not preclude the diagnosis of TTP.

A complete history and physical examination should be accompanied by appropriate laboratory tests such as ELISA or PCR tests for shiga toxins in the stool; blood or viral cultures or PCR analysis for pneumococcal or other bacterial or viral infections; autoimmune serology tests for lupus, scleroderma, and related autoimmune disorders; coagulation profile such as PT, PTT, fibrinogen, D-dimer assays, and additional clotting factor assays for disseminated intravascular coagulopathy; MRI for mental status changes; CT scan or other imaging studies and tissue biopsies for metastatic neoplasm; and flow cytometry for paroxysmal nocturnal hemoglobinuria.

Advanced renal failure, hypertension, and complications of abnormal vascular permeability such as brain edema, pleural or pericardial effusions, pulmonary edema, acute respiratory distress syndrome, ascites, and anasarca are rare in TTP. Any of these complications at presentation or during the course favors the diagnosis of thrombotic microangiopathy due to atypical HUS or other etiologies.

Management and Prognosis

Prompt plasma exchange is critical to prevent serious complications or death from TTP. The principles of management for patients with TTP are summarized in Table 48.2.

Plasma Therapy

Before plasma exchange or infusion was introduced in the 1970s,\textsuperscript{92, 93} more than 90% of patients died after presenting with symptomatic TTP. Plasma exchange and plasma infusion are the only therapies with proven efficacy for TTP presenting with thrombocytopenia and microangiopathic hemolysis.\textsuperscript{2} With these treatments, a mortality rate of 10% to 20% and 40% to 50% is expected, respectively.

---

**TABLE 48.2 PRINCIPLES OF MANAGEMENT FOR THROMBOTIC THROMBOCYTOPENIC PURPURA (TTP)**

- High index of suspicion is essential for patients presenting with thrombocytopenia or TIA/stroke.

Some patients may not have thrombocytopenia or microangiopathic hemolysis at presentation.

- Prompt treatment is critical to prevent serious complications and death.

- Daily plasma exchange is the therapy of choice for acquired TTP presenting with active thrombosis.
- Plasma infusion is used as an emergent substitute until plasma exchange is available.
- ADAMTS13 activity assay should be obtained before the patients receive any blood products.
- The diagnosis should be re-assessed during the course of therapy.
- Monitoring of ADAMTS13 during plasma therapy and remission may help clinical assessment.

For patients with persistent thrombocytopenia, ADAMTS13 >10% should suggest other causes of thrombocytopenia.

Monthly ADAMTS13 monitoring may detect impending relapses.

- Rituximab therapy should be considered for patients
  - Unable to wean off plasma exchange due to persistent and severe ADAMTS13 deficiency.
  - With persistent and severe ADAMTS13 deficiency during clinical remission.
  - Exhibiting a trend of declining ADAMTS13 levels.

Hereditary TTP
- Plasma infusion is effective for patients presenting with acute symptoms.
- Plasma exchange is used if the patient has renal failure or fluid overload.

For most patients, plasma therapy every 2-3 wk prevents acute crisis, strokes, and renal failure.

Plasma exchange is typically performed daily at 1-1.5 total plasma volumes until the platelet count is normal, then gradually tapered to ensure the platelet count is stable before the therapy is discontinued. It is believed that plasma exchange therapy removes antibodies and replenishes the deficient ADAMTS13.

Serial analysis shows that the plasma ADAMTS13 activity level often fluctuates in the first several weeks before it gradually stabilizes to a steady-state level. This explains why the response to plasma therapy may be unsteady for weeks to months and why it is important to monitor the blood counts closely after plasma exchange therapy is tapered.

ADAMTS13 levels persistently less than 10% of normal at the end of plasma therapy indicate a high risk of early relapse. On the other hand, a measurable ADAMTS13 level at the end of plasma therapy does not preclude the possibility that levels will subsequently decrease and cause later relapse. Thus, serial ADAMTS13 analysis is more informative than single tests.

Plasma infusion has the advantage that it does not require a large venous catheter and special equipment. Its efficacy is limited by the risk of fluid overload. Plasma infusion is used primarily as an emergent substitute until plasma exchange is instituted.

Cryoprecipitate-depleted plasma has been advocated as a more effective alternative of fresh-frozen plasma because it lacks large vWF multimers. However, two small randomized-controlled trials failed to demonstrate that the use of cryoprecipitate-depleted plasma is superior to fresh-frozen plasma as initial replacement therapy.

Acquired TTP is a chronic autoimmune disease punctuated with episodes of acute exacerbation. The ADAMTS13 level during clinical remission is quite variable, ranging from normal to undetectable. Normal ADAMTS13 activity levels during remission do not preclude the risk of future relapses. Serial monitoring may detect trends of declining ADAMTS13 levels before the patients develop symptomatic relapses, providing a window for immunosuppressive intervention before a relapse occurs.

Immunosuppressive Therapy

Plasma therapy does not address the underlying ADAMTS13 autoimmunity of TTP. Patients are able to achieve sustained remission primarily because the inhibitors spontaneously decrease, allowing the recovery of the ADAMTS13 activity above the threshold level. Nearly all patients will experience at least one relapse in their later lives. Some patients develop refractory disease after years of quiescent periods or several sporadic relapses.
For patients who cannot be weaned off plasma exchange due to persistent ADAMTS13 deficiency, suppression of B-cells with rituximab, a chimeric monoclonal antibody to CD20, induces clinical remission in approximately 70% to 90% of the patients. Rituximab increases the ADAMTS13 level by suppressing, but not necessarily eliminating, the ADAMTS13 inhibitors. A small increase in the ADAMTS13 activity level to 10% or higher is sufficient to induce clinical remission, allowing the patient to be weaned off plasma therapy. Rituximab is less effective in patients with high ADAMTS13 inhibitor levels.

Rituximab may decrease the risk of immediate relapse in patients with severe ADAMTS13 deficiency entering or during remission. It may also be used pre-emptively to avert relapses in patients exhibiting a trend of declining ADAMTS13 activity levels during remission. The efficacy of rituximab lasts for several months to a few years, with a median remission duration ~1.5 years. Patients may be re-treated with rituximab when their plasma ADAMTS13 activity begins to show a steady decline. The major side effects of rituximab include allergic reaction and reactivation or exacerbation of viral infections such as hepatitis B and progressive multifocal leukoencephalopathy.

Cyclosporin may be efficacious, but the experience of using cyclosporine in TTP patients remains limited. Splenectomy, which decreases the number of B-cells and immunocytes, has been recommended for patients unable to be weaned off plasma exchange or who experience frequent relapses. With rituximab demonstrating high response rates, splenectomy is performed less frequently. Other immunosuppressive therapies that have been used in TTP include corticosteroids, vincristine, cyclophosphamide, and azathioprine. These therapies are generally less effective than rituximab and more likely to cause serious side effects.

Antiplatelet Agents

For most patients, adding antiplatelet drugs such as aspirin, diprydamole, ticlopidine, or clopidogrel is unlikely to improve the response to plasma therapy. These drugs may prevent relapses in patients whose ADAMTS13 levels are low enough to cause platelet thrombosis. Nevertheless, the response to antiplatelet therapy is unreliable.

Hereditary Thrombotic Thrombocytopenic Purpura

Hereditary TTP responds to 7.5-10 ml fresh-frozen plasma per kilogram of body weight. Plasma exchange therapy is reserved for patients with renal failure. Inasmuch as thrombotic complications are unpredictable and may result in serious sequelae such as chronic renal failure or strokes, maintenance plasma therapy is recommended for most patients with hereditary TTP. The regimen should be tailored to prevent not only acute symptomatic crisis but also the development or progression of chronic organ injury. To achieve these goals, maintenance of normal platelet counts and prevent acute exacerbations. For patients not receiving maintenance therapy, serial monitoring of CBC, renal function, and urinalysis is recommended.

Special Considerations: Thrombotic Thrombocytopenic Purpura in Pregnancy

An association between pregnancy and TTP has been suspected, but never confirmed. Because TTP affects women in their reproductive years, it may occur co-incidentally during pregnancy. Patients presenting with TTP during pregnancy should be treated as other patients with plasma exchange, and with tapering of the treatment to be guided by serial ADAMTS13 levels.

A more difficult challenge is counseling and management of women with a history of TTP who desire pregnancy. Pregnancy progressively decreases ADAMTS13 levels by 30% at term, and by nearly 65% if the pregnancy is complicated with preeclampsia or the HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome. Pregnancy also increases plasma vWF levels. Therefore, pregnancy may lead to exacerbation of TTP in patients with pre-existing ADAMTS13 deficiency. Microvascular thrombosis increases maternal and fetal morbidity and mortality, and therefore every effort should be made to prevent thrombosis and thrombocytopenia during pregnancy.

For women with a history of acquired TTP and low ADAMTS13 levels during their remission, pregnancy is not advised, as it involves real risks that cannot be reliably predicted or easily managed. ADAMTS13 levels may decrease to cause maternal TTP relapses. It may also cause fetal complications without overt maternal relapses.

If pregnancy is inevitable, rituximab may be an option to preemptively increase ADAMTS13 levels before pregnancy occurs. Rituximab is a class C drug for pregnancy, based on the adverse effect of lymphocytopenia observed in animal reproductive studies. In theory, its deleterious effects may last for 12 months. There are no adequate and well-controlled studies in humans. Rituximab use during pregnancy has been reported in a woman without causing adverse consequences. Thus, potential benefits may warrant use of the drug in pregnant women despite the theoretical risks.
Serial monitoring of ADAMTS13 levels is essential in pregnant patients. If ADAMTS13 exhibits a trend of decrease toward 10% of normal, pre-emptive plasma exchange or infusion therapy is used to prevent TTP relapses and fetal complications. Patients with genetic ADAMTS13 mutations should receive adequate maintenance plasma therapy titrated to prevent thrombocytopenia and thrombosis. Some women with milder forms of hereditary TTP may become pregnant without knowing the diagnosis of the disease. These patients may develop thrombocytopenia that is often incorrectly attributed to immune thrombocytopenia or gestational thrombocytopenia, only to develop TTP exacerbation or fetal complications as the pregnancy progresses. A positive family history, a high index of suspicion, and liberal use of ADAMTS13 assays may help identify such patients for correct diagnosis and management.

Novel Therapeutic Modalities

Recombinant ADAMTS13 is under development for replacing deficient ADAMTS13 in patients with TTP. Truncated variants of ADAMTS13 or variants with substitutions at the residues critical for interaction with inhibitors may circumvent the difficulties posed by inhibitors. However, immunogenicity is a concern for variant ADAMTS13 molecules with substituted amino acid.

N-acetylcysteine, presently used for acetaminophen liver toxicity and chronic lung disease, decreases the size of vWF by reducing the disulfide bonds of vWF multimers.\textsuperscript{108} It may be an attractive therapy for TTP if its vWF-reducing activity is confirmed in human subjects.

Inhibitors of vWF-platelet aggregation such as the anti-vWF aptamer ARC1779\textsuperscript{107} or nanobody ALX-0081\textsuperscript{109} may prevent microvascular thrombosis in TTP patients. These drugs may best serve as a short-term measure to prevent serious complications or death before ADAMTS13 levels are raised by plasma replacement therapy or rituximab.

SHIGA TOXIN-ASSOCIATED HEMOLYTIC-UREMIC SYNDROME

First described by Gasser et al. in 1955,\textsuperscript{110} typical HUS refers to the constellation of renal failure, microangiopathic hemolysis, and thrombocytopenia following a bout of hemorrhagic diarrhea. This is a relatively uncommon disease but often draws public attention during outbreaks of food-borne illness.

Etiology

It is estimated that approximately 90% of North American and European children with HUS have infection with shiga toxin-producing E. coli (STEC) of the enterohemorrhagic serotype, typically serotype O157:H7. In the United States, approximately 4,000 cases of E. coli O157:H7 infections are diagnosed annually, with 15% of them developing the complication of HUS. STEC of non-O157 serotypes and even Shigella dysenteriae serotype I have also been implicated in causing HUS.

The offending organisms share the capacity of producing powerful shiga toxins, which are encoded by phage DNA and comprise several genotypes.\textsuperscript{111} Most HUS cases are caused by shiga toxin genotype 2 or 1+2. With more laboratories conducting the shiga toxin assays, increasing numbers of non-O157 E. coli serotypes such as O26:H11, O103:H2, O111:H8, and O145:H28 are detected.

Enteropathogenic E. coli has a reservoir in bovine intestine and is transmitted by meat, milk, or water contaminated with ruminant feces. Most cases of shiga toxin-associated HUS result from ingestion of contaminated food such as beef, leafy vegetables, dairy, fruits, nuts, sprouts, poultry, or water. Other modes of transmission include direct animal contact and person-to-person contact during the acute diarrheal phase. Very low infectious doses (<100 organisms) are sufficient to cause clinical disease. Outbreaks account for only 20% of the cases. Approximately 50% of the cases occur during the summer months.

The outbreaks in Germany, France, and other countries in 2011 were due to contamination with E. coli O104:H4, which evolved from an unusual progenitor of enterogaugregative E. coli through acquisition of a stx2-encoding prophage and a plasmid encoding a CTX-M-15 extended-spectrum beta-lactamase (ESBL) gene.\textsuperscript{112, 113, 114, 115}

Many strains of STEC have not been associated with hemorrhagic diarrhea or HUS, indicating that other virulence factors of the organisms are also critical for pathogenesis. The expression of additional genes on a chromosomal locus of enterocyte effacement pathogenicity island, including intimin encoded by the eae gene for intimin attachment, has a strong association with the risk of HUS.\textsuperscript{116}
STEC is one of the surveillance infections conducted by the Foodborne Disease Active Surveillance Network (FoodNet).

Pathology

The pathology of shiga toxin-associated HUS is quite different from that of TTP, as it is dominated by glomerular endothelial cell swelling or necrosis and subendothelial expansion in the kidney. Fibrin-platelet thrombi are commonly present in glomerular loops and hila and may be seen extending into small and medium-sized arteries, including the interlobular arteries (Fig. 48.2C). Neutrophil infiltration may be present. Extensive thrombosis may result in renal cortical infarcts.

Other organs such as brain, heart, intestinal tract, and pancreas may also be affected, either with edema due to abnormal vascular permeability or with ischemic injury due to microvascular stenosis or thrombosis.

Pathophysiology

It is believed that injury of the kidney and other organs is a consequence of the cytotoxic effect of shiga toxins on vascular endothelial cells. A shiga toxin molecule comprises an A-subunit and a pentameric B-subunit. The shiga toxin molecule binds via its B-subunit to globotriaosylceramide (Gb3) expressed on the membrane lipid rafts of renal microvascular endothelial or other target cells. This binding is followed by internalization of the A-subunit via endocytosis. After proteolysis, a smaller fragment of the A-subunit is generated that is capable of disrupting the 60s ribosomes, blocking protein synthesis in the target cells. The sensitivity of endothelial cells may be enhanced by cytokines such as IL-1 and TNF-α released in response to endotoxins.

Additional studies suggest that shiga toxins may also alter the expression of vasoactive factors (e.g., endothelin and nitric oxide) and adhesive proteins (e.g., vWF, αvβ3, PCAM-1, and P-selectin), or activate the alternative complement pathway. However, it is not clear whether the high concentrations of shiga toxins used in these studies are pathophysiologically relevant.

The cytotoxicity of shiga toxins leads to endothelial cell swelling, abnormal vascular permeability, and cell death. Endothelial cell disruption exposes the underlying thrombogenic glomerular basement membrane, triggering the activation of the coagulation cascade and subsequent thrombosis. Thrombosis leads to ischemic organ injury, thrombocytopenia, and abnormal shear stress causing red cell fragmentation. Vascular stenosis may also result from endothelial swelling and subendothelial expansion, causing tissue ischemia and red cell fragmentation without increasing platelet consumption. The microangiopathy may also increase vascular permeability, leading to brain edema, pleural or pericardial effusion, ascites, mesenteric or intestinal edema, and anasarca that do not correlate with thrombocytopenia or microangiopathic hemolysis.

Clinical Presentation

There is a spectrum of illness following ingestion of STEC, ranging from no symptoms to self-limited gastroenteritis, the HUS and death.

Symptomatic STEC infection leads to HUS in up to 15% of cases. Diarrhea and other gastrointestinal symptoms develop between 2 and 12 days after ingestion of pathogenic E. coli. Bloody diarrhea develops 1 to 3 days later.

Symptoms and signs of HUS begin to manifest as the diarrhea begins to improve. Risk factors for HUS after infection with shiga toxin-producing E. coli include young or old age, long duration of diarrhea, elevated leukocyte count, antimicrobial or antidiarrheal drug use, and bloody diarrhea.

The onset of hemolysis and renal failure may be dramatic, with sudden pallor, abdominal pain, vomiting, and the appearance of dark-red or nearly black urine. These manifestations may quickly lead to oliguria or even anuria. On the other hand, mild or incomplete HUS with thrombocytopenia but no anemia or azotemia is almost as frequent as the complete form of HUS.

Extrarenal complications occur in approximately 50% of patients, and may include pancreatitis, glucose intolerance, colonic necrosis and perforation, myocardial infarction, congestive heart failure, pericardial or pleural effusion, and acute respiratory distress syndrome.

Neurologic complications including irritability, confusion, transient paralysis, seizures, and coma are the most serious and often result from cerebral edema of thrombotic microangiopathy. Hemorrhagic or thrombotic stroke is quite infrequent.
Elderly individuals, especially frail nursing home residents, are more likely to experience cardiovascular and neurologic complications and death. \(^{129}\)

**Laboratory Findings**

Hematologic findings are similar to those of TTP, although the severity of thrombocytopenia is more variable and does not always reflect the severity of the clinical status. The anemia often is severe and may be accompanied by moderate polymorphonuclear leukocytosis. Hemoglobinemia may be marked. The prothrombin time and partial thromboplastin time usually are normal or minimally prolonged; fibrin degradation products or D-dimer tests are frequently elevated. \(^{130}\) Serum haptoglobin levels are typically undetectable. The bilirubin level is usually elevated. The liver transaminases and amylase may also be elevated. \(^{131}\) The blood urea nitrogen and serum creatinine levels may be quite high. The urine usually contains hemoglobin and hemosiderin in addition to albumin. Microscopically, erythrocytes, leukocytes, and casts are seen.

CT and MRI studies of the brain in patients with neurologic complications may reveal various abnormalities including restricted water diffusion; edema or posterior reversible encephalopathy syndrome (PRES); contrast enhancement; or hemorrhage in the basal ganglia, thalamus, cerebellum, or brainstem. \(^{132}\) The lesions are most commonly due to abnormal vascular permeability and may resolve on follow-up examinations and are not necessarily associated with a poor long-term neurologic outcome. Similar lesions are also often detected in patients with atypical HUS.

With perhaps rare exception, patients with shiga toxin-associated HUS have normal or slightly decreased ADAMTS13 activity levels and no inhibitory antibodies. \(^{7}\) Large vWF multimers may be decreased as abnormal shear stress in the microcirculation augments proteolysis of vWF by ADAMTS13. \(^{7}\)

**Diagnosis, Management, and Prognosis**

Conventionally, E. coli O157:H7 is detected by plating fresh feces on sorbitol-MacConkey agar. Direct detection of shiga toxins by ELISA or PCR analysis is more sensitive and also detects non-O157:H7 serotypes. \(^{133}\)

No specific treatment is available for shiga toxin-associated HUS. Early and careful management of acute renal failure and hypertension and the judicious use of packed red cell transfusions appear to constitute the safest and most effective approach to the management of HUS in children.

Plasma therapy is of no or little benefit in children. \(^{134}\) Because of the excellent results achieved in the treatment of TTP and difficulty in distinguishing HUS from TTP, adult patients are often treated with plasma exchange, although evidence in support of this practice remains circumstantial. \(^{135}\)

Recently, based on laboratory observations of complement activation by shiga toxin and endothelial P-selectin, \(^{122}\) eculizumab, a humanized monoclonal antibody of C5 originally approved for patients with paroxysmal nocturnal hemoglobinuria and aHUS, was used in three patients with severe shiga toxin-associated HUS. \(^{136}\) The patients promptly improved. This could represent a major therapeutic advance if its efficacy is reproduced in other trials.

Certain antibiotics such as ciprofloxacin may induce the expression of shiga toxins. \(^{126, 137, 138}\) Antibiotic usage increases the risk of HUS following E. coli O157:H7 infection. \(^{139}\) Until future investigation shows otherwise, bactericidal antibiotics and antimotility drugs should be avoided in patients with shiga toxin-associated colitis.

Approximately 50% of patients with shiga toxin-associated HUS require dialysis. The usual indications for dialysis support include fluid overload unresponsive to diuretics, a rapidly rising creatinine value, anuria for more than 24 hours, severe electrolyte imbalance, and serious clinical signs of uremia.

Direct person-to-person transmission occurs during the acute diarrheal phase. In some cases, excretion of the microorganisms may persist for several months. Contact isolation and frequent hand washing are recommended to minimize the spread of infection.

The overall mortality in children with epidemic HUS is 12% (range 0 to 30%). The majority of patients recover without serious consequences. Long-term renal injury such as decreased glomerular filtration rate, proteinuria, hypertension, or renal failure may be present in as many as 1 of every 4 survivors. \(^{140, 141}\) However, this risk is quite variable. Some patients may develop irritable bowel syndrome. \(^{142}\) Young women may also be at higher risk of pregnancy-related hypertension, presumably due to subclinical kidney injury. \(^{143}\) A few patients may require long-term dialysis or renal transplantation therapy. Shiga toxin-associated HUS is not expected to recur following renal graft transplantation.

**ATYPICAL HEMOLYTIC-UREMIC SYNDROME**
aHUS originally referred to the constellation of acute renal failure, microangiopathic hemolysis, and thrombocytopenia in children without a prodrome of hemorrhagic diarrhea or another apparent cause. It is now recognized that aHUS may present in adults as frequently as in children, although most of the adult patients have been given the diagnosis of TTP. Most patients with aHUS have defects in regulating the alternative complement pathway. Defective complement regulation is also found in women with pregnancy-associated aHUS. Preliminary evidence suggests that some of the patients with other co-morbidities such as bone marrow/hematopoietic stem cell transplantation also have defective regulation of the alternative complement pathway. In such patients, aHUS is believed to be induced by the co-morbidity. In addition, severe hypertension may be a complication of aHUS instead of a cause of microangiopathic hemolysis as previously believed.

Because of overlapping clinical features, aHUS is not distinguished from TTP in many reports. In fact, most patients with the so-called “TTP without severe ADAMTS13 deficiency” really have aHUS instead of TTP. Interpretation of reports in the literature is difficult when the case definitions do not provide a clear distinction between TTP and aHUS. A comparison of the distinctive features of TTP and aHUS is summarized in Table 48.3.

**Pathology**

Although aHUS and TTP share the common features of thrombocytopenia and microangiopathic hemolysis, they are quite different pathologically.

In aHUS, the affected glomerular capillaries, arterioles, and interlobular small arteries typically exhibit endothelial cell swelling or death and subendothelial expansion due to edema and/or hypercellularity, often but not invariably accompanied by thrombosis. The glomerular tufts may show mesangiolysis. Late changes may show double basement membranes, mesangial cell proliferation with expansion of the matrix and interstitial fibrosis. The lesions often include admixtures of acute and chronic changes (Fig. 48.2D-F). The prominence of chronic changes in patients at their first presentation suggests antecedent subclinical injury.

- Treatment of choice: Plasma exchange, Plasma infusion, Eculizumab
- Mortality: 10%-20%, Very low if promptly treated, - 10%-30% with plasma exchange, - Expected to be very low with eculizumab
- Long-term prognosis: Relapse, Relapse, stroke, CRF, Relapse, ESRD

Complement regulators: complement factor H, membrane co-factor protein, complement factor I, C3, complement factor B, or thrombomodulin; CFH, complement factor H; CFHR1, complement factor H-related protein 1; CRF, chronic renal failure; ESRD, end-stage renal disease; MAHA, microangiopathic hemolytic anemia; ND, not detectable; PRES, posterior reversible encephalopathy syndrome.

α If treated only for relapses.

The pathology of thrombotic microangiopathy may also be demonstrable, albeit less conspicuously, in other organs. More common is tissue edema in the brain, lung, gastrointestinal tract, mesentery and cutaneous soft tissues. Fluid accumulation may be present in the pericardial, alveolar, pleural, or peritoneal space. These changes result from abnormal vascular permeability and are uncommon in patients with TTP.

Molecular Pathogenesis

The complement system, an important part of the innate host defense against invading microorganisms, may be triggered by immune complexes or microbial lectins. The alternative pathway, via complement factors B, D, and P, amplifies complement activation by promoting the generation of alternative C3b and C5b convertases (Fig. 48.9). Complement factor H (CFH), factor I (CFI), membrane cofactor protein (MCP, or CD46), thrombomodulin (THBD), and possibly complement factor H-related proteins 1-5 (CFHR1-5) are involved in regulating self-perpetuating complement activation.

Genetic mutations of the alternative complement activators or regulators have been found in approximately 50% of aHUS patients, with a higher prevalence among patients with a family history (75%) than in patients without a family history (40%). The molecular defects include inactivating mutations of CFH (25%), MCP, CFI, and THBD (5% to 10% each); gain-of-function mutations of activators C3 (5% to 10%) and CFB (a few pedigrees). Additionally, antibodies to CFH are detected in 5% to 10% of the cases, often with concurrent homozygous or heterozygous genomic deletion of CFHR1.

The genetics of aHUS are more complex than involvement of single genes. Compound mutations are present in 10% or more of the patients. Atypical HUS may only develop in patients with more than one variant of the activators or regulators. Analysis of single nucleotide polymorphisms (SNP) of complement activators and regulators demonstrates that the risk of aHUS is significantly increased or decreased with certain SNPs and haplotypes of CFH, CD46, CFHR2, CFHR4, and intergenic CR1-CD46. Laboratory studies have demonstrated that certain combinations of common variants (complotype) of the complement activators and regulators increase the risk of the disease.

Complement factor H-related proteins 1-5 (CFHR1-5) are the products of a series of genes located immediately downstream of the CFH gene, that are mapped to a region of chromosome 1q containing multiple retrotransponson sequences. Genomic deletion of CFHR1 and CRFR3 is detected in only 3% of the control population, but is present in 28% of aHUS patients. Further analysis intriguingly reveals that genomic CFHR1 deletions are present in 90% of patients with CFH autoantibodies and 20% of patients with CFI mutations, but not different from its background prevalence in patients with other or no mutations. The presence of CFHR1 deletion markedly increases the severity of aHUS in patients with CFI mutations. CFHR1 may block the binding between CFH and its antibodies in autoimmune aHUS patients.
The genetic lesions of complement regulation affect the prognosis of aHUS. Long-term survival without advanced renal failure is approximately 80%-90% for patients with only mutations affecting MCP, and is 20%-30% for patients with mutations of CFH.

P.1090

FIGURE 48.9. A scheme of the complement system highlighting the alternative pathway and its regulators (in red). Complement factor I is a plasma serine protease which, with the help of complement factor H (CFH) or membrane cofactor protein (MCP), cleaves C3b to its inactive form (iC3b). CFH also regulates other steps in the alternative pathway. Thrombomodulin (THBD) augments the cofactor activity of CFH and promotes the activation of carboxypeptidase B2 (CPB2) by thrombin, thereby accelerating the inactivation of C3a and C5a. CFB, complement factor B; CFHR1, complement factor H related protein 1; CPB2a, activated CPB2; iC3a, inactivated C3a; iC3b, inactivated C3b; iC5a, inactivated C5a; CFD, complement factor D; CFP, complement factor P; MBL, mannose binding lectin; MASP, mannose binding lectin associated protease.

More than 50% of patients with CFI mutation have concurrent mutations affecting other complement activator or regulatory proteins. Concurrence mutations increase the risk of serious aHUS complications.

As a consequence of the complexity in its genetics, atypical HUS due to complement mutations is transmitted as an autosomal dominant trait with incomplete and variable penetrance, which is greater than 50% with CFH and MCP mutations, but much lower with mutations of the other proteins.

Pathophysiology

The clinical features of aHUS are the consequence of microvascular stenosis, thrombosis, and abnormal vascular permeability resulting from uncontrolled activation of the complement system.

When the complement system is triggered by infection or other factors, defective regulation of the alternative pathway leads to unrelenting generation of complement activation products, including C3a, C5a, and C5b-9 (membrane attack complex, MAC). It is believed that C5b-9 causes direct injury of vascular endothelial cells, whereas C3a and C5a may cause abnormal vascular permeability (Fig. 48.10).

Endothelial cell injury and disruption expose the prothrombotic components in the subendothelium, leading to the activation of the coagulation system, microvascular thrombosis, thrombocytopenia, and ischemic organ injury. Microvascular thrombosis also creates abnormal levels of shear stress, causing fragmentation of the red blood cells.
Endothelial injury causes cell swelling, subendothelial edema, and cellular proliferation. These changes may directly result in marked luminal stenosis (Fig. 48.2E,F) and ischemic organ injury. Vascular stenosis also increases the shear stress and causes microangiopathic hemolysis without concurrent thrombocytopenia. Abnormal vascular permeability may lead to tissue edema and organ dysfunction without concurrent thrombocytopenia or microangiopathic hemolysis. The combination of multiple pathophysiology pathways explains why microangiopathic hemolysis, thrombocytopenia, and organ dysfunction do not always closely correlate with each other in patients with aHUS.

Other Phenotypes of Complement Dysregulation

Excessive complement activation is also associated with the phenotype of mesangiocapillary or membranoproliferative glomerulonephropathy type 2 (dense-deposit disease). Occasionally, a patient may present with HUS, evolving to renal failure with histopathologic features of mesangiocapillary glomerulonephropathy later in life.

Complement dysregulation is also associated with age-related macular degeneration. The Y402H polymorphism in the short consensus repeat-7 (SCR-7) of CFH has been linked to age-related macular degeneration among European patients. More than 20 cases of CFI deficiency have been described from 19 pedigrees linked to increased risk of pyogenic infection. Uncontrolled complement activation also underlies the mechanism of hemolysis in patients with paroxysmal nocturnal hemoglobinuria.

FIGURE 48.10. A scheme depicting how defective regulation of the alternative complement pathway may lead to atypical hemolytic-uremic syndrome (aHUS). Four types of molecular defects have been detected in patients with aHUS, in which organ dysfunction may result from ischemic injury or interstitial tissue edema. Consequently, it is not unusual that a patient with aHUS may continue to deteriorate neurologically due to brain edema while the platelet count is stable or increasing. CFB, complement factor B; CFH, complement factor H; CFI, complement factor I; MCP, membrane cofactor
Clinical Presentation

The prevalence of aHUS has been estimated at 3 per million children. Atypical HUS is likely to be as common as TTP in adults. Both males and females are equally affected.

The onset of an acute aHUS crisis may occur spontaneously or after trigger of stress conditions such as infection, surgery, trauma, inflammation, pancreatitis, intravenous contrast agents, or pregnancy. Although renal failure, microangiopathic hemolysis, and thrombocytopenia are its common features, aHUS is a systemic disease affecting multiple organs.

Gastrointestinal symptoms such as abdominal pain, bloody or nonbloody diarrhea, nausea, and vomiting are the most common acute presenting symptoms of aHUS. Some patients have recurrence of these symptoms for months to years before the diagnosis is recognized.

Laboratory tests may reveal elevated pancreatic enzymes such as amylase or lipase, diabetes mellitus, and/or abnormal liver function tests.

Imaging studies may reveal thickening, edema, and/or ischemic changes of the intestinal or bronchial wall, mesenteric edema, ascites and pancreatitis.

Headache and waxing and waning mental status changes are common. Impaired vision due to exudative or hemorrhagic retinopathy, seizures, and coma may ensue as the disease progresses. Focal neurologic deficits may occur although these are not as frequent as in patients with TTP.

The most common findings in brain imaging studies are cerebral edema or posterior reversible encephalopathy syndrome (PRES), a reflection of abnormal vascular permeability. Ischemic changes or overt infarction may be present, but are less common. Many of these changes may not be detectable with computerized tomography.

The severity of anemia and thrombocytopenia are quite variable in aHUS. Petechiae or other bleeding symptoms may occur but are uncommon. Rising platelet counts alone should not be taken as indication of disease improvement or remission.

Chest pain, dyspnea, respiratory failure, or congestive heart failure may result from pleurisy, pericarditis, airway edema, noncardiogenic pulmonary edema, or myocardial injury, which are detectable with chest radiograms, CT imaging, echocardiography, and EKG. Troponin and CPK levels may be elevated. Hypertension may be severe but often labile. Cardiac arrhythmias may lead to sudden death.

Proteinuria, hematuria, and renal function impairment are common. Hematuria is microscopic in most cases but may be gross occasionally. The severity of renal failure is variable. Some patients may present with very mild elevation of creatinine, and others present with anuric renal failure requiring dialysis support. Occasionally, a patient presents with aHUS only after receiving a renal graft for end-stage renal failure.

Diagnosis

No simple tests exist at this time for the diagnosis of defective alternative complement regulation. The C3 level is decreased in approximately 30%-50% of the patients. The C4 level is decreased in less than 10% of the cases. These changes are not specific for aHUS. In patients with mutations of CFH or CFI, the antigen levels of the affected proteins are decreased in approximately 30% of the cases.

Mutation analysis detects abnormalities in approximately 50% of the patients. Because compound mutations are common, all genes known to be involved in alternative complement regulation need to be analyzed. CFH antibodies are detected by ELISA in 5% to 10% of patients with aHUS. The genetics of aHUS also involve SNPs, haplotypes, and combinations of common or uncommon variants of complement activators or regulators. Due to its complexity and incomplete understanding of pathogenic mechanisms, genetic study is not required for the diagnosis of aHUS.

Presently the diagnosis of aHUS relies on a process of exclusion (Fig. 48.11). aHUS is suspected in patients presenting with the constellation of microangiopathic hemolysis, any degree of renal function impairment and thrombocytopenia, and the diagnosis is presumed after exclusion of TTP and groups III and IV disorders listed in Table 48.1.
FIGURE 48.11. A scheme summarizing the current approach to patients presenting with thrombocytopenia and microangiopathic hemolytic anemia (MAHA). The patients should be empirically treated with plasma exchange unless history, physical examination, and laboratory tests strongly indicate otherwise. The indication of plasma exchange should be continually reassessed based on the evolution of clinical course and laboratory test results. Until ADAMTS13 assays are proven to be reliable, an ADAMTS13 level >10% should be correlated with clinical findings of advanced renal failure and/or abnormal vascular permeability for exclusion of thrombotic thrombocytopenic purpura (TTP). The role of eculizumab for treatment of shiga toxin-associated hemolytic-uremic syndrome (HUS) or other thrombotic microangiopathy of Group III disorders (Table 48.1) remains uncertain. DIC, disseminated intravascular coagulopathy.

aHUS needs to be distinguished from TMA via other mechanisms such as shiga toxins or microbial neuraminidases. Shiga toxin assays are indicated for patients presenting with diarrhea. Blood cultures or viral studies are indicated for patients with suspected systemic infections. There is insufficient knowledge to determine how frequent TMA occurs in patients with hematopoietic stem cell therapy, systemic autoimmune diseases, HIV infection, or various classes of drugs. Patients with autoimmune diseases may also develop MAHA due to vasculitis, which requires tissue biopsy for diagnosis. aHUS needs to be distinguished from hemolysis with elevated liver enzymes and low platelets (HELLP) syndrome and preeclampsia in women during pregnancy. Contrary to what is commonly believed, severe hypertension may be a consequence of aHUS rather than a cause of MAHA. The diagnosis of aHUS in patients without both MAHA and overt renal failure is more challenging and requires a high index of suspicion. The presence of hypertension, pleural or pericardial effusions, ascites, mesenteric or intestinal wall edema, anasarca, airway edema, acute respiratory distress syndrome, exudative retinopathy, brain edema, or posterior reversible encephalopathy syndrome (PRES) by CT or MRI strongly favors the diagnosis of aHUS over TTP.

Management

The principles of management for patients with aHUS are summarized in Table 48.4. Traditionally, aHUS patients were treated with plasma exchange. This practice was an extension of plasma exchange therapy for TTP, but its efficacy has never been rigorously investigated. It appears to be effective in a fraction of patients with aHUS.

Plasma Therapy
Many patients improve following the institution of plasma exchange therapy. Some patients deteriorate and even die after exhibiting an initial response. Others relapse after the therapy is discontinued, but do not respond to its reinstitution. Thus, the outcome with plasma therapy is uncertain for individual patients.

Knowledge of the molecular defects of aHUS may potentially predict which patients are likely to benefit from plasma exchange therapy. Plasma exchange or even plasma infusion is most likely to benefit patients with deficiency of plasma proteins such as CFH or CFI, but not patients with defective membrane-bound proteins such as MCP. Intensive plasma exchange may be effective for patients with gain-of-function C3 or CFH mutations, or CFH antibodies. For patients with multiple mutations or unknown mutations, it is impossible to predict whether they will respond to plasma therapy.

**TABLE 48.4 PRINCIPLES OF MANAGEMENT OF ATYPICAL HEMOLYTIC-UREMIC SYNDROME (aHUS)**

- Atypical HUS is a systemic disease
  - Gastrointestinal symptoms of nausea, vomiting, abdominal pain, diarrhea are common complaints.
  - Cardiopulmonary symptoms of chest pain and dyspnea may occur
  - Neurologic abnormalities such as headache, somnolence, confusion, seizures, or visual defects may occur.
  - Advanced renal failure, hypertension or complications of abnormal vascular permeability favors the diagnosis of aHUS over TTP.
  - Renal failure may be minimal or mild in some cases.
- Atypical HUS is a diagnosis of exclusion
  - TTP should be excluded with ADAMTS13 assays.
  - Stx-HUS should be excluded with stool shiga toxin assays for patients with diarrhea.
  - Other causes of MAHA should be excluded with history, coagulation tests, autoimmune serology, microbiology, and/or tissue biopsy as indicated.
  - Acute presentation of atypical HUS may be triggered by a co-morbidity (Table 48.1).
- Plasma exchange is the initial choice of therapy until TTP is excluded
- Eculizumab is the treatment of choice for aHUS
  - Improvement in thrombocytopenia and mental status change is evident after one or two doses of eculizumab.
  - Recovery of renal function may occur slowly over many months.
  - Vaccination is critical for prevention of meningococcal sepsis.
- Long-term therapy with eculizumab should be considered for patients who
  - have more than minimal renal dysfunction, or
  - are predisposed to relapse with serious complications.
- If eculizumab is discontinued, close monitoring is indicated for early detection of relapse or organ injury. Follow-up evaluation should include
  - Symptoms, physical findings, blood pressure.
  - CBC, renal function and hemolysis markers.

Stx-HUS, shiga toxin-associated hemolytic-uremic syndrome; TTP, thrombotic thrombocytopenic purpura.
purpura

As reflected by cerebral edema, posterior reversible encephalopathy syndrome, pleural or pericardial effusion, pulmonary edema, acute respiratory distress syndrome, ascites, or soft tissue swelling.

Some patients develop end-stage renal failure, months to years after plasma exchange is discontinued, without ever experiencing acute symptomatic relapses of aHUS. Thus, long-term maintenance plasma therapy is often needed for responsive patients to prevent relapses or progression of kidney injury. Long-term plasma therapy is technically demanding, poses a major stress on the patients, and its optimal regimen can only be determined empirically at best.

Eculizumab

A major advance in the treatment of aHUS is eculizumab, a humanized monoclonal antibody to C5 originally approved in 2007 for the treatment of paroxysmal nocturnal hemoglobinuria. Based on two prospective studies of 37 adult and adolescent patients, and a retrospective study of 19 pediatric patients, the U.S. Food and Drug Administration and European Medicines Agency approved eculizumab in 2011 for the treatment of childhood and adult aHUS.

In the clinical trials, patients without identifiable mutations also responded to eculizumab, suggesting that defective regulation of the alternative complement pathway plays a pathogenetic role in most if not all patients of aHUS without identifiable molecular defects.

With eculizumab, clinical improvement in mental status, gastrointestinal symptoms, and increase in the platelet count are often apparent after one or two weekly administrations. Renal function improvement may be slow but continues for many months. Long-term eculizumab therapy may lead to gradual recovery of renal function, allowing some patients to come off dialysis therapy.

The aims of eculizumab therapy for aHUS include prevention of death, and avoidance of aHUS relapse. To achieve these aims, eculizumab should be instituted as soon as the diagnosis is reasonably established and TTP is excluded.

Atypical HUS is a chronic disease that often continues to cause subclinical injury of the kidney and other organs even in the absence of overt symptoms, thrombocytopenia, or microangiopathic hemolysis. Long-term eculizumab therapy should be considered for patients who are close to requiring renal replacement therapy and patients whose aHUS, if left untreated, may cause severe hypertension or other serious extra-renal complications. If eculizumab is discontinued, close monitoring of clinical status, blood pressure, blood counts, and renal function is indicated for early detection of aHUS relapse or progressive organ injury.

Eculizumab is well tolerated with minor adverse reactions. It is important to note that eculizumab therapy may predispose patients to fulminant Neisseria meningitides infections. Patients should be given meningococcal vaccination and take prophylactic antibiotics until 2 weeks after the vaccination. Patients should also carry an identification card to facilitate emergency management of any infectious complications. Concern of serious infection has prompted some physicians to recommend long-term prophylactic antibiotic therapy.

The efficacy of eculizumab for patients with thrombotic microangiopathy in association with a co-morbidity such as those in Table 48.1 (group III), but no identifiable molecular defects in complement regulation has not been extensively investigated. Preliminary experience suggests that it is effective in some, if not all of such patients.

Eculizumab has been used in a small number of patients during pregnancy without causing adverse effects to the mother and fetus.

Eculizumab versus Plasma Exchange Therapy

Compared to plasma exchange, eculizumab offers several advantages: the high efficacy of eculizumab is documented in clinical trials; it is expected to be effective for aHUS irrespective of the underlying molecular defects; and it is easier to administer, particularly for long-term maintenance therapy.

In contrast, the efficacy of plasma exchange has never been rigorously investigated in patients with aHUS; treatment failure is not uncommon; and plasma exchange requires a venous catheter that is inconvenient, uncomfortable, and carries the risk of infection or thrombosis.

Renal Transplantation

Due to high rates of disease recurrence, aHUS patients, except those with mutations of membrane proteins such as MCP, have a very high risk (>80% to 90%) of graft failure following kidney transplantation.

P.1094
Previously, combined kidney and liver transplantation was performed based on the rationale that restoration of normal CFH in the circulation by the transplanted liver would prevent recurrence of aHUS and renal graft failure. However, because the complement system is triggered during major operations, the procedure was associated with a very high risk of morbidity and mortality. Pre-operative plasma exchange was advocated to prevent these complications.

Patients with mutations of membrane cofactor protein are expected to be cured, at least from the renal perspective, by a kidney allograft. Nevertheless, graft failure may occur if the donor is a family member who also carries the molecular trait, or if the patient carries other unidentified mutations. Due to the incomplete phenotypic expression of aHUS, family members of aHUS patients should not be organ donors. Extra-renal complications of aHUS may continue to occur after kidney transplantation. Maintenance eculizumab therapy is indicated for such patients.

If a patient with aHUS is to receive kidney transplantation, the patient should be treated with eculizumab prior to the operation. Eculizumab should be continued post-operatively to prevent recurrence of the disease causing acute complications and graft failure. Because chronic eculizumab therapy is expected to be quite effective in preventing relapse of aHUS or organ injury, concurrent liver transplantation is no longer necessary.

Prognosis

Historically, approximately 10% to 30% of aHUS patients treated with plasma exchange died during their acute presentation. The overall risk of death or end-stage renal failure was ~60%. The risk was the highest (70% to 80%) for patients with CFH mutations, compound mutations, or CFI mutation with CFHR1 deletion, and the lowest mortality (10% to 20%) occurred in patients with MCP mutations.

Many of the patients never develop recurrence of overt thrombocytopenia or microangiopathic hemolysis while they progress to advanced renal failure. The absence of hematologic relapse leads to erroneous reports in the literature that “TTP” patients without severe ADAMTS13 are less likely to relapse and have a better long-term prognosis than those with severe ADAMTS13 deficiency. Eculizumab is expected to suppress systemic complications and prevent renal function, deterioration, and death.

PLATELET AND RED CELL DAMAGE BY ABNORMAL VASCULAR SURFACES

Platelets are subject to damage by interactions with “nonphysiologic” surfaces within the vascular system. Pathologic alterations of vessels that may produce such platelet damage include stenotic and roughened heart valves, extensive atherosclerosis, metastatic cancer, and kidney disease associated with severe vascular changes in renal vessels. An increasing number of surgical techniques involve the implantation of devices containing foreign material within the vascular system. Such circulatory prostheses include cardiac valves, vascular grafts of many types, indwelling catheters, intra-aortic balloon pumps, extracorporeal membrane oxygenators (ECMO), and ventricular assist devices (VAD). Extensive efforts have been made to render such materials nonthrombogenic, but most of these devices produce varying degrees of platelet destruction as well as hemolysis.

Bleeding during cardiopulmonary bypass surgery appears to be multifactorial, including operative factors, dilution of clotting factors, inadequate neutralization of heparin, thrombocytopenia, platelet dysfunction, and enhanced fibrinolysis. Hemodilution leads to a rapid reduction in platelet counts by as much as 50% shortly after cardiopulmonary bypass surgery begins. The platelet function defect is maximal during cardiopulmonary bypass surgery and usually disappears within 24 hours of surgery. The nature of the platelet defect is controversial. Investigators report partial platelet degranulation, circulating activated platelets by flow cytometry, and defects in platelet membrane glycoprotein Ib/IX and Ib/IIa. Efforts to minimize platelet and coagulation abnormalities in association with cardiac surgery include higher heparin doses to suppress thrombin generation, heparin-coated circuit, miniaturized closed circuit, and offpump operations. Avoidance of cardiotomy suction, perhaps in combination with a direct thrombin inhibitor such as bivalirudin as the anticoagulant, may substantially minimize activation of the coagulation system. Bleeding is often reduced by infusion of normal platelets, 1-deamino-8-D-arginine vasopressin, epsilon aminocaproic acid, or aprotinin. However, indiscriminate prophylactic platelet transfusion is ineffective and may increase the risk for adverse outcomes. A higher risk of end-organ damage has been observed with aprotinin, but not with tranexamic acid or aminocaproic acid. Nitric oxide plus iloprost may reduce the deleterious effects of cardiopulmonary bypass on platelets and even reduce post-operative bleeding.

Red cell fragmentation and intravascular hemolysis are common in patients with left ventricular assist devices (LVAD), extracorporeal membrane oxygenator, or prosthetic heart valves. In such patients, monitoring of plasma hemoglobin...
concentration is recommended, as an increase in plasma hemoglobin level may herald intra-device thrombosis or malfunction. Analysis of vWF may also demonstrate a decrease in the normal large multimers in patients with LVAD. Such vWF multimer changes, presumably due to excessive proteolysis induced by abnormal shear stress profiles, are more profound in patients with nonpulsatile than pulsatile devices. The vWF changes alone may not be sufficient to cause bleeding; yet they may contribute to the bleeding diathesis induced by anticoagulation or antiplatelet therapy, other hemostatic defects such as thrombocytopenia and platelet function defects, and acquired angiodysplasia of the gastrointestinal tract.

**MISCELLANEOUS FORMS OF NONIMMUNOLOGIC PLATELET DESTRUCTION**

Extensive burns are associated with mild to moderate thrombocytopenia that results from nonimmunologic platelet destruction. Thrombocytopenia may become severe and bleeding may develop when complications of sepsis or disseminated intravascular coagulation develop. Thrombocytopenia has been well described after hepatic cryotherapy and in moderate hypothermia treatment. Certain drugs may produce thrombocytopenia by nonimmunologic phenomena. Ristocetin, an antituberculous agent no longer used clinically, promotes the attachment of vWF to its platelet receptor and initiates direct platelet-to-platelet interaction by means of an agglutination phenomenon. Studies of ristocetin-induced platelet aggregation have provided much information concerning von Willebrand disease. Oxaliplatin may cause thrombocytopenia by causing liver injury and portal hypertension, leading to splenomegaly and hypersplenism. Protamine may produce reversible sequestration of platelets in the liver, but seldom is the cause of significant thrombocytopenia. Aggregation of platelets independent of immune mechanisms plays a role in type 1 heparin-induced thrombocytopenia. Thrombocytopenia is a common feature of post-decompression sickness in divers and has been attributed to intravascular platelet aggregation.

Chapter 49
Miscellaneous Causes of Thrombocytopenia

Archana M. Agarwal
George M. Rodgers

This chapter summarizes miscellaneous forms of congenital and acquired thrombocytopenia (Table 49.1), including thrombocytopenia attributable to deficient platelet production, associated with abnormal platelet pooling in the spleen, and resulting from dilution with massive transfusions.

CONGENITAL THROMBOCYTOPENIA

Hereditary thrombocytopenias have been well documented and may be inherited as an autosomal dominant trait, an autosomal recessive trait, or an X-linked recessive trait. Bleeding can be mild, and in some instances the affected family members are virtually asymptomatic, being identified only through incidental platelet counts or family studies after the identification of the propositus. It is important to recognize these mild forms of familial thrombocytopenia because, although they may resemble autoimmune thrombocytopenic purpura, patients do not respond to steroid treatment or intravenous immunoglobulin, and this therapy may be harmful. These disorders can be classified according to platelet size (Table 49.2).

Autosomal Recessive Thrombocytopenias

Congenital Amegakaryocytic Thrombocytopenia

The presence of severe thrombocytopenia, absence of megakaryocytes in the bone marrow, and absence of any physical anomaly in an infant characterize congenital amegakaryocytic thrombocytopenia (CAMT).1 Because of the recessive nature of the disease, family history is usually negative, with both parents having normal platelet counts and function. Patients with CAMT have markedly elevated serum levels of thrombopoietin (TPO)2 and mutations in the c-mpl gene. Multiple mutations in the c-mpl gene have been reported, including deletions, nonsense mutations, and missense mutations. Many of the patients studied are compound heterozygotes with one mutation inherited from each parent.3,4,5 Because patients with CAMT develop progressive bone marrow aplasia during the course of the disease, it is likely that Mpl signaling is essential for the production of mature megakaryocytes as well as maintenance of the hematopoietic stem cell population.6

Further subgrouping of CAMT patients into two groups has been proposed based on their clinical course: Group CAMT I, with a more severe type of thrombocytopenia with constantly low platelet counts and an early onset of pancytopenia; and group CAMT II, which is characterized by a transient increase in platelet counts during the first year of life and a later or no development of pancytopenia.4 The type of mpl mutation determines the clinical course of CAMT; a total loss of the TPO receptor due to homozygous nonsense mutations, deletions, and frameshift mutations causes the more severe form of disease found in CAMT I patients. In contrast, the transient increase in platelet counts and the later development of pancytopenia in patients with homozygous or compound heterozygous missense mutations are the result of a residual function of the TPO receptor.7 Hematopoietic stem cell transplant is the only curative treatment for these patients, and matched sibling transplants have been successful.

Thrombocytopenia with Absent Radius Syndrome

The thrombocytopenia with absent radius (TAR) syndrome is a congenital malformation syndrome characterized by bilateral absence of the radii but with thumbs present, hypomegakaryocytic thrombocytopenia, and a number of additional features including skeletal and cardiac anomalies.8,9 Among the skeletal anomalies, bilateral absence of the radii may be accompanied by ulnar or humeral anomalies, and the most severe cases exhibit phocomelia. Lower limb involvement is variable and includes dislocation of the patella and/or of the hips, absent tibiofibular joint, and lower limb phocomelia. Among the cardiac anomalies, tetralogy of Fallot and atrial septal defects are common.10,11 Studies have noted a high incidence (62%) of cow’s milk intolerance, which presents as persistent diarrhea and failure to thrive.

An episode of thrombocytopenia may be precipitated by introduction of cow’s milk and relieved by its exclusion from the diet.12

**TABLE 49.1 MISCELLANEOUS CAUSES OF THROMBOCYTOPENIA**

**Congenital Thrombocytopenia**
Autosomal recessive thrombocytopenias
Congenital amegakaryocytic thrombocytopenia
Thrombocytopenia with absent radius (TAR) syndrome
Bernard-Soulier syndrome
Autosomal dominant thrombocytopenias
MYH9-related disorder
May-Hegglin anomaly
Sebastian anomaly
Fechtner anomaly
Epstein anomaly
Familial platelet disorder with predisposition to acute myelogenous leukemia
Mediterranean macrothrombocytopenia
Paris-Trousseau syndrome (in association with deletion of FLI1 gene)
Autosomal dominant thrombocytopenia with linkage to human chromosome 10 (THC2)
Gray platelet syndrome
Amegakaryocytic thrombocytopenia with radial-ulnar synostosis (ATRUS) syndrome
Variant von Willebrand disease (type 2b and platelet-type) (see Chapter 53)
X-linked thrombocytopenia
X-linked microthrombocytopenia (WAS gene mutation)
X-linked macrothrombocytopenia with dyserythropoiesis (GATA-1 mutation)
Others
22q11 deletion syndrome (DiGeorge Syndrome)

**Acquired Thrombocytopenia**
Thrombocytopenia caused by deficient platelet production
Acquired pure amegakaryocytic thrombocytopenic purpura
Chemical and physical agents that produce generalized bone marrow suppression
Drugs that selectively suppress the megakaryocyte
Drugs that cause ineffective thrombopoiesis
Thrombocytopenia caused by abnormal platelet pooling
Thrombocytopenia caused by hypothermia
Thrombocytopenia associated with infections
Thrombocytopenia associated with viral infections
Thrombocytopenia associated with bacterial and protozoal infections
Thrombocytopenia after massive blood transfusions

THC2  Gray platelet syndrome

X-linked thrombocytopenia with GATA-1 Paris-Trousseau syndrome mutation  vWD type 2B

Platelet type vWD  22q11 deletion syndrome

GATA-1 mutation platelets may have normal or increased MPV.

AML, acute myelocytic leukemia; ATRUS, amegakaryocytic thrombocytopenia with radial-ulnar synostosis; MPV, mean platelet volume; THC2, autosomal dominant thrombocytopenia with incomplete megakaryocyte differentiation and linkage to chromosome 10; vWD, von Willebrand disorder.

These patients have elevated serum TPO levels and normal c-mpl and HOX genes. However, they have a profound defect in megakaryocyte differentiation and platelet production and no response of megakaryocytes to TPO. There may be a slight increase in platelet count in response to recombinant human erythropoietin. Although specific microdeletion of chromosome 1q21.1 has been reported in the majority of individuals with TAR syndrome, it is not the disease-causing mutation. Compound inheritance of a rare null mutation in exon-junction complex subunit RBM8A has been found to be the cause of TAR syndrome. RBM8A controls the production of the protein Y14, and its low level is responsible for the cause of low platelets.

Diagnosis is rarely difficult because of obvious morphologic abnormalities in association with thrombocytopenia. Prenatal diagnosis has been described by ultrasonographic detection of morphologic abnormalities and detection of low fetal platelet counts. Congenital rubella and some variants of Fanconi syndrome should be excluded. Platelet counts gradually increase during the first 2 years of life. The degree of thrombocytopenia is usually greatest at the time of birth; platelet transfusions are frequently required and are effective. Thrombocytopenia becomes less severe during the first year of life, and most affected individuals with TAR do not require platelet transfusions after infancy.

Bernard-Soulier Syndrome

Bernard-Soulier syndrome is an autosomal recessive bleeding disorder associated with deficiency of platelet membrane proteins GPIb, GPIX, and GPV. This results in abnormal platelet interaction with ligands of these receptor proteins, which include thrombin, von Willebrand factor (vWF), P-selectin, and leukocyte integrin αMβ2, in addition to causing thrombocytopenia. This topic is described in more detail in Chapter 52.

Autosomal Dominant Thrombocytopenia

A number of families have been described who have autosomal dominant inheritance of isolated mild thrombocytopenia characterized by normal platelet survival and a normal number of bone marrow megakaryocytes, a constellation of findings that suggests ineffective thrombopoiesis. Thrombocytopenia (platelet counts between 20,000 and 100,000/µl) or a history of increased bruising is apparent early in life, and examination of the peripheral blood smear
demonstrates platelet macrocytosis (mean platelet volume >10 μm$^3$). Splenic size is always normal. Platelet aggregation abnormalities have been described in some families, but platelet membrane glycoproteins (GPs) have been normal when studied.\textsuperscript{24}

MYH9-related Disorders

A group of autosomal dominant macrothrombocytopenias caused by mutations in the MYH9 gene with variable penetrance and expression has been defined.\textsuperscript{26, 27, 28, 29} These include May-Hegglin anomaly, Sebastian syndrome, Epstein syndrome, and Fechtner syndrome. These disorders are defined by the presence of mutations involving the MYH9 gene located at chromosome 22q12.3-13.1 and include single nucleotide changes, in-frame deletions or duplications, and frameshift and nonsense mutations.\textsuperscript{30} The MYH9 gene encodes nonmuscle myosin heavy chain IIA (NMMHC-IIA).\textsuperscript{31} NMMHC-IIA is part of the nonmuscle myosin IIA hexamer that is a component of the contractile cytoskeleton in megakaryocytes, platelets, and other tissues. Thrombocytopenia is usually mild and derives from complex defects of megakaryocyte maturation and platelet formation. More specifically, these mutations likely affect the platelet release from the mature megakaryocytes.\textsuperscript{32} All of these MYH9 gene mutation-related disorders have macrothrombocytopenia, leukocyte inclusion bodies (Döhle body-like inclusions) and can have various combinations of hereditary nephritis, deafness, and cataracts (Table 49.3). Sometimes, the inclusions are rarely appreciated on conventional May-Grunwald-Giemsa staining, especially in patients with mutations at codon 702 because of their low RNA content. These cases can be diagnosed by the use of immunofluorescence assays.\textsuperscript{33} Thrombocytopenia is generally mild to moderate. Peripheral blood smears reveal enlarged platelets with frequent giant platelets.

Clinically, patients have a mild platelet-type bleeding disorder. May-Hegglin anomaly and Sebastian syndrome both have macrothrombocytopenia and granulocyte inclusions, but ultrastructural analysis of the Döhle-like inclusions demonstrates diagnostic differences between these two syndromes, and both types of inclusions can also be distinguished from Döhle bodies seen in acute infection. Patients with Fechtner syndrome and Epstein syndrome have hearing disability and nephritis. In Fechtner syndrome, cataracts are also present.\textsuperscript{33} These two disorders result from allelic mutations at amino acid 702, which cause conformational changes to the myosin head.\textsuperscript{31, 34, 35, 36} Diagnosis is suggested by detection of macrothrombocytopenia and the presence of one or more of the above-mentioned clinical features. Döhle-like inclusion bodies within neutrophils on May-Grunwald-Giemsa-stained peripheral blood are highly suggestive of an MYH9-related disorder. Abnormal staining of neutrophil inclusions with anti-NMMHC-IIA may offer greater sensitivity. Definitive diagnosis requires the demonstration of a causative mutation within the MYH9 gene.\textsuperscript{31} Treatment options for bleeding include platelet transfusion, allogeneic stem cell transplantation, or use of a thrombopoietic drug (eltrombopag).\textsuperscript{37}

Platelet-type von Willebrand disease is another autosomal dominant disorder associated with hereditary thrombocytopenia, characterized by abnormal binding of large vWF multimers to platelets. This intrinsic platelet defect results in mild thrombocytopenia, increased ristocetin-induced platelet aggregation, and a selective loss of high-molecular-weight vWF multimers from the plasma. This disorder resembles type 2b von Willebrand disease (see Chapter 53).

Familial Platelet Disorder with Predisposition to Acute Myelogenous Leukemia

Familial platelet disorder with predisposition to acute myelogenous leukemia (FPD/AML) is an autosomal dominant disorder characterized by moderate thrombocytopenia, a defect in platelet function, and predisposition to develop myeloid malignancy.\textsuperscript{38} The defect in platelet function is manifested by prolonged bleeding times and abnormal platelet aggregation. Expansion of megakaryocyte progenitors in the bone marrow or peripheral blood cells reveals diminished megakaryocyte colony formation. Bone marrow from affected patients shows decreased megakaryopoiesis. Linkage analysis of several pedigrees affected by FPD/AML has led to identification of germline heterozygous mutations in the
Gray Platelet Syndrome

hematopoietic transcription factor AML1, also known as RUNX1 and CBFA2. These mutations include missense, frameshift, and nonsense mutations and a large intragenic deletion. CBFA2 is a transcription factor that trans-activates the expression of a spectrum of genes required for normal development of hematopoietic cells. Mutation of CBFA2 has been implicated in the pathogenesis of human leukemias resulting from somatically acquired chromosomal translocations. Normal megakaryopoiesis requires TPO binding to the Mpl receptor. In FPD/AML, CBFA2 mutation leads to diminished Mpl receptor expression, resulting in impaired TPO signaling leading to thrombocytopenia. Consequently, serum TPO levels are usually elevated in these patients.

Mediterranean Macrothrombocytopenia

A relatively common and mild form of macrothrombocytopenia has been described in a group of 145 apparently healthy subjects from Italy and the Balkan peninsula. Because this abnormality was not detected in control subjects from northern Europe, the condition was named Mediterranean macrothrombocytopenia. Linkage analysis localized the gene mutation to the short arm of chromosome 17, in an interval containing the GPIba gene. GPIba, together with other proteins, constitutes the plasma vWF receptor, which is altered in Bernard-Soulier syndrome. Sequencing of the gene identified a mutation of GPIba (Ala156Val) shared by 10 of 12 pedigrees studied. These data demonstrate that for most families with Mediterranean thrombocytopenia, the genotype and phenotype are equivalent to that of a carrier of Bernard-Soulier syndrome. Clinically, patients have a mild bleeding diathesis, usually diagnosed after incidental discovery of thrombocytopenia. Peripheral blood shows platelets that are larger than normal.

Paris-Trousseau Syndrome (in Association with Deletion of the FLI1 Gene)

Paris-Trousseau syndrome (PTS) is an inherited disorder characterized by several congenital anomalies including dysmegakaryopoiesis with two morphologically distinct populations of megakaryocytes and giant α-granules in a low percentage of platelets. These features occur in association with deletion of the long arm of chromosome 11 at 11q23.3 (which includes the FLI1 gene), a region that is also deleted in Jacobsen syndrome (a variant form of PTS). Clinical features include a combination of mild to moderate psychomotor retardation, trigonocephaly, facial dysmorphism, cardiac defects, and thrombocytopenia. Hematologic history, biologic data, ultrastructural, and molecular investigations were reported from a case series of 10 patients. Thrombocytopenia is chronic, with mild clinical bleeding. Peripheral blood smears and electron microscopy show abnormal platelets with giant granules. Bone marrow findings consist of dysmegakaryopoiesis with many micromegakaryocytes. Abnormal α-granules are not seen in the bone marrow and cultured megakaryocytes. Platelets have a normal lifespan in the circulation. The number of megakaryocytes in the bone marrow is increased, accompanied by impaired maturation. Together these findings suggest that platelet release is substantially impaired. PTS occurs as a result of hemizygous loss of the FLI1 transcription factor gene, which has been shown to be critical for megakaryocyte differentiation and release of platelets. FLI1 shows monoallelic expression during a brief window in megakaryocyte differentiation. This monoallelic expression explains the dominant inheritance pattern of PTS despite the presence of one normal FLI1 allele.

Autosomal Dominant Thrombocytopenia with Incomplete Megakaryocyte Differentiation and Linkage to Chromosome 10

The genetic defect for this autosomal dominant thrombocytopenia has been mapped to a region on the short arm of chromosome 10 (10p11-12). This disorder is characterized by moderate thrombocytopenia, abnormal platelet size, and incomplete differentiation of megakaryocytes. Clinical features consist of mild to moderate bruising but absence of major bleeding even with minor surgery and childbirth, suggesting that the residual platelets have normal hemostatic function. However, platelets are deficient in GPIa and α-granule content. Morphologically, the platelets appear normal. Bone marrow examination reveals impaired megakaryocyte maturation and small megakaryocytes. Colony assay on bone marrow and peripheral blood cells reveal expanded progenitors across all hematopoietic lineages, and tremendously increased expansion of immature megakaryocytes (CFU-Mk). Serum TPO level is only moderately elevated and is usually lower than expected for the degree of thrombocytopenia.

Recently, mutations in ANKRD26 were identified in the original patients and in several additional families around the world; these mutations accounted for 10% of patients in an inherited thrombocytopenia database. The term “thrombocytopenia 2” (THC2) has been applied to this disorder.
The gray platelet syndrome for which both autosomal recessive and autosomal dominant inheritance have been described is characterized by macrothrombocytopenia with bleeding tendency, myelofibrosis, and classical abnormal platelet morphology.\(^{61}\) The \(\alpha\)-granules are absent or greatly reduced, giving the platelets a gray color on Wright-Giemsa stain. The \(\alpha\)-granules are the principal storage site for hemostatic proteins such as fibrinogen, vWF, thrombospondin, and factor V and for growth factors such as platelet-derived growth factor and transforming growth factor-\(\beta\).\(^{64}\) One result of absence of \(\alpha\)-granules is a continued leakage of growth factors and cytokines into the marrow, causing myelofibrosis.

Amegakaryocytic Thrombocytopenia with Radial-Ulnar Synostosis Syndrome in Association with HOXA11 Mutation

Homeobox genes encode regulatory proteins that are critical to bone morphogenesis as well as hematopoietic differentiation and proliferation.\(^{55}\) This defect is the first reported germline HOX gene mutation associated with a human nonneoplastic hematologic disorder, and only the third HOX gene implicated in a human disorder.\(^{56}\) HOXA11 is suggested to be endogenously expressed in very early hematopoietic precursor cells and involved in regulation of megakaryocytic differentiation.\(^{57}\) Clinical features consist of CAMT, aplastic anemia, proximal radial-ulnar synostosis, clinodactyly, syndactyly, hip dysplasia, and sensorineural hearing loss.\(^{58}\) Platelet transfusions are effective as initial symptomatic management. The only definitive treatment is hematopoietic stem cell transplantation.\(^{59}\)

X-linked Thrombocytopenia

X-linked Microthrombocytopenia (WAS Gene Mutation)

Wiskott-Aldrich syndrome (WAS), originally described in 1937, is now known as an X-linked hereditary disorder associated with combined immunodeficiency, thrombocytopenia, small platelets, eczema, and an increased risk of autoimmune disorders and cancers. It has a broad range of phenotypes.\(^{60}\) At one end of the clinical spectrum, patients exhibit platelet abnormalities only, and at the other end, patients manifest thrombocytopenia, eczema, and immune abnormalities with progressive T-cell lymphopenia, and increased susceptibility to infection. The severe form of WAS and its milder manifestations—X-linked thrombocytopenia and X-linked neutropenia—are caused by mutations in the gene for the WAS, located at Xp11.22-p11.23 and cloned in 1994.\(^{61}\) \(^{62}\) \(^{63}\) \(^{64}\) The WAS gene is composed of 12 exons and encodes a polypeptide of 502 amino acids. Most mutations consist of single-nucleotide substitutions, small insertions and deletions, and splice-site mutations, and these are distributed throughout the coding region and the intron-exon junctions.\(^{65}\) Even within families, the same genotype can be associated with varying phenotypes. Measurement of the WAS protein (WASP) is now possible, making diagnosis less difficult.\(^{66}\) The mature WASP contains numerous protein-interacting domains and appears to provide a critical link between the cellular cytoskeleton and signal transduction pathways. WASP is a key regulator of actin polymerization in hematopoietic cells. It has five well-defined domains that are involved in signaling, cell locomotion, and immune synapse formation. WASP facilitates the nuclear translocation of nuclear factor \(\kappa B\) and has been shown to play an important role in lymphoid development and in the maturation and function of myeloid monocytic cells.\(^{67}\)

Megakaryocyte mass is normal or increased in WAS. Platelet differentiation and production are normal, and platelets produced in vitro are normal in size. These observations suggest that increased destruction in the spleen is responsible for both the thrombocytopenia and decreased platelet size. Management of patients with WAS is challenging; however, early diagnosis is very important for prophylaxis and treatment.\(^{68}\) Splenectomy definitely improves platelet counts in these patients, which frequently return to normal, suggesting a role of the reticuloendothelial system in platelet removal. Notably, antiplatelet antibodies are not present.\(^{69}\) The only curative therapy remains hematopoietic stem cell transplantation, which corrects both thrombocytopenia and immunodeficiency. The administration of WAS gene corrected autologous hematopoietic stem cells may represent an alternative treatment option.\(^{60}\)

X-linked Macrotrombocytopenia with Dyserythropoiesis (GATA-1 Mutation)

The X-linked gene GATA-1 regulates the expression of a large number of genes in multiple cell types.\(^{70}\),\(^{71}\) GATA-1 transcription factor contains both DNA binding and transactivation activity within three functional domains: Two zinc fingers (known as the N finger and the C finger) and an N-terminal activation domain. The C-finger is responsible for binding of GATA-1 to typical GATA-binding sites (WGATAR consensus). The N terminus of GATA-1 constitutes an activation domain, as defined by the ability of this region to confer transcriptional activation in reporter assays in fibroblasts.\(^{72}\) Taken together, these domains act in a manner similar to a multitude of transcription factors that bind DNA and activate transcription of target genes. In addition to binding DNA, the N finger has a second essential function, recruitment of the co-factor Friend of GATA-1 (FOG-1).\(^{73}\) FOG-1, as is GATA-1, is primarily expressed in hematopoietic cells, and is absolutely essential for the development of red blood cells and megakaryocytes. Five germline mutations of GATA-1 that cause X-linked disorders have been described, and all cluster in the N-terminal zinc finger.
GATA-1 mutation-associated thrombocytopenia is clinically distinguished from WAS by the presence of large or normal-sized platelets and the absence of immunodeficiency, eczema, and lymphomas.\textsuperscript{74} Thrombocytopenia is more severe (10,000 to 40,000/µl). Clinically, bleeding and bruising in affected individuals are severe, and platelet aggregation studies have shown that platelet function is also diminished.\textsuperscript{75} The bone marrow is hypercellular, with dysplastic features in the erythroid and megakaryocytic lineages.\textsuperscript{76}

Others

22q11.2 Deletion Syndrome (DiGeorge Syndrome)

This relatively common genetic disorder occurs in 1:4,000 live births, and in addition to thrombocytopenia, is associated with cardiac abnormalities, velofacial anomalies, hypocalcemia, immune defects, and a variety of other features.\textsuperscript{77} One particular gene in the region of 22q11-TBX1 is likely responsible for cardiac defects.\textsuperscript{77} The macrothrombocytopenia seen in this disorder is mild.\textsuperscript{74}

ACQUIRED THROMBOCYTOPENIA

Deficient Platelet Production

Deficient platelet production may result from three mechanisms: Hypoplasia or suppression of the precursor megakaryocytes; ineffective thrombopoiesis despite a normal precursor mass; or, rarely, deficiency or aberration of thrombopoietic control mechanisms.

Acquired Amegakaryocytic Thrombocytopenic Purpura

Acquired amegakaryocytic thrombocytopenic purpura (AATP) is a rare cause of thrombocytopenia associated with decreased or absent megakaryocytes in otherwise normal bone marrow. The prevalence is possibly higher than reported, as many cases are underdiagnosed or misdiagnosed as immune thrombocytopenia.

The differential diagnosis of patients with severe thrombocytopenia and isolated amegakaryocytosis includes a misdiagnosis of immune thrombocytopenic purpura, as mentioned above; ethanol use or drug ingestion; immune suppression associated with diseases such as systemic lupus erythematosus; and prodromal manifestations of acquired aplastic anemia, myelodysplastic disorders, or acute leukemia.\textsuperscript{78,79} Thrombocytopenia and amegakaryocytosis caused by chemotherapy or postradiation therapy should be apparent.

The pathogenesis of AATP is uncertain. AATP can occur individually or as a component of aplastic anemia secondary to exposure to environmental agents such as viruses (cytomegalovirus [CMV], parvovirus B19), and certain toxins such as benzene.\textsuperscript{78,80} Both cell-mediated suppression of megakaryopoiesis and the role of humoral immunity in AATP have been proposed, but the exact role of either remains unclear. A marked increase of T-activated suppressor cells (CD8\textsuperscript{+}/DR\textsuperscript{+}) in association with AATP has been reported.\textsuperscript{81} AATP has also been associated with high levels of anti-TPO IgG antibodies.\textsuperscript{82} No cytogenetic abnormality has been shown to be consistently associated with AATP.\textsuperscript{83} A defect in cytokine-mediated regulation of megakaryopoiesis is another proposed mechanism leading to AATP, but conclusive data are lacking.

Patients with AATP do not have a palpable spleen. The platelets are usually small or normal in size. An increased mean red cell volume is a common finding. In most patients, an etiology cannot be determined, and empirical therapy is necessary. Platelet transfusions should be used to treat bleeding and may be required prophylactically in some patients. Although there are occasional spontaneous remissions, most sustained remissions have occurred in patients receiving immunosuppressive therapy. Treatment with intravenous immunoglobulin, prednisone, cyclophosphamide, and vincristine has not been efficacious in AATP. Myeloablative chemotherapy (busulfan and cyclophosphamide) followed by allogeneic bone marrow transplant from a fully HLA-matched sibling is effective.\textsuperscript{84} Danazol has been reported to be effective in two cases of AATP.\textsuperscript{85} Antithymocyte globulin (ATG) alone,\textsuperscript{86} rituximab,\textsuperscript{87} azathioprine,\textsuperscript{88} and cyclosporine alone or in combination with ATG, have been shown to be very effective in treatment of AATP.\textsuperscript{83,89,90} The role of recombinant interleukin-11 (IL-11, a thrombopoietic growth factor) in AATP is uncertain. The availability of thrombopoietic drugs,\textsuperscript{91} may offer another treatment option for AATP patients.

Chemical and Physical Agents That Produce Generalized Bone Marrow Suppression

Ionizing radiation, alkylating agents, antimetabolites, and cytotoxic drugs may produce thrombocytopenia as the result of predictable suppression of the marrow. The mechanisms by which these agents act are well defined, and
thrombocytopenia is a common complication when they are used in immunosuppression and cancer chemotherapy. In addition, many drugs, such as chloramphenicol, produce marrow hypoplasia as a result of idiosyncratic reactions. The pathophysiology in these cases is poorly understood.

Agents that produce thrombocytopenia may damage other bone marrow precursors as well as megakaryocytes, and the usual picture is one of diffuse bone marrow hypoplasia and pancytopenia. Rarely, only thrombocytopenia may be present. Platelets often are the last cell type to return to normal after recovery from bone marrow hypoplasia; in some patients, thrombocytopenia may persist indefinitely.

Drugs That Selectively Suppress the Megakaryocyte

Chlorothiazides. Chlorothiazides and various congeners may produce thrombocytopenia by one of at least two mechanisms: by the formation of platelet antibodies or by a poorly understood suppression of thrombopoiesis. The latter action is by far the most common. Evidence of marrow suppression is largely indirect. Serologic tests for platelet antibodies usually yield negative results. Diminution in the number of megakaryocytes has been observed in infants born of mothers who were taking these drugs, but few instances of megakaryocytic hypoplasia have been documented in adults. Mild asymptomatic thrombocytopenia may occur in as many as 25% of patients taking these agents, an observation that implies that thrombopoiesis may be a pharmacologic rather than an idiosyncratic effect. Recovery from thrombocytopenia associated with the use of thiazide drugs is slow, and thrombocytopenia usually can be reproduced only by readministration of the drug for a protracted period.

Estrogens. Estrogenic hormones appear to affect platelet kinetics in animals both by facilitating reticuloendothelial phagocytosis and by impairing thrombopoiesis. Neither effect has been convincingly demonstrated in humans, but several instances of “amegakaryocytic” thrombocytopenia have been reported after the administration of diethylstilbestrol. In one patient, thrombocytopenia recurred when the hormone was readministered.

Ethanol. Ethanol can suppress platelet production, a phenomenon that may be a common cause of mild thrombocytopenia in the alcoholic patient. In most reported cases, nutritional factors, folate deficiency, and splenomegaly were excluded, but patients did have evidence of impaired hepatic function. Platelet counts <100,000/µl occur in as many as 26% of acutely ill alcoholics. The experimental administration of ethanol produces thrombocytopenia with decreased platelet survival and platelet turnover. Bleeding is rare, and when ethanol is withdrawn, the platelet count begins to increase in 2 to 3 days and returns to normal or supranormal levels in 2 to 3 weeks. Several patients developed venous thromboembolic disease when platelet counts reached values >500,000/µl.

Pathophysiologic studies in alcohol-induced thrombocytopenia reveal accelerated platelet destruction and a subnormal compensatory increase in thrombopoiesis. Platelet function abnormalities have also been described. The bone marrow usually reveals normal numbers of megakaryocytes. Studies using mice and guinea pig megakaryocytes demonstrate that the effect of ethanol is primarily on the maturing megakaryocytes, a finding consistent with ineffective thrombopoiesis. Several cases of bone marrow hypoplasia secondary to consumption of excessive alcohol have also been described. Colony-forming unit (CFU) granulocytemacrophage-derived colony formation in one of these patients was inhibited by much lower concentrations of ethanol than that of normal volunteers.

Drugs That Cause Ineffective Thrombopoiesis

Ineffective thrombopoiesis may play a role in several different types of thrombocytopenia. Thrombocytopenia is a consistent feature of megaloblastic hematopoiesis that results from deficiency of vitamin B12 or folic acid. Although seldom severe and rarely of clinical significance, this form of thrombocytopenia results from a distinctive abnormality of platelet production called ineffective thrombopoiesis. This abnormality was first demonstrated in thrombokinetic studies and is characterized by diminished platelet production despite the presence of an increased megakaryocyte mass. Thus, it is analogous to ineffective erythropoiesis, which is also characteristic of the megaloblastic anemias. Platelet production, whether calculated per megakaryocyte or per nuclear unit, is diminished. Although the number of megakaryocytes increases in response to thrombopoietic stimuli, the normal concomitant increase in their volume does not occur. This phenomenon presumably results from impaired DNA synthesis and the consequent limitation in nuclear endoreduplication. In stained smears, the megakaryocytes often appear hyperlobulated, and circulating platelets are abnormally large. Moderate shortening of platelet survival and, rarely, hypoplasia of the megakaryocytes may be important contributory factors in the production of thrombocytopenia in some cases.
Thrombocytopenia Caused by Abnormal Platelet Pooling

The splenic pool normally contains approximately one third of the total platelet mass, and this pool may increase in size as a result of disorders that are associated with splenomegaly, such as cirrhosis with portal hypertension, sarcoidosis and other granulomatous infections, Gaucher and other lipid-storage diseases, leukemias and lymphomas, and Felty syndrome. This shift of platelets into the spleen may result in thrombocytopenia in the circulating blood despite a normal or even increased total platelet mass. The clinical picture in hypersplenic thrombocytopenia is usually dominated by the underlying disease, and numerous other hematologic abnormalities, such as neutropenia, anemia, and coagulation defects, may also be present.

The pathophysiology of thrombocytopenia in disorders associated with splenomegaly is not completely understood. Rat spleens demonstrate large numbers of platelets adherent to reticuloendothelial cells. It is also hypothesized that the splenic pool increase may occur because of very slow passage of platelets through the tortuous splenic vasculature. The platelets in the splenic pool are in equilibrium with the circulating pool and can be mobilized with an infusion of epinephrine or during plateletpheresis. This is in contrast to the irreversible thrombocytopenia caused by splenic removal of damaged or antibody-coated platelets in disorders such as autoimmune thrombocytopenic purpura. There is some evidence for accelerated platelet destruction in many instances of thrombocytopenia associated with disorders of the spleen.

Thrombocytopenia Caused by Hypothermia

In humans, mild reversible thrombocytopenia is a predictable consequence of surgical hypothermia below 25°C. Patients with thrombocytopenia secondary to cirrhosis occurs in almost all patients undergoing one- or two-cycle cryotherapy for hepatic metastases from colorectal adenocarcinoma.

Thrombocytopenia Caused by Hypothermia

In humans, mild reversible thrombocytopenia is a predictable consequence of surgical hypothermia below 25°C. Therapy is seldom indicated for thrombocytopenia alone, but splenectomy, embolic occlusion of the splenic vasculature, and splenic damage secondary to infusion of radiolabeled particles can improve the thrombocytopenia and sometimes alleviate the pancytopenia completely. Patients with thrombocytopenia secondary to cirrhosis with portal hypertension may benefit from portocaval shunts or transjugular intrahepatic portosystemic shunts.

Thrombocytopenia Associated with Infections

Purpura was recognized as a manifestation of pestilential fevers 2,000 years ago. Several factors are now known to cause bleeding in association with infections, of which thrombocytopenia is the most common.

Thrombocytopenia Associated with Viral Infections

Viruses may produce thrombocytopenia by several different mechanisms: Impaired platelet production as a result of invasion of megakaryocytes by the virus, impaired platelet production caused by toxic effects of viral proteins on...
progenitor cells, viral-induced hemophagocytosis, destruction of circulating platelets by the virus, and increased platelet
destruction caused by binding of viral-induced autoantibodies or viral antigen-antibody complexes.

The administration of live measles vaccine produced significant yet subclinical thrombocytopenia in most normal
children. Degenerating vacuolated megakaryocytes were evident 3 days after administration of the vaccine. The nadir
of the platelet count occurred 7 days after vaccination. There are now several reports of thrombocytopenia occurring
after immunization with measles-mumps-rubella vaccine, monovalent measles vaccine, and measles-mumps vaccine. Thrombocytopenia has been severe (<20,000/µl), and some patients have had significant hemorrhagic complications. The majority of the patients have been <2 years of age, but the age range was 1 to 40 years. Thrombocytopenia after vaccination for hepatitis A and B and varicella has also been noted. Children with neonatal infections with mumps and rubella are often thrombocytopenic, and hepatomegaly and splenomegaly may also be present. CMV infection is usually asymptomatic in immunocompetent adults. However, there are reports of severe thrombocytopenia and even thrombocytopenia with hemolysis. It is unclear whether the thrombocytopenia is caused by a direct cytopathologic effect of the virus on megakaryocytes, viral-induced hemophagocytosis, or immunologic destruction.

Parvovirus B19 is the etiologic agent responsible for erythema infectiosum. It is also cytotoxic to erythroid progenitors and
can cause aplastic crises in patients with hemolytic anemia and chronic bone marrow failure in immunocompromised
hosts. Thrombocytopenia may occur in some of these patients.

and recent studies demonstrate cytotoxic effects of viral nonstructural-1 proteins on megakaryocytes. Thrombocytopenia has been reported following the administration of adeno-viral gene transfer vectors. The interaction between adeno-virus and platelets leads to platelet activation and rapid exposure of P-selectin on the platelet surface. P-selectin interacts with major P-selectin ligand on leukocytes, leading to the formation of platelet-leukocyte aggregates. Adeno-virus also activates endothelial cells either directly or indirectly through activated platelets. It is followed by increases in total amounts of vWF and of ultralarge vWF multimers in plasma as well as an increase in the number of circulating endothelial cell-derived microparticles. Endothelial cell activation and the associated up-regulation of adhesion molecules (VCAM-1) contribute to leukocyte and/or platelet leukocyte aggregate rolling and transendothelial migration, a critical process for tissue macrophage influx. This is followed by removal of activated platelets by tissue macrophages.

Thrombocytopenia Associated with Bacterial and Protozoal Infections

Thrombocytopenia commonly is associated with septicemia resulting from both Gram-negative and Gram-positive
bacteria. This complication is particularly common in infants and children, and the presence of unexplained
thrombocytopenia, particularly in this age group, should always alert the physician to the possibility of septicemia. The
etiology of thrombocytopenia may be multifactorial. Thrombocytopenia may be caused by disseminated intravascular
coagulation (DIC), and the diagnosis of DIC may be apparent when coagulation studies are performed. Thrombocytopenia
has also been described in patients with Gram-negative or Gram-positive septicemia, and 46% of these patients had
elevated platelet-associated immunoglobulin G without evidence of DIC. These studies were interpreted as demonstrating
the presence of platelet destruction caused by splenic destruction of immune complex-coated platelets. These data must
be reinterpreted with third-generation immune complex capture assays that can better define platelet autoantibodies and
immune complexes.

Platelet adherence to damaged vascular surfaces may also account for thrombocytopenia in certain bacterial infections,
such as meningococccemia. Endotoxins, exotoxins, or platelet-activating factor may damage platelets, resulting in
increased clearance. Patients with sepsis syndrome may develop hemophagocytic histiocytosis with phagocytosis of
platelets, white cells, and platelets in bone marrow histiocytes.

Thrombocytopenia may also be caused by direct platelet toxicity caused by the microorganism. Thrombocytopenia occurs
in >80% of patients with malaria, and platelets from malaria patients have been demonstrated to contain plasmodia.
Significant ultrastructural changes in platelets of patients with malaria are present, and the extent of abnormal findings
 correlates with the level of parasitemia.

The pathophysiology of thrombocytopenia in malaria has recently been studied in a mouse model of experimental malaria
induced by Plasmodium berghei. Signaling through multipotent immunomodulator CD40L and its receptor CD40,
expressed on activated platelets, initiates the caspase cascade, resulting in apoptosis of the platelet and the formation of
platelet microparticles. Early depletion of platelets leads to an altered immune response with significantly decreased
levels of proinflammatory cytokines, such as interferon-γ and interleukin-2 (IL-2), as well as increased levels of IL-10, indicating a role for platelets in the regulation of pathogenic cytokines and cell-mediated immune responses. Cell-mediated rather than the humoral immune response has been shown to play a major role in development of thrombocytopenia.

Theoretically, any bacterial or protozoal infection can be associated with thrombocytopenia that is caused by one of the mechanisms hypothesized in this chapter. There are reports of thrombocytopenia in Lyme disease and Mycoplasma pneumoniae infections, a manifestation of these infections that appears to be uncommon. Patients with thrombocytopenia associated with infection should be tested for the presence of DIC. At this time, no other clinically available tests can be used to define the precise etiology in patients without evidence of DIC. The most important therapy for infection-related thrombocytopenia is that directed at the underlying infection. Platelet transfusions, with or without intravenous IgG, can be used to control bleeding until antimicrobial therapy is effective.

Thrombocytopenia after Massive Blood Transfusion

Massive blood transfusion is defined as complete replacement of a patient’s blood volume within 24 hours, usually 10 units of packed red blood cells for an average-sized adult. Because packed red blood cells do not contain a significant number of functional platelets and do not replace labile clotting factors, there has been concern about the incidence of developing hemostatic abnormalities and clinical bleeding in patients given only packed red blood cells.

Some studies demonstrate a correlation between the number of units of packed red blood cells transfused and both reduction in platelet counts (“dilutional thrombocytopenia”) and increases in prothrombin and partial thromboplastin times. However, significant changes (platelets, 50,000 to 100,000/µl) are not apparent until patients have received >15 units of blood. Severe thrombocytopenia, defined as a platelet count <50,000/µl, is most common in patients receiving >20 units of blood. Microvascular bleeding occurs in 20% to 60% of patients who are massively transfused, but neither the platelet count nor changes in coagulation studies can be used to predict which patients will bleed. Although bleeding appears to be more dependent on thrombocytopenia than on coagulation abnormalities, prophylactic administration of platelets was no more effective than equivalent volumes of prophylactic fresh-frozen plasma infusions in preventing bleeding. Therefore, it is recommended that platelet and plasma replacement during massive transfusions be guided by serial monitoring of platelet counts, prothrombin time, and partial thromboplastin time, and that platelet counts be kept >75,000/µl and prothrombin time and partial thromboplastin time <1.5 times normal. The coagulopathy associated with massive blood transfusion is discussed further in Chapter 54.

Chapter 50 Bleeding Disorders Caused by Vascular Abnormalities

This chapter discusses causes of bleeding that are not the result of thrombocytopenia, coagulation factor deficiency, or qualitative platelet defects. Bleeding disorders caused by these various “vascular” abnormalities represent a heterogenous group of diseases, and in considering the differential diagnosis, it is convenient to consider cutaneous causes, connective tissue abnormalities, vascular lesions, and intravascular causes.

CLINICAL APPROACH TO THE PATIENT

The initial approach to the bleeding patient is discussed in Chapter 45. When considering “vascular” causes of bleeding, the appearance of the lesions (petechiae vs. more extensive ecchymosis, size, shape, color), location and pattern of involvement, associated features (fever, ulcers, scars, livedo reticularis), and the clinical setting are helpful clues. Table 50.1 lists some common physical finding patterns helpful in considering the differential diagnosis of vascular disorders.

Purpura is the term used to describe the skin lesions that develop when red blood cells extravasate from capillaries. Purpura refers to either pinpoint lesions called petechiae or more widespread lesions known as ecchymoses. Purpura can be differentiated from other erythematous lesions by the use of diascopy, which is the application of a glass slide to the border of the lesions. True purpura does not blanch with pressure.

MECHANICAL PURPURA

External pressure such as blunt trauma results in ecchymoses when the force is sufficient to disrupt vascular integrity and allow extravasation of red blood cells. The size of the resulting lesion is dependent on the durability of the tissue traumatized, the vascularity of the region, the density of the surrounding tissue, and the time elapsed. The extent of bruising can increase over time, and tracking through tissue planes can occur, resulting in bruises in areas remote from the area of trauma. The color of the lesion is in part dependent on the location of the red cells—lesions near the surface have a more reddish color, and deeper lesions appear bluish. This finding is due to optical scattering in the dermis, and the fact that blue wavelengths scatter and reflect more than red.

Bruises change color with time, and the color of bruise has been used to determine the age of lesions. However, evidence suggests that there is more variability in color changes than previously recognized.

Mechanical purpura can be seen on occasion with minor trauma such as blood pressure cuff monitoring in anticoagulated patients or even vigorous scratching. Young adults playing active sports such as basketball can develop calcaneal petechiae resulting from relatively minor, but repetitive, heel trauma. Periorbital, face, or neck purpura can occur after a sudden increase in intravascular pressure with a Valsalva maneuver and has been described after bungee jumping.

Suction purpura occurs when negative pressure is applied to the skin in sufficient force to result in extravasation of erythrocytes. Young healthy people develop petechiae with 350 to 400 mm Hg negative pressure, but the required amount of pressure to induce purpura decreases with age to as low as 100 mm Hg. The application of rubber suction devices to the forehead can result in circumscribed purpura. This seems to occur mostly when new parents apply children’s suction toys to their foreheads and has been termed cyclops purpura. A similar, relatively common cause of
Suction purpura is seen in adolescents who place a drinking glass over their chin and suck out the air to form a vacuum, ultimately causing chin or perioral purpura. Adolescents are also prone to develop small purpuric lesions in the neck region from “hicckeys” or “love bites,” another form of suction purpura.

Large areas of contusions develop with blunt force injuries. Certain patterns of contusion can help identify the type of device causing the injury. Skin bruises corresponding to the sites of seat belts are known as “seat belt mark” signs. It is important to recognize these, as the presence of this sign should alert physicians to the higher likelihood of internal injuries. A direct blow from a linear or cylindric object causes parallel lines (“tram-line” appearance) with central clearing, as the blood beneath the site of highest impact is displaced laterally. Similarly, a bruise in the shape of a circle with central clearing may occur as a result of a blow from the circular edge of a pipe or spherical objects. Caution, however, should be used in interpreting these types of bruises, as simple bruises can sometimes occur with “ring resolution.” Circular contusions 1 to 1.5 cm in diameter may be due to fingertip pressure and grab marks or bite marks, and they show semicircular arch contusions, but are highly variable. Certain bruising patterns can suggest child or elder abuse, but results should be interpreted carefully.

Larger ecchymotic areas also may demonstrate other patterns that can be a clue to underlying pathology. The well-known Cullen sign refers to bluish discoloration around the umbilicus, and Grey-Turner sign is flank ecchymosis. Both may indicate hemorrhagic pancreatitis or a rectus sheath hematoma. Scrotal ecchymosis may be a clue to intraperitoneal hemorrhage, and perianal ecchymosis has been described as a manifestation of aneurysmal rupture into the sigmoid mesocolon. “Raccoon eyes” and mastoid ecchymosis (Battle sign) may indicate a basilar skull fracture after head trauma. Ecchymosis occurring in patients with swollen calves suggests a ruptured popliteal cyst with gravitational spread of the bruise down to the ankle and occasional linear appearance (“tide mark” appearance) with sparing of the foot and lower ankle due to the pressure of footwear.

**STRUCTURAL MALFORMATIONS OF VESSELS**

**Hereditary Hemorrhagic Telangiectasia**

Hereditary hemorrhagic telangiectasia (HHT) was first described in 1864 by Sutton and later recognized and reported by Rendu, Osler, and Weber, and it is thus also known as Osler-Weber-Rendu syndrome. It is an autosomal dominant disorder characterized by multiple telangiectatic lesions involving the skin and mucous membranes associated with epistaxis and other bleeding complications. HHT has an estimated prevalence of 1 in 8,000, with complete penetrance by 40 years of age. Genetic studies have identified several mutations responsible for the vascular malformations. Mutations in the endoglin gene on chromosome 9 (HHT1) or in the activin receptor-like kinase (ALK1) gene on chromosome 12 (HHT2) account for ~85% of the cases. Currently more than 500 mutations in the ALK1 or endoglin genes have been identified, and each family studied appears to have a unique mutation. Endoglin is an integral membrane glycoprotein expressed on endothelial cells in arterioles, venules, and capillaries. This glycoprotein and ALK1 serve as a binding protein for transforming growth factor-β (TGF-β).

TGF-β regulates many transcriptional targets and plays a crucial role in vascular development and homeostasis. Recently identified mutations in the MADH4 gene abnormalities are associated with juvenile polyposis and HHT, and linkage studies suggest additional mutations exist on other chromosomes. An HHT mutation database is available at http://www.hhtmutation.org.

AIHE, acute infantile hemorrhagic edema; EDS, Ehlers-Danlos syndrome; HHT, hereditary
hemorrhagic telangiectasia; PPGSS, papular-purpuric gloves and socks syndrome.

The mechanisms by which these genetic defects result in telangiectatic lesions have not been identified. Ultrastructural analysis of cutaneous HHT lesions suggests that postcapillary venule dilation is the earliest identifiable morphologic abnormality. As the venules enlarge, they become convoluted and interconnect with arterioles through capillary segments. The capillary segments eventually disappear, and direct arteriolar-venular communications are established (Fig. 50.1). An infiltrate of mononuclear cells appears in the perivascular region of the HHT lesions.

The bleeding manifestations are thought to occur because of mechanical fragility of these vessels. Common abnormalities in the hemostatic system do not seem to represent a major factor in the underlying bleeding tendency. HHT patients manifest a variety of other complications including shunting, emboli, and thrombosis.

Clinical Manifestations

The cutaneous lesions usually appear in affected persons by 40 years of age, and they increase in number with age. The lesions measure 1 to 3 mm in diameter and are sharply demarcated in appearance (Fig. 50.2). They blanch with pressure, but the blanching may be incomplete as a result of “strangulation” of coiled loops of vessels. The telangiectatic lesions are most commonly found on the face, lips, nares, tongue, nail beds, and hands. Some patients have only a few lesions, necessitating a thorough search in anyone suspected of having HHT. Bleeding from these cutaneous telangiectasias is uncommon and rarely of clinical importance. One report suggests that capillaroscopy of the dorsal hands can detect morphologic changes in the skin microcirculation, including microscopic telangiectatic lesions, but the clinical utility of this is undefined.
FIGURE 50.1. Arteriovenous malformations in hereditary hemorrhagic telangiectasia. In a fully developed cutaneous telangiectasia, the venule (V) and its branches have become dilated and convoluted throughout the dermis. The connecting arterioles (A) have also become dilated and communicate directly with the venules without intervening capillaries. A perivascular infiltrate is present. The thickened wall of a dilated postcapillary venule is also shown. L, lumen of the vessel. (From Guttmacher AE, Marchuk DA, White RI. Hereditary hemorrhagic telangiectasia. N Engl J Med 1995;333:918-924, with permission.)

Epistaxis is the presenting complaint in up to 90% of patients with HHT. This symptom results from bleeding telangiectatic lesions over the inferior turbinates and nasal septum. Symptoms usually occur before 35 years of age and are highly variable. Approximately one-third of patients have mild symptoms requiring no treatment, and another third have
moderate symptoms requiring only outpatient treatment. The remaining third have severe symptoms often requiring inpatient treatment, transfusions or chronic iron replacement therapy, and surgery. The nosebleeds may become more difficult to control as the patient ages.

Pulmonary arteriovenous malformations (PAVMs) occur in 30% of patients with HHT, and 85% to 90% of people with PAVM are found to have HHT. Genetic linkage studies have found that patients with endoglin mutations have significantly higher rates of PAVMs (40%) than HHT patients with other mutations (14%). The PAVMs are primarily located in the lower lung lobes and are multiple. These PAVMs may result in a significant right-to-left shunt, and patients may develop dyspnea, cyanosis, clubbing, fatigue, decreased exercise tolerance, migraine headaches, and polycythemia. Paradoxical emboli can occur and result in brain abscesses, transient ischemic attacks, and strokes. The prevalence of cortical infarcts has been reported to be as high as 14% in patients with a single PAVM and increases to 27% in patients with multiple PAVMs. These lesions may also bleed and result in hemothorax; pregnant women with PAVMs appear to be at increased risk.

The detection of PAVMs may be difficult in patients with few or no symptoms. Physical examination may uncover an end-inspiratory bruit. A chest radiograph may detect a coin lesion but often misses smaller lesions. Gravitational shifts in blood flow to the lung bases result in increased right-to-left shunting in the sitting or standing position. Physiologic tests such as measuring O₂ saturation in the supine and standing position (on room air and 100% O₂) can detect the positional change in shunting and can be used to screen patients for PAVMs. However, the best screening test for PAVM appears to be contrast echocardiography. Patients with a positive screening test should undergo an unenhanced spiral computed tomography (CT) to confirm and further characterize the PAVM. Pulmonary angiography is a less sensitive study but is necessary in treatment planning.

Approximately 20% of patients with HHT develop significant upper and lower gastrointestinal (GI) tract hemorrhage. Bleeding is rare before the fifth decade of life. Approximately 40% of the bleeding episodes occur from upper GI tract lesions, whereas only 10% occur in the colon, and a full one-half are indeterminate after evaluation. Spontaneous regression of GI bleeding is rare, and steady progression or chronic intermittent bleeding is the norm.
Hepatic involvement occurs in 70% of patients, but symptoms and complications are rare. Patients may have hepatomegaly, a hepatic bruit or thrill, or elevated liver function studies. Types of intrahepatic shunting include hepatic artery to hepatic vein (arteriovenous), hepatic artery to portal vein (arterioportal), and portal vein to hepatic vein (portovenous). These shunts can lead to clinical complications of high-output heart failure, portal hypertension, encephalopathy, biliary ischemia, and nodular regenerative hyperplasia. The dominant type of shunt identified on multiphasic CT does not correlate strongly with the clinical syndrome. Nodular regenerative hyperplasia is found with a 100-fold increased prevalence compared to the general population, and along with portal hypertension can lead to a misdiagnosis of cirrhosis (pseudocirrhosis). It is important to consider this diagnosis in the setting of a liver mass, as biopsy should generally be avoided when suspected. Additionally, if patients with known focal nodular hyperplasia are being treated with estrogen or progesterone therapy, close monitoring is indicated with discontinuation of hormones in the case of symptomatic tumor enlargement. Hepatic AVMs can be detected by dynamic CT, color Doppler ultrasound, magnetic resonance imaging/magnetic resonance angiography (MRI/MRA), or celiac angiography. CT evidence for AVMs includes both the characteristic heterogenous enhancement of the entire liver as well as a dilated common hepatic artery.

The neurologic manifestations of HHT result from PAVM in up to two-thirds of cases. The remainder of the neurologic symptoms are the result of cerebrovascular telangiectasias, AVMs, aneurysms, and cavernous hemangiomas. Ten to twenty percent of patients with HHT have cerebral AVM, but only 10% of people who have cerebral AVM are found to have HHT. The cerebral AVMs are often multiple. The annual risk of bleeding from cerebral AVM is low, reported as 0.41% to 0.72%/year (compared to 2% to 4% risk for sporadic, non-HHT AVM). MRI is recommended for detecting these lesions.

**TABLE 50.2 CURACAO CRITERIA FOR THE DIAGNOSIS OF HEREDITARY HEMORRHAGIC TELANGIECTASIA (HHT)**

1. Epistaxis—spontaneous and recurrent
2. Telangiectasias—multiple, at characteristic sites (lips, oral cavity, fingers, nose)
3. Visceral lesions—with or without bleeding (gastrointestinal, pulmonary, cerebral, hepatic)
4. Positive family history—a first-degree relative with HHT

The presence of three of the above criteria indicate definite HHT; the presence of two criteria are suspicious for HHT.

The clinical diagnostic criteria (Curacao criteria) are listed in Table 50.2. Genetic testing is now available, but requires sequencing the entire coding regions of ALK1 and endoglin, and is complex and expensive. Consultation with a medical geneticist is recommended.

**Management**

Asymptomatic patients with HHT should be screened with a thorough history, careful physical exam, complete blood count (CBC), and stool guaiac studies. A brain MRI to screen for cerebral AVMs is recommended, and contrast echocardiography to screen for PAVMs should be performed in all patients at least once after the age of 10. Children younger than 10 should be screened with oxygen saturations in the sitting and supine position every 1 to 2 years, with further testing for saturations <97%. Hepatic AVM screening is controversial, but if considered, an ultrasound is the preferred study.

Recurrent epistaxis can be a perplexing problem, and few trials exist that compare various treatment modalities. Recent efforts to classify the nasal vasculature pattern and develop an epistaxis severity scoring system should pave the way for randomized trials of the various approaches. Prophylactic measures include humidification and saline nose drops. Nasal trauma from vigorous nose blowing, straining, and finger manipulation should be avoided. Antihistamines should also be avoided to prevent drying of the nasal mucosa. Mild bleeding can be treated with absorptive packing and direct pressure. Cautery is commonly used to stop persistent bleeding, but repeated cauterizations can result in necrosis and septal perforation, and should be avoided. Fibrin glue spray was of benefit in a small study. The neodymium:yttrium-
P.1110

Genetic counseling should be part of the treatment, and referral to a designated HHT center should be considered in most cases. Seventeen U.S. and Canadian HHT centers currently exist and are listed on the HHT Foundation International, Inc.
A recent review summarizes all aspects of HHT diagnosis and management. Vascular Malformations

Vascular malformations result from localized errors of angiogenic development. The underlying molecular genetics of angiogenesis are complex (see Chapter 19). Mutations in angiogenic pathways can result in a variety of malformations, including capillary or venous angiomas, cerebral cavernous malformations (CCMs), and AVMs, either as isolated or multifocal lesions. Bleeding problems occur from rupture or leakage from these vascular anomalies, and the clinical sequelae depend on their location.

Skin lesions are the most common vascular malformation and include a variety of birthmarks. Hemoptysis can result from pulmonary vascular anomalies including AVM and a rare disease known as pulmonary capillary hemangiomatosis. Hematuria may rarely be due to genitourinary AVMs or hemangiomas.

GI bleeding may be due to vascular malformations such as the blue rubber nevus syndrome, gastric antral vascular ectasia, telangiectasias, and AVM. GI angiodysplastic lesions deserve special attention, given their frequency. They appear to be due to degenerative dysplasia and are the most frequent cause of obscure GI bleeding. The cause is thought to be intermittent obstruction of the submucosal veins where they penetrate the muscular layers of the colon, ultimately leading to dilated, tortuous submucosal veins and venules. Small intestinal angiodysplastic lesions can be particularly hard to detect, but wireless capsule endoscopy can facilitate this diagnosis. Endoscopic-based therapy or surgery may be required for treatment. This disorder is frequently associated with aortic stenosis, and there are reports of cessation of bleeding after aortic valve repair. Continuous estrogen-progestin treatment is not useful in the prevention of rebleeding from GI angiodysplasia.

Central nervous system vascular lesions include AVMs, berry aneurysms, and cavernomas. Bleeding from these lesions may account for 30% of spontaneous intraparenchymal lobar bleeds. Autopsy studies show the presence of intracranial aneurysms in 1% to 5% of the adult population, and 20% to 50% of these aneurysms rupture. They are sporadically acquired, but patients with autosomal dominant polycystic kidney disease may have up to a 40% incidence. Screening is recommended for families with two immediate relatives with intracranial aneurysms and all patients with autosomal dominant polycystic kidney disease. Histologically, there is a decrease in the tunica media causing structural defects, leading to aneurysmal dilatation at branch points at the base of the brain. Rupture leads to subarachnoid hemorrhage with symptoms ranging from headache and nuchal rigidity to drowsiness, stupor, and coma.

CCMs are vascular lesions characterized by abnormally enlarged capillary cavities without intervening brain parenchyma. The most common presentation is with seizures and cerebral hemorrhage. Sporadic and familial forms exist, with the familial form showing autosomal dominant inheritance with incomplete penetrance. The familial forms usually have multiple CCM lesions. Three CCM loci have been identified, and the clinical and neuroradiologic features compared. CCM3 carriers have an earlier age of onset of cerebral hemorrhage. CCMs are not usually visible on angiography, but T1- and T2-weighted images on MRI show characteristic findings.

Other Vasculopathies

Amyloidosis

Patients with multiple myeloma or systemic amyloidosis may have light chain deposits in the cutaneous blood vessels. These vessels are particularly fragile, and purpura can occur as a result of minor trauma (“pinch purpura”). The eyelids and periorbital regions are particularly prone to developing purpura (Fig. 50.3), and a classic sign is postproctoscopic periorbital purpura occurring after proctoscopies (for diagnostic rectal biopsies done in the past) or after Valsalva maneuvers. Purpura also commonly develops in other flexural skin areas such as the nasolabial folds, neck, axillae, and umbilicus. Biopsies of the cutaneous vascular lesions demonstrate amyloid deposits in the dermis and subcutaneous tissues, and inflammatory cells are scarce. The diagnosis and treatment of these disorders are discussed in detail in Chapter 99.
Moyamoya disease is a chronic cerebral vasculopathy initially described in Japan. The disease is characterized by occlusion of the terminal portion of the internal carotid arteries, or the proximal aspects of the middle or anterior cerebral arteries. An abnormal vascular network of collaterals develops in the regional area of occlusion. Cerebral infarcts are common in children, but adults have a higher propensity for intracranial hemorrhage. The risk of bleeding appears to be highest in adult Asians. Features of moyamoya phenomenon differ in U.S. patients, with women aged 30 to 50 most commonly affected, predominantly with ischemic symptoms. The etiology is unknown, and diagnosis rests on characteristic angiographic findings.

Cerebral Small Vessel Disease

Cerebral small vessel disease usually refers to arterioles <100 µm in size consisting of an internal elastic membrane and a tunica media one to two layers thick, or small arteries measuring 100 to 400 µm in size with tunica media composed of smooth muscle cells three to four layers thick. These vessels are usually end arteries. A constellation of syndromes is now recognized as causing cerebral small vessel disease, and these are mostly characterized by recurrent ischemic strokes with progressive cognitive impairment. Bleeding, however, is a recognized complication of most of these disorders, and it is important to recognize that many disorders have a substantially increased risk of bleeding with anticoagulants.

![FIGURE 50.3. Periorbital purpura in a 58-year-old woman with immunoglobulin A κ plasma cell dyscrasia associated with secondary amyloidosis. (This photograph was kindly provided by Drs. Theresa Scholz and Pamela Nemzer, Department of Dermatology, University of Utah Health Sciences Center.)](image)

Degenerative cerebral microangiopathy is characterized by lipohyalinosis of small vessels associated with aging and increasing in severity with vascular risk factors such as hypertension, diabetes, and hyperhomocysteinemia. The vessel walls thicken due to sclerosis, hyalinosis, and lipid deposition. Most of the bleeding appears to occur at or near the bifurcation of affected arteries where prominent degeneration of the media and smooth muscles is most appreciated. Occlusion leads to lacunar infarcts, and rupture can lead to cerebral microbleeds and lobar intracranial hemorrhages.
Cerebral amyloid angiopathy typically presents with lobar hemorrhages in patients older than 70 years, and is due to several types of mutations that lead to the accumulation of b-amyloid material in the media and adventitia of small cortical and leptomeningeal vessels. This leads to a “vessel in vessel” appearance on pathology studies. Because of the higher risk of bleeding, strict avoidance of anticoagulation and antiplatelet agents are recommended.

Cerebral autosomal dominant arteriopathy with stroke and ischemic leukoencephalopathy (CADASIL) is a cerebral vasculopathy occurring in patients usually between the ages of 40 and 60. Patients present with subcortical strokes and a slowly progressive dementia and may have mood disorders, migraine headaches, and in the later stages, pseudobulbar palsy. The diagnosis is suggested by a characteristic finding of widespread leukoencephalopathy on MRI. White matter lesions located in the temporal poles of the brain are considered pathognomonic for CADASIL syndrome. Recent studies suggest that cerebral microbleeds are found in 31% to 69% of patients with CADASIL syndrome and intracranial hemorrhaging occurs in 25% of patients. The vascular defect lies in the smooth muscle cells, with electron microscopy showing exocytosis of granular osmophilic material from the vascular smooth muscle cells and pericytes.

Type 4 collagen is a component of the vascular basement membrane in the brain, and recent mouse studies indicate that mutations can lead to microvascular fragility and result in intracranial hemorrhage. Some familial forms of intracerebral hemorrhage also appear to be due to mutations in the COL4A1 gene.

BLEEDING DUE TO DISORDERS OF PERIVASCULAR TISSUE

Ehlers-Danlos Disease

The Ehlers-Danlos syndromes (EDSs) are a group of rare connective tissue disorders caused by abnormalities of collagen synthesis or processing. The prevalence is estimated to be 1 in between 10,000 and 20,000 births. A simplified classification system has identified six major types of EDS and their genetic defects. The clinical features include hyperextensible, fragile skin associated with joint hypermobility. The majority of patients with EDS also report a history of excessive bruising and bleeding. Other bleeding manifestations may include subcutaneous nodular hematomas, mucosal oozing after dental procedures, hemoptysis, and GI bleeding. In most patients, screening tests show no hemostatic abnormalities, and the bleeding is thought to result from abnormalities in the perivascular collagen leading to fragility of the subcutaneous vessels. However, several authors have noted abnormal bleeding times and platelet function studies, as well as factor deficiencies in individual patients.

Certain types of EDS have an increased risk of major bleeding. In particular, vascular EDS (type IV) has unique clinical features of interest to hematologists. This disorder is due to quantitative or qualitative defects in type 3 collagen, which is particularly abundant in the arterial wall and intestine. Patients with this disorder are prone to develop arterial aneurysms and dissections, significant bleeding from spontaneous rupture of medium-sized abdominal arteries, and intestinal rupture.

Carotid-cavernous fistula is another well-documented complication, and clinical diagnosis is based on the findings of pulsatile exophthalmia, tinnitus, thrill, and headache. In addition to vascular abnormalities, patients with vascular EDS have characteristic facial features (prominent eyes, thin nose, small lips, and lobeless ears) and thin translucent skin with a conspicuous venous network. Papyrus scarring (Fig. 50.4) may be present, but patients usually have minimal joint hypermobility (often limited to the hands) or skin hyperextensibility. Median life expectancy is 48 years with one-fourth of the patients developing complications by age 20, and 80% developing complications by age 40. The diagnosis can be confirmed by skin fibroblast cultures with biochemical analysis of type 3 collagen with or without screening for COL3A1 mutations. If vascular EDS is suspected but the above tests are negative, patients should be screened for TGF-β receptor gene mutations, as clinical features overlap with the newly described Loeys-Dietz syndrome (see below).

Patients with EDS, particularly vascular EDS, should generally avoid contact sports and isometric exercise and are advised to avoid medications with antiplatelet properties. Arterial rupture should be considered in the differential diagnosis when these patients present with new-onset symptoms such as abdominal pain. Diagnostic procedures that involve arterial puncture are relatively contraindicated because of a high incidence of complications. If surgery is mandatory, extreme care should be used in the manipulation of vascular tissues. Postpartum hemorrhage is a major risk for pregnant patients with EDS, and the management of pregnancy has been reviewed in case reports. Patients with vascular EDS can develop uterine or vessel rupture in the peripartum period, and should be followed in high-risk centers. Genetic counseling and referral to the Ehlers-Danlos National Foundation (www.edfnf.org) should be considered.

Marfan Syndrome

Marfan syndrome is a genetic disorder with characteristic ocular, skeletal, and cardiovascular abnormalities, affecting 1 in 5,000 individuals. Easy bruising has been reported but does not seem to be a major feature of the Marfan syndrome. However, the risk of postpartum hemorrhage is reported to be increased. The basic defect is due to a mutated fibrillin gene on chromosome 15. Fibrillin is a component of extracellular microfibrils.
The clinical manifestations of scurvy depend on the severity of vitamin C deficiency. Patients classically develop perivascular supportive tissues, which predispose to capillary fragility and delayed wound healing. Humans require vitamin C in the diet to promote the peptidyl hydroxylation of procollagen. The abnormal collagen results in defective perivascular supportive tissues, which predispose to capillary fragility and delayed wound healing.

Scurvy can be contacted at http://www.pxenape.org/.

Loeys-Dietz Syndrome

The pathogenesis of Loeys-Dietz syndrome has been described. Patients with Loeys-Dietz syndrome have a phenotype characterized by hypertelorism, bifid uvula or cleft palate, and arterial tortuosity with vascular aneurysms, resulting in dissections and arterial rupture. The severity of the craniofacial abnormalities appears to correlate with the outcome. The natural history of Loeys-Dietz varies from Marfan syndrome and EDS, with median survival of 37 years (vs. 48 and 70 years, respectively), but with a much lower complication rate after vascular surgery. It is of note that childhood aortic dissections occurred in patients with aortic diameters <5 cm, and it is recommended that repair occur when the maximum dimension of the ascending aorta exceeds the 99th percentile in children.

Osteogenesis Imperfecta

Osteogenesis imperfecta (OI) is an autosomal dominant disease characterized by brittle bones with pathologic fractures as a result of a deficiency in bone matrix. Approximately 95% of cases are caused by mutations in the genes COLA1 and COLA2, which code for the pro-α1(1) and pro-α2(2) peptides of type 1 collagen.

There are two α1-chains and one α2-chain in each type 1 collagen, and many different mutations in the genes coding for these subunits have been characterized. Eight clinical types of OI are currently recognized. Approximately 25% of patients have been noted to bruise easily; this tendency appears to vary with the clinical type. Skin contains predominantly type 1 collagen, and bruising is thought to be the result of defective supporting structures. The ecchymoses are generally mild and insignificant compared to the broader clinical picture. Recent reports describe patients with extradural hematomas, subdural hematomas, and retinal bleeds after minor trauma in patients with OI, occasionally being misinterpreted as child abuse.

Excessive bleeding from wound sites after surgery has also been described. Recombinant factor VIIa and desmopressin have been reported to be useful in postoperative bleeding in case reports. The Osteogenesis Imperfecta Foundation can be accessed at http://www.oif.org.

Pseudoxanthoma Elasticum

Pseudoxanthoma elasticum is an inherited connective tissue disorder that results in calcification of elastic fibers, especially in the internal elastic lamina of medium-sized arteries. The basic genetic defect is now known to be a variety of loss of function mutations in the gene encoding the transmembrane transporter protein ABC-C6. This protein is in the multiple drug resistance family of proteins and may function as an efflux pump, but it is not yet known what the substance transported is or how the mutation causes the disease. It is possible that this defect could result in accumulation of compounds that could lead to the calcification of the elastin fibers.

Patients with pseudoxanthoma elasticum have skin that becomes grooved and thickened over time and has been described as resembling Moroccan leather. Other cutaneous features include the development of yellow cutaneous plaques usually in the neck or axillary region or in other flexural sites. Cardiovascular disease results from calcification of the arterial internal elastic lamina. Criteria for the diagnosis of pseudoxanthoma elasticum have been published.

Bleeding can result when the calcified vessels rupture. The manifestations include bruising, epistaxis, and bleeding from the uterus, bladder, and joints. GI bleeding occurs in 13% of patients, usually between 20 and 30 years of age, and is usually of gastric origin. Treatment should include the avoidance of gastric irritants and careful control of hypertension and hypercholesterolemia. Regular ophthalmology evaluations are also recommended, as is the avoidance of antiplatelet agents and trauma. First-degree relatives should be screened. The National Association for Pseudoxanthoma Elasticum can be contacted at http://www.pxenape.org/.

Scurvy

Humans require vitamin C in the diet to promote the peptidyl hydroxylation of procollagen. The absence of vitamin C, collagen strands are weakened as a result of abnormal triple helical structures. The abnormal collagen results in defective perivascular supportive tissues, which predispose to capillary fragility and delayed wound healing.

The clinical manifestations of scurvy depend on the severity of vitamin C deficiency. Patients classically develop perifollicular petechiae (Fig. 50.5). The petechiae can coalesce and form purpura, particularly in a “saddle” distribution,
and patients may develop gingival or intramuscular hemorrhage. Up to 75% of patients have a multifactorial normochromic, normocytic anemia. Other manifestations include peripheral edema and fatigue.

Patients at risk for scurvy include elderly edentulous patients who cook for themselves, alcoholics, mentally ill patients, and people on unusual diets. The treatment is replacement of ascorbic acid in doses of 200 mg/day.\textsuperscript{111, 113}

Steroid-induced Purpura

Patients on chronic steroids develop thinning of the connective tissues, and minor trauma can result in extensive purpura, especially in older patients. Avoidance of trauma is the best prophylaxis for bleeding in these patients.

Solar Purpura

Senile purpura or solar purpura is a common phenomenon first described in 1817 by Bateman. The lesions are typically located on the extensor surfaces of the forearms and dorsum of the hands and occur without recognized preceding trauma (Fig. 50.6).\textsuperscript{114} The prevalence in hospitalized patients older than 65 years of age is approximately 5% but increases exponentially with age to include up to 30% of men 90 years of age or older.\textsuperscript{115} The skin in elderly people is thin as a result of loss of subcutaneous fat and changes in both the amount and quality of collagen. Skin lesions are thought to develop by incidental lateral displacement of slack skin with resulting capillary shearing. The lesions tend to last longer than other purpuric lesions and do not generally undergo the changes in hue that other ecchymotic lesions do.\textsuperscript{114} Hemostasis tests are normal, and no treatment other than reassurance is indicated.

FIGURE 50.6. Senile purpura (also known as Bateman purpura) in a 70-year-old man. (This photograph was kindly provided by Dr. Kappa Meadows, Department of Dermatology, University of Utah Health Sciences Center.)

VASCULITIS

The nomenclature of the vasculitides is quite confusing, but an international consensus conference has developed a system based on vessel size. This classification system recommends abandoning the term hypersensitivity vasculitis in favor of microscopic polyangiitis for small vessel vasculitides with few or no immune complexes and cutaneous leukocytoclastic vasculitis for small vessel vasculitis with isolated skin involvement.116

Cutaneous Leukocytoclastic Vasculitis

Leukocytoclastic vasculitis is characterized by immune complex deposition in postcapillary venules resulting in an inflammatory infiltrate, red cell extravasation, fibrinoid necrosis of the vessel wall, and fragmentation of nuclei (leukocytoclasis). The lesions typically develop 7 to 10 days after exposure to the offending antigen.

Palpable purpura is the classic clinical finding associated with cutaneous small vessel vasculitis. The lesions are the result of extravasation of erythrocytes into the inflamed dermis; therefore, the lesions do not blanch with pressure. The lesions range in size from pinpoint to several centimeters in diameter and are most prominent on the lower legs. The diagnosis should be confirmed by skin biopsy. Evaluation for the etiologic agent can be challenging and requires a detailed history to identify causative agents (Table 50.3).117, 118 Helpful laboratory studies include CBC, blood cultures, serum protein electrophoresis, cryoglobulins, hepatitis screen, rheumatoid factor, antinuclear antibody, antineutrophil cytoplasmic antibodies (ANCAs), and complement. Systemic involvement should be determined by the history and physical as well as urinalysis, chest radiography, and electrocardiography.

TABLE 50.3 ETIOLOGIES OF LEUKOCYTOCLASTIC VASCULITIS

Underlying disorders

Malignancy (leukemia, lymphoma, myeloma, cryoglobulinemia)

Autoimmune disease (systemic lupus, ulcerative colitis, periarteritis nodosa, Sjögren syndrome, viral hepatitis, primary biliary cirrhosis, etc.)

Infections (viral, bacterial, mycobacterial, fungal)
Drugs/chemicals
Penicillin, aspirin, phenothiazines, tetracycline, retinoids, colony-stimulating factors, contrast dye, insecticides, herbicides

Idiopathic
Antineutrophil Cytoplasmic Antibody-Positive Vasculitis
A major advance in understanding and classifying the vasculitides has been the recognition of ANCs in specific vasculitic syndromes. Patients with ANCA-associated small vessel vasculitis include three major categories, which are histologically identical. Speed in the diagnosis of ANCA-associated small vessel vasculitis is critical, as early treatment with immunosuppressive drugs can prevent life-threatening organ damage.\(^117\)

Wegener granulomatosis is distinguished by necrotizing granulomatous inflammation and pulmonary, upper respiratory, and renal involvement. Vascular inflammation in these areas can cause epistaxis, hemoptysis, and hematuria. Churg-Strauss disease is defined by the presence of necrotizing granulomas with asthma and eosinophilia. Vasculitis affects the nerves, GI tract, and skin primarily. Microscopic polyangiitis is recognized by the characteristic histology with the absence of asthma and granulomas. This vasculitis typically occurs in males older than 50 years of age. Prodromal symptoms include fever, myalgias, and arthralgias. Microhematuria, proteinuria, and oliguric renal failure may develop, and 30% to 40% of patients develop cutaneous lesions (splinter hemorrhages, palpable purpura). Pulmonary involvement occurs in one-third of patients.

Cryoglobulinemia
Essential cryoglobulinemic vasculitis is a vasculitis with cryoglobulin immune deposits. Cryoglobulins are immunoglobulins (Igs) that form a precipitate in cooled serum. They were first described by Wintrobe and Buell in 1933.\(^119\) The cryoglobulins can precipitate in dermal vessels and result in leukocytoclastic vasculitis\(^120\) and palpable purpura. When the cryocrit is significantly elevated (e.g., in lymphoproliferative diseases), hyaline thrombi can form and result in vasculopathy without associated vasculitis.\(^120\)

Clinically, patients develop crops of purpuric macules, papules, and patches most prominently over the lower extremities that are occasionally associated with burning or pruritus. Cutaneous infarcts and petechiae are also occasionally present. Only rarely are these symptoms precipitated by exposure to cold; more commonly, prolonged standing or exercise is the inciting event. Systemic manifestations of cryoglobulinemia include arthralgias, asthenia, neuropathy, and renal disease.\(^120\) Cryoglobulinemia is further discussed in Chapter 101.

Hypergammaglobulinemic Purpura
Hypergammaglobulinemic purpura (HP) is a syndrome first described by Waldenström in 1943; this disorder is characterized by polyclonal hypergammaglobulinemia associated with recurrent attacks of palpable or nonpalpable purpura.\(^121\) The syndrome has a marked predilection for women. The onset is often in the third and fourth decades of life, but young children and octogenarians have also been reported to develop this syndrome.\(^122\) The attacks of purpura are often sudden in onset and sometimes occur after prolonged standing, exercise, dancing, wearing tight-fitting clothes (e.g., jeans), and alcohol ingestion.\(^122, 123\) Some patients have premonitory symptoms such as stinging, itching, or mild pain before the development of purpura. The purpura typically involves the lower extremities and is palpable in approximately 75% of cases.\(^124\) Associated systemic symptoms include arthralgias (particularly adjacent to the purpura), low-grade fever, and lower extremity edema. The purpura usually resolves over 2 to 10 days. Recurrences are common but highly variable. Some patients have up to four attacks per week; others have only rare recurrences.\(^124\)

HP can be divided into primary and secondary forms. Primary HP occurs with no underlying disease process; secondary HP is identified when the typical symptoms of HP develop in patients with underlying diseases such as Sjögren syndrome, systemic lupus erythematosus, or other autoimmune, inflammatory, or neoplastic diseases.\(^123, 124\) The purpuric lesions can occur years before or after the diagnosis of autoimmune disease.

The laboratory features of HP include hypergammaglobulinemia, elevated erythrocyte sedimentation rate, mild anemia, and mild leukopenia. Both primary and secondary HP have a high prevalence of positive rheumatoid factor (88% to 100%).\(^123, 124\) Anti-Ro antibodies are similarly elevated in both primary HP and HP associated with Sjögren syndrome\(^122\) and
in up to 100% of HP associated with systemic lupus. \(^\text{124}\) Histopathologically, the lesions show inflammation of the superficial dermal vessels with an early neutrophil infiltrate followed by a mononuclear cell infiltrate and varying degrees of leukocytoclasis. Skin biopsies are often positive under direct immunofluorescence for IgM and IgG. Circulating immune complexes have also been identified.\(^\text{121, 124}\)

Treatment in the past has been described as unsatisfactory.\(^\text{123}\) However, a recent prospective, nonrandomized trial of 17 patients suggests that milder cases respond to indomethacin or hydroxychloroquine (200 mg twice daily) and more severe cases respond to prednisone at doses more than 20 mg/day.\(^\text{126}\) Plasmapheresis results in only temporary relief of symptoms.\(^\text{125}\)

A relative deficiency of IgG\(_2\) has been reported in some patients despite the hypergammaglobulinemia. IgG subclass determination should be considered in HP patients with recurrent infections.\(^\text{126}\)

Urticarial Vasculitis

Patients who present with purpura after resolution of urticaria may have urticarial vasculitis. Typically, the urticarial lesions burn, sting, or itch and last longer than 24 hours. The trunk and proximal extremities are affected more than the distal extremities. Residual hyperpigmentation may be present after resolution of the skin lesions. The pathogenesis appears to be due to immune complexes that activate complement and lead to mast cell degranulation. Patients with normal complement levels usually have minimal, if any, systemic involvement, whereas patients with depressed complement levels may have more severe disease.\(^\text{127}\) Hypocomplementemetic urticarial vasculitis is due to anti-C1q precipitins.

Acute Infantile Hemorrhagic Edema

Acute infantile hemorrhagic edema is a leukocytoclastic vasculitis confined to the skin in infants 4 to 24 months of age. Patients present with the dramatic onset of ecchymotic purpura involving the limbs and face with inflammatory edema in an otherwise healthy child. Spontaneous and complete resolution occurs in 1 to 3 weeks. Pathology shows leukocytoclastic vasculitis. Perivascular IgA deposits are often identified, and some authors consider this disorder to be a variant of Henoch-Schönlein purpura (HSP).\(^\text{128}\)

Henoch-Schönlein Purpura

HSP is an acute vasculitic syndrome with features of colicky abdominal pain, nephritis, arthritis, and palpable purpura. The manifestations of the syndrome were initially described by Schönlein in 1837 and further developed by Henoch in 1874.\(^\text{129, 130}\) The disease occurs primarily in children, with a peak incidence occurring between 4 and 11 years of age. There appears to be a seasonal variation, with most reported cases occurring from fall to spring and a paucity of cases in the summer.\(^\text{129, 131}\) Many of the cases occur after upper respiratory infections. Epidemiologic studies generally suggest that HSP occurs as sporadic cases, but clustering does occasionally occur. In 1987, a series of 20 cases occurred in Connecticut in a 5-month span and were found to be clustered in one ethnic group.\(^\text{132}\) This space-time clustering suggests a possible role for an infectious agent in precipitating the disease. Other infections, medications, insect bites, and malignancy have also been described as potential precipitating factors.

Biopsies of the superficial dermis and bowel in HSP show an acute vasculitis of precapillary arterioles and postcapillary venules. Immunofluorescent staining commonly shows IgA deposits in the walls of the arterioles of both the involved and noninvolved skin.\(^\text{133}\) In patients with renal involvement, a proliferative and necrotizing vasculitis is described, and IgA deposits are found in the glomerular mesangium.\(^\text{134}\) Circulating immune complexes containing IgA are detected in approximately 70% of patients shortly after the onset of purpura, followed by the appearance of complement and IgA, IgM, and IgG immune complexes later in the disease course.\(^\text{135}\) A variety of genetic polymorphisms that may predispose patients to developing HSP have been investigated.\(^\text{136}\)

The onset of symptoms is usually acute, with fever and palpable purpura involving the extremities and buttocks.\(^\text{129, 130}\) The purpuric lesions appear in symmetric crops with a predilection for extensor surfaces of the extremities (Fig. 50.7). They are most abundant around the knees, ankles, and elbows.\(^\text{130}\) A transient oligoarticular arthritis involving the large joints occurs in approximately 40% of cases, and the pain is often out of proportion to the physical findings. Renal involvement is manifest as proteinuria or hematuria. The renal abnormalities are almost always transient in younger children, but up to 20% to 25% of older children and adults have progressive renal disease.\(^\text{129, 137}\) Poor prognostic factors for renal disease include nephrotic syndrome and >50% glomerular crescent formation on renal biopsy.\(^\text{138}\)
Diffuse, crampy abdominal pain occurs in more than one-third of the cases and may occur before the characteristic purpura. The abdominal pain can be severe enough to mimic a surgical abdomen, and appears to be due to submucosal bleeding, edema, and ulcerations. Because abdominal pain is common, it is important to be aware that rare complications requiring surgery do occur, and include intussusception, perforation, and bowel necrosis. An abdominal ultrasound should be considered in the evaluation of abdominal pain, as other studies may miss ileoileal intussusception. GI bleeding presenting as melena or hematochezia can occur and is occasionally severe. Scrotal involvement is not uncommon, affecting up to 20% males, and can mimic testicular torsion.

Criteria for the classification of HSP have been published. The presence of two of the following four criteria can usually accurately differentiate HSP from other forms of vasculitis: Palpable purpura, age of onset 20 years or younger, acute abdominal pain, and biopsy showing granulocytes in the walls of arterioles or venules. A biopsy is not required in children with the classic presentation of HSP. The prognosis depends in part on the age at presentation. Children usually recover completely from HSP, but relapses may occur over a 3- to 6-week period before complete resolution of symptoms.

Adults have more severe disease at presentation, with a worse renal prognosis. Supportive care alone is used to treat mild cases. Steroids may be useful to alleviate symptoms in severe cases, but do not prevent renal complications from developing. Nonsteroidal anti-inflammatory drugs are beneficial for symptom relief in some patients, and plasmapheresis is of reported use with renal involvement. Patients with crescentic nephritis are treated with methylprednisolone, immunosuppressive drugs, plasmapheresis, and renal transplant.

Serum Sickness

Serum sickness is a specific clinical syndrome with systemic features and immune complex-induced vasculitis. The clinical syndrome typically occurs 7 to 12 days after administration of heterologous serum. The features include fever, urticaria, palpable purpura or other rash, and lymphadenopathy. The purpura is caused by immune complex deposition, and skin
biopsies show a necrotizing angiitis. Drugs such as cefaclor, penicillin, hydralazine, sulfonamides, and thiazide diuretics have been associated with serum sickness-like reactions.

**PURPURA ASSOCIATED WITH INFECTION**

Infectious agents can cause petechiae, purpura, and diffuse bleeding manifestations through a variety of mechanisms including disseminated intravascular coagulation, vasculitis, septic emboli, vascular toxins, and direct vascular or endothelial invasion. Certain clinical syndromes in the latter two categories are considered here. Septic emboli are briefly discussed under the section on vascular obstruction.

**Acute Febrile Illness with Petechiae**

Petechiae are often associated with acute febrile illnesses in children and immediately raise the concern for possible meningococcemia. Although a florid meningococcal infection may be instantly recognizable, children who present with small skin hemorrhages and fever, but who are not acutely ill, can be a diagnostic challenge. Petechiae that are present only above the nipple line in the distribution of the superior vena cava are often due to the coughing or vomiting that accompanies the acute infection. Bacterial agents such as streptococcal infections, pneumococcus, and Haemophilus influenzae may cause fever and petechiae. Viral illnesses due to enterovirus and adenovirus are well-known causes of fever and petechiae as well. To help clinicians distinguish between the agents responsible (and to avoid missing an early meningococcal infection), algorithms have been developed.

**Papular-purpuric Gloves and Socks Syndrome**

Patients with sharply demarcated purpura involving the hands and feet may have a syndrome known as papular-purpuric “gloves and socks” syndrome as shown in Figure 50.8. This syndrome was initially described in 1990 and has been confirmed in several other reports. Patients are usually adolescents or young adults that present in the spring or summer with pruritic edema and erythema of the hands and feet. Petechiae and confluent purpura follow, with a relatively sharp demarcation at the wrists and ankles. Oral mucosal involvement is common, and patients may have other systemic signs or symptoms including lymphadenopathy, fever, elevated liver function studies, and cytopenias. Rare presentations may include a perioral petechial rash or more generalized petechial eruption. The syndrome is self-limited and usually resolves within 1 to 2 weeks. The etiologic agent is usually parvovirus B19, but cytomegalovirus, hepatitis B, measles, rubella, and human herpesvirus 6 have also been implicated. Immunohistochemical studies show viral invasion of endothelial and epidermal cells.

**Rickettsial Diseases**

Rickettsiae infection results in damage to the endothelial cell with a characteristic multifocal lymphohistiocytic immune response causing increased vascular permeability, decreased perfusion, and activation of coagulation.

Rocky Mountain spotted fever is transmitted by the bite of ixodid ticks and, therefore, has a peak incidence in the United States in May, June, and July. The incubation period is 2 to 14 days (mean, 7 days), and symptoms usually include the sudden onset of fever, chills, headache, and myalgia. A pink macular rash develops on the wrists, hands, and ankles and spreads to cover most of the body. After 2 to 7 days, the lesions become petechial, and hemorrhagic areas may coalesce to form large areas of ecchymosis. The major complications are a result of vascular injury, and multiple organs may become involved. Diagnosis is based on serologic studies showing a rise in antibody titers or biopsy of the skin lesions with immunofluorescent identification of the organisms. Treatment is with a tetracycline or chloramphenicol.

Other rickettsial diseases such as Mediterranean spotted fever, Asian tick typhus, and Queensland tick typhus are generally milder and have an eschar (tache noire) at the site of the primary tick bite. The treatment is the same as for Rocky Mountain spotted fever.

**Brazilian Purpuric Fever**

Brazilian purpuric fever is a disease of pediatric patients that usually begins with purulent conjunctivitis followed 7 to 16 days later by acute onset of fever, bacteremia, petechiae purpura, and vascular collapse. The etiologic agent is H. influenzae biogroup aegyptius. The purpuric tendency appears to be due to direct invasion of endothelial cells with subsequent vascular damage.

**Rat Bite Fever**

Rat bite fever is an acute illness caused by rodent bite or exposure due to organisms that are part of their normal oral flora. Over 200 cases have been reported in the United States. Most U.S. cases are caused by Streptobacillus moniliformis, whereas cases in Asia are due to Spirillum minus. The onset of symptoms
is usually within 1 week of the bite but can occur several weeks after the wound has healed. Initial symptoms include abrupt onset of fever, chills, headache, malaise, and cough followed in 75% by morbilliform or petechial rash involving the palms and soles. Hemorrhagic vesicles on the peripheral extremities may be particularly suggestive of the diagnosis. Migratory polyarthritis develops in 50% of patients with the Streptobacillus type. The case mortality rate if untreated is 10%. Treatment is with procaine penicillin, tetracycline, or streptomycin.
Strongyloides

Strongyloides stercoralis is endemic to parts of South America, Central Africa, South East Asia, and the Southern United States (particularly Kentucky and Tennessee). Disseminated strongyloidiasis can occur in patients receiving chemotherapy or steroids, and in otherwise immunocompromised patients. Periumbilical purpura that resembles “multiple thumbprints” has been described, and it appears to be associated with a poor prognosis. More diffuse purpura may develop as well. Biopsy of the skin lesions frequently reveals larva. Other bleeding manifestations include alveolar hemorrhage and GI bleeding.

Vibrio vulnificus

An increasing number of infections caused by Vibrio vulnificus are being reported in the United States, particularly in Gulf coastal communities. The consumption of raw oysters is one of the primary mechanisms of infection along with localized wound infections due to exposure to infected salt water. Almost all patients are immunocompromised because of liver disease, diabetes, hemochromatosis, or steroid use. Patients present with abrupt onset of fever, chills, hypotension, and the development of hemorrhagic bullae. These bullae can develop into necrotic ulcers. The hemorrhagic complications appear to be due to a secreted metalloprotease, which has prothrombin-activating and fibrinolytic activities.

Hemorrhagic Fever Viruses

The hemorrhagic fever viruses are a diverse group of small RNA viruses with a lipid envelope. The clinical presentations vary, but symptoms usually begin with fever, headache, and myalgias progressing to generalized malaise. These symptoms last 3 to 4 days and are followed by petechiae, mucosal bleeding, and GI tract hemorrhage. However, infection of the endothelium may be common to all, and direct disruption of endothelial cells may occur. Some of the viruses have almost no cytopathologic effect; however, others are highly destructive to the endothelial cells. Activation of immune cells with the release of cytokines and chemokines that target endothelial cells is another suggested mechanism of damage. Release of tissue factor from damaged cells can trigger coagulation abnormalities, and varying degrees of thrombocytopenia and disseminated intravascular coagulation are present and contribute to the bleeding diathesis.

The major etiologic agents and the distinctive clinical features are outlined in Table 50.4. A high index of suspicion is required to diagnose hemorrhagic fever virus. Risk factors for naturally occurring cases include foreign travel, handling of animal carcasses, contact with sick animals or people, and arthropod bites within 21 days of the onset of symptoms. Lack of identifiable risk factors should raise the suspicion of a bioterrorist attack.

Rapid diagnosis is currently available only by sending clinical specimens to the Centers for Disease Control and Prevention or the U.S. Army Medical Research Institute of Infectious Disease in Frederick, Maryland. Suspected cases should be reported immediately to the health department. Protective measures from nosocomial spread should be followed.

PURPURA ASSOCIATED WITH VASCULAR OBSTRUCTION

Although oversimplified, it is often convenient to think of some disorders as causing purpura by intravascular obstruction with subsequent hemorrhage due to necrosis, vasculitic injury, or consumptive coagulopathy. Table 50.5 lists disorders that can be grouped together as causing abruptly decreased blood flow with subsequent bleeding. Note that cold agglutinins are not included because necrosis and bleeding are not expected complications.

Cryofibrinogens are cold-precipitable plasma proteins that dissolve as plasma is rewarmed. The proteins are distinct from cryoglobulins, which precipitate on cooling of serum (after the plasma proteins have been removed). Approximately 3% to 13% of hospitalized patients have detectable cryofibrinogens when appropriate assays are used.\(^ {164, 165} \) Cryofibrinogens can be associated with underlying malignancies or inflammatory processes (secondary cryofibrinogenemia) or be present as an isolated finding (essential cryofibrinogenemia).

Although patients with cryofibrinogenemia are often asymptomatic, they may present with symptoms of lower extremity or acral ulcers, cold intolerance, cutaneous purpura, livedo reticularis, gangrene, or Raynaud phenomenon.\(^ {166} \) Paradoxic bleeding may occur and appears to be proportional to the cryocrit.\(^ {165} \) Many patients have an elevated total fibrinogen level.\(^ {164} \) It is hypothesized that the abnormal cryofibrinogen is due to high levels of α\(_1\)-antitrypsin and α\(_2\)-macroglobulin that inhibit plasmin, resulting in decreased fibrinolysis.\(^ {165} \) The cutaneous lesions develop as a result of fibrin thrombi obstructing the small and medium-sized dermal vessels.\(^ {166} \) Biopsies from the edge of ulcers show eosinophilic thrombi with sparse lymphocytic infiltrate.\(^ {167} \) Leukocytoclastic vasculitis has also been described.\(^ {168} \) To measure cryofibrinogens, blood should be anticoagulated with ethylenediaminetetraacetic acid, citrate, or oxalate. The sample should be maintained at 37°C until centrifuged, and the separated plasma should be chilled at 4°C for 72 hours. Chilling the sample in this way increases the sensitivity for detection. The cryocrit is expressed as a percentage of the plasma sample volume.

Cryofibrinogenemia may be asymptomatic and require no treatment. Mild cases can be treated with avoidance of cold, and procedures that include cooling. Patients with more severe symptoms are usually treated with streptokinase, other fibrinolytic agents, or plasmapheresis. A small clinical trial and case reports have suggested that stanozolol, an androgenic steroid with fibrinolytic activity, can produce excellent results.\(^ {166, 169} \) Immunosuppressant agents have been reported to be effective in some patients.\(^ {165} \) Heparin use is discouraged.\(^ {165} \)

Cholesterol Embolization Syndrome
Cholesterol embolization syndrome is an increasingly recognized disorder caused by dislodged cholesterol crystals from atherosclerotic plaques. This occurs after vascular procedures or can be due to warfarin (blue-toe syndrome) and results in renal insufficiency, peripheral emboli, and possibly GI or central nervous system involvement. Livedo reticularis is the most common skin finding and can be best appreciated with the patient in the upright position. Cyanosis, purpura, ulcers, and gangrene can all occur. Biopsies of the cutaneous lesions, including livedo reticularis, demonstrate thrombi with cholesterol “clefts,” since the cholesterol is dissolved during fixation.

Fat Embolism Syndrome

Fat emboli syndrome is poorly understood. It is characterized by hypoxemia, tachypnea, petechiae, and changes in mental status occurring after long bone and pelvic fractures or intramedullary fixation. It may result from release of fat from bone marrow resulting in diffuse microvascular fat emboli. Although embolization of fat is common after trauma, only a few patients develop the fat emboli syndrome. Pulmonary dysfunction typically occurs 12 to 24 hours after fracture or operative fixation and is manifested as hypoxemia and tachypnea. The delay in symptoms suggests the role of a biochemical reaction leading to lung toxicity. Forty percent of patients develop petechiae, particularly in the axilla and subconjunctiva 24 to 48 hours after the event. Up to 70% of patients develop mental status changes. Fat droplets can be identified on bronchoalveolar lavage, and fat globules have been identified in pulmonary capillary blood obtained through a wedged pulmonary artery catheter.

Silicone Embolism Syndrome

Liquid silicone is an inert material used in illegal subcutaneous injections for breast augmentation and other cosmetic procedures. A recent review of the literature showed many similarities with the fat emboli syndrome in 33 patients. The most common symptoms are respiratory distress and hypoxemia occurring within 72 hours of the procedure with fever, alveolar hemorrhage (64%), and petechiae (18%). Six patients presented with neurologic symptoms occurring during or several hours after the injections and all patients deteriorated rapidly. Transbronchial biopsies show vacuolated globular deposits of silicone in the interstitial capillaries.

Septic Emboli

Calciphylaxis

Calciphylaxis is a small vessel vasculopathy characterized by calcifications of the tunica media of small to medium-sized cutaneous and subcutaneous vessels. The vasculopathy leads to development of tissue ischemia, necrosis of the skin and subcutaneous fat, and sometimes deeper tissues. Patients typically have end-stage renal disease and are on hemodialysis, but the disorder has now been described in a variety of other conditions. Clinically, painful dusky, purple-hued subcutaneous nodules and induration occur on the trunk, buttocks, or proximal extremity, and can progress to necrotic ulcers with eschars. In retrospective review, obesity, liver disease, steroid use, calcium phosphate product of >70 mg²/dl, and an aluminum >25 ng/ml were identified as risk factors. The diagnosis is usually made by biopsy of one of the lesions showing calcification of the tunica media with intimal proliferation and microthrombosis. Treatment involves lowering the calcium phosphate product when elevated by using sevelamer hydrochloride as a substitute for calcium phosphate binders, and decreasing the phosphate intake and calcium in the dialysate bath. Elevated parathyroid levels can be managed with calcimimetic agents or parathyroidectomy. Wound management is of key importance, as sepsis is the leading cause of death.

Livedoid Vasculopathy

Livedoid vasculopathy is a cause of lower extremity purpura progressing to shallow ulcerations that heal with atrophic hypopigmented scarlike plaques (atrophie blanche). Biopsy of the lesions shows hyaline vascular changes with intraluminal thrombosis. It is associated with multiple coagulation abnormalities.

Pigmented Purpuric Dermatitis

Pigmented purpuric eruptions encompass a group of related skin diseases that have in common the clinical appearance of red-brown skin pigmentation (caused by hemosiderin deposits) associated with purpura or petechiae. These lesions tend to develop on the lower extremities of middle-aged people and are usually chronic. Histologically, there is a mononuclear upper dermal infiltrate without evidence of leukocytoclasis. Extravasated red blood cells are present around the
capillaries, and hemosiderin deposits are found in older lesions. Six skin diseases are commonly classified as pigmented purpura. In Schamberg progressive pigmentary dermatosis, the lesions appear as orange-brown patches of skin with “cayenne pepper spots” at the borders or within the lesion (Fig. 50.9). Majocchi purpura annularis is distinguished by an annular 0.5- to 2.0-cm patch of reddish-brown macules. Eczematoidlike purpura has a seasonal pattern and appears as pinpoint lesions that spread rapidly over 2 to 4 weeks and develop a slight scale. The lesion in pigmented purpura lichenoid dermatitis (Gougerot-Blum purpura) is a reddish-brown macule with telangiectasias. These lesions tend to coalesce and form plaques. Itching purpura presents with an acute onset of pigmented macules associated with severe pruritus. Lastly, lichen aureus is described as “grouped copper-orange to purple lichenoid papules forming an irregular, usually singular, plaque.” The etiology of pigmented purpura is unknown, but some degree of venous stasis is apparent in many patients and may be a factor in its development. The importance of these lesions is to differentiate them from other causes of chronic purpura with hemosiderin deposits such as purpura associated with abnormal proteins. The lesions may clear in up to two-thirds of patients with long-term follow-up. Some patients with longstanding pigmented and purpuric dermatitis develop mycoses fungoides, and the differentiation between mycoses fungoides and pigmented purpuric lesions can sometimes be difficult.
FIGURE 50.9. Skin lesions associated with Schamberg progressive pigmentary dermatosis. Note the irregular patches of punctate hemorrhagic lesions with yellow-brown discoloration of hemosiderin deposits. (From Sherertz EF. Pigmented purpuric eruptions. Semin Thromb Hemost 1984;10:190-195, with permission.)

Pigmented purpuric eruptions have been described in children\textsuperscript{178} (Fig. 50.10), and may be familial. Treatment in the past has been with fluorinated steroids, but recently, psoralen plus ultraviolet light of A wavelength has been found to be effective in some cases.\textsuperscript{179}
Purpuric Contact Dermatitis

Purpura can be a presenting sign of allergic contact dermatitis and is often due to textile dyes in clothing. This diagnosis should be considered in patients who develop purpura only in areas of skin contact with clothing. Several allergens in textile dyes have been identified.\textsuperscript{180} Other reported antigens include benzoyl peroxide, epoxy resin, and agave sap.\textsuperscript{181}

Drug Reactions

Drug reactions can cause nonthrombocytopenic purpura by a number of different mechanisms, including leukocytoclastic vasculitis, serum sickness, and, occasionally, a pigmented purpura. Some of the drugs associated with pigmented purpuric dermatosis include acetaminophen, aspirin, glipizide, hydralazine, meprobamate, dipyridamole, creatine, thiamine, interferon, injected medroxyprogesterone acetate, and infliximab.\textsuperscript{182} A fixed drug reaction can occur, with an isolated purpuric appearing lesion occurring in a location without preceding trauma (Fig. 50.11).
FIGURE 50.11. A fixed drug eruption lesion. This 30-year-old woman developed this thigh lesion after taking ibuprofen. (This photograph was kindly provided by Dr. Pamela Nemzer, Department of Dermatology, University of Utah Health Sciences Center.)

PSYCHOGENIC PURPURA

Autoerythrocyte Sensitization

Autoerythrocyte sensitization is a rare disorder characterized by recurrent spontaneous ecchymotic lesions in patients with otherwise normal hemostasis. The syndrome was first described in 1955 by Gardner and Diamond after their discovery that intradermal injections of autologous red blood cells reproduced the skin lesion. Since the original description, more than 200 cases have been described, with the largest series collected by Ratnoff.

The cutaneous lesions are usually preceded by localized symptoms, including pain and a burning or stinging sensation in the involved area. The area then becomes erythematous, raised, and warm, and within hours, ecchymoses occur in the inflamed area. The ecchymoses can range in size from 1 to 2 cm to extensive involvement of the trunk or an extremity. The erythema and swelling usually subside within 48 hours of the development of ecchymoses. The lesions can recur weeks to years later. The ecchymotic lesions are usually only one symptom among many. Patients commonly have systemic symptoms including headaches, paresthesias, syncopal episodes, abdominal pain, nausea, vomiting, chest pain, dyspnea, dysuria, and arthralgia.

Autoerythrocyte sensitization typically affects adolescent to middle-aged females who have significant underlying emotional problems. Patients are commonly found to suffer from depression, anxiety, and inability to handle hostile feelings, as well as hysterical and masochistic character traits. They have often sustained significant physical and emotional trauma in the past, and up to two-thirds of the patients describe significant emotional stress present at the time the initial purpuric lesions develop.

The skin lesions can classically be reproduced in most patients with the intradermal injection of 0.1 ml autologous whole blood, packed red blood cells, or red cell stroma. However, this test has limited sensitivity, and some authorities recommend using clinical criteria to diagnose this disorder. No specific therapy is of proven value in psychogenic purpura. Psychotherapy appears to be beneficial in some younger patients but is less effective in the older population.

Autosensitivity to DNA
A similar syndrome of recurrent ecchymoses after a prodrome of localized itching was described in 1961 by Levin and Pinkus. This patient developed the typical skin lesions described above after the intradermal injection of frozen and thawed buffy coat leukocytes or purified calf thymus DNA. There are few data concerning the emotional background of these patients. Since the initial description, a few other cases have been reported, but some of these also had a positive reaction to intradermal injection of blood or washed red cells. Chloroquine can induce remissions, and cyproheptadine was useful in one patient.

Factitious Purpura
Self-inflicted ecchymoses can be difficult to diagnose. This disorder should be considered when there is a clear secondary gain present, when the lesions only occur in accessible areas, or when ecchymotic lesions assume unusual shapes. Circular, wellcircumscribed lesions around the upper limbs and breasts may be a result of sucking of the skin.

Religious Stigmata
Purpuric religious stigmata are bruises that allegedly occur spontaneously and resemble the wounds of the crucified body of Christ. The phenomenon usually occurs in women, and many have belonged to a religious order. The etiology is unknown.

Chapter 51 Thrombocytosis and Essential Thrombocythemia

The normal reference interval for platelet counts in adults approximates 150,000 to 450,000/µl; patients with platelet counts higher than the upper limit of normal have thrombocytosis, which can be broadly classified as reactive (secondary), essential (clonal or primary), or inherited (Table 51.1). Routine screening of healthy individuals has identified persons with asymptomatic thrombocytosis; some of these people will have essential thrombocythemia (ET). In contrast, hospitalized patients with elevated platelet counts usually have reactive thrombocytosis (RT). At least 90% of all patients with thrombocytosis have RT due to an underlying clinical disorder. It is important to distinguish ET from RT or inherited thrombocytosis because patients with the former disorder may be at risk of ischemic or bleeding complications, or evolution to myelofibrosis or acute leukemia, whereas patients with the latter disorders usually require only treatment of their underlying medical condition, with minimal or no treatment in the case of inherited thrombocytosis.

REACTIVE (SECONDARY) THROMBOCYTOSIS

Epidemiology and Pathophysiology

A retrospective Turkish survey of the incidence and etiology of thrombocytosis over a 5-year period demonstrated that of 124,340 patients who had platelet counts determined, 2,000 patients (1.6%) had at least one platelet count ≥500,000/ml. RT was identified in 96.7% of these 2,000 patients, with infection being the most common cause of RT. Another survey found that tissue injury (surgery) was the most common cause of RT. Increased thrombopoiesis seen in infectious, inflammatory, or malignant disorders results from cytokines and other acute-phase response mediators active in these circumstances. Mediators that have been linked to RT include interleukin (IL)-6 and thrombopoietin (TPO). TPO may act as an acute-phase protein in some, but not all circumstances. Both thrombocytosis and thrombocytopenia have been reported in iron-deficiency anemia. Patients with solid tumors (e.g., lung, ovarian cancers) have a 30% to 40% incidence of thrombocytosis. Extreme thrombocytosis may occur after splenectomy or in patients with hyposplenia or asplenia.

Treatment

Although no trials have formally addressed the need for treating RT, the general recommendation is not to treat the elevated platelet count, either with antiplatelet or with myelosuppressive therapy. However, there are case reports describing thrombotic events in RT patients and studies identifying a thrombosis risk in hospitalized patients or cancer patients with RT. In general, these patients have well-established cardiovascular risk factors, such as smoking, diabetes, older age, and the like, or they have venous thromboembolism risk factors such as cancer, or as seen in a hospitalized population. One approach may be that when RT is encountered in such patients with cardiovascular risk factors, antiplatelet therapy can be considered. Hospitalized patients with RT should receive venous thromboembolism prophylaxis, and primary therapy for all RT patients should focus on treating the underlying disorder.

Inherited Thrombocytosis

Inherited thrombocytosis is suspected in patients with a lifelong history of asymptomatic thrombocytosis, especially if other family members are also affected. The genetic mutations in inherited thrombocytosis are heterogeneous and may or may not involve mutations in the thrombopoietin gene (THPO) or its receptor (MPL). At least four different mutations in THPO associated with increased TPO production and inherited thrombocytosis have been described in European and Japanese kindreds. Thrombocytosis was inherited in an autosomal dominant manner in all four families. The TPO molecule in these patients is normal, and increased translation appears to explain elevated levels of TPO in these patients. At least three different MPL mutations have been linked to inherited thrombocytosis; affected kindreds are of European, African-American, Arabic, and Japanese ancestry. Approximately 7% of African-Americans are heterozygous for the MPL-Baltimore mutation. Thrombocytosis in patients with MPL mutations appears to result from either constitutive receptor activation or reduced receptor binding affinity for TPO.

Clinical findings in patients with inherited thrombocytosis can be classified by whether the patients have THPO or MPL mutations. In general, those with THPO mutations have elevated TPO levels and mild splenomegaly, but a low incidence of vascular complications and low risk of evolution to acute leukemia and myelofibrosis, although development of bone marrow disease was described in two family members with inherited thrombocytosis due to THPO mutations. Some patients with MPL mutations and inherited thrombocytosis have been reported to experience thrombosis, splenomegaly, and myelofibrosis, but these complications have not been reported in African-American patients with MPL-Baltimore.

P.1123

Clonal Thrombocytosis Other Than Essential Thrombocythemia

Clonal or primary thrombocytosis includes not only ET (discussed later) but also a prominent feature of the other myeloproliferative neoplasms and certain myelodysplastic syndromes. Between 35% and 50% of patients with chronic myeloid leukemia (CML), polycythemia vera, or myelofibrosis may have elevated platelet counts. The diagnosis, clinical aspects, and management of these disorders are discussed in Chapters 81, 82 and 83.

Clonal thrombocytosis is also seen in myelodysplastic syndromes associated with certain cytogenetic features (trisomy 8, 5q- syndrome, and chromosome 3 abnormalities), as well as the presence of ringed sideroblasts. However, the frequency of thrombocytosis in myelodysplasia is lower than in the myeloproliferative neoplasms. Myelodysplastic syndromes are discussed in Chapter 79.

DIFFERENTIAL DIAGNOSIS AND CLINICAL APPROACH TO THROMBOCYTOSIS

When evaluating a patient with thrombocytosis, the key consideration is to exclude ET and CML from reactive or inherited thrombocytosis and other disorders. Thrombocytosis may be a presenting feature of CML. Inasmuch as CML patients are at risk of conversion to acute leukemia, and there is targeted therapy for CML, BCR-ABL, and cytogenetic testing is important in patients with thrombocytosis who do not have inherited or reactive etiologies. Patients with RT usually have major symptoms of an underlying inflammatory, infectious, or malignant disorder. However, patients with occult malignancy may initially present without obvious cancer symptoms. Post-splenectomy thrombocytosis will usually be obvious, but patients with asplenia or hyposplenism will be identified by observing Howell-Jolly bodies on the blood smear and by abdominal imaging showing a vestigial spleen or no splenic tissue. The World Health Organization (WHO) criteria for ET are discussed in the next section, and focus on distinguishing essential thrombocytosis from the
other myeloproliferative neoplasms. These criteria provide no direct definitions of RT. Thus, the physician is left with practical clinical criteria to suggest an RT if a patient does not have an obvious underlying disorder. Such criteria might include the presence of fever, an elevated C-reactive protein or erythrocyte sedimentation rate, a blood smear showing reactive or toxic changes in the leukocytes, the presence of iron deficiency, or the post-splenectomy state.\textsuperscript{3, 5}

FIGURE 51.1. An approach to evaluating thrombocytosis. A life-long personal history and family history of thrombocytosis would suggest a diagnosis of inherited thrombocytosis. If that diagnosis is excluded, reactive etiologies should next be considered. If an underlying cause is identified and is treatable, thrombocytosis should resolve with appropriate therapy. If neither inherited nor reactive thrombocytosis is likely, testing for clonal thrombocytosis should be performed; this should include BCR-ABL and JAK2 testing. The appropriate tests include bone marrow evaluation and cytogenetics for myeloproliferative neoplasms and myelodysplasia. CML, chronic myeloid leukemia; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; MF, myelofibrosis; ET, essential thrombocytosis; MDS, myelodysplasia; MPL, thrombopoietin receptor gene; MPN, myeloproliferative neoplasms; PV, polycythemia vera; THPO, thrombopoietin gene.

One approach to the evaluation of thrombocytosis is shown in Figure 51.1. Inherited thrombocytosis can be rapidly excluded if there is no life-long history of thrombocytosis and the family history is negative. Patients who may possibly have inherited thrombocytosis can be further evaluated with testing for THPO and MPL mutations. Because >90% of patients with thrombocytosis will have a reactive etiology,\textsuperscript{3, 4, 5} significant effort should be made in excluding secondary thrombocytosis before considering testing for myeloproliferative neoplasms, including ET.

**ESSENTIAL THROMBOCYTHEMIA**

**Definition**
ET is a clonal myeloproliferative disorder characterized by excessive production of platelets that is independent of usual drivers of thrombocytosis. This thrombocytosis is in many ways analogous to the erythrocytosis characteristic of the related disorder, polycythemia vera. This “family resemblance” between what we now recognize as BCR/ABL-negative myeloproliferative disorders was initially pointed out by William Dameshek more than 60 years ago.22

Epidemiology

Evolving diagnostic criteria (discussed below) make it difficult to characterize the incidence and prevalence of ET. In studies published between 2001 and 2008, an incidence of 1.5/100,000 was reported.23,24 Prevalence based on insurance claims data in the northeastern United States has been reported to be 24 cases/100,000 population.25 However, these reports antedate the 2008 revision of the WHO diagnostic criteria for ET, which includes a lower platelet threshold and could potentially alter the reported prevalence and incidence.

The median age at diagnosis is in the mid-50s in large reported series, and females represent 60% to 70% of cases.26,27 Cases have been reported in children but are uncommon.28,29,30 First-degree relatives of ET patients have an increased risk of ET.31

Risk for developing ET appears to be associated with environmental factors linked to other myeloid neoplasms, such as radon and gamma irradiation.32,33 Hairdressers, electricians, and farmers appear to be at increased risk to develop ET compared to other occupations, although it should be remembered that these risks are still quite low.32,33

Diagnostic Criteria

For many years, the diagnosis of ET was based on the demonstration of significant sustained thrombocytosis (typically greater than 600 × 10^9/L) in the absence of a reactive etiology.34 However, the observation that a specific gain-of-function mutation in Janus associated kinase 2 (JAK2V617F) is found in virtually all cases of polycythemia vera and in most cases of ET,35,36 provided an additional positive criteria for the diagnosis of ET.

The 2008 revision of the WHO criteria for the diagnosis of ET is shown in Table 51.2.34 The first criterion represents a reduction in the threshold for thrombocytosis from 600 × 10^9/L to what is in essence the upper limit of the normal platelet count and addresses concerns that the higher threshold prevented the detection of early disease.37,38,39 The second criterion requires demonstration of the characteristic bone marrow morphology of ET.40

As discussed earlier in this chapter, a number of other myeloid neoplasms may be associated with thrombocytosis. This is particular true when employing the lower platelet threshold of the 2008 criteria. Polycythemia vera is excluded by the absence of an elevated hematocrit or hemoglobin concentration with adequate iron stores demonstrated on a Prussian blue-stained marrow specimen or a normal serum ferritin: if iron stores are absent, a trial of iron replacement that does not elevate the hematocrit or hemoglobin above normal is required.34 Primary myelofibrosis is excluded by the absence of excessive reticulin deposition on the marrow biopsy. Chronic myelogenous leukemia is excluded by the absence of the BCR/ABL mutation. Myelodysplastic syndromes and other myeloid neoplasms are excluded by absence of characteristic marrow abnormalities, such as ringed sideroblasts.41

**TABLE 51.2 WORLD HEALTH ORGANIZATION DIAGNOSTIC CRITERIA FOR ESSENTIAL THROMBOCYTHEMIA**

**Diagnosis requires meeting all four criteria**

1. Sustained platelet count ≥450 × 10^9/L

2. Bone marrow biopsy specimen showing proliferation mainly of enlarged mature megakaryocytes; no significant increase or left shift of neutrophil granulopoiesis or erythropoiesis

3. Not meeting criteria for polycythemia vera, primary myelofibrosis, chronic myelogenous leukemia, myelodysplastic syndrome, or other myeloid neoplasm (details discussed in text)

4. Demonstration of JAK2V617F or other clonal marker; or, in the absence of a clonal marker, no evidence for reactive thrombocytosis. However, the presence of a condition associated with reactive thrombocytosis does not exclude essential thrombocytosis if first three criteria are met

In the absence of the JAK2V617F mutation, exclusion of nonclonal reactive processes remains a key element of the diagnosis of ET. Etiologies of RT specifically cited in the criteria that should be excluded by history or laboratory studies include iron deficiency, previous splenectomy, recent surgery, active inflammation, connective tissue disorders, metastatic cancer, and lymphoproliferative diseases. In polycythemia vera, mutations of JAK2 in exons other than the site of the V617F mutation have been found in a significant number of JAK2V617F-negative cases. Similar findings have not been reported for ET.

The 2008 revised criteria have generally performed well in validation studies, although at least one study suggests that they function poorly in distinguishing ET from early stage primary myelofibrosis. They also may be of less utility in children with ET, who are often polyclonal and JAK2V617F-negative.

Pathophysiology

In polycythemia vera, in vitro studies of erythroid progenitors have shown hypersensitivity to erythropoietin or erythropoietin independence, as well as hypersensitivity to other growth factors such as IL-3 or granulocyte-macrophage colony stimulating factor (GM-CSF). In an analogous manner, megakaryocyte progenitors from ET patients have been reported to show a similar response pattern to IL-3, GM-CSF, and/or IL-6 in vitro. Such studies provide some rationale for a proposed hypothesis that inflammation may be a driver of clonal evolution in ET.

However, the primary focus of pathophysiologic investigation in ET is on specific mutations found in myeloproliferative disorders and their contributions to its pathogenesis. The involved or potentially involved genes include JAK2, ASXL1 (additional sex combs-like 1), CBL (Casitas B-lineage lymphoma), DNMT3A (DNA methyl transferase 3α), EZH2 (enhancer of zeste homolog 2), IDH1 (isocitrate dehydrogenase 1) and IDH2, LNK (lymphocyte specific adaptor protein), the TPO receptor/ligand MPL (myeloproliferative leukemia virus), SF3B1 (splicing factor gene B1), NF1 (nuclear factor 1), SUZ12 (suppressor of zeste 2 homolog), and TET2 (ten-eleven translocation oncogene family member 2). Brecqueville and colleagues studied several of these genes in 53 ET patients. A total of 70% of patients had mutations in one or more of the genes studied (Table 51.3).

JAK2V617F is the most common mutation found in ET, and is detected in 50% to 75% of patients. As Table 51.3 indicates, it may occur alone or with other mutations. As noted earlier, JAK2V617F is a gain-of-function mutation resulting in constitutive activation of signaling through the JAK/STAT pathway.

Expression of JAK2V617F in hematopoietic progenitors in vitro or in whole animals leads to a myeloproliferative disorder phenotype resembling polycythemia vera. It has been proposed that the extent of the JAK2V617F allele burden distinguishes ET from polycythemia vera. However, JAK2 mutations do not appear to be universally present in ET, and data from other myeloproliferative disorders suggest it is a late pathogenetic event. The precise mechanistic contributions of JAK2 mutations to ET pathogenesis, their interactions with other genes and significant hematopoietic proteins such as ASXL1, TET2, and MPL remain to be clarified.

Data from Brecqueville et al., Mutation analysis of ASXL1, CBL, DNMT3A, IDH1, IDH2, JAK2, MPL, NF1, SF3B1, SUZ12, and TET2 in myeloproliferative neoplasms. Genes Chromosomes Cancer 2012;51:743-755.

Clinical and Laboratory Features

Most ET patients are asymptomatic at time of presentation, although some may be diagnosed after a thrombotic event or in the course of evaluation of vasomotor symptoms such as dizziness and headache, which may reflect vascular occlusion. Erythromelalgia (burning dysesthesia in the fingers or toes relieved almost instantly by aspirin) is a characteristic symptom of myeloproliferative thrombocytosis, whether from ET or polycythemia vera. Distal ischemia ("blue toes syndrome") and cutaneous changes such as livedo reticularis or ulceration are occasionally found; frank limb gangrene is fortunately rare.

Presenting blood counts and physical examination results from three series are shown in Table 51.4. Although hemoglobin concentration and white blood cell counts are typically normal, anemia and/or leukocytosis > 15 × 10⁹/L may be found in 15% to 20% of patients. The white blood cell differential is usually normal but may show the basophilia, eosinophilia, or left-shift characteristic of myeloproliferative disorders. Splenomegaly, whether palpable or radiographic, is found in fewer than 25% of cases without transformation to myelofibrosis.

The characteristic bone marrow feature is proliferation of large, mature-appearing megakaryocytes (Fig. 51.2). Marrow cellularity is increased in approximately a third of cases, but is otherwise normal. The presence of significant reticulin deposition, dyserythropoiesis, or dysmyelopoiesis should raise suspicion for other diagnoses.

Patients with ET exhibit evidence of aspirin-reversible increased platelet activation in vivo (increased circulating levels of beta thromboglobulin, platelet factor 4, and thrombomodulin and increased urinary thromboxane B2 excretion), whereas paradoxically exhibiting defective platelet function in vitro, both by classic platelet aggregation or platelet function analyzer (PFA)-100 studies. Some ET patients with platelet counts > 1,000 × 10⁹/L develop a bleeding diathesis due to an acquired type 2 von Willebrand syndrome which is reversed by platelet reduction.

Patients with leukemic transformation excluded.

Natural History and Prognosis
The median overall survival of ET patients appears to exceed 22 years and does not significantly differ from that of the age-adjusted general population (Fig. 51.3).26 A plurality (40%) of deaths is unrelated to ET; the next greatest contributor is thrombosis (26%). Solid tumors (14%) are the next most common cause of death, followed by leukemia, either de novo or post-myelofibrotic (8%) and myelofibrosis (4%).26 Compared to polycythemia vera patients, the 15-year cumulative risks of thrombosis (27% vs. 17%), leukemia (7% vs. 2%) and myelofibrosis (6% vs. 4%) are lower in ET patients.26

Reported risk factors for overall survival include age >60 years, history of thrombosis, anemia, and leukocytosis >15 × 10^9/L; age, anemia, and platelet count >1,000 × 10^9/L, are reported risk factors for leukemic transformation.27 Studies have reported that JAK2V617F-negative ET patients have a lower arterial thrombotic risk than JAK2V617F-positive ET patients.26, 76 In contrast, the JAK2V617F allele burden itself may or may not predict a greater thrombotic diathesis.26, 77 Among JAK2V617F-negative ET patients, the presence of other markers of clonality such as mutations in human androgen receptor (HUMARA), TET2, ASXL1, or MPL, predicts an increased thrombotic risk.78

FIGURE 51.2. Characteristic megakaryocyte proliferation in a marrow specimen from an essential thrombocytemia (ET) patient.

P.1126

The standard model for thrombotic risk in ET has two components: age >60 years and history of thrombosis. The absence of both denotes low risk, and the presence of either denotes a high risk of thrombosis. A model proposed more recently, the International Prognostic Score for ET-thrombosis (IPSET-thrombosis), incorporates the two elements of the standard model as well as the presence of cardiovascular risk factors and JAK2V617F mutation status. The IPSET-thrombosis model defines low, intermediate, and high risk categories. Approximately half the patients in the low risk category from the standard model are relocated to the intermediate category in the IPSET-thrombosis model, whereas the standard model high risk patients are distributed essentially evenly between the three IPSET-thrombosis categories. The two models are outlined in Table 51.5.

TREATMENT

The goal of treatment in ET is the prevention of thrombotic events, the primary cause of morbidity and mortality. Therefore, treatment strategy is based on thrombotic risk stratification. At present, only the standard risk stratification model has been validated as a guide to therapy. Low risk patients can be managed with low dose aspirin or, under some circumstances, observation only. Cytoreduction of the platelet count is recommended for high risk patients.

High risk: ≥ 3 points

“Cardiovascular risk factors include diabetes, hypertension, and/or tobacco use.

The IPSET-thrombosis model has not been prospectively validated as a guide to therapy, but the developers of the model have suggested that cytoreductive therapy be considered in any patient with a history of thrombosis and in older patients with cardiovascular risk factors and/or JAK2V617F mutation. Aspirin therapy is recommended for younger patients without a thrombosis history but with either cardiovascular risk factors and/or JAK2V617F mutation.80

The bleeding associated with acquired von Willebrand syndrome in ET can be resolved by reduction of the platelet count to a value approximating normal.83

Aspirin

Aspirin therapy, usually at 100 mg/day or less, is generally well tolerated in ET patients, with a low risk of bleeding.84 Antiplatelet agents such as aspirin reduce the risk of venous thrombosis in ET patients with the JAK2V617F mutation, and the risk of arterial thrombosis in patients with cardiovascular risk factors. Its benefits in other low risk patients are unclear.85 Aspirin and antiplatelet agents should be avoided in patients with a history of bleeding. Although markedly elevated platelet counts are not a risk factor per se for aspirin-induced bleeding,85 acquired von Willebrand syndrome may be unmasked by aspirin in patients with platelet counts greater than 1,000 x 10^9/L.73 Many physicians regard it as prudent to assess von Willebrand factor activity prior to initiating aspirin in such patients.83

Cytoreductive Therapy

Hydroxyurea

Hydroxyurea is considered the first-line cytoreductive agent in ET.81, 82, 86, 87 Some of the beneficial effects of hydroxyurea in ET and other myeloproliferative disorders may reflect reduction of leukocytosis and leukocyte-platelet interaction.88 The extent to which hydroxyurea reduces JAK2V617F expression in ET patients is disputed.89, 90, 91, 92

Anagrelide

The platelet-reducing drug anagrelide is a reasonable second choice for patients intolerant of, or unresponsive to, hydroxyurea.93, 94 As a first-line agent in ET, anagrelide has been reported to be non-inferior to hydroxyurea.95 Unlike hydroxyurea, it does not affect leukocytosis.

Interferon

Administration of recombinant interferon can also be considered in patients refractory to hydroxyurea or to both hydroxyurea and anagrelide.96, 97, 98 The systemic side effects and need for subcutaneous injection limit its acceptability to some patients.99 High risk pregnant females with ET can be successfully managed with interferon.100

Other Agents/Modalities

Busulphan is an agent of established efficacy in myeloproliferative disorders such as ET,82, 101 however, its risk profile as an alkylating agent makes it less attractive than hydroxyurea, anagrelide, or interferon. Apheresis can utilized to obtain rapid reduction in the platelet count in emergencies associated with severe thrombocytosis such as bleeding with acquired von Willebrand syndrome or limb gangrene or in preparation for surgery, but should be accompanied by cytoreductive drugs.83 JAK2 inhibitors currently available appear to be of primary benefit in post-ET myelofibrosis rather than in ET itself.

Post-essential Thrombocythemia Myelofibrosis

Myelofibrosis may be a late complication of ET, with an incidence of approximately 1.6 per thousand person-years of follow-up and is the cause of death in approximately 4% of ET patients.95 Patients may develop transfusion-dependent anemia and/or thrombocytopenia, and symptomatic splenomegaly. JAK2 inhibitors appear to have benefit in the
management of cytopenias and splenomegaly in myelofibrosis. In general, management follows the pattern outlined for primary myelofibrosis in Chapter 83.

Chapter 52 Qualitative Disorders of Platelet Function

Thomas J. Kunicki
Much of our current understanding of normal platelet structure-function relationships has been derived from the study of patients with congenital platelet disorders. These syndromes are the subject of excellent recent reviews.\textsuperscript{1, 2, 3, 4, 5}

NORMAL PLATELET FUNCTION: A SUMMARY

When a blood vessel is damaged, circulating platelets interact with components of the extracellular matrix, particularly collagen, and a complex series of receptor-ligand interactions ensue that ultimately lead to the formation of a stable platelet plug or thrombus (Fig. 52.1). This process is a continuum of at least three phases that we can describe as initiation, extension, and consolidation, each of which entails the cooperation of a different group of receptors.

In the initiation phase (Fig. 52.2), plasma von Willebrand factor (VWF) binds to collagen via its A3 domain and becomes structurally altered such that its A1 domain then binds to the platelet membrane receptor glycoprotein Ib-IX-V complex (GPIb complex). This association is a requisite step in the adhesion of platelets to exposed thrombogenic surfaces at sites of vessel wall injury or in regions of atherosclerotic plaque rupture. Concurrently, a more stable platelet monolayer is formed on the collagen surface mediated predominantly by the platelet-specific receptor GP VI (GPVI) and platelet integrin $\alpha_{II} \beta_{3}$.

The engagement of these receptors enhances platelet activation leading to the extension phase (Fig. 52.3), mediated largely by the conversion of prothrombin to thrombin at the activated platelet surface and the secretion of active compounds from platelet granules ($\alpha$-granules and $\delta$-granules) that can further stimulate platelets. One of these, adenosine diphosphate (ADP), plays a particularly important role in the platelet response, binding to its cognate platelet receptors to augment platelet activation. The activated platelet also produces and/or releases additional agonists, including the agonist thromboxane A2 (TXA2). Most of the receptors involved in the events of the extension phase are members of the G protein-coupled receptor family.

In the consolidation phase (Fig. 52.4), platelet-platelet cohesion (aggregation), mediated by the binding of fibrinogen and/or VWF to the activated platelet integrin $\alpha_{II} \beta_{3}$ (GPIIb-IIIa), together with the assembly of a fibrin network, results in the generation of platelet-rich aggregates or thrombi. Further complexity is inherent in this final phase of platelet plug formation, and current research indicates an essential role for outside-in signaling through integrins and via receptor tyrosine kinases, including members of the Eph kinase family.

Inherited or acquired defects that affect any phase of this complex process can result in excessive thrombosis or bleeding. Hereditary disorders can be divided into groups (Table 52.1), based on whether they predominantly influence the initiation, extension, or consolidation phases of platelet-dependent hemostasis. Platelet dysfunction can also be a manifestation of many acquired disorders, and these are also discussed in this chapter.

DIAGNOSIS AND CLASSIFICATION OF PLATELET DYSFUNCTION: AN ALGORITHM

The preliminary diagnosis of platelet dysfunction must be made on the basis of patient history, and the diagnosis then confirmed by specific laboratory tests of platelet function. A practical algorithm for this purpose, depicted in Figure 52.5, is reproduced with permission from the excellent review by Bolton-Maggs et al.\textsuperscript{5}

Bedside Exam and Patient History
An accurate and detailed patient and family history is a key element in the assessment of platelet disorders. One should bear in mind that bleeding histories are subjective and that bleeding can be variable, often evolving or decreasing throughout a person's lifetime. In particular, children may not have yet had enough hemostatic challenges to develop a strong clinical. The subjectivity of the oral history is reflected in a recent statistic that at least one quarter of persons who complain of serious bleeding do not have a bleeding disorder, whereas at least one third of persons who have no bleeding can be shown to have von Willebrand disease (vWD) or a platelet disorder. 

FIGURE 52.2. Initiation of platelet adhesion by matrix components, particularly collagen. Platelets employ a number of collagen receptors. These include VWF-mediated binding of collagen to the glycoprotein Ib (GPIb) complex (a heptamer composed of GPIba, GPIbβ, GPV, and GPIX), the direct engagement of collagen by the integrin α2β1 and GPVI/FcRγ. Engagement and clustering of GPVI initiates tyrosine phosphorylation of FcRγ by a Src family kinase (SFK). The tyrosine kinase Syk then binds and is activated, in turnactivating phospholipase Cy, which then initiates phosphoinositide hydrolysis, secretion of ADP, and the production of TXA2. ADP and TXA2 augment platelet activation by binding to their respective platelet receptors.
The extension phase of platelet plug formation accelerates and augments the activation of the platelet and is mediated largely by G protein-coupled receptors, including: the purinergic receptors P2Y1 and P2Y12, which are bound by ADP; the α and β isoforms of the thromboxane A2 (TXA2) receptor TP; the protease-activated receptor (PAR) family members PAR1 and PAR4, that are recognized by thrombin; and the α2A-adrenergic receptor that is specific for epinephrine.

To overcome the subjectivity of a history for superficial mucocutaneous bleeding, the International Society on Thrombosis and Hemostasis (ISTH) suggests that bleeding should be considered clinically significant when there are two or more distinct bleeding sites such as the skin, nose, gums, vagina, gastrointestinal tract, or genitourinary tract. This includes either spontaneous bleeding or provoked bleeding, such as that which might result from dental work, parturition, trauma, or surgery. In addition, a bleeding history involving only a single site should be considered significant when it is so severe as to warrant blood transfusions. Finally, a single bleeding symptom that recurs on three or more unrelated and separate occasions should also be considered significant.
FIGURE 52.4. The consolidation phase of platelet thrombus formation occurs through the bridging of adjacent integrin αIIbβ3 complexes by fibrinogen or VWF, as well as other adhesive proteins.

### TABLE 52.1 DISORDERS OF PLATELET FUNCTION

**Hereditary platelet dysfunction**

**Initiation phase**
- Bernard-Soulier syndrome
- GPVI deficiency

**Extension phase**
- Secretion disorders/granule deficiencies
- α-Granule abnormalities (gray platelet syndrome)
- δ-Granule (dense body) abnormalities
- Hermansky-Pudlak syndrome
- Chediak-Higashi syndrome
- Wiskott-Aldrich syndrome
- α/δ-Granule deficiency
- Defects of signal transduction and secretion
Impaired liberation of arachidonic acid
Cyclooxygenase deficiency
Thromboxane synthetase deficiency
Thromboxane A$_2$ receptor abnormalities
Defects in calcium mobilization
Defects of platelet procoagulant activity

**Consolidation phase**
Glanzmann thrombasthenia

**Miscellaneous**
Hereditary macrothrombopathy/sensorineural hearing loss

**Acquired disorders of platelet function**

**Drug-induced platelet dysfunction**
Analgesics
Antibiotics
Cardiovascular drugs
Psychotropic drugs

**Secondary platelet dysfunction**
Uremia
Paraproteinemia

**Myeloproliferative disorders**

A number of quantitative approaches to assess the relative severity of patient bleeding have been proposed, some including a normalization based on patient age.$^9$,$^10$ However, such approaches work best for a comparison of cohorts of related individuals with comparable bleeding disorders, such as families of patients with vWD.

The distinction between normal individuals and those with bleeding disorders is not always clear cut. Care should be taken in all patients to note the use of medicines, either “over the counter,” herbal, or prescription, that are known to influence platelet function. This is particularly true of medications such as aspirin, other nonsteroidal anti-inflammatory drugs (NSAIDs), ticlopidine or clopidogrel, integrin αIIbβ3 antagonists (e.g., Abciximab, tirofiban, and eptifibatide), epoprostenol, statins, cilostazol, sildenafil, fluoxetine, and large doses of various β-lactam antibiotics (penicillins > cephalosporins).$^7$

Bleeding manifestations typical of platelet dysfunction include: (1) Unexplained or extensive bruising; (2) epistaxis, particularly if lasting more than 30 minutes, causing anemia or admission to hospital; (3) menorrhagia, particularly if this has been present since the menarche; (4) oral cavity bleeding; (5) bleeding during childbirth; (6) bleeding following invasive procedures; and (7) bleeding following dental extraction.
FIGURE 52.5. A scheme for the analysis of patients with suspected hereditary platelet dysfunction. In order to establish a precise diagnosis, specific laboratory tests are needed to establish a defect in platelet number or function. Generally, an automated full blood count, blood film, platelet aggregometry, and quantification of platelet nucleotides are necessary. The purpose of this algorithm is to assist the investigator in the systematic interpretation of laboratory results. To complete a diagnosis, specialty analyses may be necessary, and these are included for the specific disorder. Such assays might include flow cytometry to measure expression of surface glycoproteins, such as αIIb or β3 (GT), GPIb or GPIX (BSS).

In addition, quantitation of annexin V binding (Scott syndrome) and genetic analyses to identify specific gene mutations might be needed: αIIb or β3 (GT), WAS (WAS and XLA) and MYH9. Certain disorders can be caused by mutations in more than one gene (e.g., HPS and BSS), so genetic analysis has not been considered as a definitive test in all cases. The algorithm includes the most frequent or best characterized heritable platelet disorders. Symbols and abbreviations: ↓, reduced aggregation; AA, arachidonic acid; BSS, Bernard-Soulier Syndrome; CHS, Chediak-Higashi syndrome; COX, cyclooxygenase; δ-SPD, dense-granule disorder; EM, electron microscopy; GPS, gray platelet syndrome; GT, Glanzmann thrombasthenia; HPS, Hermansky-Pudlak syndrome; MYH9, MYH-9-related disorder; P2Y12, deficiency of P2Y12 ADP receptor; QBS, Quebec platelet syndrome; Rev., reversible aggregation; RIA, radioimmunoassay; RIPA, ristocetin-induced platelet aggregation; Sec., secretion; TXA2, thromboxane A2; WAS, Wiskott-Aldrich syndrome. From Bolton-Maggs PH, Chalmers EA, Collins PW, et al. A review of inherited platelet disorders with guidelines for their management on behalf of the UKHCDO. Br J Haematol 2006:603-633.

Severe platelet dysfunction is present from early childhood onward. Following delivery of an affected infant one may find intracranial and/or subdural hemorrhage, excessive bleeding from the umbilical stump or after circumcision, or easy bruising after handling. As the infant becomes more mobile, easy or extensive bruising following relatively mild trauma can be indicative of platelet dysfunction. Prolonged epistaxis is a common finding throughout childhood and can even become life threatening. In adults, menorrhagia and bleeding during childbirth are common and potentially serious, whereas bleeding following any invasive procedure should be anticipated. 5

Mild platelet dysfunction is more likely to manifest itself at any age most commonly following a definable hemostatic challenge, such as surgery or dental extractions. Easy bruising is a very nonspecific symptom, and many cases are difficult to distinguish from what would otherwise be considered a normal response.

Consanguinity increases the likelihood of an autosomal recessive platelet disorder, and a family history is invaluable in establishing the diagnosis of inherited platelet dysfunction.

Laboratory Assessment
A number of laboratory-based evaluations are critical for an accurate diagnosis of platelet dysfunction.

Whole Blood Platelet Count

A key element in assessing platelet dysfunction is an accurate whole blood platelet count. Automated counts should be viewed as provisional. Inasmuch as macrothrombocytes or platelet aggregates created inadvertently during blood processing will not be counted, the whole blood platelet count should be confirmed by an optical method.

Global Coagulation Tests

To rule out abnormalities in clotting factors, all patients should have a prothrombin time, an activated partial thromboplastin time, and thrombin time performed. Laboratories should determine their own age-related normal range. It is also critical to investigate all patients for VWD, which is far more common than platelet function disorders and creates a similar bleeding phenotype.

Bleeding Time

The bleeding time is historically a common measure of platelet function. However, because the test is poorly reproducible, time consuming, and insensitive, the bleeding time has gradually fallen out of favor as a clinically useful test.11 In cases of mild platelet dysfunction, the bleeding time is often normal or minimally prolonged;11 in severe cases, it will usually be prolonged.

Unfortunately, the bleeding time does not correlate well with the in vivo bleeding tendency within individual patients, and an accurate bleeding history is considered by many to be a more valuable screening test. Nonetheless, a prolonged bleeding time should be considered sufficient grounds to perform additional tests of platelet function.

Platelet Function Analyzer-100

The platelet function analyzer-100 (PFA-100) measures the rate of thrombus formation under high shear in citrated whole blood that is perfused through a membrane aperture coated with collagen/epinephrine or collagen/ADP. The closure time (CT) will be significantly prolonged in Glanzmann thrombasthenia (GT) and Bernard-Soulier syndrome (BSS) using either ADP/collagen or epinephrine/collagen membrane cartridges.12,13 Consequently, the PFA-100 can be used to screen patients to exclude these diagnoses.

The PFA-100 may be sensitive to platelet storage pool disease (SPD), primary secretion defects, the Hermansky-Pudlak syndrome (HPS), and the Quebec syndrome. However, because falsenegative results occur in patients with all of these disorders, there are those who question its usefulness as a screening tool.12,14 The PFA-100 is affected by platelet count and hematocrit, and is dependent on normal VWF levels and naturally occurring (genetic) differences in platelet membrane GPVI or α2β1 expression.13,14,15

Platelet Aggregation

Platelet aggregation in platelet-rich plasma remains an important test in the analysis of platelet function. The typical agonists that are used to induce platelet aggregation are ADP, epinephrine, collagen, arachidonic acid (AA), ristocetin, the TX receptor agonist U46619, thrombin or the thrombin receptor-activating peptide. Because the level and/or activity of each of the receptors for the agonists can vary among normal subjects, it is recommended that dose-response curves to each agonist be obtained from the patient under study and compared to a reference range obtained from multiple normal subjects.16 When thrombin is the agonist, an inhibitor of fibrin polymerization, such as glycine-proline-arginine-proline peptide, must be added to the PRP, or alternatively, plasma-depleted washed platelets must be used.

Platelet aggregation is sensitive to platelet count, and at counts ≤120,000/µl, the response to some agonists will be impaired. In thrombocytopenic samples, the best options are to adjust a control sample to the same count as the patient or to perform studies on washed platelets where the platelet number can be normalized. Consideration should also be given to more specialized tests, such as a measure of P-selectin expression or integrin αIIbβ3 activation by flow cytometry. The expected aggregation responses associated with specific diagnoses are covered in the appropriate sections.

Adenine Nucleotide Content and Release

Measurement of platelet adenosine nucleotide (ADP and adenosine triphosphate [ATP]) content and release can be used in the diagnosis of storage pool and release defects.17 A finding of normal platelet aggregation does not exclude the diagnosis of SPD. It is recommended that patients suspected of having platelet dysfunction should have both platelet aggregation and adenine nucleotide release performed, unless it is certain that the laboratory performing the platelet
Aggregation assays can demonstrate that their assay conditions are sensitive to defects in platelet nucleotide amount or release.

Platelet nucleotide content and release varies with age. Ideally, age-related normal ranges should be established for total and released levels of ATP and ADP and their ratios. Platelet aggregation, nucleotide content, and nucleotide release in children over 12 months of age do not differ significantly from adult values, whereas collagen-induced platelet nucleotide release has been shown to be reduced in neonates compared with children older than 1 year. Agonist-induced secretion of platelet granule contents has been shown to be reduced in both term and premature babies due to immature signal transduction pathways.

Flow Cytometry

Flow cytometry is routinely used to measure platelet surface receptor density, platelet activation, α-granule release, procoagulant phospholipid expression, and microvesicle production. A common application of flow cytometry is the assessment of GPIb complex and integrin αIIbβ3 expression in the diagnosis of BSS and GT. Individuals who are heterozygous for these disorders are also readily distinguished. An important benefit of flow cytometry is the small quantities of blood required, an attractive feature in young children or thrombocytopenic individuals.

Electron Microscopy

Transmission electron microscopy (TEM) of fixed/embedded platelet thin sections can be performed by a limited number of specialized personnel, but is critical in the assessment of platelet granule defects and changes in platelet ultrastructure (e.g., in the evaluation of patients with MYH-9 defects). Whole-mount EM can be used to quantitate δ-granule content because this is readily identified in unstained preparations.

Additional Assays

Several additional assays are available in specialized laboratories that can provide further information relevant to the diagnosis of the particular platelet disorder, including analysis of receptor expression, specific molecular or genetic defects, protein phosphorylation, formation of signal transduction intermediates, or a characterization of the platelet proteome. The utility of these tests in clinical diagnoses is currently under intense investigation.

Overview of Treatment Options for Platelet Disorders

Although the number of clearly identifiable platelet dysfunction syndromes is growing, our choice of treatment options remains limited. Minor membrane bleeding may be controlled with topical agents in the nasal or oral cavities with antifibrinolytic agents. Epsilon-aminocaproic or tranexamic acids will decrease blood loss associated with epistaxis or menorrhagia. Some patients may benefit from Stimate as documented by DiMichele and Hathaway, whereas others actually bleed more with this agent due to the fibrinolysis induced by this medication. For this reason many centers recommend the use of Stimate in conjunction with Amicar or Cyklokapron.

In the case of menorrhagia, hormonal suppression is the mainstay for women who do not wish to undergo endometrial ablation for hysterectomies. In combination with antifibrinolytics and Stimate, even severe bleeding may be controlled; however, more aggressive therapy including platelet infusion may be required to control bleeding before these agents take effect.

Platelet transfusion may pose a dilemma to those physicians wishing to avoid alloimmunization in patients who may require multiple transfusions throughout their lifetimes to control hemorrhage. This is particularly true for those patients who are lacking membrane GPs, such as αIIbβ3 or GPIb. In this setting patients are at risk of developing isoimmunization, making antibodies against the “foreign” proteins that they lack and thus becoming refractory to all subsequent platelet transfusions.

A significant challenge in patients who require frequent platelet infusions to control life-threatening bleeding. Patients with GT have not only developed antibodies to αIIb and/or β3 but also demonstrated anti-idiotypic antibodies that bind to fibrinogen, thus creating a hemorrhagic disorder far worse than the underlying platelet dysfunction. In general, physicians avoid platelet transfusion apart from cases of severe hemorrhage. Isoimmunization appears to be rare in Glanzmann but the risk of alloimmunization is still a major concern, therefore leukocyte depletion of transfused platelets is recommended to decrease the frequency of sensitization.
Activated recombinant Factor VII (rFVIIa) has been used to slow or arrest bleeding associated with platelet dysfunction. Dosages have varied widely but many patients have responded to this regimen when others have failed. Used in combination with antifibrinolytics, minor bleeding can be controlled in certain patients. This treatment is often used prior to platelet transfusion in order to avoid blood product exposure and isoimmunization.

For those patients who present with recurrent life-threatening bleeds, bone marrow transplant or stem cell infusion following immune ablation is recommended before the patients have extensive blood product exposure. Successful transplantation with normal stem cells represents long-term cure for these patients. Although complications related to stem cell transplantation cannot be overlooked, successful engraftment essentially eliminates the significant risk of mortality related to hemorrhage in patients with severe disorders.

Patients with rare platelet dysfunction syndromes are now included in many of the rare bleeding disorder international and regional registries that will aid physicians in understanding the natural course, optimal therapy, and life expectancy for each of the syndromes listed below, as well as the numerous platelet disorders that have yet to be defined. Definitive molecular and biochemical diagnoses will dictate appropriate therapy in these patients. With improvement in platelet function measurement and proteomic approaches one should see significant improvement in early diagnosis and medical management.

HEREDITARY DISORDERS OF PLATELET FUNCTION

Defects in the Initiation Phase: Bernard-Soulier Syndrome

BSS is a rare disorder first described in 1948 as “dystrophie thrombocytaire hemorrhagipare congenitale” caused by abnormal expression or activity of the platelet GPIb complex. Etiology

BSS platelets have a quantitative or qualitative abnormality of the membrane GPIb complex, a heptamer composed of four leucine-rich GP that are the products of distinct genes (Fig. 52.2). The prominent member of the complex, GPIb, is a heterodimer composed of disulfide-bonded GPIbα and GPIbβ subunits. GPIb then forms a noncovalent complex with GPIX, and two GPIb-IX trimers then associate noncovalently with one molecule of GPV. The amino-terminal type A domain of GPIbα binds directly to VWF, mediating normal platelet adhesion during the initial phases of primary hemostasis, whereas BSS platelets do not adhere to the extracellular matrix when perfused at a high shear rate. The defect in the GPIb complex also explains the failure of affected platelets to agglutinate in the presence of ristocetin, even in the presence of normal plasma or VWF.

Mutations in the gene for GPIbα, GPIbβ, or GPIX, but not GPV, have been shown to result in decreased expression of the GPIb complex and the BSS. Defects range from virtually absent GPIb to variant forms in which patients retain measurable amounts of apparently dysfunctional GPs.

BSS is usually inherited as an autosomal-recessive disorder, and consanguinity is common in reported kindreds. Heterozygotes typically have “giant” platelets and reduced levels of the GPIb complex and may or may not be symptomatic.

Clinical Features

Bleeding symptoms are usually evident shortly after birth or in early childhood. The clinical manifestations include purpura, epistaxis, gingival bleeding and menorrhagia, and more rarely gastrointestinal bleeding, major hematomas, or hematuria. Severe bleeding episodes can result from trauma and surgical procedures, such as tonsillectomy, appendectomy, splenectomy, oral surgery, and menses. However, individual bleeding can vary substantially in severity and frequency.

Laboratory Findings

The typical laboratory findings include an increased bleeding time, mild thrombocytopenia, giant platelets on blood smear, and defective adhesion to collagens in vitro. Platelet morphologic abnormalities are a hallmark of BSS, featured by large platelets with a diameter as high as 10 µm. A defective platelet agglutination in response to ristocetin, as measured by aggregometry in vitro, is a unique characteristic of BSS that differentiates this syndrome from other rare inherited disorders that are also associated with macrothrombocytopenia, such as the MHS9-related disorders. A firm diagnosis requires the combined findings of increased bleeding times, macrothrombocytopenia, defective ristocetin-induced agglutination, and low or absent levels of platelet GPIb-V-IX (CD42a-d) by flow cytometry.
In bone marrow aspirates, megakaryocytes are normal or increased in number, but they reveal no characteristic morphologic abnormalities when viewed by light microscopy. Electron microscopic studies have revealed abnormalities of the dense tubular system and vacuolization of the demarcation membrane system. 

Management

Therapeutic approaches include both general and specific treatment of bleeding. Patients should be warned to avoid trauma and antiplatelet medication, such as aspirin, and to maintain proper dental hygiene. Females may benefit from contraceptive therapy once they reach puberty. Treatment of bleeding or prophylaxis during surgical procedures usually requires blood or platelet transfusion with the associated risk of developing antiplatelet alloantibodies. Desmopressin and rFVIIa administration have been shown to shorten the bleeding time in some patients. In rare cases of life-threatening bleeding, a bone marrow or umbilical cord hematopoietic stem cell transplantation may be considered. Responses to antifibrinolytic agents are more variable, and the administration of adrenal corticosteroids and splenectomy are usually ineffective.

Platelet-reactive isoantibodies have been generated by BSS who have received multiple blood or platelet transfusions. These antibodies produce a particularly severe clinical complication because they will bind to and may neutralize the function of GPIb on transfused platelets. This results in impaired adhesion of the transfused platelets. The presence of such antibodies can be established by a finding of impaired in vitro aggregation of normal platelets induced by ristocetin and bovine VWF in the presence of patient plasma. Alloimmunization is also a common side effect of multiple platelet transfusions, and this may necessitate the subsequent use of HLA-matched platelets.

P.1133

Variation in the Initiation Phase: Collagen Receptor Polymorphisms

A lifelong bleeding disorder and the unique absence of in vitro platelet aggregation to collagen have been associated with a deficiency of either of the collagen receptors, integrin α2β1 or GPVI, yet specific gene defects have not been identified. Careful evaluation is needed to establish a specific molecular defect in either receptor.

The Integrin α2β1

Among normal individuals, platelet α2β1 levels can vary up to tenfold and correlate with differences in adhesiveness to type-I or type-III collagens and genetic variants of the α2 subunit gene ITGA2. We identified several single nucleotide polymorphisms (SNPs) within the coding sequence of the α2 gene ITGA2 that correlate with platelet α2β1 density and define six major ITGA2 haplotypes.

Clinical Relevance of α2 Polymorphisms

In VWD, platelet adhesive functions are impaired due to the decrease in functional VWF multimers in plasma and platelets. Inheritance of the ITGA2 haplotypes associated with lower α2β1 density will increase the risk of bleeding in patients with either type I and type2 VWD.

The association of ITGA2 haplotypes with risk for arterial thrombosis has been studied in acute coronary syndromes, diabetic nephropathy, and stroke. Although several studies have found that the inheritance of high-density ITGA2 haplotypes correlates with increased thrombosis, this association is not a consistent observation.

Platelet Glycoprotein VI

GPVI is a major platelet GP (60 to 65 kDa) that has been confirmed as an important receptor for collagen since the initial identification of a patient with a mild bleeding disorder whose platelets lacked GPVI and exhibited defective collagen-induced responses. Autoantibodies against GPVI can cause substantial shedding of this receptor through metalloproteinase cleavage.

Glycoprotein VI Polymorphism

Aside from isolated cases of GPVI defects, it is important to note that there is variation in platelet GPVI content among normal healthy subjects, which is directly proportional to normal variation in mean platelet volume. This variation is manifested in a significant difference in prothrombinase activity induced by GPVI-specific agonists such as the snake venom protein convulxin or collagen-related peptide (CRP). The direct association between platelet α2β1 density and GPVI content is also attributable to variation in mean platelet volume, which has a proportional effect on levels of other
receptors, including αIIbβ3. Variation in GPVI content represents yet another genetically controlled risk factor predisposing individuals to hemorrhagic or thromboembolic disorders.

Defects in the Extension Phase

Secretion Defects: Storage Pool Disease

SPD is a heterogeneous group of congenital disorders that have in common a deficiency of granules or their constituents that results in a defect in ADP release from activated platelets and abnormal secretion-dependent platelet aggregation.\(^1\) Defective platelet secretion can result from the absence of or defects in one or both of the dominant types of platelet granules: The α-granule or the δ-granule (dense body). Thus, three subgroups of SPD are now distinguished. The isolated deficiency of α-granules (α-SPD) has been studied for several years and is more commonly known as the Gray platelet syndrome (GPS)\(^8\), the exclusive abnormality of dense-granules (δ-SPD) can be congenital or acquired, as in myeloproliferative syndromes or rheumatologic disorders; \(^17\) and abnormalities of both α- and δ-granules are classified as αδ-SPD.\(^17\)

α-Granule Storage Pool Disease: Gray Platelet Syndrome

GPS is a very rare disorder with less than 100 cases reported worldwide and is characterized by a selective deficiency in the number and content of α-granules.\(^17\)\(^,\)\(^8\) The formation of α-granules in immature megakaryocytes proceeds normally, but the granule number then decreases during maturation, and the mature megakaryocytes are left with only small abnormal granules that are few in number. Some of the normal protein constituents of α-granule membranes, such as GPIV, integrin αIIb-β3, and P-Selectin remain in the abnormal granules and will be normally redistributed during platelet activation. The defect is limited to megakaryocytes and platelets. Recent evidence suggests that GPS is associated with mutations in NBEAL2 (neurobeachin-like 2 gene), which encodes a protein containing a BEACH domain that is predicted to be involved in vesicular trafficking and may be critical for the development of platelet α-granules.\(^39\)\(^,\)\(^40\)\(^,\)\(^41\)

Several proteins are synthesized but not stored properly in the abnormal α-granules. These include platelet factor 4, β-thromboglobulin, fibrinogen, fibronectin, vWF, platelet-derived growth factor, and thrombospondin. Other organelles, such as lysosomal granules, mitochondria, and δ-granules (dense bodies) are present in normal numbers, and δ-granules contain normal amounts of adenine nucleotides and serotonin.

Clinical Features

GPS is inherited as an autosomal trait and is associated with mild to moderate thrombocytopenia (20,000 to 150,000/µl) and moderately enlarged platelets.\(^17\)\(^,\)\(^8\) The bleeding time is usually prolonged, and platelet survival may be shortened, but splenomegaly is not common. As in other platelet function defects, a history of mild bleeding is the norm, and treatment is seldom required. The bone marrow exhibits normal megakaryocyte numbers and increased reticulin, occasionally around clusters of megakaryocytes, but myelofibrosis is not a feature of this disorder. In Wright-stained blood smears, the platelets appear large, misshapen, agranular, and gray. In electron photomicrographs, an almost total lack of α-granules is evident in platelets and in megakaryocytes.

When analyzed by EM, it is the only disorder that is characterized by the selective absence of platelet α-granules. Megakaryocytes show defective α-granule biogenesis, with impaired uptake and storage of endogenously synthesized proteins, such as platelet factor 4, β-thromboglobulin, or VWF, and defective sequestration of exogenous proteins, such as fibrinogen, albumin, or factor V. On the other hand, in the platelet, the α-granule marker P-selectin is retained and is redistributed to the surface upon activation. Both autosomal recessive and autosomal dominant inheritance have been reported, implicating more than one gene in the etiology of the disease. Myelofibrosis of bone marrow is an additional feature that is attributed to the spontaneous release of platelet-derived growth factor and transforming growth factor-β1 from megakaryocytes.

Laboratory Findings

Gray platelets have a normal aggregation and release in response to AA or ionophore and generate TX normally. Platelet aggregation induced by ADP, epinephrine, thrombin, or collagen is variably affected. Release from dense bodies usually is subnormal, particularly when induced by thrombin. Abnormal calcium influx and mobilization from intracellular stores have also been reported. The platelet count is often reduced and can be as low as 50,000 per µl. By EM, the platelets have reduced numbers or a complete absence of α-granules.
Management
Because of the rare nature of α-granule disorders, there is not a very extensive clinical database upon which to make generalizations about effective treatment of the bleeding problem. However, these patients should be managed in the same manner as other patients with mild bleeding disorders. In the case of major bleeding or surgical challenge, they may require platelet transfusion.

Isolated δ-Storage Pool Disease
δ-SPD is characterized by easy bruising, mucocutaneous bleeding, and excessive post-operative and post-partum hemorrhage.17

Clinical Features
The symptoms can become more severe if the patient ingests aspirin or other antiplatelet agents, and patients with SPD should be advised to avoid such drugs. Platelet counts are typically normal, and the bleeding time is usually prolonged. The platelets are morphologically normal on Wright-stained smears, but they are deficient in dense bodies by EM. The diagnosis of δ-SPD must be made by the finding of a decrease in dense granule constituents and/or EM to demonstrate the absence of dense granule-limiting membranes and contents. The most consistent finding is that adenine nucleotides are reduced with an increased ratio of ATP to ADP and normal levels of lysosomal enzymes.

The platelet content of serotonin, however, can be variably reduced. Whole-mount EM recognizes calcium, but it cannot differentiate the absence of a dense granule from the absence of its calcium. Dense granules can also be quantitated by fluorescent microscopy because, whether full and empty, δ-granules take up the fluorescent dye quinacrine (mepacrine).42

Laboratory Findings
Because of the defect in δ-granules and the decreased level of ADP, primary aggregation responses in vitro are normal, but secondary aggregation may be diminished. Typically, there is an impaired response to collagen and a deficient secondary wave with ADP, epinephrine, and low concentrations of thrombin, but ristocetin aggregation is normal. Although this functional defect is often encountered in this disorder, it cannot be relied upon as a diagnostic criterion. The platelets are also deficient in serotonin, calcium, and pyrophosphate, which are stored in the δ-granules.17 The bleeding time is increased, with normal platelet counts and morphology. Subsets of patients have been identified who have a prolonged bleeding time, decreased dense bodies, and ADP release but normal platelet aggregation. The diagnosis of δ-granule SPD can best be made following a combination of studies, including bleeding time, platelet aggregation, an assessment of storage pool adenine nucleotides, thrombin-induced radioactive serotonin uptake and release, and TEM. There is suggestive evidence that δ-SPD is inherited as an autosomal dominant characteristic, but neither the causative gene nor the molecular nature of the basic defect have yet been determined.

Management
To treat the symptoms of SPD, desmopressin (DDAVP) can normalize the bleeding time in some patients, often within 1 hour after infusion.23 This treatment is particularly effective in improving hemostasis after procedures.

Combined αδ-Storage Pool Disease
In αδ-SPD, which is much less common than isolated δ-SPD, δ-granules and/or their contents are uniformly decreased, and the deficiency of α-granules and/or their constituents can vary.17 Platelets in these patients form significantly smaller thrombi in flowing blood than is seen with platelets from patients with δ-SPD. The defects are also not uniformly among the platelet population, such that α-granules and δ-granules may be completely absent in one portion of the population yet present in nearly normal levels in another.43

The mode of inheritance appears to be autosomal dominant, but a basic molecular defect and a genetic basis have not yet been determined.

Animal Models and Etiology
The comparative study of granule deficiencies in the mouse or rat can provide clues to understanding the etiology of SPD. For example, the gunmetal mouse44 and the fawn-hooded hypertensive rat45 are characterized by reduced platelet α- and δ-granules, a disorganization of megakaryocyte internal membranes, and impaired α-granule protein retention. Mutations in RabggtA result in defective geranylgeranyl transferase, which catalyzes the attachment of lipid geranylgeranyl groups to Rab proteins.44 Rab proteins are small guanosine triphosphatases (GTPases), which split GTP to provide energy for
membrane fusion events and for attachment to cytoskeletons. By analogy, it is possible that mutations in the human gene RABGGTA are also responsible for human αδ-SPD, but this remains to be proven.

Clinical Features

Bleeding in this disorder is clinically similar to bleeding in δ-SPD and GPS, and is manifested by a prolonged bleeding time with normal platelet counts. Except for their bleeding tendency, patients with αδ-SPD appear otherwise healthy.

Laboratory Findings

Defects in secondary platelet aggregation are typical, and defects in primary aggregation are even more extreme than seen in δ-SPD. Because of variability, in vitro platelet aggregation in αδ-SPD is not an appropriate diagnostic criterion, and an accurate diagnosis requires measurement of δ- and α-granule constituents and/or EM of platelet organelles. The lysosomal enzyme content of αδ-SPD platelets is normal.

Management

Because of the few numbers of patients with combined αδ-SPD, there is little clinical information upon which to develop a treatment scheme. However, this disorder can likely be managed in the same manner as the isolated δ-SPD (see above).

Quebec Platelet Syndrome (Factor V Quebec)

The Quebec platelet syndrome is an extremely rare, autosomal dominant disorder that was originally identified by the finding of low levels of platelet α-granule factor V but normal plasma factor V. It is characterized by protease-related degradation of many platelet α-granule proteins, including P-selectin. The α-granule ultrastructure is normal. Increased expression of α-granule urokinase-type plasminogen activator is thought to lead to spontaneous intracellular activation of the fibrinolytic pathway resulting in the generation of plasmin, which cleaves multimerin that would otherwise stabilize factor V.

Clinical Features and Laboratory Findings

Many cases may go undiagnosed because there are no characteristic morphologic features or platelet aggregation abnormalities. The main laboratory finding is defective procoagulant activity, reflected by a failure to assemble the prothrombinase complex. A related defect, platelet Factor V New York, is also characterized by decreased levels of platelet Factor V, although there is no indication of Factor V proteolysis, as in Factor V Quebec.

Management

The Quebec platelet syndrome is unresponsive to platelet transfusions. It is the current opinion that fibrinolytic inhibitors are the most effective means to control bleeding. Otherwise, treatment should be similar to that given to patients with bleeding disorders.

Hermansky-Pudlak and Chediak-Higashi Syndromes

The HPS and Chediak-Higashi syndrome (CHS) are rare autosomal recessive disorders that have in common platelet dense granule deficiency, albinism, and lysosomal granule defects.

Hermansky-Pudlak Syndrome

HPS is as an autosomal-recessive trait that has a worldwide distribution but is most prevalent in Puerto Rico.

Etiology

The genetic causes of HPS are diverse. Mutations in at least seven genes have been linked to this disease, and the absence of platelet dense bodies is thought to result from a defect in organelle development.

Clinical Features and Laboratory Findings

A diagnosis of HPS is based on the presence of oculocutaneous albinism and absent platelet dense bodies on whole-mount EM. Typical findings are a lifelong history of easy bruising; minor bleeding episodes, such as mucus membrane bleeding; epistaxis, and metromenorrhagia. Many patients will require whole blood or platelet transfusions when bleeding symptoms become more severe. Pulmonary fibrosis and inflammatory bowel disease, associated with infiltration of ceroid-pigmented reticuloendothelial cells in the lung and colon, have been reported in several cases of this syndrome.
In platelet aggregation assays, there is an absence of the secondary wave in response to ADP and epinephrine, and the response to collagen is also abnormal. Usually, the template bleeding time will also be longer than normal.

Management

Localized and limited treatment of the bleeding symptoms is the norm in HPS.\(^49\), \(^53\) The albinism necessitates skin and eye protection, and the bleeding can be controlled topically with thrombin and Gelfoam. Prophylactic use of intravenous 1-desamino-8-D-arginine vasopressin or Stimate is recommended for procedures such as tooth extractions or biopsies. Menstrual bleeding can be regulated by birth control pills. In the event of major surgeries or severe bleeding episodes, platelet or red blood cell transfusions may be required.

Chediak-Higashi Syndrome

SPD also may be associated with the CHS.\(^1\), \(^54\) In addition to defective platelet dense granules and oculocutaneous albinism, CHS is also characterized by immune deficiency and progressive neurologic dysfunction. In CHS patients, the granule abnormalities are not restricted to the megakaryocyte lineage, and numerous cell types exhibit giant cytoplasmic inclusions that are enlarged vesicles.

Etiology

Numerous cases of CHS have been reported to result from mutations in the lysosomal trafficking regulator gene (LYST) located on chromosome 1q42.1-42.2. Mutations in the LYST protein can be associated with defective natural killer cell function.\(^55\) However, LYST mutations cannot be identified in all CHS patients, suggesting the existence of causative defects in other genes.\(^56\) Several proteins are known to interact with LYST, including the SNARE complex protein HRS, signaling protein 14-3-3, and casein kinase II.\(^57\) It has been proposed that LYST may be an adaptor protein that brings into close proximity proteins that mediate intracellular membrane fusion reactions. Along this vein, LYST contains several consensus motifs that play distinct roles in vesicle transport and fusion.

Clinical Features and Laboratory Findings

Platelet counts are normal prior to development of the accelerated phase. The dense granule defect results in mucocutaneous bleeding and a prolonged bleeding time. The secondary wave of platelet aggregation is impaired, there is an increased ATP-to-ADP ratio, decreased platelet serotonin, and decreased platelet calcium. Some patients have a normal number and shape of dense bodies, but most often there is an absence of or marked reduction in dense bodies.

Management

Prior to the accelerated phase, hemostatic problems can be treated as in the case of other mild platelet disorders. With time, infections and a lymphoproliferative accelerated phase are serious developments that can result in death within the first decade.\(^1\), \(^54\) Although experience is still limited, hematopoietic cell transplantation is a potentially effective therapy for correcting and preventing hematologic and immunologic complications of CHS.\(^58\)

Griscelli Syndrome

Mutations in RAB27A, a gene for a small GTPase involved in vesicular transport and organelle dynamics, are considered to be the cause of GS.\(^59\) The ashen mouse with mutated RAB27A is a model of GS and exhibits a reduction in the number of platelet dense granules. However, the hemostatic phenotype of these mice is affected by the genetic background, and it is likely that additional modifier gene polymorphisms have an important influence on the hemostatic phenotype.

Clinical Features and Laboratory Findings

GS is a rare autosomal recessive disorder in which patients present with abnormal pigmentation, immunodeficiency, and development of the accelerated phase.\(^60\) GS patients have no obvious bleeding prior to the accelerated phase, and it has not been firmly established that there is a characteristic platelet dense granule defect. Hypopigmented hair with a silvery-gray sheen and pigment clumps is a characteristic of GS, but these are larger and less homogeneously distributed than one sees with CHS patients. The giant cytoplasmic granules typical of CHS cells are not seen in GS cells.

Management

Like CHS, the disease is usually fatal by the first decade of life. The same management as observed with CHS will likely be effective in patients with Griscelli syndrome.\(^1\), \(^54\)

Paris-Trousseau (Jacobsen) Syndrome

The Paris-Trousseau (Jacobsen) syndrome is an autosomal dominant disorder characterized by thrombocytopenia, a history of relatively mild bleeding, the presence of giant α-granules in a minor proportion of platelets, and two
morphologically distinct populations of megakaryocytes in the bone marrow, some of which exhibit signs of abnormal maturation. Additional congenital abnormalities include mental retardation, cardiac abnormalities, and cranio-facial abnormalities. This is an extremely rare disorder, and only 10 childhood cases have been reported.\(^{61}\)

These patients have deletions of the long arm of chromosome 11q that include the gene FLI1, which encodes a transcription factor that plays a critical role in normal megakaryocytogenesis. Thus, the hemizygous deletion of FLI1 generates a subpopulation of megakaryocyte progenitors that fail to differentiate normally, forming small immature megakaryocytes that undergo massive lysis.\(^{62}\) Those platelets with giant α-granules fail to release their contents normally upon stimulation.

**Arthrogryposis-Renal Dysfunction-Cholestasis Syndrome**

The gene VPS33B encodes a protein that is involved in protein trafficking. A mutation of the gene is the cause of ARC syndrome.\(^{63}\) ARC is an autosomal recessive disorder with multiple systemic abnormalities, one of which is platelet dysfunction is caused by a deficiency in platelet α-granules.\(^{64}\) This disorder is diagnosed by severe distinguishing features other than the platelet dysfunction, and affected individuals usually do not survive their first year.

**Inherited Disorders of Primary Membrane Receptors**

**Congenital Defects of P2Y12**

The adenine nucleotides ADP and ATP are both released from platelet δ-granules during activation induced by a variety of agonists, and both can augment or modulate the platelet functional response through autocrine and paracrine mechanisms by binding to platelet purinergic receptors.\(^{65}\)

Two platelet purinergic receptors are specific for ADP, the Gq-protein-coupled receptor P2Y1 and the Gi-protein-coupled receptor P2Y12. One receptor, the P2X1 ion channel, is bound by ATP. The P2Y and P2X receptors operate in a temporally distinct manner and selectively trigger distinct intracellular signaling pathways. Recent advances in our understanding of P2Y receptor physiology suggest that these receptors are a potentially relevant target of antithrombotic therapy. P2Y1 mediates ADP-induced intracellular calcium ion mobilization and shape change, and P2Y12 is coupled to adenylyl cyclase inhibition and is responsible for ADP-induced macroscopic platelet aggregation.\(^{66}\)

At the same time, we have only a perfunctory understanding of the function of P2X1 in platelet activation. It is known, however, that P2X1 function is linked to calcium ion influx.\(^{66}\)

**Etiology**

P2Y12 defects are inherited as autosomal recessive traits,\(^{67}\) and heterozygous individuals display a mild abnormality in platelet function similar to that observed in patients with SPD. In two cases, different homozygous frameshift mutations cause premature termination of translation. In another case, one allele presented a reading frameshift caused by the deletion of two nucleotides, whereas the other case had a normal coding sequence but a reduced expression, possibly resulting from another mutation in a regulatory region of the gene.\(^{68}\)

**Clinical Features and Laboratory Findings**

A limited number of patients have been described with congenital abnormalities of P2Y12 resulting in bleeding diatheses and abnormalities of platelet function.\(^{6}\) The common clinical findings in these patients are a lifelong history of mucosal bleeding, easy bruising and/or excessive post-operative bleeding, and mildly to severely prolonged bleeding times. Laboratory findings were a weak and rapidly reversible primary wave of aggregation induced by ADP and abnormal aggregation induced by collagen, arachidonate, and TXA2 analogs. Aggregation induced by high concentrations of thrombin was normal. ADP-induced shape change is normal, but ADP fails to inhibit the expected normal rise in cAMP levels seen after stimulation with prostaglandin E1.

**Management**

Inasmuch as there are generally no serious side effects, DDAVP is recommended for prophylaxis and treatment in these patients.\(^{23}\)

**Thromboxane A2 Receptor**
Defective TXA2 receptor function is characterized by impaired platelet aggregation in response to the TXA2 analog U46619, a variable response to other agonists comprising a reduced primary wave and absent secondary wave, and defective secretion.  

Epinephrine Receptor

A selective absence of an aggregation in response to adrenaline has been reported as a heritable trait in association with easy bruising and reduced expression of platelet α2-adrenoceptors. However, the aggregation response to adrenaline among normal individuals is itself quite variable, and a relative decrease in the aggregation response to adrenaline may represent the lower segment of a common asymptomatic population variant.

Inherited Defects in Signal Transduction Pathways

Cyclooxygenase Defects

Defects in platelet cyclooxygenase (COX) or TX synthase give the same laboratory findings as seen in TXA2 receptor defects (see above), but can be distinguished from the latter by the preservation of platelet aggregation in response to prostaglandin-H2 or the TXA2 analog U46619.

Scott Syndrome

Scott syndrome is a rare autosomal recessive disorder characterized by a defect in calcium-induced phospholipid scrambling and prothrombin conversion on platelets and other blood cells. When Scott platelets are activated, phosphatidylserine is not transported from the inner to the outer phospholipid leaflet of the membrane. The binding of factor Va-Xa and factor VIIIa-IXa complexes is impaired, resulting in decreased thrombin generation and impaired platelet-dependent fibrin formation on subendothelium. It has been reported that Scott syndrome may be explained, at least in part, by mutations in an ATP-binding cassette transporter A1 implicated in the exofacial translocation of phosphatidylserine.

Additional Defects

Patients have been described with: A lineage-specific Gαq subunit deficiency and impaired αIIbβ3 activation; reduced Gαi1 expression and signaling; defective calcium ion mobilization and an abnormal response to ionophore A23187; a reduced production of inositol 1,4,5-triphosphate and phosphatidic acid, diminished plekstrin phosphorylation and defective phospholipase C activation; and a specific defect in phospholipase Cβ2 expression. Pseudohypoparathyroidism type 1b, which is associated with a mild bleeding disorder, is caused by a defect in the heterotrimeric G protein subunit Gsα, which regulates adenylyl cyclase.

Defect in the Consolidation Phase: Glanzmann Thrombasthenia

GT is an autosomal-recessive disorder characterized by defective in vitro platelet aggregation and a lifelong bleeding tendency due to quantitative or qualitative abnormalities of the platelet GPIIb-IIIa, also known as the integrin αIIbβ3.

Etiology

A qualitative or quantitative defect of either GPIIb or GPIIIa is the basic biochemical basis for GT. GPIIb-IIIa is a calcium-dependent heterodimer that binds preferentially to fibrinogen or vWF, but also to fibronectin or vitronectin. The genes for GPIIb and GPIIIa are distinct but are physically located within 1 Mb of each other on the long arm of chromosome 17 (17q21-22). A genetic defect in either GPIIb or GPIIIa can inhibit synthesis of that subunit and/or prevent normal assembly and processing of the functional receptor. This results in the lack of a fibrinogen receptor and defective fibrinogen binding after platelet activation. Platelet aggregation, which requires this protein, is therefore deficient or completely absent.

A continually maintained database is accessible on the Internet (https://haemgen.haem.cam.ac.uk/thrombogenomics/) which contains a list of over 100 mutations that give rise to GT. The αIIb and β3 genes (ITGA2B and ITGB3, respectively) are both affected, and although post-translational defects predominate, reduced mRNA stability can also be a cause. Integrin synthesis occurs in the megakaryocytes with αIIbβ3 complex formation in the endoplasmic reticulum. Noncomplexed or incorrectly folded gene products fail to undergo processing in the Golgi apparatus and are rapidly degraded intracellularly.
In GT, isoantibodies specific for the deleted GPs have been demonstrated in the blood of multiply transfused patients, and these can reproduce the thrombosthenic defect in normal transfused platelets.

Clinical Features

Thrombasthenia is inherited as an autosomal-recessive trait, and consanguinity is common within affected kindreds, resulting in geographic clusters of patients. Hemorrhagic symptoms occur only in patients homozygous for GT mutations, whereas the heterozygous condition is mostly asymptomatic, even though platelets from heterozygotes have only one half the normal level of αIIbβ3. The sites of bleeding in GT are clearly defined: Purpura, epistaxis, gingival hemorrhage, and menorrhagia are nearly constant features; gastrointestinal bleeding and hematuria are less common but can cause serious complications. Bleeding at menarche is severe enough to require transfusions in most patients. Deep visceral hematomas, a characteristic of coagulation disorders such as hemophilia, are not usually seen in GT. Bleeding symptoms normally manifest rapidly after birth, even if most patients are diagnosed before the age of five. Epistaxis is a common cause of severe bleeding, and is typically more severe in childhood. In general, the bleeding tendency in GT decreases with age. Post-traumatic and post-operative hemorrhage can be serious, and pregnancy and delivery represent a severe hemorrhagic risk, because bleeding may not always be preventable by platelet transfusions. Although GT can be a severe hemorrhagic disease, the prognosis is excellent with careful supportive care. Death from hemorrhage in diagnosed patients is rare unless associated with trauma, other disease (e.g., cancer), or chronic isoimmunization.

Laboratory Findings

A prolonged bleeding time, deficient clot retraction, and deficient platelet aggregation with ADP, collagen, epinephrine, or thrombin are typical findings. Ristocetin-induced aggregation, on the other hand, and coagulation tests are normal. Thrombasthenic platelets are present in normal numbers and are morphologically normal when viewed by light microscopy.

Management

With GT patients, it is important to anticipate bleeding risks before performing procedures, and because the risk for bleeding is so unpredictable, it is prudent to administer prophylactic platelet transfusions even in the absence of a prior history of bleeding.

Localized bleeding can be treated by limited measures, such as fibrin sealants or topical thrombin and antifibrinolytic agents (ε-aminocaproic acid, tranexamic acid). Epistaxis and gingival bleeding can be controlled by nasal packing or the application of gel foam soaked in topical thrombin. The risk of gingival bleeding can be minimized by regular, proper dental care. When tooth extractions must be performed or when hemorrhage accompanies the loss of deciduous teeth, bleeding can be significantly reduced by the application of individually prepared plastic splints that provide physical support for hemostasis.

Severe menorrhagia is common and can be effectively treated with high doses of progesterone, followed by maintenance treatment with birth control pills. Severe gastrointestinal bleeding is an isolated but severe problem. Iron deficiency anemia can develop insidiously with gingival oozing or minor menorrhagia. Confronted with a severe bleeding episode or as prophylaxis for invasive procedures, most GT patients receive blood transfusions, regardless of bleeding history. Transfusions should be continued until wound healing is complete. However, a significant number of transfused patients can develop HLA-specific alloantibodies or GPIIb-IIIa-specific isoantibodies, which seriously complicate transfusion therapy and limit future treatment. Isoantibodies can block normal transfused platelet aggregation and/or lead to the rapid removal of transfused platelets by immune mechanisms. It is not yet possible to predict the propensity of individual GT patients to develop such antibodies. Antibodies may be successfully removed prior to surgery by immunoadsorption on Protein A Sepharose, but this is a complex procedure restricted to specialized centers. Pregnancy and delivery represent a severe hemorrhagic risk. Platelet transfusions are required not only prior to delivery, but afterward as well. Successful delivery by cesarean section, with platelet transfusions, has been reported.

The use of rFVIIa (NovoSeven®; Novo Nordisk A/S, Malov, Denmark) is an alternative approach for early cessation of bleeding in GT, especially in the case of patients who have developed antibodies and/or have a history of transfusion refractoriness. It seems that rFVIIa enhances deposition of αIIbβ3-deficient platelets on the subendothelial matrix through an interaction with fibrin formed by the increased thrombin generation leading to increased clot stability. However, some question the efficacy of rFVIIa in children with GT. In a few GT patients, the bleeding symptoms have been considered sufficiently serious to warrant allogeneic bone-marrow transplantation.
Additional Hereditary Defects of Platelet Function (with Thrombocytopenia)

MYH-9-related Thrombocytopenia Syndromes

MYH-9-related disorder encompasses autosomal dominant macrothrombocytopenia syndromes previously classified as May-Hegglin anomaly, Sebastian, Fechtner, and Epstein syndromes and certain inherited thrombocytopenias that have in common mutations within MYH9, the gene for nonmuscle myosin heavy chain II-A (NMMHC-IIA).86

Etiology

NMMHC-IIA is part of the nonmuscle myosin IIA hexamer that is a component of the contractile cytoskeleton in megakaryocytes, platelets, and other many other cell types. Mutations of MYH9 that give rise to MYH-9-related disorder disrupt the stability of the nonmuscle myosin IIA hexamer or its association with regulatory proteins. This results in defective megakaryocytopoiesis that leads to thrombocytopenia. Additional platelet function defects arise from abnormal shape change or impaired expression of the GPIb complex.87 As in many other inherited hematologic disorders, incomplete penetrance accounts for a poor correlation between the MYH9 genotype and clinical phenotype as well as variability in phenotype among individuals with identical mutations.86

Clinical Features

Patients with MYH-9-related disorder present with bleeding, sensorineural hearing loss, glomerulonephritis, and/or eye abnormalities. The severity of the bleeding symptoms is out of proportion to the moderately decreased platelet count, suggesting the concurrence of a platelet function defect. Life-threatening bleeding has been reported, but is the exception. The combination of macrothrombocytopenia and one or more of the recognized clinical features of MYH-9-related disorder is strong evidence for this diagnosis.

Laboratory Findings

Platelet counts are normally from 20,000 to 130,000/µl, and are associated with an increased mean platelet volume and a conspicuous population of very large platelets. The presence of Dohle-like bodies within neutrophils on stained peripheral blood smears is highly suggestive of MYH-9-related disorder. An abnormal staining of neutrophil inclusions with antibodies specific for NMMHC-IIA is a more sensitive index of the syndrome, but a definitive diagnosis must be based on the identification of a causative mutation within MYH9.

Management

The symptoms of MYH-9-related disorders are highly variable, and therefore treatment of individual patients should be guided as much as possible by personal and family history.8 In general, management would be the same as for other mild platelet disorders.

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome (WAS) is an X-linked recessive disease characterized by microthrombocytopenia, eczema, and immunodeficiency.1 The WAS gene encodes the WAS protein (WASP), and mutations in WAS result in decreased or absent expression of WASP, a key regulator of actin polymerization in hematopoietic cells playing a role as an adapter protein. The reduction in or absence of WASP results in premature proplatelet formation in the bone marrow and the microthrombocytopenia characteristic of WAS.

Etiology

WAS arises from mutations in WAS, the gene for the protein WASP that is expressed in all hematopoietic cell lineages. Isolated X-linked thrombocytopenia (XLT) is also caused by mutations in WAS and is a variant of the same disease but generally lacks severe immune deficiency.88

Clinical Features

Infants with WAS often present with bruising and purpura in the neonatal period with an increased risk of intracranial hemorrhage. Gastrointestinal bleeding or prolonged bleeding after circumcision may be a presenting feature. Eczema develops during the first year of childhood and can varying in severity, from widespread and debilitating in children with “classic” WAS to mild or absent in those with the XLT. Infections begin in the first 6 months of life. Bacterial infections occur more often, particularly otitis media and respiratory tract infections, whereas severe viral infections and opportunistic infections occur less frequently. In the XLT phenotype, eczema and infection do not occur. With increasing
age, hemolytic anemia and vasculitis become the most frequent manifestations of the autoimmune component of this disease. Another life-threatening complication of WAS is malignancy, usually but not exclusively lymphoreticular in origin.

Laboratory Findings
Thrombocytopenia (ranging from 5,000 to 50,000/µl) with small platelets is evident at birth. Despite normal bone marrow megakaryocyte numbers and morphology, there may be ineffective thrombocytopoiesis with reduced platelet survival.

Management
The management of WAS should address bleeding manifestations, recurrent infections, eczema, autoimmune disorders, and the risk of malignancy. When available, bone marrow or stem cell transplant is the treatment of choice as early as possible. Proper management is benefited by a multidisciplinary approach, which should include an immunologist. When transfusion is necessary, HLA-compatible and irradiated platelets should be used in order to avoid sensitization. Because of the immune deficiency, platelets to be transfused should always be irradiated and certified free of cytomegalovirus. Splenectomy can result in an increase both in platelet number and size, but the risk of sepsis is increased post splenectomy, and a risk-benefit analysis of this operation must be considered for individual patients. Splenectomy does not influence the development of malignancy or autoimmune disorders, and it may thus be more successful in the milder phenotype of XLT.

ACQUIRED DISORDERS OF PLATELET FUNCTION

Drug-induced Platelet Dysfunction
An adult patient that presents with a normal platelet count, mucocutaneous bleeding, and a negative family history, defined as no bleeding among first degree relatives, should be evaluated for an acquired disorder. Although inherited platelet disorders are rare, acquired disorders of platelet function are encountered frequently.

A diverse variety of medications, from ionophores to ADP analogs, certain systemic diseases, and various procedures can induce platelet dysfunction (Table 52.2). Even common dietary substances, such as garlic or fish oil, can impair platelet function. This chapter focuses on commonly used drugs that can impair platelet function at therapeutic doses. Other drugs that are used to treat thromboembolic disorders are discussed in detail in Chapter 62.

The extent of platelet dysfunction produced by drugs in healthy individuals is usually not clinically significant. On the other hand, patients with coagulation disorders, uremia, thrombocytopenia, and patients receiving heparin or Coumadin as anticoagulant therapy, can exhibit serious bleeding when they receive a drug that attenuates platelet function. In addition, the inherent variation in platelet reactivity among normal individuals can greatly influence the susceptibility of an individual to the antiplatelet effects of dietary supplements or drugs.

TABLE 52.2 DRUGS AFFECTING PLATELET FUNCTION

Analgesics
Aspirin
Nonsteroidal anti-inflammatory drugs
Acetaminophen
Antibiotics
β-Lactams: Penicillins, cephalosporins
Cardiovascular drugs
Aspirin
Aspirin inhibits platelet function via irreversible acetylation of platelet COX-1 and the resulting inhibition of TXA2 synthesis. A single high dose of aspirin (e.g., 325 mg or more) or consecutive smaller doses (e.g., 81 mg) taken for 3 or more days will produce essentially complete inhibition of TXA2 production. The hemostatic risk following aspirin is
Integrin αIIbβ

Vitamin K

produce clinical bleeding as a result of both platelet dysfunction and the N-
dependent clotting factor synthesis.

Several days of treatment and will not resolve until 7 to 10 days after discontinuation. Moxalactam and cefotetan can

β

when there is co-

interactions.

Aspirin sensitivity is a hotly contested area of investigation.

Individual differences in platelet responsiveness to aspirin have been noted. In some normal individuals, aspirin ingestion
can modestly elevate the bleeding time and have a small impact on platelet aggregation in vivo, more so in men than in
women, but in certain patients with otherwise minor platelet dysfunction, the bleeding time can be markedly prolonged
and platelet aggregation severely impaired after aspirin ingestion. The search for a genetic basis for this difference in
aspirin sensitivity is a hotly contested area of investigation.

Other Nonsteroidal Anti-inflammatory Drugs

NSAIDs reversibly inhibit platelet COX-1, and normal platelet function is gradually restored when these drugs are stopped.
For example, ibuprofen (600 mg daily) will prolong PFA-100 CTs, but these will conform to baseline within 24 hours after
drug in-take is ceased. It is uncommon to see clinical bleeding in normal individuals as a result of an NSAID, but
gastrointestinal bleeding due to gastric ulceration is not uncommon. Paradoxically, ibuprofen can also exhibit a
prothrombotic effect if it is ingested within 2 hours of taking aspirin, inasmuch as it can transiently block acetylation of the
COX-1 target site.

Cyclooxygenase-2 Inhibitors

COX-2 inhibitors provide the anti-inflammatory effects of COX blockade without affecting platelet function. COX-2 is
expressed in endothelial cells, fibroblasts, and monocytes and is up-regulated in response to growth factors, cytokines,
endotoxin, and hormones. Even though COX-2 inhibitors have no direct effect on platelets, they increase the risk for
thrombosis and cardiovascular disease because they inhibit vascular (endothelial) cell synthesis of prostacyclin, a natural
inhibitor of platelet activation and thrombosis.

P2Y12 Antagonists

Platelet responses to natural agonists are normally enhanced by the binding of released ADP to platelet purinogenic
receptors. The thienopyridines clopidogrel and ticlopidine bind irreversibly to the platelet purinogenic receptor P2Y12 and
thereby inhibit platelet responses induced by both exogenous ADP and ADP released from platelet δ-granules. However,
clopidogrel has replaced ticlopidine as the preferred medication because the latter is associated with potentially life-
threatening hematologic side effects (thrombotic thrombocytopenic purpura, agranulocytosis, and aplastic anemia).
Steady-state inhibition of platelet function occurs after 3 to 5 daily doses of 75 mg clopidogrel, but it can be achieved
sooner with a 300-mg loading dose. Even though clopidogrel has a greater effect than aspirin on the bleeding time, there
is no greater risk of bleeding in vivo. The combination of clopidogrel and aspirin is currently used to prevent or treat
arterial thrombosis. The effect of clopidogrel on platelet function is irreversible, such that after cessation of clopidogrel,
platelet function returns to roughly 50% of normal levels by 72 hours, and its effect is completely reversed by 7 days.

Antibiotics

Large doses of various β-lactam antibiotics (penicillins more often than cephalosporins) can cause clinical bleeding,
abnormal platelet function in vitro, and increased bleeding times, because of a nonspecific effect on ligand-receptor
interactions. The effect on platelet function can be manifested by a dose-dependent reduction in platelet aggregation in
vitro to ADP, epinephrine, and collagen. The clinical effect is exaggerated in hypoalbuminemic patients because the level
of free drug is increased and thus more interact with the platelet surface. β-Lactam compounds influence clinical bleeding
when there is co-existing hemostatic defect, such as in uremia, thrombocytopenia, or vitamin K deficiency.

β-Lactams appear to modify the platelet membrane and decrease agonist binding. The effect can become event after
several days of treatment and will not resolve until 7 to 10 days after discontinuation. Moxalactam and cefotetan can
produce clinical bleeding as a result of both platelet dysfunction and the N-methylthiotetrazole side-chain effect on
vitamin K-dependent clotting factor synthesis.

Integrin αIibβ3 Antagonists

2626
Specific inhibitors of integrin αIIbβ3 are potent inhibitors of platelet function, and three are currently approved by the FDA: Abciximab is a chimeric human-mouse monoclonal Fab fragment; tirofiban is an arginine-glycine-aspartate-based peptidomimetic; and eptifibatide (integrelin) is a synthetic cyclic heptapeptide based on the lysine-glycine-aspartate motif of the snake venom disintegrin barbourin.

These antagonists, which inhibit platelet aggregation effectively because they prevent fibrinogen and VWF binding to αIIbβ3, are used commonly in patients undergoing percutaneous coronary intervention (PCI), concurrently with heparin and other antiplatelet therapy such as aspirin. Bleeding is a common side effect of these antagonists and occurs in ~10% of recipients, but intracranial bleeding (<0.5%) and death due to bleeding (<0.1%) are rare. The duration of the antiplatelet effect of these drugs varies: Although unbound abciximab is cleared rapidly, elimination of bound drug is significantly slower and some residual receptor blockade (~25%) can be detected for up to 7 days; the inhibitory effects of the other two small molecules are directly proportional to their elimination half-life and usually disappear within hours of drug removal.¹⁰¹

Uremia

Patients with uremia are at risk for bleeding complications because of a number of factors that include minor coagulation abnormalities, platelet dysfunction, thrombocytopenia, or the widespread use of medications that compromise hemostasis.¹¹² Defects in all stages of platelet hemostasis including adhesion, secretion, and aggregation have been noted in studies of platelet function in uremic patients.

Factors That Influence Hemostasis

Nitric oxide is a potent modulator of vascular tone that limits platelet adhesion to the endothelium and platelet-platelet interaction by increasing the formation of cGMP,¹⁰³ and enhanced nitric oxide synthesis has been demonstrated in uremic patients. The inhibition of nitric oxide formation in a rat model of uremia completely normalized the bleeding tendency in rats.¹⁰⁴

Additional platelet changes have been noted. Deficient platelet stores of ADP and serotonin have been described in uremic platelets, suggesting that these platelets have an acquired storage pool deficiency. Elevated cAMP levels may be responsible for an acquired defect of COX activity with reduced ability to synthesize TXA2. Alterations in intraplatelet calcium mobilization have also been reported and theorized to be associated with uremic bleeding.¹⁰⁵

In uremic patients, integrin αIIbβ3 has a reduced ability to bind both VWF and fibrinogen,¹⁰⁶ most likely due to a conformational change in this integrin. Hemodialysis improved fibrinogen binding, leading to the hypothesis that a dialyzable toxic substance is responsible in part for altered platelet function. Uremic substances that inhibit platelet function in concentrations detectable in uremic plasma include: Urea, guanidine-succinate, parathyroid hormone, phenol, and tryptophan products.¹⁰⁷ Small peptides containing the RGD that could potentially inhibit αIIbβ3 function accumulate in uremic patients due to reduced clearance.¹⁰⁸

The Effects of Anemia

Anemia predisposes uremic patients to bleeding complications.¹⁰⁹,¹¹⁰ When the hematocrit is reduced, platelets travel closer to the center of the vascular lumen and are thus less likely to interact with the subendothelium. In addition, red blood cells release ADP and TXA2 which enhances platelet aggregation.¹¹¹ Hemoglobin also scavenges nitric oxide and therefore a reduced hematocrit would be associated with enhanced nitric oxide activity and promoting platelet inhibition and vasodilatation. Finally, significant anemia in current vintage dialysis populations often co-occurs with other major problems such as iron deficiency, malnutrition, and inflammation in the sickest patients. This may further confound observational studies of bleeding risk in current dialysis patients.

Secondary Effects of Medications

The bleeding risk in uremic patients is increased by exposure to antiplatelet agents and anticoagulants, including aspirin, αIIbβ3 antagonists, heparin, and warfarin.¹¹²

Clinical Features

The bleeding sites in the uremic patient are gastrointestinal and intracranial. Through gastrointestinal bleeding, chronic renal failure patients may lose 4 to 6 times as much blood per day as normal individuals through peptic ulcer disease,
gastric bleeding, telangiectasias in the stomach, duodenum, jejunum, and colon, and duodenitis and esophagitis. In a long-term follow study of 1,609 chronic hemodialysis patients, there was a tenfold higher incidence of intracerebral hemorrhage compared to the general population.107

Laboratory Findings
Platelet aggregation to exogenous agents is often but not always defective, such that the sensitivity to aggregating concentrations of collagen, ADP, and epinephrine is decreased, and TXB2 generation and δ-granule ADP content are reduced relative to control platelets.104

Management
The most effective treatment of uremic bleeding includes hemodialysis and peritoneal dialysis, although a transient worsening of platelet function may be encountered immediately following.115 When platelet function was prospectively evaluated after renal transplantation, platelet aggregation, F-actin, and platelet cytoskeletal abnormalities were completely normal by 8 weeks after renal transplant. Red blood cell transfusions and/or administration of erythropoietin (rHUEPO) have been observed to decrease bleeding, shorten the bleeding time, and increase platelet adhesiveness when given to hemodialyzed patients.116 However, some patients may become hypercoagulable. Administration of DDAVP can shorten the bleeding time and is effective for short-term control of bleeding in some uremic patients as a result of changes in vWF activity.117

Cardiovascular disease is common in patients with chronic renal insufficiency and end-stage renal disease. Antiplatelet medications are associated with an increased risk of bleeding, compared to the risk associated with their use in patients who do not have end-stage renal disease. Among patients undergoing PCI and treated with abciximab, those with renal insufficiency had a greater tendency of major bleeding.118

Paraproteinemias
Bleeding is a common complication of paraproteinemias associated with multiple myeloma, Waldenstrom macroglobulinemia, monoclonal gammopathies, and even polyclonal hypergammaglobulinemia.119,120 The etiology is complex, but various mechanisms have been proposed, such as thrombocytopenia or platelet dysfunction, inhibitors of specific coagulation factors, circulating monoclonal proteins that bind to and promote clearance of coagulation factors, and hyperviscosity syndrome.

Clinical Features and Laboratory Findings
Hematologic findings that are limited to purpura and mucocutaneous bleeding are most often encountered in patients with IgA myeloma and macroglobulinemia. Platelet dysfunction likely results from nonspecific binding of immunoglobulins to the platelet surface.121

Myeloproliferative Disorders
Chronic myeloproliferative disorder (MPD) defines a group of Philadelphia chromosome-negative disorders that includes essential thrombocythemia (ET), polycythemia vera (PV), and agnogenic myeloid metaplasia and chronic idiopathic myelofibrosis.122 Various platelet defects have been reported in patients with MPD, including defective platelet aggregation and secretion, subnormal uptake of serotonin, abnormal expression of Fc receptors, specific defects in integrin αIIbβ3 expression or activity, and an acquired SPD.

Etiology
Vainchenker et al. showed that acquired JAK2 V617F mutation in hematopoietic precursors causes PV.123 The V617F mutation results in the loss of inhibitory activity of the JH2 pseudokinase segment of JAK2 leading to enhanced activity of the JH1 kinase of JAK2, which renders hematopoietic precursors hypersensitive to thrombopoietin, erythropoietin (EPO), insulin growth factor 1, stem cell factor, and granulocyte colony-stimulating factor. The result is a trilinear myeloproliferation that explains the common proliferative features of ET, PV, and MF.124,125

Clinical Features and Laboratory Findings
Microvascular disturbances in ET and PV, including erythromelalgia, and atypical and typical transient cerebral, ocular, and coronary ischemic attacks, are caused by platelet-mediated transient and occlusive thrombosis in the end-arterial circulation. An inconsistent pattern of laboratory abnormalities has been encountered, with poor correlation between lab results and bleeding severity. As in MDS and acute leukemia, platelet dysfunction appears to result from defective megakaryocyte maturation and/or thrombopoiesis.

The endogenous synthesis of TXA2 by platelets, reflected by the stable urine metabolite TXB2, is increased in ET and PV patients. This increased biosynthesis of TXA2 is a reflection of spontaneous platelet activation in vivo.

Management

Correction of hematocrit to normal by phlebotomy will reduce the major arterial and venous thrombotic complications, but fail to prevent the platelet-mediated microvascular circulation disturbances in PV patients because thrombocythemia persists. Complete relief and prevention of microvascular and major thrombosis in ET and PV patients, in addition to phlebotomy, are obtained by treatment with aspirin but not with warfarin.

Chapter 53
Inherited Coagulation Disorders

Jerry S. Powell
George M. Rodgers
Inherited disorders of coagulation result from the deficiency or functional abnormality of one of the plasma proteins involved in providing normal coagulation. There are other proteins that regulate the kinetics of coagulation, and abnormalities in one of these proteins usually result in increased risk of thrombosis; these proteins will not be covered in this chapter. If von Willebrand disease (vWD) is included, the inherited coagulation abnormalities (Table 53.1) are common; for example, vWD may affect up to 1% of the population. The other inherited coagulation disorders occur less often.

Since the purpose of the coagulation cascade is to rapidly produce fibrin to form a clot, the clinical manifestation of any deficiency or functional abnormality in any coagulation protein will be similar, i.e., clinical bleeding, with greater bleeding associated with more severe deficiency. Therefore, the manifestations and complications of clinical bleeding will be described in this chapter in the section on hemophilia A. A recent review of treatment of hemophilia A has been published with proposed algorithms for therapy.

**NOMENCLATURE**

Historically, the best known inherited coagulation disorder is hemophilia, which dramatically manifested itself in the royal families of Europe in the 20th century, following a spontaneous mutation that apparently arose in Queen Victoria in
England. The international Roman numeral designations for these disorders are summarized in Table 18.1. Like abnormal hemoglobins, qualitatively abnormal fibrinogens are designated by the name of the city in which they were first discovered, as in fibrinogen Paris.

PRINCIPLES OF PATHOPHYSIOLOGY

With the exception of fibrinogen and prothrombin, the coagulation factors are trace proteins. Clinical laboratory measurements of their activity depend on bioassays, which detect both quantitative absence of a specific factor and a qualitative functional abnormality in a factor that is present in normal amounts. Further laboratory testing is required to determine the actual concentration of the protein, usually by enzyme-linked immunoabsorbent assay (ELISA) methodology. Thus, for example, in hemophilia A, the bioassay measures factor VIII coagulant activity (factor VIIIc) and refers to the functional property of the factor VIII molecule that corrects the coagulation defect of patients with hemophilia A. The amount of protein measures the amount of antigen by ELISA and is referred to as factor VIII Ag (Table 53.2). Many hemophilia treatment centers currently proceed to determine the genotype for individual persons with inherited coagulation disorders; such analysis is helpful to predict the severity of the clinical phenotype, to predict the risk of inhibitor development, and to aid in family counseling.

Most qualitative abnormalities in coagulation factors result in loss of function of the protein in the coagulation cascade. However, some mutations produce qualitative abnormalities that result in "gain of function." Such factors are called abnormal or aberrant factors to distinguish them. The most clearly defined disorders of this type are the dysfibrinogenemias, in which the abnormal fibrinogen typically is not completely nonfunctional, but may also inhibit the function of normal fibrinogen. Other disorders characterized by aberrant coagulation factors include the B variant of hemophilia B and some of the variants of prothrombin deficiency. Aberrant procoagulant proteins also may be synthesized in acquired deficiencies of the vitamin K-dependent factors (see Chapter 54). An example of a "gain of function" mutation for factor IX was described recently, factor IX Padua, in which a leucine was substituted for arginine at position 338 (R338L) and, despite a normal concentration of factor IX protein in plasma, the factor IX clotting activity was eight times normal, resulting in clinically significant thrombosis.

HEMOPHILIA A

Hemophilia A refers to the inherited coagulation disorder characterized by deficiency of function of the coagulation protein called factor VIII. Except for vWD, it is the most common inherited coagulation disorder, and is X-linked. As the most common bleeding disorder, historians assume that it is the severe and often fatal hemorrhagic diathesis that affected the male children of certain families and that was well recognized in antiquity, as noted in the writings of Rabbi Simon ben Gamaliel (2nd century A.D.) in the Talmud, and those of Maimonides, the Hebrew physician and philosopher, and Albucasis, the Arab (twelfth century). Complete monographs have reviewed the early literature. However, the bleeding disorder that occurred in males throughout the royal families of Europe due to a mutation that arose with Queen Victoria, long assumed to be the more common hemophilia A, turned out, after extensive medical forensic investigation, to be hemophilia B.

![Figure 53.1](image)

**FIGURE 53.1.** The relationship of factor VIII procoagulant activity and factor VIII-related antigen (von Willebrand factor [vWF]) in the plasma of normal subjects and patients with hemophilia or von Willebrand disease. (From Hoyer LW. The factor VIII complex: structure and function. Blood 1981;58:1-13, with permission.)

Pathophysiology

The hemostatic abnormality in hemophilia A (factor VIII deficiency, classic hemophilia) is a deficiency or functional abnormality of the plasma protein factor VIII. It normally circulates in the plasma bound to a much larger molecule, vWF. The half-life of factor VIII in the absence of vWF is much shorter, as seen in individuals with the vWF Normandy mutation, resulting in loss of the protein sequences for the binding interaction site between factor VIII and vWF, and causing low levels of factor VIII and clinical bleeding that appears similar to the bleeding seen in patients with hemophilia A. The production of vWF is coded by an autosomal gene, and this protein is qualitatively normal and is present in normal or increased amounts in patients with hemophilia A (Fig. 53.1). The function of the coagulation protein factor VIII is to serve (when activated) as a cofactor for the serine protease enzyme factor IX, and accelerate the reaction as part of the coagulation cascade. No other function for factor VIII has been clearly characterized.

Incidence

Hemophilia A has been recognized in all areas of the world and in all ethnic groups. Estimates of its incidence approximate 1 in 5,000 males, or 1 in 10,000 persons. A population-based study of the southeastern United States by the Centers for Disease Control and Prevention found that 11 cases per 100,000 persons had hemophilia A and that the prevalence was similar among different racial groups. This same survey estimated that in 1994, there were 13,320 cases of hemophilia A in the United States.
Genetics

Hemophilia A is a classic example of an X-linked recessive trait. In such a disorder, the defective gene is located on the X chromosome; the factor VIII gene maps to Xq28, on the distal end of the long arm of the X chromosome. In males who lack a normal allele, the defect is manifested by clinical hemophilia (Fig. 53.2; generation I, number 1). The affected male does not transmit the disorder to his sons (generation II, numbers 4 and 5) because his Y chromosome is normal. However, all of his daughters are obligate carriers of the trait because they inherit his X chromosome (generation II, numbers 2 and 3). Most of these women are unaffected clinically because of the presence of a normal allele from the mother. The female carrier transmits the disorder to half of her sons (generation III, numbers 6 and 7) and the carrier state to half of her daughters (generation III, numbers 8 and 9). Due to Lyonization of the X chromosome, if the normal factor VIII allele is inactivated more often by chance, then some of the carrier females may have clinical bleeding. The severity of their bleeding depends on their factor VIII activity level; and, rarely, a woman can have very low factor VIII activity and present with symptoms of moderate or even severe hemophilia.

FIGURE 53.2. The inheritance of hemophilia A and hemophilia B. The pedigree is hypothetical. Squares indicate male; circles indicate female; fully shaded squares or circles indicate affected members; half-shaded circles indicate carriers. X, normal X chromosome; x, abnormal X chromosome.

The severity of bleeding varies in different kindreds, and closely depends on the particular genetic defect. Since the same gene defect is present in the kindred, each of the affected males will have very similar clinical phenotypes. As expected, hemophilia A has been observed several times in twins. Occasionally, however, the coinheritance of other genetic defects can influence the clinical symptoms of hemophilia A patients. An example is the coinheritance of the factor V Leiden mutation (discussed in Chapter 55) with hemophilia A. These patients have a milder clinical phenotype than expected for the same molecular defect in factor VIII. The coinheritance of the factor V Leiden mutation or other prothrombotic risk factors in children with severe hemophilia A may delay the first symptomatic bleeding event.

Intriguing, and yet to be fully explained, is the fact that in over a third of families with hemophilia A, there is no evidence or history of abnormal bleeding in other members of the family. This percentage is consistent with the Haldane hypothesis, which predicted that maintenance of a consistent frequency of a genetic disorder in the population would require that approximately one-third of cases result from spontaneous mutation. In other instances, neonatal deaths or
the passage of the trait through a succession of female carriers may explain the negative family history. For practical purposes, therefore, a negative family history is of little value in excluding the possibility of hemophilia A. Mutations that cause hemophilia A originate in males at least threefold more often than in females. The large size of the factor VIII gene (186 kb), the presence of hot spots (e.g., CpG dinucleotides), and the fact that the X chromosome is unpaired in males may predispose for the factor VIII gene to undergo spontaneous mutation.\textsuperscript{20, 21, 22, 23}

Nearly 3,000 individuals with hemophilia have had their factor VIII genes analyzed; this genetic information is collected in the Hemophilia A Mutation Database (HADB, formerly the Hemophilia A Mutation, Structure, Test and Resource Site[HAMSTeRS] database).\textsuperscript{21} The genetic defects of hemophilia A encompass deletions, insertions, and mutations throughout the factor VIII gene.\textsuperscript{24} Point mutations involving CpG dinucleotides are especially common. Approximately 5% of patients with hemophilia A have large (>50 nucleotides) deletions in the factor VIII gene.\textsuperscript{25}

Approximately 45% of severe hemophilia A cases result from a major inversion of a section of the tip of the long arm of the X chromosome, one breakpoint of which is situated within intron 22 of the factor VIII gene.\textsuperscript{26} This common inversion is associated with severe hemophilia A, and a higher incidence of inhibitor formation. It is presumed that in the absence of homologous X chromosome pairing during male meiosis, an intrachromosomal recombination event occurs on the single X chromosome, resulting in this inversion. This event typically occurs in the father of the mother of a child with severe hemophilia A, and often leads to relief of guilt feelings in the mother, as the genetic mutation is not “her fault.” Another common inversion (intron 1) accounts for 5% of patients with severe factor VIII deficiency.\textsuperscript{27} Thus, two inversions of the factor VIII gene are seen in nearly one-half of all severely affected patients with hemophilia A. In contrast, point mutations are most likely found in patients with mild to moderate hemophilia A.\textsuperscript{28} The first case of hemophilia A caused by unequal homologous Alu/Alu recombination has been reported.\textsuperscript{29} Because there are ~50 Alu repeats in the factor VIII gene, it is possible that many cases of hemophilia may result from this mechanism.\textsuperscript{29} More than 95% of hemophilia A patients have mutations detected.\textsuperscript{22, 30, 31} Approximately 2% of hemophilia A patients have no detectable mutations in the coding region of the factor VIII gene.\textsuperscript{32} These results indicate that a substantial number of families with severe hemophilia A can undergo accurate gene tracking and carrier analysis. The intron 1 and 22 inversions responsible for 50% of severe hemophilia A cases can be sought using long and inverse polymerase chain reaction (PCR) techniques. Various algorithmic approaches to rapid laboratory genetic testing have been described,\textsuperscript{30, 33, 34} and a recent method of performing linkage analysis of hemophilia A in families in whom mutations could not be identified has been reported.\textsuperscript{35}

There is a strong association between genetic mutations that lead to absence of large portions of the factor VIII protein and the development of antibodies to therapeutic factor VIII infusions. These antibodies generally develop within the first 50 infusions of factor VIII, as expected when the immune system detects a protein to which it has not been exposed previously.

Variants

Hemophilia A with autosomal dominant transmission has been reported; however, it is important to distinguish these “variant hemophilia A patients” with negative X-linked transmission from patients with variant vWD (type 2N, vWD Normandy), an autosomal vWD subtype caused by defective factor VIII binding to vWF and with a clinical picture similar to hemophilia A.\textsuperscript{36}

Carrier Detection

Despite the high rate of spontaneous de novo mutations in hemophilia A, detection of females who are carriers is important. When the family history of a patient suggests risk for being a carrier, then coagulation-based assays are performed, followed by DNA testing. The daughter of a man with hemophilia is an obligate carrier, whether she has symptomatic bleeding or not. Similarly, if a female has two sons with hemophilia, then she is likely a carrier; if she has one son with hemophilia and a family history of hemophilia, then she is likely a carrier; but if she has one son with hemophilia and a negative family history, then the odds are approximately 67% that she is a carrier. A number of specialized laboratories perform molecular testing for the factor VIII gene. It is most efficient and less expensive if the DNA of the relative with hemophilia is available to identify the specific genetic mutation in that kindred; then only that specific mutation is evaluated in the potential carrier.\textsuperscript{37}

P.1146
Coagulation-based assays may be useful in confirming or excluding the carrier state, although they have limitations. The regularity with which the abnormal factor VIII gene is suppressed by the normal allele in female carriers of hemophilia varies because of the phenomenon of random X chromosome inactivation (the Lyon hypothesis). Thus, although the mean concentration of factor VIIIc in the plasma of heterozygous female carriers is “50% of that in normal women,” observed values scatter widely around this mean and often overlap with those found in the normal population. This is a result, in part, of the large error of assay methods and the wide range of factor VIIIc levels in normal subjects.

Although the demonstration of low levels of factor VIIIc by means of the usual assay methods strongly suggests the presence of the carrier state, the converse statement cannot be made with equal certainty—that is, the presence of normal levels of factor VIIIc does not reliably exclude the carrier state. Furthermore, pregnancy and hormonal medications may increase the levels of factor VIIIc in female carriers. Normal women and carriers with blood types A, B, or AB have higher levels of factor VIIIc and vWFAg than those with blood type O.

The use of immunoassays for vWF has improved carrier detection in hemophilia A. These methods allow measurement of levels of vWF, which are normal or increased in carriers of the disorder, despite mild but variable deficiencies of factor VIIIc. Results obtained when a bioassay and an immunoassay are performed on the same sample, and the ratio of VIIIc to vWF is computed, differentiate between the carrier population and the normal population with minimal overlap. This ratio normally ranges from 0.74 to 2.20 and was found to be from 0.18 to 0.90 in obligatory carriers. The overall detection rate ranged from 72% to 94% in such obligatory carriers and from 48% to 51% in women without hemophilic sons or fathers. In the latter group (possible carriers), 50% would be predicted to be carriers. Abnormally low ratios of VIIIc:vWF (false positives) have been encountered in an occasional normal subject, which may be attributable to nonspecific variables such as stress. Pregnancy and the use of oral contraceptives, blood type, or contamination of plasma samples with thrombin or other proteolytic enzymes may produce falsely high ratios (false negatives) in documented obligatory carriers. Linear discriminant analysis has been recommended for the expression and analysis of such laboratory data.

The carrier detection rates using standardized assays with discriminant analysis exceed 90%.

DNA-based Assays

Molecular analyses of the factor VIII gene identify mutations in 97% of hemophilia A patients. Based on the frequency of the intron 22 inversion, severe hemophilia A patients should be initially screened for this defect. Inversion-negative patients and those with mild or moderate hemophilia A should have systematic sequencing of the factor VIII promoter, exons, and splice junctions performed. Such an approach has been reported to identify mutations in 97% of hemophilia A patients.

DNA-based assays have been adapted for prenatal diagnosis and for pre-implantation genetic diagnosis in association with in vitro fertilization. One commonly used method is to obtain chorionic villi samples during the eleventh to twelfth gestational week and perform direct genotype testing. Alternatively, genetic linkage analysis of polymorphisms can be performed. The subject of genetic counseling in hemophilia has been reviewed.

Hemophilia in the Female

Hemophilia has been well documented in human females. The most common form is that seen in a minority of heterozygous carriers, discussed previously, in whom X chromosome inactivation may occur at an unusually early stage of embryogenesis, resulting in unusually low levels of factor VIII.

A second cause of female hemophilia is a mating between an affected male and a carrier female (Fig. 53.2; generation IV, number 10). One-half of the female offspring of such a match would inherit two abnormal X chromosomes, one from the father and one from the mother. Such homozygous female hemophilia was once thought to be lethal and to inhibit the development of the embryo. That this is not true was first suggested by the successful experimental production of hemophilia in female dogs. Homozygous hemophilia is now well authenticated in several women and resembles the disorder seen in affected males in all respects.

Clinical Manifestations of Hemophilia

Prior to effective replacement therapy, the life expectancy for a child born with severe hemophilia was less than 20 years. These boys would die from exsanguinating hemorrhage after a trivial traumatic injury, from spontaneous internal bleeding or from spontaneous intracranial hemorrhage. It is dramatic that a boy born today with severe hemophilia A can expect to have a normal life expectancy.

However, the most characteristic bleeding manifestations in hemophilia are spontaneous bleeding in weight-bearing joints, leading to severe hemarthrosis. The frequency and severity of these joint bleeds are related to the functional activity level of factor VIII in plasma (Table 53.3). Three categories of severity have been defined by a consensus
Severe hemophilia (factor VIII level <1 IU/dl) is manifested clinically by repeated and severe hemarthroses, resulting almost invariably in crippling arthropathy in the absence of replacement therapy; such severe cases often are called classic hemophilia. Moderate hemophilia (factor VIII level of 1 to 5 IU/dl) is associated with less frequent and less severe hemarthroses and seldom results in serious orthopedic disability. In mild hemophilia (factor VIII level of 6 to 40 IU/dl), hemarthroses and other spontaneous bleeding manifestations may be absent altogether, although serious bleeding may follow surgical procedures or traumatic injury. As indicated in Table 53.3, most patients with hemophilia A have severe disease. However, one epidemiologic survey reported variable differences in the incidence of severity between individual states within the United States; for example, 13% of hemophilia cases were of moderate severity in Massachusetts, whereas 35% of cases in Georgia were classified as moderate severity.\(^{11}\)

Hemarthrosis

Hemarthrosis is the most common manifestation of the inherited coagulation disorders (Fig. 53.3). Joint bleeding and the consequent damage to weight-bearing joints remain the most common debilitating symptom in severe hemophilia.

Pathophysiology

Bleeding presumably originates from the synovial vessels and develops spontaneously or as the result of imperceptible or trivial trauma. Spontaneous joint bleeding in the absence of identifiable mild trauma is unusual in patients with moderate hemophilia and very rare in patients with mild hemophilia. Hemorrhage occurs into the joint cavity or into the diaphysis or epiphysis of the bone. In the acute stage, the synovial space is distended with blood. Muscular spasm further increases the intrasynovial pressure. Hemorrhage into the periarticular structures is a common complicating feature that occurs most often around small joints. The inflammatory response to joint bleeding is highly variable and not well studied. However, in many patients permanent joint damage, detectable by MRI, appears to occur after only one or two minor bleeds into a single joint.\(^{58}\)

The joint may regain normal function after the first few episodes of hemarthrosis. More often, however, the absorption of intraarticular blood is incomplete, and the acute bleeding leads to chronic inflammation of the synovial membrane with the development of long-term damage to the joint. Sometimes, the joint remains swollen, tender, and painful for months, and in this setting may often suffer episodes of rebleeding. Such a joint is often termed a “target joint,” and should be treated aggressively with physical therapy and appropriate factor replacement to interrupt the vicious cycle of
inflammation, swollen synovium, and recurrent bleeding. Release of inflammatory cell proteolytic enzymes initiates destruction of cartilage and bone.\(^{69}\)

Acute hemarthroses almost invariably recur from time to time. With each recurrence, the synovium becomes progressively more thickened and vascular; folds and villi, which predispose to synovial injury during even minimal activity, may form. Proliferating synovium often fills and distends the joint, which remains swollen and enlarged in the absence of bleeding or pain (chronic proliferative synovitis).\(^{60}\) Together with the weakening of the periarticular supporting structures, this process predisposes the joint to recurrent episodes of bleeding. Repeated episodes of hemarthrosis, with the associated subchondral and synovial ischemia, result in progressive loss of hyaline cartilage, particularly at the margins of the joint. Large punched-out areas of destruction are sometimes produced by subchondral hemorrhages and, in the cancellous structure of the bone, cavitation may be caused by intraosseous hemorrhage. Through disuse, diffuse demineralization of the involved bones also may occur. Subperiosteal hemorrhages are not common.

FIGURE 53.3. Hemophilic arthropathy. This figure illustrates the sequelae of recurrent joint bleeding.

The terminal stage of hemarthrosis is called chronic hemophilic arthropathy.\(^{61}\) It is manifested by fibrous or bony ankylosis of larger joints; complete destruction may take place in the smaller articulations because of the weaker joint structure and the thinner cortices of the smaller bones. Other permanent sequelae of hemarthrosis include atrophy and proliferation of bone, roughening of the articular surfaces with lipping and osteophyte formation, bone necrosis and cyst formation, stunted growth as the result of interference with the nutrition of the bone, and accelerated development and overgrowth of the epiphyses caused by excessive blood flow (Figs. 53.3 and 53.4). Chronic hemophilic arthropathy is less common now because of widespread use of prophylactic replacement therapy and improved availability of factor replacement therapy.

Magnetic resonance imaging is superior to standard radiography for assessment of early arthropathy.\(^{62}\) A scoring system for magnetic resonance joint evaluation has been reported\(^{62}\) (Table 53.4).
It should be emphasized that with modern prophylactic therapy of regular factor infusions to maintain the plasma factor concentration above 1% of normal, boys are now reaching adolescence and young adulthood with essentially normally functioning joints. However, such a program of regular infusions with currently available factor therapies requires intensive medical and family support.

Clinical Presentation

Most persons with severe hemophilia report a characteristic warm, tingling sensation before the onset of symptoms of joint bleeding and hemarthrosis; this is called the aura. The earliest definite symptom is pain, which in the acute form may be excruciating. Physical examination reveals muscle spasm and limited motion of the affected joint. If therapy is not initiated immediately, typically within approximately 30 minutes, then the joint may progress so that it is warm and grossly distended and discolored,

P.1148

but external evidence of bleeding may be minimal or absent in chronically damaged large joints because of thickening of the articular capsule. Generally, only one joint is involved at a time, although bleeding may develop simultaneously in two or more joints. The weight-bearing joints are most commonly affected and the knees are the joints most often severely affected. However, because of the success of total knee and total hip replacement surgeries, the ankles are the most commonly affected joints that lead to chronic problems that interfere with quality of life for persons with severe hemophilia.
FIGURE 53.4. Elbow and knee joints in a patient with hemophilia A. Thickening of synovium with deposition of calcium is shown in (A) and (A1); increased intercondylar notch is shown in (B); increased density and decreased interarticular space are shown in (A), (B), and (C); and lipping along the borders of the joint surfaces is shown in (C).

Subcutaneous and Intramuscular Hematomas

Large ecchymoses and subcutaneous and intramuscular hematomas were common in hemophilia A prior to the use of regular infusion therapy, reflecting the substantial amounts of time patients had factor levels less than 1% of normal. With modern treatment protocols designed to keep plasma levels above 1% of normal, and immediate home infusion when a bleeding episode occurs, the frequency of large soft tissue bleeds has decreased dramatically. Such hemorrhages, when not treated promptly, characteristically spread within fascial spaces and dissect deeper structures (see Fig. 45.2). Subcutaneous bleeding may be extensive. When not treated promptly with factor infusion, the bleeding continues; and at the site of origin, the tissue is hard, indurated, raised, and purplish black. From this center, the hemorrhage extends in all directions, with each successive concentric extension less deeply colored. The point of origin of the hemorrhage may be absorbed entirely while the margin is still progressing. Intramuscular and subcutaneous hematomas may produce leukocytosis, fever, and severe pain in the absence of significant discoloration of the overlying skin.

Hematomas may produce serious consequences from the compression of vital structures. Bleeding into the tongue, throat, or neck may develop spontaneously and is especially dangerous because it may compromise the airway with surprising rapidity. Gangrene may result from pressure on arteries; and the development of compartment syndrome and, if not promptly treated, ischemic contractures are common sequelae of hemorrhage into the calves or forearms. Peripheral nerve lesions of varying severity are common complications of untreated hemorrhage into joints or muscles. Hemophilic cysts are discussed in the section Special Aspects of Treatment.

Psoas and Retroperitoneal Hematomas

Spontaneous hemorrhage into internal fascial spaces and muscles of the abdomen is common in severe hemophilia A, reflecting plasma factor levels less than 1% of normal. Bleeding into or around the iliopsoas muscle produces pain of progressively increasing severity and tenderness; when it occurs on the right side, it may closely simulate acute appendicitis. Femoral nerve involvement may be partial or complete, with the development of pain on the anterior surface of the thigh. The psoas sign is positive, and the hip is held in partial flexion. Paresthesias, partial or complete anesthesia, and, ultimately, weakness or paralysis of the thigh extendors with eventual muscular atrophy may ensue. Retroperitoneal hemorrhage and intraperitoneal hemorrhage also are common. Computed tomography may be helpful in the diagnosis of these hematomas. Prompt factor infusion is critical to normalize coagulation and should be continued until the hematoma has resolved completely, as any residual hematoma is at higher risk for rebleeding and pseudocyst formation.

Gastrointestinal and Genitourinary Bleeding

Hemorrhage from the mouth, gums, lips, frenulum, and tongue is common and often serious. The eruption and shedding of deciduous teeth usually occur without abnormal bleeding, but may occasionally be accompanied by hemorrhage that lasts for days or weeks if not treated. Epistaxis occurs in many patients and may be of exsanguinating proportions. Hematemesis, melena, or both are not uncommon. The source of the bleeding is usually the upper gastrointestinal tract. In most patients in whom bleeding is persistent or recurrent, it originates from a structural lesion, most commonly a peptic ulcer or gastritis. Hemorrhage may be accompanied by abdominal pain, distention, increased peristalsis, fever, and leukocytosis. Intramural bleeding into the intestinal wall may result in intussusception or obstruction.

Hematuria is more common than gastrointestinal bleeding, but it is less often the result of a demonstrable pathologic condition in the genitourinary tract. The bleeding may arise in the bladder or in one or both kidneys and may persist for
days or weeks. When clots form, ureteral colic may develop. Typically, the hematuria resolves after factor infusion, but if persistent, then a short course of prednisone may prove helpful to shorten the course of hematuria.

### Traumatic Bleeding

Patients with coagulation disorders seldom bleed abnormally from small cuts such as razor nicks, reflecting the normal function of platelets, as measured by platelet function tests. All laboratory assays of platelet function are normal in patients with severe hemophilia A. After larger injuries, however, hemorrhage out of proportion to the extent of the injury is characteristic. The bleeding reflects both increased acute bleeding rates beyond what is expected after the trauma, and persistent bleeding as slow continuous oozing occurs for days, weeks, or months. Such traumatic bleeding may be massive and life-threatening unless coagulation replacement therapy is provided by immediate factor infusion.

Delayed bleeding is common. Thus, although hemostasis after an injury or a minor surgical procedure may appear to be adequate, hemorrhage, often of sudden onset and serious proportions, may develop several hours or even days later. This phenomenon apparently occurs because the processes of primary hemostasis are only temporarily effective. Delayed bleeding may occur in patients with mild hemophilia and is a significant hazard after minor surgical procedures, particularly those performed on an outpatient basis, such as tooth extraction and tonsillectomy.

Venipuncture, if skillfully performed, is without danger for the person with severe hemophilia, primarily because of the elasticity of the venous walls. If venipuncture is traumatic, digital pressure on the puncture site or a pressure dressing may prevent further complications. Subcutaneous, intracutaneous, and small intramuscular injections seldom produce hematomas if firm finger pressure is maintained for at least 5 minutes. Large intramuscular injections should be avoided. Vaccination using intramuscular injections is acceptable with minimal increase in bleeding risks.

### Other Clinical Aspects

Infants usually are asymptomatic because they are insulated from trauma. However, trauma during birth or afterwards may trigger life-threatening bleeding. Infants of women who are known carriers may be at risk during delivery, and instrumentation during vaginal delivery should be avoided. Currently, the usual standard of care is to avoid testing the infant in utero due to the risks inherent in current techniques available to test the fetus, and to allow normal vaginal delivery with back-up Caesarean section available if any difficulties arise during birth. Typically, hematomas are seen first when children become active, and hemarthroses seldom develop until they begin to walk. Occasionally, evidence of the disorder is not seen until patients reach teenage years or young adult life. Spontaneous hemorrhage may be cyclic in nature. Petechiae, which are characteristic of disorders of platelets and blood vessels, are rare in patients with hemophilia but have been noted in severely affected patients during an exacerbation of bleeding. Hemorrhage from the umbilical cord or stump is unusual, but prolonged bleeding after circumcision is common and brought hemophilia to the attention of the ancient Hebrews. Pulmonary and pleural bleeding are uncommon, although mediastinal and pleural shadows have been noted radiographically and presumably originate from fresh or old hematomas. Intraocular hemorrhage is uncommon, but bleeding into the orbit and conjunctiva occurs often. Spontaneous rupture of the spleen has been reported. Intracranial bleeding is discussed in the section Special Aspects of Treatment. The website for the National Hemophilia Foundation is www.hemophilia.org and contains useful information and links to more detailed information on this bleeding disorder.

### Course and Prognosis

In recent years, the prognosis in severe hemophilia has improved dramatically. With modern therapy using regular factor infusions to maintain adequate plasma factor concentrations to prevent nearly all spontaneous bleeding episodes, a person born with severe hemophilia A can expect to live an essentially normal lifespan. No other genetic disease has made such dramatic progress in the past 50 years. It is not yet clear whether hemophilia protects older hemophilia patients from thromboembolic disorders, atherosclerosis, or cardiovascular diseases. Despite the lack of stringent prospective clinical studies for this emerging problem of aging patients with severe hemophilia and other medical problems, reviews of current practice and expert opinion on how to treat aging patients with severe hemophilia have been published.

A, abnormal; N, normal; v, variable; vWF, von Willebrand factor.

Certain PTT reagents may not detect mild deficiency of factors VIII, IX, and XI.

*a* Findings are significantly different in some variants.

*b* Coagulation abnormalities are caused by deficiency of factor VIIIc.

*c* Patient's plasma may inhibit normal coagulation.

*d* Abnormality may be corrected by increasing calcium concentration and may be magnified by diluting the thrombin solution.

*e* Abnormality varies depending on technique.
Results of one-stage techniques may be uninterpretable.

Laboratory Diagnosis

The activity of the various coagulation factors is expressed in terms of units, defined as the activity present in 1 ml of fresh plasma from normal donors. The concentration of all coagulation factors in normal pooled plasma is thus 1 IU/ml or 100 IU/dl, or 100% activity. It should be noted that the activity levels in blood bank plasma are somewhat lower, approximately 80 IU/dl because of the dilution with anticoagulant.

Routine clinical laboratory tests (noncoagulation) are normal in patients with hemophilia A. The presence or absence of anemia or of signs of blood regeneration depends on the severity and frequency of bleeding, as in any individual patient. Neutrophilia may accompany severe hemorrhage, and the destruction of red blood cells in the hematoma may be reflected in elevated LDH, AST, or bilirubin. As in other instances of posthemorrhagic anemia, the bone marrow reflects the response to blood loss.

Screening Tests of Hemostasis and Coagulation

The partial thromboplastin time (PTT) usually is prolonged in patients with hemophilia A (Table 53.5). The biochemical conditions for most laboratory assays of PTT are set so that the PTT is abnormal if the factor VIII level is <25% of normal; however, some PTT reagents are insensitive to mild factor VIII deficiency. Therefore, in most situations the abnormality of the PTT can be normalized by mixing the patient’s plasma with normal plasma in a ratio of 1:1; and this test, called a mixing study, is routinely used to detect whether neutralizing factor VIII antibodies are present. The platelet count usually is normal, but may be elevated in the stress reaction to hemorrhage.

Factor VIIIc Assays

Assay of factor VIII is a simple technique, but requires trained and experienced technicians, as the results are sensitive to errors in laboratory technique, or to errors in proper handling of the blood specimen. In clinical practice, if the laboratory results do not seem to fit the clinical picture, then most clinicians will repeat the laboratory test, and/or discuss the results with the laboratory personnel. Two-stage methods, one-stage methods, and micromethods are suitable for diagnosis. The one-stage techniques are used most widely because they are simple to perform. They require either a supply of plasma from a known individual with severe hemophilia, which is available commercially, or artificial substrate plasma. Two-stage assays detect approximately 20% more factor VIII than do one-stage methods, and they are less subject to variables such as fluctuations attributable to contaminating traces of thrombin or other proteolytic enzymes.

The World Health Organization makes international standards, but many laboratories purchase commercial secondary standards that are calibrated to the international standard. Under most circumstances, a pool of citrated plasma carefully collected from normal subjects and frozen in individual laboratories also serves as an acceptable standard.

The factor VIII assay has a large potential for error, even in expert hands. Therefore, when borderline values are obtained, the assay should always be repeated. Extensive studies of the many variables of the factor VIII assay have been reported. In the clinical setting of delivery of a boy with a question of hemophilia A, assays for both factor VIII and vWF may be carried out with reasonable accuracy on material obtained by fetoscopy—that is, mixtures of blood and amniotic fluid or unmixed fetal blood.

The availability of a new recombinant form of factor VIII (B domain-deleted factor VIII, Xyntha) raised concerns about accurate laboratory monitoring of patients receiving this product. Chromogenic substrate assays or typical one-stage PTT assays using physiologic phospholipids are needed to quantitate factor VIII levels accurately in patients receiving B domain-deleted factor VIII. Alternatively, a standard one-stage PTT assay using B domain-deleted factor VIII as the assay
standard would be appropriate. The use of concentrate standards (rather than plasma standards) diluted in factor VIII-deficient plasma has been proposed as a solution to resolve discordant results using different assay methods. Analysis of appropriate methods for laboratory assays of factor VIII activity levels after therapeutic infusions of the newer factor VIII products with extended half-life will be an important part of the small phase III clinical trials initiated in 2012. The Scientific Subcommittee on Standards of the International Society of Thrombosis and Haemostasis is involved in defining appropriate standards for these new products.

Factor VIIIAg (cAg) Assays

Highly specific but complicated assays using immunoradiometric methods and ELISA techniques are available to measure factor VIIIAg (VIIIAg). The latter methods use liquid- and solid-phase principles and both natural factor VIII antibodies and monoclonal antibodies. The results of both of these techniques demonstrate the absence of factor VIIIAg in most severely affected hemophiliacs and correlate well with factor VIIIc measurements in most cases. Results are more variable when mild hemophiliacs are tested. In most series, “10% of patients have detectable levels of factor VIIIAg and a low VIIIc-to-VIIIAg ratio (the CRM-positive variant). Immunoassays for vWF are discussed in the section Laboratory Diagnosis.

Differential Diagnosis

The diagnosis of hemophilia A is seldom difficult, especially in the severely affected patient with repeated and often serious hemorrhagic manifestations, including such characteristic signs as hemarthrosis. Typically the PTT is abnormal and leads to specific assays for clotting factor activity and mixing studies to rule out neutralizing inhibitors of coagulation activity. Hemarthrosis with significant orthopedic disability is rare in patients with coagulation disorders other than hemophilia A or B.

In patients with mild forms of the disorder, however, failure to recognize the existence of the disease or to make the correct diagnosis is more likely. Such patients rarely have a history of spontaneous bleeding, and the family history tends to be vague or negative. A history of abnormal bleeding after minor trauma may be difficult to establish due to variability in bleeding. Occasionally, mild hemophilia A may present with a normal PTT when the factor VII activity assay result is greater than 25%; thus a normal PTT may be misleading. It must be emphasized that individuals with mild hemophilia are still at risk for hazardous hemorrhage during surgery or during surgical procedures. A survey of hemophilia carriers found that mild reduction in factor VIII or IX levels (41 to 60 IU/dl) was associated with excessive bleeding. A normal PTT value, therefore, cannot be relied on to exclude the possibility of hemophilia. In the mildly affected patient, specific factor assays must be performed to confirm or exclude the diagnosis of hemophilia.

The results of screening tests (Table 53.5) usually are sufficient to exclude the possibility of acquired hemorrhagic disorders associated with serious bleeding. Such disorders are seldom associated with a prolonged PTT and a normal prothrombin time (PTT), a combination that strongly suggests an inherited disorder or an inhibitor. Among the inherited disorders characterized by this combination of findings (hemophilia A, hemophilia B, and deficiencies of factors XI, XII, prekallikrein, and high-molecularweight kininogen [HMWK]), deficiency of the latter three factors can be readily excluded because their deficiency is not associated with excessive clinical bleeding. Factor XI deficiency in males may mimic mild hemophilia, and hemophilia B is clinically identical to hemophilia A. Both factor XI deficiency and hemophilia B must be distinguished from hemophilia A in the laboratory using specific factor activity assays. The best way to accomplish this goal in evaluating patients with an isolated prolonged PTT is by performing specific assays of these three factors in the order of their statistical frequency—that is, VIII, IX, and XI. A PTT mixing study should also be performed to exclude an inhibitor. A definitive diagnosis is of great importance because specific products are used to treat each of these disorders.

Severe vWD in males may be indistinguishable from mild hemophilia A. Confirmatory tests for vWD are needed to make this distinction. Patients with the uncommon type 2N vWD may also be clinically indistinguishable from patients with hemophilia A. This diagnosis is important to establish, because therapeutic infusions of recombinant factor VIII (r-FVIII) would be ineffective due to the shortened half-life of factor VIII resulting from the absence of effective binding to von Willebrand protein. An X-linked family history of bleeding supports a diagnosis of hemophilia A in these patients, and an autosomal recessive family history of bleeding supports a diagnosis of type 2N vWD. Statistically, one would expect a rare family that might carry both genetic disorders; clearly that situation may be problematic to resolve without additional genetic testing.

Bleeding manifestations in hemophilia may simulate a variety of conditions. However, serious confusion results only when the
correct diagnosis has not been considered and appropriate laboratory studies have not been ordered. Thus, a deep hematoma may be mistaken for a suppurative condition, and surgical drainage may be attempted. Bleeding into a small joint may produce a clinical and radiologic picture suggestive of sarcoma; when larger joints are involved, findings simulate tuberculosis, arthritis, or Perthes disease. Bleeding elsewhere may suggest local causes such as kidney tumor, pulmonary disease, or peptic ulcer. For example, blood clots due to hemophilia bleeding in the renal collection system might appear as masses on a CT scan and be confused with cancer, leading potentially to inappropriate invasive procedures to obtain tissue for cancer diagnosis.

Intra-abdominal bleeding raises particularly serious diagnostic and therapeutic problems in the patient with hemophilia, even when the hemophilia condition has been accurately diagnosed. Thus, hemorrhage into the psoas, when on the right side, may simulate acute appendicitis so closely that, in the opinion of many experienced clinicians, there is no reliable clinical means to differentiate between the two diagnoses. A retroperitoneal hematoma may be mistaken for an appendiceal abscess. Intrapertoneal hemorrhage and bleeding into and around other viscera may simulate perforating peptic ulcer, bowel obstruction, or virtually any acute intra-abdominal condition. Computed tomography scanning and sonography may be particularly helpful in differentiating between intra-abdominal conditions that require surgical intervention and retroperitoneal and psoas hemorrhages. In any case, early therapeutic infusion of factor VIII will prevent further bleeding and carries no additional risk for the individual with hemophilia. Therefore, when there is a question and further diagnostic tests are planned, factor VIII should be administered first and promptly before the diagnostic tests are performed.

**HEMOPHILIA B**

Hemophilia B was recognized as a separate disorder from hemophilia A in 1947. Hemophilia B (Christmas disease, factor IX deficiency) was established as different from hemophilia A by Aggeler et al. in 1952. Hemophilia A is approximately 5 times more common than hemophilia B. A 1994 survey estimated that there were 3,640 cases of hemophilia B in the United States. As expected, it appears that the severity of hemophilia B is a consequence of the plasma factor IX concentration, and that for any particular plasma concentration, the clinical severity is similar for hemophilia A and B. However, in contrast with hemophilia A, most of the genetic causes of hemophilia B are not large deletions or inversions; therefore in many patients there is some antigenic protein, and often some low level of function of the mutated protein. Consequently, the clinical phenotype is often less severe. As with hemophilia A, hemophilia B is classified as severe, moderate, or mild based on the percentage of functional factor IX in coagulation activity assays. In addition, because of the presence of low levels of factor IX protein in more patients with hemophilia B, there are fewer persons with hemophilia B that develop neutralizing inhibitors (approximately 3% versus more than 25% in hemophilia A).

Historically, when plasma from patients with hemophilia B was tested against autologous antibodies, three distinct groups were defined: A cross-reactive material (CRM)-positive variant, the most common form; a CRM-negative variant; and a third form of the disorder in which antibody neutralization was variable in extent and was approximately proportional to coagulant factor IX activity (the CRM-reduced variant). These distinctions are only of historical interest now.

In a disorder called hemophilia B Leyden, the clinical manifestations tend to diminish during puberty in association with a rise in the factor IX level from as low as 1 IU/dl in childhood to levels of 20 IU/dl or more in adult life. The Leyden variant is characterized as CRM-negative at birth but becomes CRM-positive or CRM-reduced with advancing age. The genetic basis for factor IX Leyden is that mutations occur in the factor IX gene promoter region; this region contains an androgen response element that, with age, stimulates factor IX gene transcription and protein synthesis.

In another variant of hemophilia B, the PT is prolonged when performed with ox brain thromboplastin. This disorder has been called hemophilia Bm, and is characterized by the presence in the plasma of CRM that neutralizes both autologous and heterologous antibodies to factor IX. The degree of abnormality of the ox brain PT is proportional to the plasma level of CRM in both affected males and carrier females. This variant results from mutations in the carboxy terminus of the factor IX molecule, resulting in a factor IX molecule that interacts abnormally with ox brain thromboplastin.

Numerous factor IX mutations have been recognized. Factor IX purified from the plasma of affected members of one kindred did not fragment normally when activated in vitro (hemophilia B Chapel Hill). The molecular defect was found to be a substitution of histidine for arginine at position 145, a defect that inhibits cleavage by factor Xa.

Studies of factor IX obtained from another family revealed biochemical abnormalities identical to those characteristic of the descarboxy analog of this factor that is found in vitamin K deficiency or produced by coumarin drugs. Such molecules lack Ca$^{2+}$-binding sites and do not undergo conformational changes induced by Ca$^{2+}$. Another report concerns a unique variant with deficient Ca$^{2+}$ binding and an abnormally high-molecular-weight (factor IX Zutphen).
Hemophilia B is inherited as an X-linked recessive trait, but the locus on the X chromosome of the gene controlling factor IX production is remote from that involved with factor VIII biosynthesis. Factor IX levels <10% have been documented in a few women, including some with chromosomal abnormalities. Ten useful polymorphisms have been described that are associated with the factor IX gene. An updated listing of mutations is available at www.kcl.ac.uk/ip/petergreen/haemBdatabase.html. Unlike hemophilia A, the spontaneous mutation rate is low, and most patients with hemophilia B have positive family histories.

Factor IX defects may be severe, moderate, or mild. Severe defects result from large gene deletions, nonsense mutations, and inversions; these defects are associated with absence of factor IX protein. Milder gene defects such as splice-site or missense mutations result in a dysfunctional protein with some residual activity. Missense mutations account for ~80% of mutations in severe hemophilia B patients.

Detection of Carriers

Detection of heterozygous carriers of hemophilia B involves the same principles and limitations as described for hemophilia A. Carrier detection based on coagulation assay alone usually is more reliable than is the case with hemophilia A. Thus, in one series of 45 obligatory carriers, the mean factor IX level in the plasma was 33 IU/dl; 40 from the group had levels <50 IU/dl, and 10 had levels <25 IU/dl. As a consequence of these low levels of factor IX, abnormal hemorrhage is not uncommon in carriers of hemophilia B.

Results of immunoassays of factor IX and the ratio of factor IX-related antigen to coagulant factor IX levels in the carrier population overlap with the normal population to a considerable degree, particularly in the CRM-positive variants. Such studies provide a lower overall detection rate among obligatory carriers of hemophilia B than is the case with hemophilia A. Levels of factor IX-related antigen obtained by immunoassay are significantly increased by the use of oral contraceptives. The use of DNA probes and monoclonal immunoassays provide highly accurate methods for determining carrier status. Rapid carrier testing using allele-specific microarray methods has been described. This method permits detection of a majority of common factor IX mutations in a single assay. Prenatal diagnosis of hemophilia B has been successful in the CRM-negative variants. Modern methods for prenatal diagnosis use genetic testing and are quite reliable. Determination of carrier status is based on several factors, including pedigree analysis, factor IX assay results, and genotype.

Clinical Features

Severity of bleeding in hemophilia B is less than in hemophilia A (Table 53.3), but the clinical manifestations of the two disorders are identical for the same activity levels of the coagulation factors. Specific factor assays are necessary to distinguish between hemophilia A and hemophilia B. Mild factor IX deficiency should always be considered in the differential diagnosis of patients with coagulation-type bleeding and normal routine coagulation test results (PT, PTT). Many PTT reagents do not detect mild factor IX deficiency (factor IX levels of 20% to 30%).

Laboratory Diagnosis

The laboratory diagnosis of hemophilia B involves the same approach and methods as those described for the recognition of hemophilia A (Table 53.5). The screening tests reveal similar abnormalities in the two disorders, except that the PT is abnormal in the B<sub>α</sub> variant when either ox brain or Thrombotest is used as the thromboplastin.

Hemophilia A may be easily distinguished from hemophilia B by a specific factor assay. One-stage and two-stage assays for factor IX use the same principles as those discussed for factor VIIIc. Sensitive immunoassay methods for factor IX have been developed.

VON WILLEBRAND DISEASE

The historical confusion that has surrounded the pathogenesis of vWD is apparent from the many names that have been applied to this disorder. These designations include angiohemophilia, vascular hemophilia, pseudohemophilia, constitutional thrombopathy, and idiopathic prolonged bleeding time. von Willebrand first recognized the disorder in a 1926 study of the inhabitants of the Åland Islands. Three cardinal manifestations of this bleeding disorder are mucocutaneous hemorrhage rather than hemarthrosis and deep-muscle bleeds; autosomal dominant inheritance, rather than sex-linked as seen in hemophilia A; and prolonged bleeding time. Evaluation of one large kindred revealed variable
severity of bleeding symptoms, with some obligate heterozygote carriers being asymptomatic. von Willebrand thought that the hemostatic defect resulted from combined defects in platelet function and vascular endothelium. The discovery that plasma from normal volunteers or patients with hemophilia A corrected the hemostatic defect of vWD suggested that a plasma protein distinct from factor VIII caused vWD. In 1972, von Willebrand factor (vWF) was purified. Genetic variants were correlated with various vWF structural abnormalities, and demonstration of the heterogeneous nature of vWD was furthered by development of vWF multimer analysis by gel electrophoresis. In its most common form (type 1), the disorder is characterized by mild mucocutaneous hemorrhage, which is attributable to deficiency of both vWF and factor VIII. The disorder is not homogeneous, however, in part because of the multiple physiologic functions played by vWF. The recognition of a number of variants, together with the demonstration of multiple genetic patterns, suggested that vWD is very heterogeneous. However, all forms of vWD can be traced to insufficient amounts of vWF or defective function of this protein. Recent reviews of this area have been published, and a consensus document on vWD sponsored by the National Institutes of Health reviewed all aspects of the disorder.

Incidence

Epidemiologic studies indicate that vWD is the most common bleeding disorder, affecting about 1% of the population. The high incidence of the disease is not limited to certain ethnic groups; however, only a fraction of people come to medical attention because of bleeding symptoms. This may be because of either the relatively mild nature of the disease in many affected individuals, or a lack of recognition by patients of excessive bleeding in response to either physiologic challenge (e.g., heavy menstrual bleeding) or trauma.

Nomenclature

The identification of numerous variants of vWD has led to attempts to simplify classification of this disorder. An updated classification system has been proposed (Table 53.6). Quantitative defects are divided into partial deficiency (type 1) and severe deficiency with virtually complete absence of vWF (type 3). The qualitative defects (type 2) are divided into four categories according to the nature of the defect of vWF function. Type 2A refers to variants with impaired interaction between vWF and platelets, resulting from a deficiency of intermediate- and high-molecular-weight multimers of vWF. Type 2B refers to variants in which vWF exhibits increased affinity for its receptor, platelet GPIb. Paradoxically, bleeding in these patients develops as a result of clearance of larger vWF multimers and platelets from the circulation. Type 2M refers to variants with defective interaction between vWF and the platelet GPIb receptor that is not due to deficiency of high-molecular-weight multimers of vWF from plasma, but rather results from defects within the GPIb-binding domain of vWF. Finally, variants of vWD in which decreased affinity of vWF for factor VIII results in depressed plasma factor VIII levels are classified as type 2N. Thus, six major categories of vWD are defined, each having distinct pathophysiology.

vWF, von Willebrand factor.

Genetics

A gene on chromosome 12 codes for the synthesis of the vWF macromolecule. The genetic message is composed of 52 exons covering a span of 158 kb. The vWF gene encodes for a protein with multiple copies of homologous motifs, including three “A,” three “B,” two “C,” and four “D” motifs (see Fig. 53.5). These motifs in turn encode protein domains that subserve the various functions of vWF. The A1 domain contains binding sites for platelet GPIb, ristocetin, and collagen, the A2 domain contains a protease-sensitive domain that may have a role in regulating vWF function, the A3 domain contains a second collagen-binding domain, the C1 domain has an RGD sequence capable of interacting with platelet glycoprotein IIb/IIIa, and the D’ and D3 domains contain a factor VIII-binding sequence.

vWD appears to be inherited by multiple genetic mechanisms (Table 53.7). The most common form of the disorder (type 1 vWD) accounts for ~70% of all cases of vWD. Diagnostic criteria for type 1 vWD have been proposed, including a history of bleeding symptoms, a positive family history of bleeding symptoms, and bleeding that is attributable to quantitatively low vWF levels. Population screening suggests that the prevalence of vWD may be as high as 1% of the population, but only a minority of these patients subsequently present with clinically significant bleeding. vWD is inherited as an incompletely dominant autosomal trait with variable penetrance, even among members within a single kindred. Because of variable penetrance and expression of vWD, only ~33% of children may be affected. Figure 53.6 illustrates one of the original pedigrees described by von Willebrand.

Twin studies demonstrated that “60% of the variation in vWF level and “50% of the variation in factor VIII level is attributable to genetic factors. Genetic loci outside of the vWF gene contribute to variation of vWF level. Individuals with blood group O have vWF levels that are on average 30% lower than those of people with blood group A, B, or AB, and it is likely that carbohydrate groups attached to vWF play a subtle role in clearance of vWF from plasma. In addition, variation in expression of levels of other hemostatically active proteins, such as variation in the level of platelet adhesion receptors, may modulate the severity of symptoms conferred by vWF deficiency. vWF levels are under hormonal and other controls, which further complicates disease expression. Variation in levels of as much as 20% has been reported with menstrual cycle, with levels lowest in the early follicular phase (before day 7 of the cycle); and levels increase with age, rising ~15% for each decade increase in age. As will be discussed later, the criteria for diagnosing quantitative vWD deficiency, and the specificity of historic bleeding, have introduced controversy in what constitutes type 1 vWD and have led to the potential for the new diagnostic entity of “low vWF”.

Mild to moderate quantitative deficiency of vWF characterizes patients with type 1 vWD, whereas virtual absence of vWF characterizes type 3 disease. Two large studies of families with a diagnosis of type 1 vWD and genetic evaluation of patients with type 3 disease have begun to shed light on the genetics of quantitative vWF deficiency.

Very low vWF levels in the range of 5 to 20 IU/dl tend to be highly inheritable and are frequently associated with “dominant negative”-acting mutations. Mutations in these patients with type 1 vWD appear to be different than those with type 3 disease, such that type 1 disease is not simply explained by being heterozygous for a type 3 allele. Genetic defects associated with these more severe type 1 phenotypes encode amino acid changes that in turn lead to defects in protein expression. Mechanisms responsible for decreased plasma vWF level include reduced secretion related to impaired intracellular transport of vWF subunits, increased clearance from the circulation, or accelerated catabolism as a result of increased susceptibility to degradation by ADAMTS13. Changes that were most likely to cause a “dominant negative” mechanism are often missense mutations that change the number of cysteine residues in the vWF protein. Although such changes probably affect vWF synthesis and trafficking in the cell, at least one common mutation (Tyr1584Cys) also results in enhanced degradation by ADAMTS13. One non-cysteine-related mutation is seen in vWD Vicenza. In these patients, a mutation encoding for Arg1205His results in accelerated clearance of plasma vWF, with levels of vWF in the range of 15 IU/dl. With DDAVP stimulation, timed plasma sampling revealed that the released vWF had a circulation half-life that was approximately one-sixth of normal. Several other similar mutations have recently also been described.
FIGURE 53.5. A: Structure and functional domains of von Willebrand factor (vWF). The open rectangles indicate domains of pre-pro-vWF. The first 22 amino acids of pre-pro-vWF are the signal sequence. The left arrow identifies the site of
cleavage of the signal peptide, resulting in pre-vWF monomers. Pro-vWF monomers form dimers, and the vWF propeptide (vWAgII) is cleaved from mature vWF (right arrow indicates cleavage site). Dimer S-S and multimer S-S indicate locations of disulfide bonds that covalently link monomeric vWF into dimers and dimeric vWF into multimers, respectively. The red rectangle identifies exon 28, which encodes the A1 and A2 domains of mature vWF. Functional domains are identified above the open rectangles. The factor VIII binding site is located in the D' and D3 domains in the amino-terminal 272 amino acids of mature vWF. The A domains of vWF contain the binding site for the platelet glycoprotein (gp) Ib/IX complex, as well as binding sites for heparin, collagen, and sulfatides. The gpIIb/IIIa complex binding site of activated platelets is located at the carboxy-terminal portion of the C1 domain and contains the Arg-Gly-Asp sequence. The numbers below the open rectangles indicate amino acid numbers: Signal peptide, 22 amino acids; propeptide (vWAgII), 741 amino acids; mature vWF, 2,050 amino acids. B: Mutations associated with type 2A von Willebrand disease (vWD). The open rectangle represents vWF exon 28 encoding domains A1 and A2. The arrow indicates the site of proteolysis seen in type 2A vWD. Mutations are identified using the single-letter code for amino acids. I and II identify group I and group II missense mutations that result in impaired synthesis of vWF or increased sensitivity to proteolysis in plasma, respectively. The disulfide bridge shown represents the boundary of the Cys 509-Cys 695 loop in the A1 domain. Type 2A vWD mutations associated with defective vWF multimerization are not shown in this figure; these latter mutations occur in the propeptide (vWAgII) D1 and D2 domains. C: Mutations associated with types 2B and 2M vWD. The large open rectangle represents exon 28, which encodes domains A1 and A2 of vWF. The mutations responsible for type 2B vWD are shown above the rectangle. Most type 2B mutations lie between residues 540 and 578 of mature vWF. The mutations responsible for type 2M vWD are shown below the rectangle. Asterisks identify mutations that reduce the platelet-dependent function of vWF and vWF multimeric size. δ indicates deletion of an amino acid sequence. Ancillary findings | DDAVP usually produces significant increase in plasma VIIIc and vWF | DDAVP produces rise in factor VIIIc, DDAVP, with but functional vWF intravascular platelet aggregation and thrombocytopenia in some cases; ristocetin-induced platelet aggregation enhanced in presence of patient's plasma; cryoprecipitate does not aggregate platelets in vitro unless ristocetin is added | Variable response to DDAVP, with rise in factor VIIIc, DDAVP, but functional vWF intravascular platelet aggregation and thrombocytopenia in some cases; ristocetin-induced platelet aggregation enhanced in presence of patient's plasma; cryoprecipitate does not aggregate platelets in vitro unless ristocetin is added | Response to Transfusion of vWF | DDAVP or DDAVP may lacking; produce intravascular endothelial platelet aggregation vWF absent and thrombocytopenia; cryoprecipitate produces in vitro platelet aggregation

DDAVP, 1-deamino-8-d-arginine vasopressin; vWF, von Willebrand factor.

At higher levels of vWF, linkage of the vWF level to the vWF gene is found less often. The recent European type 1 vWF cohort study demonstrated this observation. Almost all families with vWF levels <30 IU/dl showed linkage to the vWF gene, but the proportion fell to only 51% with vWF levels >30 IU/dl. These data were corroborated in the Canadian study.146

FIGURE 53.6. Pedigree of patients described by von Willebrand. Three families are emphasized: S, E, and J. Clinical details of bleeding events in these families have been reported. Open circles indicate female nonbleeders, open squares indicate male nonbleeders. Shaded circles and squares indicate female and male bleeders, respectively. Solid symbols indicate family members who experienced severe bleeding, and crosses indicate family members who experienced hemorrhagic deaths. (Modified from von Willebrand EA. Über hereditäre pseudohämophilie. Acta Med Scand 1931;76:521-550, with permission of the publisher.)

Complete absence of vWF is responsible for the most extreme form of vWD, and this is classified as type 3 vWD.128 As one might predict, a large variety of genetic abnormalities scattered throughout the vWF gene have been reported in families with type 3 vWD. These have included large gene deletions, small gene deletions, frame-shift mutations, splice-site mutations, nonsense mutations, and point mutations.149

Type 2 vWD is characterized by production of a qualitatively defective protein, and the genetics of these variant forms is more straightforward than that of type 1 vWD. In families affected by types 2B and 2M, as well as in the majority of families with type 2A vWD, inheritance is autosomal dominant. Rare cases of type 2A disease are transmitted in an autosomal recessive fashion, as are most cases of type 2N disease. vWF gene sequencing studies combined with vWF
The basic defect in vWD is a deficiency or abnormality of vWF function. vWF is synthesized in endothelial cells and megakaryocytes. The primary transcription product is 2,813 amino acids in length and undergoes extensive further processing, including dimerization and polymerization, to form very-largemolecular-weight “multimers”. Multimerization and intracellular trafficking of vWF through the endoplasmic reticulum and Golgi apparatus and into storage granules is directed by the vWF propeptide (vWFpp). vWFpp is cleaved off the “mature subunit” after multimer assembly. Large vWF multimers, which may exceed 20 million daltons in size, are stored in endothelial cells in Weibel-Palade bodies and in platelet α-granules.

The majority of circulating vWF is present in plasma, with a concentration of ~10 μg/ml. The circulating half-life of plasma vWF is ~8 to 12 hours. Approximately 15% of circulating vWF is present intracellularly within platelets. Ultralarge multimers released from endothelial cells into the plasma are further degraded to smaller multimers through the activity of a “vWF cleaving protease”. The cDNA sequence identified this protein to be the thirteenth member of the ADAMTS family (a disintegrin and metalloproteinase with thrombospondin type 1 motifs, ADAMTS13). vWF is cleaved between tyrosine 1605 and methionine 1606 located in the A2 domain. High shear stress and tethering of vWF by platelets most likely enhance exposure of the cleavage site. The physiologic importance of enzymatic degradation of vWF after release is demonstrated clinically by the association of an inherited form of thrombotic microangiopathy (Schulman-Upshaw syndrome) with congenital absence of the protein due to defects of the ADAMTS13 gene, and the observation of plasma deficiency of the protein with presence of autoantibody in most patients with sporadic thrombotic thrombocytopenic purpura. Endothelial cell stores of vWF can be released therapeutically with administration of desmopressin.

vWF is required for normal platelet adhesion (see Chapter 17), and also acts as a carrier of factor VIII in the plasma. When vWF is deficient or aberrant, both factor VIII deficiency and abnormalities in the early steps of primary hemostasis result. vWD is thus manifested as a multifaceted hemostatic defect. Both abnormalities—factor VIII deficiency and abnormal primary hemostasis—give rise to characteristic and distinct laboratory abnormalities, and both defects contribute to the bleeding tendency.

Abnormalities of Primary Hemostasis

Convincing evidence exists that the platelets, although intrinsically normal, do not adhere to subendothelium normally in the setting of deficient or defective vWF. This abnormality is well demonstrated by methods that measure platelet adhesion to subendothelial surfaces under flow conditions (the Baumgartner technique). The physiologic stimulus for interaction of vWF with platelets is not completely defined, but tethering of vWF on exposed subendothelial cell matrix or shear stress may cause vWF to undergo conformational change. Results of experimental studies suggest that in the absence of vWF, platelet adhesion to collagen in a flowing stream of blood may be particularly deficient at high rates of shear, when only a short time is available for formation of a platelet-collagen bond. Deficient platelet plug formation has been observed directly in experimental wounds. In vitro, the interaction of vWF with the platelet GPIb receptor can be induced by addition of the antibiotic ristocetin, by the snake venom protein botrocetin, or by subjecting platelets to high shear stress in the presence of vWF. For the effective support of platelet adhesion, vWF is multimerized into long chains (strings), which can exceed 2 μm in length. Plasma vWF demonstrates a spectrum of sizes; however, the longest vWF multimers are the most efficient at supporting platelet adhesion.

Abnormalities of Secondary Hemostasis

A second function of vWF is as a molecular chaperone for factor VIII, increasing the plasma half-life of factor VIII approximately fivefold. This effect may occur through protection of factor VIII from activated protein C-mediated degradation. Furthermore, the binding of vWF to subendothelium at sites of vascular injury could serve to co-localize...
factor VIII, where it can participate in its role in the regulation of hemostasis on the activated platelet membrane. It is generally thought that whereas vWF is synthesized in endothelial cells and megakaryocytes, factor VIII is synthesized by hepatocytes. When the drug desmopressin (DDAVP, 1-deamino-8-D-arginine vasopressin) is administered to normal subjects or individuals with mild quantitative deficiency of vWF or factor VIII, levels of both molecules rise. Studies of hemophilia patients and patients with type 3 vWD on replacement therapies suggest that both vWF and factor VIII must be endogenously synthesized in order for there to be coordinated release after DDAVP. The cell responsible for that coordinated synthesis remains controversial.

Response to Transfusion

When blood products containing the vWF-factor VIII complex are infused into patients with hemophilia A, peak levels of factor VIIIc are present immediately after the infusion; this activity then declines rapidly, with an overall half-life of 8 to 10 hours (Fig. 53.7). Twenty-four hours later, factor VIIIc activity is minimal. This response is highly predictable and is discussed in a later section concerning replacement therapy for hemophilia A. In most patients with vWD, the infusion of normal vWF-factor VIII complex produces an initial rise in factor VIIIc that is predicted from the preinfusion level and the amount of factor infused. This is followed by a sustained but variable rise in factor VIIIc activity that reaches a plateau about 24 hours later and may persist for 48 to 72 hours. This phenomenon is highly variable and irregular; in some patients, a rapid initial fall of factor VIIIc is followed by a secondary rise in activity. This disproportionate response to transfused factor VIII has been called the secondary transfusion response, a feature that is apparently unique to vWD. Various hypotheses have been advanced to explain the disproportionate response to transfusion described above. The leading hypothesis is that the infused vWF results in stimulation of increased factor VIII release into the plasma with the attachment of the newly released factor VIII onto infused vWF. 

![Graph showing response to transfusion](image)

**FIGURE 53.7.** The phenomenon of new factor VIII synthesis in patients with von Willebrand disease (vWD) who receive plasma transfusion. Open circles indicate changes in the plasma factor VIII levels of a patient with vWD after infusion of plasma from a patient with severe hemophilia A. A significant and sustained increase in the factor VIII levels of the recipient was observed even though no active factor VIII was present in the infused plasma. Solid circles indicate effects of infusing plasma from a patient with vWD into a patient with severe hemophilia A. The factor VIII level in the infused plasma was 15% of normal. Note the slight and transitory effects. (From Shulman NR, Cowan DH, Libre EP, et al. The physiologic basis for therapy of classic hemophilia (factor VIII deficiency) and related disorders. Ann Intern Med
Transfusions of blood products containing vWF shorten the bleeding time to a variable degree in patients with vWD. This corrective effect seldom persists for more than a few hours, even after massive transfusions that raise vWF to high levels. The correction of the bleeding time apparently requires the large molecular forms of vWF that are present in cryoprecipitate and select intermediate-purity factor VIII concentrates, but that are completely absent from monoclonally purified or recombinant concentrates of factor VIII. Failure of the skin template bleeding time of patients with vWD to show sustained correction with appropriate replacement therapy has been noted, and does not necessarily predict defective surgical hemostasis. This apparent paradox may be a result of sensitivity of the bleeding time test to platelet α-granule vWF, which is not replenished during vWF replacement therapies.

Clinical Manifestations

The bleeding manifestations in vWD are heterogeneous but consistent with the dual roles of vWF in supporting both primary and secondary hemostasis. Thus, in the mild forms of vWD, the clinical picture is dominated by cutaneous and mucosal bleeding, which appears to be mainly the result of disordered primary hemostasis. In the most severe forms of the disorder, in which factor VIII levels are low, hemarthroses and dissecting intramuscular hematomas may develop. As in mild classic hemophilia, serious hemorrhage resulting from traumatic injuries or after surgical procedures is a significant hazard in severe vWD. Petechiae are rare, but hematoma formation and the extent of bruising are excessive compared with the inciting trauma.

The bleeding manifestations in the usual patient with type 1 vWD are mild, however, and many patients are virtually asymptomatic. The disorder may be symptomatic at any age, but it is not always recognized. Easy bruising is common in vWD, but it is not specific. Mucosal bleeding is particularly common. Childhood epistaxis, a life-long history of easy bruising, bleeding with dental extraction, heavy menstrual bleeding or anemia attributed to excessive menstrual blood losses, or postpartum hemorrhage are all included in the spectrum of vWD symptomatology. Systemic bleeding disorders are often not considered in women with menorrhagia, but clinical studies reveal that the prevalence if vWD is significant in individuals who present with this complaint. Angiodysplasia of various vascular beds, particularly those in the gut, has been demonstrated in some patients with vWD and may be an important contributory factor in chronic gastrointestinal bleeding. In type 1 vWD, symptoms usually become milder during pregnancy or with estrogen therapy, when the vWF and factor VIIIc levels rise significantly. The disorder may also decrease in severity with advancing age. Bleeding manifestations tend to be more prominent in patients with more severe quantitative deficiency and in patients with qualitative (type 2) defects.

While eliciting the history of bleeding, one should bear in mind that women are often inaccurate assessors of whether their menstrual flow is normal or excessive. Supplemental questioning regarding the frequency of changes of menstrual protection, and questions regarding a history of iron deficiency anemia and transfusion, may be informative. Retrospective studies of women with vWD show that abnormal bleeding can often be traced to menarche. Family history also may provide important clues to a diagnosis. The physician should specifically seek a history of the response to hemostatic challenge, such as dental extraction, tonsillectomy, surgical procedures, menstruation, peripartum hemorrhage, and transfusion. A model questionnaire with a scoring system has been published. Coexistent conditions or drug effects can strongly influence the severity of bleeding symptoms. Risk of hemorrhage may increase in patients with concomitant liver disease, uremia, gastrointestinal ulcer, or angiodysplasia. Excessive bleeding in response to challenge with aspirin may also point toward a bleeding disorder, but this history is not specific for vWD. Valproic acid use can result in lower vWF activity levels, as may hypothyroidism and valvular heart disease. Conversely, oral contraception frequently ameliorates menorrhagia.

Laboratory Diagnosis

Criteria for the laboratory diagnosis of vWD are imperfect. One goal of applying a series of laboratory evaluations is to exclude other causes of bleeding. When specifically considering vWD, the laboratory evaluation may be complicated. Even with the more elaborate confirmatory tests now available, the diagnosis of this disorder may be difficult and may require repeated observations over a period of time. Both vWF and factor VIII are “acute-phase reactants,” increasing with stress, trauma, estrogen therapy, or pregnancy, such that levels may fluctuate from time to time. Evaluation of a patient at a time remote from acute infection, pregnancy, or strenuous activity is preferable. However, pregnancy and acute-phase reaction are unlikely to obscure diagnosis in patients with more severe quantitative deficiency or qualitative defects.
Diagnosis of vWD is complicated, because of both the breadth of vWF functions and the spectrum of disorders that constitutes vWD. Consequently, a battery of studies should be considered to evaluate a patient conclusively for vWD. Screening tests such as bleeding time, Platelet Function Analyzer-100 (PFA-100), and PTT lack sensitivity; specific tests such as those for vWF antigen, vWF activity, and factor VIII level are preferred. Correlating the values of these various quantitative assays with each other, or obtaining qualitative tests such as vWF multimer analysis or lowdose ristocetin-induced platelet aggregation, may provide important clues toward a diagnosis of type 2 vWD (Table 53.7).

**Bleeding Time and Platelet Function Analyzer-100**

The template bleeding time, the Ivy bleeding time, or technical modifications thereof may be useful in detecting the abnormality characteristic of vWD. However, the bleeding time may be normal in many patients with vWD. Consequently, the bleeding time adds to the diagnosis of vWD if it is prolonged, but otherwise may have little clinical utility in the diagnosis and management of patients with vWD. The bleeding time may not improve following replacement therapy with vWF, and monitoring is generally not recommended, because surgical bleeding can generally be prevented by replacement of plasma vWF.

Standardization issues, inconvenience, and residual scarring of patients are some of the issues that have fostered development of in vitro tests to replace the bleeding time. The PFA-100 evaluates platelet adhesion and aggregation to collagen in a whole-blood assay under high shear conditions. Citrate-anticoagulated whole blood is aspirated through an aperture in a collagen-coated membrane, and the device measures the time from first flow until flow ceases as the “closure time.” PFA-100 closure times are sensitive to multiple factors, including vWF function, platelet count, platelet function, and hematocrit. Initial studies using the PFA-100 in patients with diagnosed vWD indicated that the assay was sensitive to most forms of vWD. However, when the closure time test was applied in clinical settings where patients were referred for evaluation of bleeding symptoms, the sensitivity of the PFA-100 for diagnosis of vWD ranged from 62% to 80%, with specificity ranging from 84% to 89%. In addition, the closure time may remain normal in acquired vWD despite a very reduced plasma vWF level, because the platelet vWF level may remain normal. The PFA-100 closure time may also be normal in patients with type 2N vWD, in which the major defect is low factor VIII levels. As with the bleeding time, correction of plasma vWF level in the absence of concomitant correction of the platelet vWF may be insufficient to correct the closure time, so this test may not be very helpful for perioperative monitoring of patients on replacement therapy.

P.1157

**Partial Thromboplastin Time and Factor VIIIc Assay**

Among the simple screening tests (Table 53.5), the PTT may be abnormal, reflecting reduced levels of factor VIIIc. Plasma levels of factor VIIIc vary greatly in this disorder and range from as low as 3 IU/dl in patients with type 3 vWD to normal levels in patients with mild type 1 vWD. Because factor VIIIc deficiency is often mild in patients with vWD, a diagnosis of vWD may be missed by the routine screening PTT. Consequently, a specific assay is required to reliably detect factor VIIIc deficiency in patients with vWD.

von Willebrand Factor Immunoassay

The immunoassay of vWF is a quantitative measure of vWF protein that is one of the most sensitive methods available for the diagnosis of vWD. A variety of methods have been used, all of which depend on antibodies specific to vWF. The electroimmunodiffusion method of Laurell was initially widely used because it was simple to perform, but ELISA or automated assays using related methodologies have now largely replaced this technique. Average levels of vWF antigen (vWF:Ag) obtained by different laboratories will vary, but a level of ~45 to 50 IU/dl is the lower limit of normal reported by many laboratories. The ratio of factor VIII to vWF also varies by laboratory but normally ranges from ~0.7 to 2.2 (Fig. 53.1). Plasma levels of vWF:Ag are regulated to some extent by carbohydrate residues attached to the protein; ~25% lower vWF antigenic levels have been noted in patients with blood type O compared to patients with other blood types. The contribution of blood group O is more marked in patients with mild qualitative vWF deficiency, where the low vWF level is less likely to be related to abnormalities of the vWF gene. Whether these patients actually have vWD type I is subject to debate, and the role of blood group in the diagnosis of vWF deficiency remains to be resolved. Patients with type 2 vWD may have normal vWF:Ag levels, emphasizing the need to use more than just a vWF antigen assay to evaluate a patient for vWD.

von Willebrand Factor Functional Assays
vWF has multiple functions, and assays have been devised to specifically evaluate many of these. The function most often clinically assessed is its ability to interact with platelets. An assay that evaluates the ability of vWF to interact with collagen has also been proposed as a functional assay. The relevance of collagen-binding activity analysis is questioned for routine screening, and collagenbinding activity assay has not gained widespread acceptance in the United States. Finally, vWF binding of factor VIII can be assessed in special circumstances when questioning whether mild factor VIII deficiency is due to failure of vWF chaperone function. vWF functional assay generally correlates well with vWF:Ag in patients with quantitative disorders of vWF. Observing a discrepancy between vWF function and vWF:Ag provides a useful clue for qualitative defects, provided that the testing laboratory uses the same control plasma for determining both assays. Ristocetin Cofactor Activity and Ristocetin-induced Platelet Aggregation

The assay for ristocetin cofactor activity (vWF:RCo) is a quantitative technique for estimating the ability of vWF in patient plasma to bind target platelets that are specially prepared or preserved for use in the assay. Ristocetin induces an activated conformation of vWF such that it will then bind platelets via the platelet GPIb receptor, mimicking the in vivo sequence of events that allows interaction between subendothelial tissue-bound vWF and platelets. Quantitation of vWF:RCo is held to be the single most sensitive and specific assay for vWD by multiple authorities. vWF:RCo activity is adversely affected by loss of the larger-molecular-weight vWF multimers. The discrepancy between vWF:RCo and vWF:Ag that is observed in qualitative defects characterized by loss of both the intermediate- and higher-molecular-weight multimers (such as type 2A vWD) is thought to result from this. Ristocetin cofactor activity is also generally utilized to follow a vWD patient's response to therapeutic interventions. However, obtaining typical ristocetin cofactor activity is a time-consuming procedure, and assay standardization remains somewhat problematic. Automation of the vWF:RCo assay has resulted in a clinically more available, but less sensitive technique, which requires modification to detect levels below 10 to 20 IU/dl. Simpler ELISA-based methods using monoclonal antibody to the GPIb-binding domain of vWF have been explored for estimating vWF activity. Unfortunately, commercial functional epitope assays have not performed sufficiently well to allow them to replace vWF:RCo assay, and these assays do not measure the increased functionality of the larger vWF multimers directly.

Ristocetin-induced platelet aggregation (RIPA) is a distinct test from ristocetin cofactor activity. RIPA is a qualitative test that involves evaluating the rate or extent of agglutination of patient-derived platelet-rich plasma in response to the addition of the antibiotic ristocetin. The concentration of vWF and platelets present in the test plasma, as well as the amount of ristocetin added, affect RIPA. The assay is relatively insensitive to mild deficiency of vWF, but decreased aggregation response is observed in both more severe deficiency and in patients with Bernard-Soulier syndrome (in which platelets are missing the GPIb receptor). Titration down the amount of ristocetin added in the assay may be of specific interest in defining variants of vWD in which there are “gain of function” mutations (type 2B and platelet-type [pseudo] vWD). These two conditions are characterized by increased sensitivity of patient vWF or platelets to the effect of ristocetin. However, insensitivity of patient samples to low-dose ristocetin aggregation is seen in occasional patients with type 2B vWD in whom there is marked reduction in the amount of high- and intermediate-molecular-weight multimers, and genetic analysis may be required to distinguish some cases of type 2B from type 2A vWD. In addition, low-dose ristocetin aggregation of patient-derived platelet-rich plasma cannot differentiate type 2B vWD from the rarer platelettype (pseudo) vWD, and mixing studies using patient plasma and donor platelets have been devised to help make that distinction at the phenotypic level.

von Willebrand Collagen-binding Activity

vWF contains collagen-binding sites in both the A1 and A3 domains of the vWF protein, and collagen-binding activity (vWF:CB) may be an important function that allows vWF to adhere to platelets at sites of vascular injury. Like ristocetin cofactor activity, vWF:CB is dependent on multimer size, with the larger multimers binding collagen more avidly. The assay is generally done in an ELISA format, in which type I and/or type III collagen is plated into microtiter wells, and the amount of vWF captured is assayed. vWF:CB correlates well with vWF:Ag in normal individuals and those with quantitative deficiency of vWF, and discrepant results are indicative of vWD subtypes that are characterized by deficiency of larger vWF multimers. A single case of vWD characterized by mutation of the vWF A3 domain with isolated loss of collagen-binding function despite the presence of a normal multimer distribution has been described. Although some studies suggest that vWF:CB testing complements assays of vWF:Ag and vWF:RCo in distinguishing type 1 vWD from type 2A and 2B variants, the role of vWF:CB testing in routine clinical practice remains to be determined.
Assay of von Willebrand Factor’s Ability to Bind Factor VIII

Factor VIII binding by vWF (vWF:FVIIIb) can be measured in a few reference coagulation laboratories, and is indicated for the evaluation of patients suspected of having factor VIII deficiency on the basis of defective vWF chaperone function (type 2N vWD). In this ELISA format assay, ELISA plate wells are coated with antibody to vWF in order to capture vWF from patient plasma. After washing patient-derived factor VIII from the well, the ability of patient-derived vWF to capture r-FVIII is assessed using a chromogenic or immunoassay for factor VIII, and the quantity of patient-derived vWF:Ag in the well is quantified by standard ELISA technique. The calculated ratio of captured r-FVIII to vWF:Ag is expected to be in the normal range when testing plasma from a patient with hemophilia A, whereas it will be abnormally low in the rare cases of type 2N vWD.

Multimeric Analysis of von Willebrand Factor

Normal vWF in plasma consists of a complex series of multimers, ranging in size from about 500 to 20,000 kDa. vWD initially diagnosed by abnormal assays for factor VIIIc, vWF antigen, or ristocetin cofactor activity should be further characterized by multimeric analysis. In this test, the spectrum of vWF molecular sizes of the patient's vWF is assessed by size-based separation of vWF multimers via agarose gel electrophoresis, and vWF multimers are imaged by immunologic methods coupled to autoradiography or other detection methods. Multimer analysis is characterized as either “low-resolution” (which differentiates the largest multimer forms from the intermediate and smaller forms), or “high-resolution” (which resolves each multimer band into three to five satellite bands), which inform on the activity of ADAMTS13 on plasma vWF. Multimer analysis will confirm the presence of the entire spectrum of vWF multimers in normal individuals and those with type 1 vWD, and allows identification of the loss of intermediate- or high-molecular-weight multimers of vWF as is characteristic of the type 2A and type 2B qualitative defects. Unfortunately, the distinction between type 2A and type 2B vWD is not always possible using multimer analysis alone, necessitating further testing. Multimeric analysis is a very labor-intensive test and is usually performed only in coagulation reference laboratories. The multimeric composition of plasma from normal subjects and patients with vWD is shown in Figure 53.8. This methodology has been reviewed.

Genetic Testing in von Willebrand Disease

Direct mutational analysis by vWF gene sequencing, allele-specific PCR, or restriction enzyme analysis is useful in confirming a diagnosis of type 2 variant vWD. The functional domain structure of the vWF gene results in clustering of the various type 2 vWD defects in limited areas of the vWF sequence. vWF exon 28 encodes for the A1 loop of vWF responsible for the interaction of vWF with platelet GPIib, and vWD variants characterized by defects of this interaction (types 2B and 2M) are encoded by genetic mutations clustered in this exon. Exon 28 also encodes the A2 domain, which contains the ADAMTS13-sensitive bond tyrosine1605-methionine 1606. Mutations that increase the susceptibility of this bond to cleavage by ADAMTS13 underlie a high fraction of type 2A vWD (previously classified as 2A, subtype 2). Less commonly, type 2A vWD results from a defect of the multimerization process. The carboxy terminus of the vWF peptide encoded by exons 51 to 52 is involved in initial vWF dimer formation in the rough endoplasmic reticulum. The vWFpp (encoded by exons 3 to 17) directs further multimerization via cross-linkage of the amino-terminal D’ and D3 of the mature vWF protein (encoded by exons 18 to 28). As one might expect, type 2A vWD on the basis of failure of multimerization (previously classified as 2A, subtype 1) has been attributed to genetic abnormalities in each of these regions of the genome. Mutations responsible for defective interaction of vWF with factor VIII (type 2N vWD) are predominantly clustered in exons 18 to 20, which encode for the factor VIII-binding domain of vWF; however, rare cases have been attributed to mutations in exons 24 and 25. An online database of defects found in vWD patients can be accessed at www.vwf.group.shef.ac.uk. Figure 53.5 shows the location of these various genetic abnormalities schematically. Rapid, complete vWF gene sequencing has been reported.
FIGURE 53.8. Multimeric composition of von Willebrand factor from normal plasma and that from types I, IIA, IIB, IIC, IID, and IIE von Willebrand disease (vWD), as well as from a type IIC heterozygote (IICH). Using the revised classification scheme, these types would correspond to 1, 2A, 2B, 2A, 2A, and 2A, respectively. The three brackets include the smallest normal oligomers, with arrows pointing to the central predominant band in each. In type 1 vWD, the relative concentration of large multimers varies. (From Zimmerman TS, Ruggeri ZM. von Willebrand disease. Hum Pathol 1987;18:140–152, with permission.)

Genetics of Type 1 and Type 3 vWD

Mild to moderate quantitative deficiency of vWF characterizes patients with type 1 vWD, whereas virtual absence of vWF characterizes type 3 disease. Genetic analysis is not generally required to make these diagnoses, but may provide useful additional information concerning pathogenesis of a patient's condition, responsiveness to DDAVP, or risk for alloantibody formation. In distinction from type 2 vWD, genetic defects underlying quantitative vWF deficiency are distributed throughout the vWF gene, complicating evaluation. In addition, for families with patients who demonstrate normal multimer structure and higher vWF levels, the chances of finding linkage to the vWF gene are reduced, and family members are usually asymptomatic. Type 3 patients with large gene deletions are particularly prone to develop anti-vWF alloantibodies after treatment with vWF-containing concentrates.

Type 1 von Willebrand Disease and “Low von Willebrand Factor”

Patients with bleeding attributed to decreased production of qualitatively normal vWF are classified as having type 1 vWD. Most patients with vWD (70% to 80%) fall into this category. The majority of patients have a mildly symptomatic disorder, but bleeding may increase with physical trauma, surgery, or during menstruation. vWF levels are low, with concordant reduction of vWF:Ag and vWF:RCo (and vWF:CB, if that is measured). Factor VIII levels are generally equal to or higher than vWF levels, and all vWF multimers should be present if that analysis is performed as part of the patient evaluation. The diagnosis of type 1 vWD may be simpler in an individual with mucosal bleeding symptoms, a strong family history of similar symptoms, and quantitative vWF level (vWF:Ag and/or vWF:RCo) <30 IU/dl. Although not required for a diagnosis of type 1 vWD, the probability of finding linkage of the phenotype to the vWF gene in such an individual would be high, such that both therapeutic choices and genetic counseling would be straightforward.

Unfortunatly, many factors make the diagnosis of type 1 vWD difficult. Mild bleeding symptoms are common in hemostatically normal people (see Chapter 45). In addition, the relative risk of bleeding for individuals with only modest reductions in vWF level appears to be minimal. Finally, because of the strong influence of blood group on vWF levels, there is a high prevalence of blood group O among individuals with mildly depressed vWF levels. These observations have led to the recent proposal of the concept of “low vWF”. The term “low vWF” could be applied to patients with vWF levels below the normal reference range but above some lower limit. A recently convened “expert group” brought together by the National Heart, Lung and Blood Institute is considering this proposal. Studies of families of patients with a diagnosis of type 1 vWD suggest that linkage to the vWF gene is less often seen when the vWF level rises above 30 IU/dl,
suggested that this might be a candidate for the lower limit of the “low vWF” category.\textsuperscript{145, 198} Empiric therapy to raise vWF levels in patients with “low vWF” at times of hemostatic challenge would be reasonable for patients with a history of bleeding, but the genetic counseling issues would clearly be different.\textsuperscript{144}

On the other hand, two population-based studies have shown that “low vWF” causes increased bleeding.\textsuperscript{199, 200} These latter studies would suggest that abnormally low ristocetin cofactor activity, and not the presence of a mutation, should primarily be used to identify bleeders.

Type 3 von Willebrand Disease

Type 3 vWD is the most severe form of vWD, because it results from complete failure of vWF synthesis. This bleeding disorder is generally diagnosed during infancy. Hematoma formation is common, epistaxis may be life-threatening, and hemorrhage may occur as a result of the low factor VIII levels that are seen in this condition. Plasma from patients with type 3 vWD contains virtually no detectable vWF, and vWF is not present in either platelets or endothelial cells. Factor VIII level is generally in the range of 1 to 10 IU/dl, similar to that seen in moderate to mild hemophilia A. Multimeric analysis of the little vWF present yields variable results, in some cases revealing only small multimers.\textsuperscript{193} Type 3 vWD is rare, with an estimated frequency of 1 in a million people.\textsuperscript{201} Genetic analysis reveals either homozygous or compound (double) heterozygous defects of the vWF gene, with gene deletions, frame-shift mutations, missense mutations, or nonsense mutations. Careful laboratory evaluation of the parents of patients with type 3 disease may reveal mild quantitative deficiency of vWF. In a review of 117 obligate heterozygotes, the mean plasma vWF level was 45 IU/dl, with a range from 5 to 130 IU/dl.\textsuperscript{144} Parents are frequently asymptomatic, consistent with the impression that type 3 disease is inherited as a recessive trait. Consanguinity is common in kindreds with this variant. In some patients with type 3 vWD, large gene deletions have been identified on one or both vWF alleles.\textsuperscript{128, 202} Such patients are at increased risk of developing inhibitory alloantibodies to vWF after transfusion therapy.\textsuperscript{202}

Because these patients lack vWF in their endothelial cells and platelets, there is no rise in vWF level in response to DDAVP. For replacement therapy, these patients require vWF-containing concentrates. This is usually provided in the form of specific intermediate-purity factor VIII concentrates that have been documented to contain intact vWF.\textsuperscript{155} Because these patients possess a normal factor VIII gene but are missing the vWF chaperone, posttransfusion factor VIII recovery and survival may be longer in a patient with type 3 vWD than in a patient with hemophilia A, owing to endogenous factor VIII production. Although life-threatening bleeds require immediate replacement of both vWF and factor VIII, replacement with vWF alone may be sufficient if therapy is begun 12 to 24 hours before elective surgery.\textsuperscript{203}

Qualitative Defects of von Willebrand Factor

Several subsets of patients with vWD differ substantially from those with the common quantitative deficiency states (Table 53.6).\textsuperscript{128} Classified as type 2 variants, these qualitative defects of vWF are less common, but they may represent up to 20% to 25% of cases of vWD. Type 2 forms of vWD are suspected when the severity of the patient’s symptoms seems in excess of the observed vWF and factor VIII levels, when there is discordant reduction between vWF antigen and vWF functional activity or factor VIII assay, or when there is concomitant vWF deficiency and thrombocytopenia. Discrimination between qualitatively normal and abnormal vWF can be difficult; however, when the ratio of vWF:RCo to vWF:Ag or vWF:CB to vWF:Ag is found to be <0.6, dysfunctional vWF should be considered. The sensitivity and specificity of such ratio screening depends to a large extent on the expertise and precision of the laboratory performing the assays, but the predictive value of ratios decreases when the level of vWF antigen is <20 IU/dl. Examining the structure of patient vWF may provide further definition of the nature of the qualitative defect. This can be demonstrated by vWF multimer analysis. If required, further information is provided by supplemental studies of vWF function, or via genetic analysis of the vWF gene (Fig. 53.5).\textsuperscript{126, 128, 191} Type 2 defects were initially classified using a Roman numeral system, but further understanding of the genetics of vWD led to the consolidation and reclassification into types 2A, 2B, 2M, and 2N,\textsuperscript{128} based on the nature of the vWF functional defect. In addition to the well-defined variants described in this chapter, other forms of vWD continue to be described.

Type 2A von Willebrand Disease

vWD with defective interaction of vWF with platelets due to deficiency of intermediate- and high-molecular-weight forms of vWF is classified as type 2A vWD.\textsuperscript{128} This form of the disorder is generally inherited as an autosomal dominant trait,\textsuperscript{204} and it accounts for the majority of patients with type 2 defects. Levels of factor VIIIc and vWF:RCo in the plasma may be normal or reduced. The vWF activity as assayed by either vWF:RCo or vWF:CB is significantly lower than vWF:Ag because of the absence of the larger multimers (which are more potent in their ability to interact with platelet GPIb and collagen). Analysis of vWF multimers reveals a relative reduction in intermediate- and high-molecularweight species.\textsuperscript{127} Protein studies followed by genetic analysis of the basis of type 2A vWD revealed multiple mechanisms for the generation of this
In some patients, there is failure to synthesize full-length multimers (type 2A, subgroup 1). Mutations associated with impaired vWF multimerization have been localized to the vWFpp (formerly called type IIC), the region of the mature vWF protein associated with the amino terminus area of multimer formation (formerly called type IIE), and the carboxy terminus region that is involved in initial dimer formation (formerly called type IID). Subtle abnormalities uncovered by high-resolution multimer analysis or genetic evaluation can be used to distinguish these subtypes of type 2A vWD. The spectrum of multimers released into plasma after DDAVP administration would not be expected to improve significantly in these patients whose defects prevent normal multimer assembly.

A second group of type 2A patients has been described in whom there is excessive catabolism of fully multimerized vWF after vWF is released into the plasma. These patients demonstrate mutations in exon 28, encoding the A1 and A2 regions of vWF. These mutations allow increased proteolysis of multimerized vWF by ADAMTS13. Again, high-resolution multimer gel studies may be informative by demonstrating increased “satellite” band intensity, which accumulates as a result of excessive ADAMTS13 activity. Because intracellular vWF is protected from cleavage by ADAMTS13, these patients may demonstrate very transient improvement in both vWF:RCo and multimer spectrum after DDAVP administration.

Inheritance of type 2A vWD is generally autosomal dominant, with the majority of cases caused by mutations clustered in the region of exon 28, which encodes the vWF A2 homologous repeat (Fig. 53.5). Rare recessive forms of type 2A vWD have been reported with some multimerization defects (formerly called types IIC and IID).

Because of the underlying structural abnormality of the vWF produced in these patients, neither stress nor pregnancy significantly increases the functional amount of vWF protein in the plasma. As noted above, the administration of DDAVP does not result in a significant rise in vWF:RCo in patients with type 2A vWD, in which the underlying mechanism is defective multimerization or transport, but a very short-lived correction may be observed in patients with mutations associated with increased vWF cleavage by ADAMTS13.

Type 2B von Willebrand Disease

Type 2B vWD is a paradoxical bleeding disorder, characterized by increased interaction of patient vWF with platelets which is demonstrated in vitro in the presence of low doses of ristocetin. Increased in vivo interaction of the larger multimers of type 2B vWF with platelets is thought to result from mutations that either allow increased access of platelets to the A1 loop of vWF or that stabilize that interaction. This may in turn allow increased generation of vWF-platelet complexes, which are subsequently cleared from circulation, resulting in thrombocytopenia.

This bleeding disorder is characterized by deficient vWF function attributable to mild reduction of vWF:Ag, a somewhat more marked deficiency of vWF:RCo activity (and vWF:CB, if measured). Multimeric analysis reveals a deficiency of the highest molecular-weight vWF multimers. Measurements of factor VIIIc are variable. Many patients with the type 2B variant have mild persistent thrombocytopenia. The platelet count may fall further during physiologic stresses, pregnancy, in association with surgical procedures, or after the administration of DDAVP.

Additional laboratory evaluation is required to support a diagnosis of type 2B vWD. In most cases, multimeric analysis reveals absence of higher-molecular-weight forms of plasma vWF, but distinction of type 2B from type 2A vWD is not possible by multimeric analysis alone. To show the distinct “gain in function” in type 2B disease, RIPA studies are done to reveal enhanced interaction of patient vWF and platelets with low doses of the drug. Finally, to differentiate the more common type 2B vWD from the rare platelet-type (pseudo) vWD, one should prove that the defect resides in vWF. This is done either through performing mixing studies of patient plasma with donor platelets or by analysis of the patient’s vWF gene.

Type 2B vWD is inherited as an autosomal dominant trait. A small cluster of mutations within the portion of vWF exon 28 that encodes the vWF A1 domain that interacts with platelet GPIIb accounts for all the cases of type 2B vWD that have been reported (Fig. 53.5).

Recent studies evaluating a large number of patients with type 2B vWD mutations revealed diversity in laboratory findings. Not all patients had reduced vWF:RCo activity or abnormal multimeric analysis, and not all patients had thrombocytopenia. Type 2B patients with normal multimers did not develop thrombocytopenia.

Type 2M von Willebrand Disease
The type 2M vWD variant is defined by diminished platelet-dependent vWF function that is not attributed to deficiency of vWF multimers. Affected patients have factor VIII levels in the range of 5 to 30 IU/dl, attributed to mutations at the factor VIII-binding site near the amino terminus of the vWF subunit. Indeed, genetic studies indicate that the majority of mutations underlying type 2N vWD involve vWF exons 18, 19, and 20, which encode the bulk of the factor VIII-binding domain of vWF. The other functions of vWF in patients with type 2N vWD are qualitatively normal, and thus vWF laboratory parameters (vWF:Ag, ristocetin cofactor activity, etc.) are usually normal (unless there is coinheritance of type 1 vWD). This variant was originally named vWD Normandy but has been renamed type 2N vWD in the revised classification. The factor VIII-binding defect in these patients is inherited in an autosomal recessive manner, and thus affected patients must inherit 2N alleles from each of their two parents, or inherit type 1 vWD from one parent while inheriting a 2N allele from the other. Patients with factor VIII deficiency and a bleeding disorder that is not clearly transmitted as an X-linked disorder or who demonstrate an unexpectedly short in vivo survival of infused factor VIII should be evaluated for type 2N vWD. Diagnosis requires performance of an assay that assesses the interaction of factor VIII with vWF, or genetic studies of the vWF gene. A survey of almost 400 unrelated patients with either hemophilia A or type 1 vWD indicated a prevalence of type 2N vWD in these patient populations of 3% and 1.5%, respectively. Consideration of this diagnosis is important because both therapy and genetic counseling are distinct from that of mild hemophilia A.

Platelet-type (Pseudo) von Willebrand Disease

Platelet-type (pseudo) vWD resembles type 2B vWD in most respects, except that the basis for platelet-type vWD is a structural defect in platelet GP Ibβ rather than a defect of vWF (thus platelet-type [pseudo] vWD is a form of platelet dysfunction). However, as with type 2B vWD, a genetic defect results in increased interaction between GP Ib and vWF. Phenotypically, platelet-type (pseudo) vWD is manifested by mild thrombocytopenia, a prolonged bleeding time, and variable deficiency of plasma vWF and factor VIIIc. The reductions in plasma vWF and factor VIIIc may be a result of the attachment of these proteins to platelets that are subsequently removed from the circulation. This “consumption” of vWF and platelets results in preferential loss of high-molecular-weight multimers from patient plasma. In vitro platelet aggregation studies reveal platelet agglutination at unusually low concentrations of ristocetin. Spontaneous intravascular platelet clumping may also occur. Platelet-type (pseudo) vWF is inherited as an autosomal dominant trait in most families.

Distinction of platelet-type vWD from type 2B vWD is based on showing that the enhanced interaction of platelets with vWF is either platelet-based or resides in the plasma phase (type 2B vWD). This can sometimes be demonstrated through low-dose ristocetin-based aggregation assays using mixtures of normal donor and patient samples, or genetic analysis can be used. To date, all cases of platelet-type vWD have been traced to genetic variations of platelet GPI Ibα. These include missense mutations that alter the amino acid sequence from Gly233 to Met 239. This region of the protein adopts a β-sheet conformation after interaction with vWF, and these mutations may function to stabilize this conformation. In addition, a 27-bp gene deletion that encodes for deletion of proline 421 through serine 429 has been shown to underlie platelet-type vWD in one kindred. Thus, genetic analysis of the GPI Ibα gene could confirm a diagnosis of platelet-type vWD in cases in which phenotypic studies were unsuccessful.

CLINICAL DISORDERS OF THE FIBRINOGEN MOLECULE

P.1161
The clinical disorders of fibrinogen are complex, and depending on the types of mutation may present with bleeding or with thrombotic symptoms, or both. These disorders can be divided based on whether the defect is predominantly a quantitative or qualitative abnormality of the fibrinogen molecule. Quantitative abnormalities are disorders associated with the complete absence of fibrinogen (afibrinogenemia) or with low levels of fibrinogen (hypofibrinogenemia). Qualitative abnormalities are disorders resulting from synthesis of an abnormal fibrinogen molecule (dysfibrinogenemia) with altered functional properties. Dysfibrinogenemia may be asymptomatic and identified only through laboratory studies, or it may be associated with either hemorrhagic or thrombotic consequences.

Fibrinogen is a 340-kDa plasma protein that circulates at a concentration of 1.5 to 3.5 mg/ml. It is a symmetric disulfidelinked dimer with a central E domain linked via “coiled coil” peptide chains to outer D domains. Each half-molecule consists of a set of three different peptide chains, termed Aα, Bβ, and γ, which are linked at their amino termini by disulfide bonds to form the E domain. The D domains are formed by disulfide linkages near the carboxy termini of the peptides. Fibrinogen is synthesized in hepatocytes by coordinated expression of three separate genes on chromosome 4. The rate-limiting step in fibrinogen synthesis is transcription of the Bβ gene. Fibrinogen is an acute-phase reactant, and levels may rise considerably with inflammation. The circulation half-life of plasma fibrinogen is ~4 days. Fibrinogen participates in multiple physiologic processes, including fibrin clot formation mediated by the enzymatic activities of thrombin and factor Xlla, and cohesion of activated platelets through interaction with the GP IIb/IIIa receptor. Fibrinogen also acts as a plasma carrier for factor XIII. Fibrinogen physiology has been reviewed.

The congenital disorders of fibrinogen associated with afibrinogenemia and hypofibrinogenemia are reviewed in the next section, followed by a discussion of the dysfibrinogenemias. Afibrinogenemia is a very uncommon condition. The first case was described in 1920 (reviewed in Ref. 226), and ~300 cases have been reported since then (see database at isth. org). Congenital hypofibrinogenemia was first reported in 1935 (reviewed in Ref. 227), and at least 40 cases have been reported in the literature. However, it is likely that many of the cases of hypofibrinogenemia were actually cases of dysfibrinogenemia with a reduced level of circulating clottable fibrinogen. Congenital disorders of fibrinogen are rare, and, in practice, most commonly observed disorders are acquired as a result of liver disease or consumptive processes.

Pathogenesis of Quantitative Fibrinogen Disorders

In congenital afibrinogenemia and hypofibrinogenemia, defects in synthesis, secretion, or intracellular processing of the final gene product result in deficiency of plasma fibrinogen. When newly synthesized fibrinogen is not secreted, the protein may accumulate in the rough endoplasmic reticulum of hepatocytes or other cells, resulting in amyloid-like accumulations. In both afibrinogenemia and hypofibrinogenemia, the fibrinolytic system and other coagulation pathways are completely normal. Similarly, there is no evidence of blood coagulation activation, which could cause consumption, or degradation of the fibrinogen molecule. The fibrinogen gene locus is located on chromosome 4; it contains three distinct genes that encode for the Aα, Bβ, and γ peptide chains that compose the fibrinogen molecule. The inheritance pattern of afibrinogenemia is autosomal recessive in nature, and many reported cases are the result of consanguineous relationships between asymptomatic parents with symptomatic homozygote offspring. The molecular basis for quantitative fibrinogen disorders has been reviewed. Genetic defects are scattered throughout the three fibrinogen genes that code for the three polypeptide chains—Aα, Bβ, and γ. Multiple genetic defects have been reported, including deletions, point mutations, missense mutations, and uniparental isodisomy. Deletion of an 11-kb region of the fibrinogen α gene appears to be a recurrent finding in unrelated families from both Europe and the United States. A database of genetic defects that have been identified in patients with congenital fibrinogen abnormalities is accessible at www.geht.org/databaseang/fibrinogen. An unexpectedly large number of individuals with congenital fibrinogen disorders have been described in southern Iran.

Afibrinogenemia

Inherited afibrinogenemia is a rare autosomal recessive disorder, with an estimated frequency of 1 in a million individuals. It is somewhat of an anomaly that patients who are afibrinogenemic have little hemorrhage, despite the fact that their blood cannot clot normally. This may in part be due to the presence of functional vWF, which allows platelet adhesion and aggregation, with the formation of loose thrombi even in the absence of fibrinogen. A similar phenotype was recently described for afibrinogenemic mice created by gene-targeted knockout. In patients with afibrinogenemia, life-threatening hemorrhages do occur, but in many situations the bleeding is not as severe as is seen in hemophilia. The diagnosis is often made early in infancy, when prolonged umbilical stump bleeding occurs. A major cause of death is intracranial hemorrhage during infancy or childhood. The clinical manifestations include mucosal membrane bleeding, such as epistaxis, menorrhagia, or gastrointestinal hemorrhage. A review of the cases entered into
the North American Rare Bleeding Disorder Registry indicated that most bleeding events were triggered by trauma, with only 20% to 30% occurring spontaneously. Increased incidence of first-trimester abortion, placental abruption, and postpartum hemorrhage have been observed in patients with afibrinogenemia. Fetuses of female afibrinogenemic patients rarely reach full term unless replacement therapy is given. Although 20% of afibrinogenemic patients are affected with hemarthrosis, the severity is generally less than that seen in patients with hemophilia. Replacement therapy for patients with afibrinogenemia is available, although there may be some concern with increased risk of thrombosis during therapy. Transgenic afibrinogenemic mice demonstrate abundant thrombus formation in a vascular injury model. The basis for this is not well understood, but may be in part related to the fact that fibrinogen has non-substrate-binding sites for thrombin that could potentially modulate thrombin availability to activate platelets. Patients with congenital hypofibrinogenemia do not typically have any spontaneous bleeding unless the fibrinogen level is <50 mg/dl. These patients may actually have hypodysfibrinogenemia, which is discussed in a later section of this chapter.

Laboratory Diagnosis

Screening coagulation tests from afibrinogenemic and hypofibrinogenemic patients typically show a marked prolongation of all tests where the endpoint is the appearance of fibrin clot, as severe fibrinogen deficiency renders plasma nonclottable. These tests include the PT, PTT, thrombin clotting time, and reptilase time. These test abnormalities, when due to functional deficiency of clottable fibrinogen, are usually corrected when patient plasma is mixed with normal plasma. A diagnosis of afibrinogenemia depends on the specific finding of undetectable fibrinogen antigen in the plasma of these patients. Platelet fibrinogen is also absent. Mild thrombocytopenia has been reported in some afibrinogenemic patients, but typically the platelet count is usually not lower than 100,000/µl. The bleeding time is prolonged in approximately one-third of patients with afibrinogenemia, presumably caused by the failure of platelets to aggregate in the absence of plasma or platelet fibrinogen. These abnormalities are correctable by infusion of plasma, or more recently therapeutic concentrates of fibrinogen. Furthermore, afibrinogenemic patients who undergo hypersensitivity reaction skin testing do not typically show an induration response to allergens. They show only erythema because the later phases of the hypersensitivity reaction depend on the deposition of subcutaneous fibrin.

Differential Diagnosis and Therapy of Afibrinogenemia

Congenital quantitative defects in fibrinogen must be carefully distinguished from acquired quantitative defects in the fibrinogen molecule, which are often seen in the setting of liver disease or disseminated intravascular coagulation. Acquired hypofibrinogenemia has been reported after therapy with L-asparaginase, which impairs hepatic synthesis of fibrinogen, and in patients with aplastic anemia treated with antithymocyte globulin and corticosteroids. In the absence of purified fibrinogen concentrates, cryoprecipitate administration is used for replacement therapy for patients with severe afibrinogenemia. Prophylactic therapy is recommended only for pregnant patients, or patients with a history of central nervous system (CNS) hemorrhage. Replacement therapy is indicated for any episode of acute active bleeding, preoperatively, and in pregnant patients. Fibrinogen levels between 50 and 100 mg/dl are usually adequate for normal hemostasis. Levels >100 mg/dl are recommended for maintenance during pregnancy, based on empiric clinical observations. Weekly infusions are recommended, but one should be aware that fibrinogen requirements may rise significantly around the time of parturition, and that levels as high as 150 mg/ml may be helpful to avert abruption. Each bag of cryoprecipitate contains ~250 mg of fibrinogen, and one bag of cryoprecipitate typically raises plasma fibrinogen levels of an adult by ~10 mg/dl; thus 5 to 10 bags of cryoprecipitate are usually sufficient in the average adult patient. Because the fractional catabolic rate of fibrinogen is 25% per day, acute-care patients should receive one-third of their loading dose daily for as long as fibrinogen support is desired. There are plasma concentrates of fibrinogen now available that may provide advantages over the use of cryoprecipitate. Measurement of plasma fibrinogen levels after infusion is recommended to confirm that a patient has obtained the desired therapeutic effect. The complications of replacement therapy in afibrinogenemia include allergic reactions, development of antifibrinogen antibodies, and anaphylaxis. Thromboembolic complications following cryoprecipitate infusions include deep venous thrombosis and pulmonary embolism; the risk of these complications may be increased when an inhibitor of fibrinolysis or oral contraceptive therapy is also administered. Low-molecular-weight heparin in combination with fibrinogen replacement has been used to avoid these thromboembolic complications. Antifibrinolytics alone may be sufficient to prevent bleeding from mucosal sites, but caution should be exercised in patients with a personal or family history of thrombosis.
Dysfibrinogenemia

The first reported case of dysfibrinogenemia mediated by a qualitatively abnormal fibrinogen molecule occurred in 1965, and since that time >300 families have been reported with this disorder. The molecular genetic basis of fibrinogen dysfunction has been fairly well established in many families that have been studied. However, uncertainty persists concerning the linkage of genetic defects of fibrinogen and the disease phenotype expressed by patients, as environmental factors and other concomitant genetic abnormalities may be influencing disease manifestations. There is an intriguing report of an increased association of dysfibrinogenemia with chronic thromboembolic pulmonary hypertension. A database containing an updated list of the genetic defects associated with dysfibrinogenemia is accessible at http://site.geht.org/site/Pratiques-Professionnelles/Base-de-donnees-Fibrinogene/Database-English-Version/Fibrinogen-variants-Database-_.html.

Molecular Basis of Dysfibrinogenemia

The reported abnormalities in the fibrinogen molecule include defects in each of the major steps of fibrin formation and stabilization. The conversion of fibrinogen to an insoluble fibrin clot requires that the molecule first be cleaved by thrombin between arginine 16 and glycine 17 of the Aα chain to release fibrinopeptide A, and between arginine 14 and valine 15 of the Bβ chain to release fibrinopeptide B. This produces a fibrin monomer capable of undergoing the second step, fibrin polymerization. Once these molecules polymerize, they are stabilized by the action of factor XIIIa. Fibrinogen also supports the hemostatic process through interaction with platelets during platelet cohesion (aggregation). Finally, during the process of wound healing and tissue remodeling, the fibrin clot undergoes fibrinolysis by concerted activities of plasminogen and plasminogen activators. Fibrinogen dysfunction may affect any of these various steps of fibrin clot formation, platelet interaction, or lysis. It is therefore expected that the dysfibrinogenemias can be associated with abnormal clinical bleeding, thrombotic tendency, disorders of wound healing, or no clinically apparent disease. Domain location of a mutation does not necessarily predict the associated disease phenotype. Defects of fibrinopeptide release have been associated with both hemorrhagic and thrombotic complications. Similarly, disruption of D-D interactions have been associated with both bleeding and thrombosis. Patients who have heterozygous dysfibrinogenemia typically have ~50% of normal fibrinogen levels, which should be adequate for hemostasis. Clottable fibrinogen protein measurements may not be a reliable indicator of plasma fibrinogen concentration, because functionally abnormal molecules are not always incorporated into the clot. An abnormal fibrinogen may inhibit the conversion of normal fibrinogen to fibrin, so the tendency for many of these patients to bleed is higher than one would suspect. Hypodysfibrinogenemia occurs when an abnormality of the fibrinogen molecule results in decreased secretion or increased clearance of the protein. More than 20 families have been reported with hypodysfibrinogenemia. Autosomal amyloidosis has been attributed to genetic disorders of fibrinogen, as well as to genetic disorders of several other proteins (including transthyretin, gelsolin, apolipoprotein A, and lysozyme).

P.1163

Hereditary renal amyloid disease has been associated with genetic defects of the Aα chain, and renal amyloid has recurred in renal transplants. Hepatic amyloid disease has also been attributed to abnormalities of fibrinogen.

Dysfibrinogenemia is typically inherited as an autosomal dominant trait with high levels of penetrance. Most of these patients are heterozygotes, but a few homozygotes and some rare compound heterozygotes have been reported in the literature. Approximately 40% of dysfibrinogenemic patients are asymptomatic, and 45% to 50% have a bleeding disorder. The remaining 10% to 15% have either a thrombotic disorder (venous or arterial) or both bleeding and thrombotic tendencies. The bleeding associated with dysfibrinogenemia is generally mild and includes soft tissue hemorrhage, easy bruising, and menorrhagia. Although intraoperative and postoperative bleeding have been reported, most bleeding is not life-threatening.

There are only a few families in which a thrombotic tendency can be unambiguously associated with dysfibrinogenemia, and criteria for making this association have been proposed. These criteria include a demonstrated molecular defect, thrombosis at an early age or in multiple family members, presence of no other predisposing factor for thrombosis, strong association between the fibrinogen defect and thrombus complications within a family, and association of the same molecular defect with thrombosis in another, unrelated kindred. The true prevalence of thrombosis among patients with dysfibrinogenemia is unknown. Studies indicate a distinct thrombotic tendency in individuals with dysfibrinogenemia related to defects in the α-C domain of the Aα chain of fibrinogen, especially if new cysteine residues are encoded that can become disulfide-linked to albumin. In contrast, dysfibrinogenemic patients with defective cross-linking experience primarily defective wound healing.
Laboratory Diagnosis of Dysfibrinogenemia

The thrombin clotting time remains a sensitive screening test for dysfibrinogenemias, and the PT appears to be more sensitive than the PTT to the effects of dysfibrinogenemia. In some cases, clot formation may be absent. Reptilase is a snake venom enzyme that differs from thrombin in that it cleaves only fibrinopeptide A of fibrinogen. The reptilase time is often more prolonged than the thrombin clotting time, especially in patients who have defective fibrinopeptide A release. Some dysfibrinogenemias exhibit a very short thrombin clotting time, and these patients may have thrombotic complications. The fibrinogen concentration can be either low or normal in these patients. Most patients with dysfibrinogenemia have a significant discrepancy between the level of clottable fibrinogen and that detected by immunologic methods. Criteria for diagnosing dysfibrinogens using ratios of immunologic and functional fibrinogen assays have been reported, but the sensitivity and specificity of these criteria are not well characterized. The euglobulin clot lysis time is a crude measure of fibrinolytic potential, and may be helpful in detecting abnormal fibrinogens that show increased susceptibility to fibrinolysis. For example, with fibrinogen St. Louis, the euglobulin clot lysis time is shortened, and fibrinogen degradation products are elevated in the plasma. Laboratory testing for fibrinogen abnormalities has been reviewed.

The diagnosis of inherited dysfibrinogenemia must be distinguished from hypofibrinogenemia, which is either acquired or congenital in nature. Acquired dysfibrinogenemia occurs typically in the setting of severe liver disease, and the suspicion can be readily investigated by evaluation of liver function tests. Acquired dysfibrinogenemias are also associated with malignancies that produce an abnormal fibrinogen molecule, such as some hepatomas (see Chapter 54), multiple myeloma, and renal cell carcinoma, as well as autoimmune disorders. An algorithm has been proposed for the orderly evaluation of patients in whom dysfibrinogenemia is a consideration.

Acquired inhibitors to fibrin formation that interfere with fibrinogen-to-fibrin conversion may also be confused with dysfibrinogenemia. These acquired inhibitors include heparin-like molecules, elevated levels of fibrin split products, and antibodies at concentrations such as may occur in macroglobulinemia, multiple myeloma, or other disorders that interfere with fibrin polymerization. Acquired antibodies against the fibrinogen molecule are quite rare but have been reported in association with a variety of diseases.

Therapy

The majority of patients with dysfibrinogenemia do not require any specific therapy. Any bleeding complications that develop can be managed with transfusion of either plasma or cryoprecipitate. The role of the newer fibrinogen concentrates in treating patients with dysfibrinogenemia has not been clarified through appropriate clinical trials yet. Antifibrinolytic drugs have been used in some patients but should be especially avoided in patients who have thrombotic tendencies. Patients who have repeated venous thrombotic episodes may actually require long-term antithrombotic therapy. A patient with life-threatening thrombophilic manifestations was successfully managed with plasma exchange prior to surgery, but one wonders whether simple anticoagulation therapy would have been sufficient to provide a satisfactory outcome. In women with dysfibrinogenemia, recurrent miscarriages may be prevented using prophylactic cryoprecipitate, and successful pregnancy outcomes in such cases have been reported.

FACTOR XIII DEFICIENCY

The initial hemostatic plug is not sufficient to prevent blood loss unless it is stabilized by the action of plasma factor XIII (fibrinstabilizing factor). A complex set of reactions among thrombin, fibrin, and plasma factor XIII is necessary for clot stabilization (see Chapter 18). When fibrin begins to polymerize after thrombin cleaves the fibrinopeptides, a complex forms between thrombin and fibrin, which promotes the conversion of factor XIII to factor XIIIa. Fibrin is the main catalytic substrate for factor XIIIa, factor XIIIa transforms the unstable, noncovalently associated fibrin clot to a stable covalently cross-linked set of fibrin fibers that are mechanically stronger, more rigid, and more elastic. A cross-linked fibrin clot is more resistant to mechanical as well as enzymatic degradation by plasmin than uncross-linked fibrin because α2-plasmin inhibitor is also cross-linked to fibrin to inhibit plasmin activity. Factor XIIIa is a transglutaminase that catalyzes the formation of intermolecular γ-glutamyl-ε-lysyl covalent (isopeptide) bonds between the γ chains and α chains of fibrin strands within the clot. Cross-linkage of γ-chain Gln 398 and Lys 406 residues appears to occur earlier, with α-chain linkages between Gln 328 and 366 with Lys 508, 556, and 562 occurring more slowly. In addition, several other plasma and extracellular matrix proteins are linked to the fibrin clot through the action of factor XIII. Cross-linking of thrombin-activatable fibrinolysis inhibitor into fibrin clots further increases the resistance of the clot to plasmin degradation. Cross-linkage of fibrin to adhesive proteins such as vWF, fibronectin, thrombospondin, and vitronectin may improve adhesion to vessel walls and may play a role in cell migration during wound healing. In fact, fibronectin is the second most abundant material in the fibrin clot, accounting for 4% of the total protein.
The importance of factor XIII function in normal health is emphasized by the clinical scenarios characteristic of inherited and acquired deficiency of factor XIII. In the following section, the pathogenesis, molecular genetics, clinical laboratory, diagnostic, and therapeutic elements of the diagnosis and treatment of factor XIII deficiency are discussed.

**Pathogenesis**

In 1944, Robbins postulated that a deficiency of fibrin-stabilizing factor, which later became known as factor XIII, would produce a serious bleeding disorder. However, it was not until the first case of factor XIII deficiency was described in 1960 that the severe nature of this bleeding disorder was recognized. During the last five decades, >200 cases of congenital factor XIII deficiency have been reported in the literature. It is estimated that ~1 person in every 1 million to 5 million people has factor XIII deficiency. The disorder is inherited as an autosomal recessive trait.

The factor XIII molecule is present in both plasma and in blood platelets and monocytes. The plasma concentration of factor XIII is 14 to 28 µg/ml. Approximately half that concentration circulates within blood platelets. Tissue-based factor XIII resides in monocyte/macrophages. Structurally, platelet and monocyte factor XIII consists of only A dimers, present within the cytoplasm of both platelets and megakaryocytes. The plasma factor XIII molecular complex is a heterotetramer, containing two of each of the A and B subunits. The A subunit mediates factor XIII function, containing an activation peptide, calcium-binding site, and enzymatic domain with an active site sulfhydryl residue that is characteristic of this class of enzymes. The three-dimensional structure for the A subunit has been determined by x-ray crystallography. The majority of the A subunit in circulation is derived from cells of marrow origin. The B subunit of plasma factor XIII is synthesized in the liver and probably associates with the A subunit in the plasma phase after release from the hepatocyte. The B subunit appears to promote stabilization of the A subunit in plasma and may play an important role in regulating both the localization of the A subunit to the fibrin clot and thrombin-dependent activation of the protein. Two distinct forms of factor XIII deficiency have been described, based on whether the A and B subunits are absent or present. In type I deficiency there is absence of the B subunit, with resultant decreased concentration of the A subunit in plasma, but platelet A subunit content is maintained. In type II deficiency, the A subunit is absent and the B subunit is present.

**Molecular Genetics**

Since the protein was initially described in human serum in 1944, both the A and B subunits have been purified, and cDNA sequence and gene structure have been established. The A subunit is encoded on chromosome 6, containing 15 exons and spanning a region of 160 kb. A common genetic polymorphism of the A subunit has been described that results in Val34 replacement by Leu just three amino acid residues from the site of cleavage of the activation peptide. This polymorphism may influence factor XIII activation and has been investigated in reference to risk for myocardial infarction. The B subunit is encoded by chromosome 1. Because the mode of inheritance of factor XIII deficiency is autosomal recessive in nature, only homozygotes or compound heterozygotes are clinically symptomatic. The homozygotes reported in the literature are often children of consanguineous marriages.

In the cases reported to date, factor XIII deficiency is more frequently attributed to mutation of the gene encoding the A subunit, confirming the functional importance of this subunit. To date, over 70 mutations have been described. The majority of defects observed are “point mutations” resulting in stop codons, missense errors, or frame-shifts and small deletions. Inherited deficiency of the factor XIII A chain is not restricted to any specific ethnic group.

Factor XIII B chain deficiency is a very rare autosomal recessive disorder, with very few reported cases in the literature. One unique patient displayed a complete absence of the B chain and a shortened half-life of the A chain. Interestingly, this B chain-deficient patient had many of the same symptoms as an A chain-deficient patient. The ability of the B chain to promote A chain binding to the fibrinogen molecule may account for this clinical finding. Only ~5 mutations have been reported in the B chain gene.

**Clinical Aspects**

Clinically affected factor XIII-deficient patients typically have plasma levels that are <1% of normal, with bleeding attributed to accelerated fibrin clot degradation. The bleeding phenotype in patients with inherited factor XIII deficiency is unusually severe. Abnormal bleeding manifests shortly after birth, when bleeding from the healthy umbilical cord remnant occurs. This has been a prominent feature, reported in up to 80% of cases, but this complication was observed in only 22% of the 34 cases reported to the North American Rare Bleeding Disorders Registry. Umbilical stump bleeding is an uncommon presentation for other congenital bleeding disorders. Rebleeding at circumcision is also
common. Other bleeding manifestations in these patients include soft tissue hemorrhage, hemarthrosis, hematomas, and the development of large pseudocysts. The most life-threatening complication of factor XIII deficiency is spontaneous intracranial hemorrhage. Intracranial hemorrhage is more prevalent in factor XIII deficiency than in other inherited bleeding disorders. Approximately 25% of factor XIII-deficient patients experience intracranial hemorrhage. Bleeding is usually spontaneous, and prevention of intracranial hemorrhage forms the basis for the recommendation of prophylactic therapy of factor XIII-deficient patients. Surgery in these patients is often complicated by abnormal wound healing and excessive postoperative bleeding, which can occur either immediately or later. Delayed bleeding may occur several days after surgery or tissue injury, and patients may experience cycles of repetitive bleeding that span weeks to months. Poor wound healing is reported in ~20% of patients with factor XIII deficiency. The affected males in some families also have oligospermia, resulting in infertility. Furthermore, infertility in affected females results from spontaneous abortions. Females with this deficiency cannot carry a pregnancy to term unless plasma factor XIII levels are maintained at levels that prevent bleeding. The manifestations of factor XIII deficiency vary greatly among patients and may not necessarily present as bleeding symptoms. It has been hypothesized that heterogeneity of genetic defects underlying the deficient state accounts for the clinical variability in disease expression. Factor XIII-deficient mice display a similar phenotype to the human condition.

Differential Diagnosis

Congenital or acquired factor XIII deficiency must be considered when a patient has a major bleeding disorder and all of the initial screening laboratory tests are normal, including PT, PTT, and platelet count. Bleeding can occur spontaneously or after major surgery. It remains imperative in the adult to exclude both inherited and acquired factor XIII deficiency, because patients can develop antibodies to factor XIII that interfere with fibrin stabilization. Specific antibodies to factor XIII were reported in patients taking isoniazid, phenytoin, procainamide, penicillin, and valproic acid. Factor XIII antibodies also occur in association with autoimmune disease, in patients with monoclonal gammopathy, or as an idiopathic occurrence. Acquired factor XIII deficiency has been reported in Henoch-Schönlein purpura, liver disease, Crohn disease, and ulcerative colitis.

Laboratory Diagnosis

The PT and PTT assays are normal (Table 53.5). The solubility of a fibrin clot in 5M urea or 1% monochloroacetic acid (clot stability assay) is the most useful screening test for factor XIII deficiency.

In these conditions, clots formed in the absence of factor XIII activity dissolve within 60 minutes. In contrast, normal clots covalently modified by factor XIIIa remain insoluble for at least 24 hours. This is a qualitative assay, and as little as 5% of the normal factor XIII activity level can render a clot insoluble in urea. Unfortunately, clot stability testing is not well standardized. If clot solubility is found, a mixing study with normal plasma is recommended to exclude factor XIII inhibitor. Deficiency of α2-antiplasmin may also cause a bleeding disorder with normal coagulation screening studies and increased urea clot solubility; a specific assay for α2-antiplasmin should be considered, to exclude this possibility. Quantitative measurements of factor XIII activity can also be done, and these tests are useful to confirm factor XIII deficiency that is suspected based on an abnormal qualitative clot solubility assay. Specialized laboratories may measure either ammonia production (an end product of the factor XIIIa reaction) or the incorporation of fluorescent or radioactive amines (such as dansylcadaverine) into proteins such as casein. However, the most sensitive and specific measurement of factor XIIIa activity remains the functional assay measuring the stability of a covalently cross-linked fibrin clot. Finally, immunologic based assays that detect factor XIII antigen are available, such as ELISAs specific for either the A or B subunits of factor XIII. Results of immunologic assays correlate with factor XIII activity assays, but immunologic assays are not widely available.

PROTHROMBIN DEFICIENCY

Inherited prothrombin deficiency is an exceedingly rare, autosomal recessive bleeding disorder, with a frequency of <1 in 1 million. To date, <40 mutations have been identified from <100 reported cases (Ref. 296, isth.org database). As with some of the other factor deficiencies, the frequency of prothrombin deficiency is greater in countries where consanguineous marriages occur. Phenotypically, prothrombin deficiency is classified as either hypoprothrombinemia (type I), distinguished by reduced prothrombin activity and reduced prothrombin antigen, or dysprothrombinemia (type II), distinguished by reduced prothrombin activity but normal prothrombin antigen.

Pathophysiology
Similar to deficiencies of the other vitamin K-dependent coagulation factors, prothrombin deficiencies result from mutant prothrombins that are either CRM-negative (hypoprothrombinemia) or CRM-positive (dysprothrombinemia). The CRM-negative form may be more common, is a product of missense, nonsense, insertion, or deletion mutations, and is characterized by a true deficiency of prothrombin, with a strong correlation between functional assays and immunoassays. The CRM-positive form is a product of missense mutations and is characterized by antigenically competent prothrombin, usually in quantities much greater than the associated functional activity.

By convention, these mutant prothrombins have been named according to the proband's origin, e.g., prothrombin Cardeza. The prevalence of prothrombin deficiency in Puerto Ricans led to the recent description of several unrelated families of Puerto Rican ancestry having a common mutation, prothrombin Puerto Rico I, with characteristics of both hypoprothrombinemia and dysprothrombinemia. Dysprothrombins with amino acid substitutions at or near the factor Xa cleavage sites inhibit activation to thrombin. Amino acid substitutions elsewhere in prothrombin can affect the function determined by that region, including the catalytic domain (Quick I, Molise, Perijé), and fibrinogen-binding (Quick I). Figure 53.9 summarizes some of these mutant prothrombins and their concomitant functional abnormalities.

Clinical Features

Epistaxis, menorrhagia, and posttraumatic bleeding are the most common complaints. Hemarthroses and muscle hematomas have also been reported. The extent of prothrombin deficiency does not necessarily correlate with clinical
bleeding. Although hemostasis can be maintained by prothrombin levels >25% of normal, significant bleeding is usually seen when prothrombin levels are <2% of normal. Of the severe prothrombin deficiency patients reported to the Rare Bleeding Disorders Registry, 20% experienced intracranial bleeding. Prothrombin-deficient heterozygotes have 40% to 60% of normal prothrombin activity; compound heterozygotes and homozygotes usually have <10% of normal prothrombin activity. As of yet, no human cases of total prothrombin deficiency have been reported. Based on studies with knockout mice, such a complete deficiency is thought to be incompatible with life, leading to a loss of vascular integrity, arrested development, and tissue necrosis, ultimately resulting in embryonic or neonatal lethality. This effect is thought to result from a developmental activity of thrombin on yolk sac vasculature. The genetic elimination of prothrombin in an adult mouse model was also not compatible with survival.

Laboratory Diagnosis

A summary of laboratory findings in prothrombin deficiency is included in Table 53.5. Prothrombin deficiency is associated with normal thrombin times but prolonged PT and aPTT, which can be corrected in mixing studies. Specific factor assays for prothrombin are used in diagnosis. Acquired prothrombin deficiency, caused by either vitamin K deficiency or an antiprothrombin antibody associated with antiphospholipid antibodies, should be considered before making the diagnosis of inherited prothrombin deficiency. Fresh-frozen plasma (FFP) and prothrombin complex concentrates (PCCs) are used to treat prothrombin deficiency, as outlined later, in Table 53.8.

Note: The replacement therapy regimens suggested in this table are for major bleeding or surgical prophylaxis. Patients with minor bleeding may require lower dosages of these replacement products. Confirmation of hemostatic levels of the appropriate coagulation factor being replaced should be done, with dosage adjustments performed as needed.

<sup>a</sup>Labeled in ristocetin cofactor units. Alphanate and Wilate can also be used to treat von Willebrand
disease.

\textsuperscript{b} Recommended only if purified factor replacement therapy is not available.

\textsuperscript{c} Not routinely available in the United States.

\textsuperscript{d} Plasma after removal of cryoprecipitate is satisfactory.

\textsuperscript{e} Prothrombin complex concentrates are thrombogenic and should be used only for major bleeding or major surgery. Antifibrinolytic drugs (\(\varepsilon\)-aminocaproic acid, tranexamic acid) should not be used in conjunction with prothrombin complex concentrates.

\textsuperscript{f} A factor XIII concentrate is now available in the United States. See text for details.

\textbf{FACTOR V DEFICIENCY}

Inherited factor V deficiency, also known as labile factor deficiency, proaccelerin deficiency, and parahemophilia, is a rare autosomal recessive bleeding disorder first described by Owren,\textsuperscript{308} with an estimated frequency of 1 in 1 million.\textsuperscript{295} To date, \(>100\) mutations have been identified from \(>200\) reported cases,\textsuperscript{309,310,311} and a database at isth.org lists \(>120\) factor V mutations. As with some of the other factor deficiencies, the frequency of factor V deficiency is greater in countries where consanguineous marriages occur.\textsuperscript{295} Phenotypically, factor V deficiency is classified as either type I, distinguished by reduced factor V activity and reduced factor V antigen, or type II, distinguished by reduced factor V activity but normal factor V antigen.

\textbf{Pathophysiology}

The majority of factor V deficiencies result from a failure to either synthesize or secrete factor V. The mutants responsible for these deficiencies are CRM-negative (type I); CRM-positive factor V mutations (type II) have also been detected.\textsuperscript{312} The CRM-negative form is a product of missense, nonsense, insertion, or deletion mutations and is characterized by a true deficiency of factor V, with a strong correlation between functional assays and immunoassays. Factor V New Brunswick, a CRM-positive form, is caused by a missense mutation and is characterized by antigenically competent factor V with reduced activity, most likely due to reduced stability of factor Va.\textsuperscript{313,314}

By convention, many of these mutant factor Vs have been named according to the proband’s origin, e.g., factor V Stanford\textsuperscript{315} and factor V Ogden.\textsuperscript{316} Factor V Quebec is associated with a moderate reduction in plasma factor V levels and a severe reduction in platelet factor V, but also other \(\alpha\)-granule proteins, including multimerin (a factor V carrier molecule within platelets), and is thus more properly considered a platelet disorder.\textsuperscript{317} Approximately 20\% of the circulating pool of factor V is contained within platelets. This platelet pool of factor V and low levels of tissue factor pathway inhibitor seen in factor V deficient patients may explain the milder bleeding phenotype in this bleeding disorder.\textsuperscript{310}

\textbf{Clinical Features}

Epistaxis, menorrhagia, and posttraumatic bleeding are the most common complaints. Trauma-induced hemarthroses and muscle hematomas have also been reported.\textsuperscript{295} Gastrointestinal or CNS bleeding is observed very rarely. Although neonatal bleeding has seldom been observed, factor V deficiency has been associated with other congenital abnormalities.\textsuperscript{318} Hemostasis can be maintained by factor V levels \(>10\%\) to \(20\%\) of normal, but moderately severe bleeding
is usually seen when factor V levels are <10% of normal. Factor V-deficient heterozygotes have 40% to 60% of normal factor V activity; compound heterozygotes and homozygotes usually have <10% of normal factor V activity. Bleeding symptoms may correlate better with platelet factor V content rather than the plasma factor V level. 317

A genetic model of factor V deficiency utilizing factor V-knockout mice underscores the importance of factor V in not only hemostasis but development, as fetal loss in utero is markedly increased. 319 Based on these knockout-mouse studies, complete factor V deficiency is apparently incompatible with life, but <0.1% of normal factor V activity is sufficient to rescue completely deficient mice. 320 As of yet, no human cases of total factor V deficiency have been reported, and even patients with a homozygous or compound heterozygous factor V deficiency usually have some residual factor V activity.

Laboratory Diagnosis

A summary of laboratory findings in factor V deficiency is included in Table 53.5. Factor V deficiency is associated with P.1167

normal thrombin times but prolonged PT and aPTT, which can be corrected in mixing studies. A PT-based factor V assay or an ELISA can be used to verify quantitative reductions in factor V. Good results have been obtained using aged oxalated or ethylenediaminetetraacetic acid plasma as a factor V-deficient substrate, 321 as well as artificially depleted substrate plasmas. Acquired factor V deficiency, caused by liver disease, disseminated intravascular coagulation, or antibodies to factor V, should be excluded before making the diagnosis of inherited factor V deficiency. Upon confirmation of factor V deficiency, however, a specific assay for factor VIII should also be performed to rule out the rare combined factor V/factor VIII deficiency, 322 treatment of which entails a different replacement therapy. Currently, FFP is used to treat factor V deficiency, as outlined later, in Table 53.8.

FACTOR VII DEFICIENCY

Factor VII deficiency was first described in 1951 by Alexander et al. under the name serum prothrombin conversion accelerator (SPCA) deficiency. Approximately 200 cases of true factor VII deficiency have been reported, and the population prevalence is estimated to be 1 in 500,000, 295 making it the most common of the “rare bleeding disorders.” Also known as stable factor or proconvertin deficiency, the condition is inherited as an autosomal recessive trait that produces severe deficiency in the homozygote and mild deficiency, usually without clinical manifestations, in the heterozygote. As in other rare bleeding disorders, it is more common in cultures where consanguineous marriage is practiced.

Pathophysiology

Factor VII is secreted as a single-chain proenzyme glycoprotein of ~50 kDa by hepatocytes. Factor VII has the shortest plasma half-life of all coagulation factors (~5 hours), and its plasma concentration is very low, ~500 ng/ml. 322 Factor VIIa is detectable in trace amounts in normal plasma, 324 and sensitive assays indicate that ~1% of circulating factor VII is in the activated form. 324 The circulating half-life of activated factor VIIa is approximately 2.5 hours. 325 Tissue factor increases the rate of activation of factor VII significantly, 324 and current theory is that coagulation is initiated in the presence of tissue factor that is exposed at sites of vascular injury or contributed by blood monocytes. 326

The factor VII gene includes nine exons and spans 128 kb on chromosome 13. 327 It is located just upstream of the factor X gene. In a mouse knockout model in which factor VII is completely lacking, fatal hemorrhage occurs perinatally. 328 In humans, factor VII deficiency occurs as a recessive trait resulting from homozygous or compound heterozygous mutations. Many mutations of the factor VII gene have been reported, with >200 mutations listed in 2012 in a database at isth.org. Most reported genetic defects are single-base substitutions, including missense, splice-site, and nonsense mutations. Most mutations affect only a few patients, but one mutation (Ala242Val) was detected in 23 “apparently” unrelated Jews in Israel. 296 More extended haplotype testing suggests a “founder effect”. 296 Although Dubin-Johnson syndrome is associated with factor VII deficiency, 330 the genetic defect underlying that syndrome is located on chromosome 10, and the association of Dubin-Johnson syndrome and factor VII deficiency may simply reflect a high consanguinity rate in one population. 281 Combined deficiency of factor VII along with the other vitamin K-dependent coagulation proteins or as a deficiency with a single other coagulation protein has been reported in rare families (see below).

Clinical Features

Only severe factor VII deficiency is associated with hemorrhagic symptoms, and heterozygous carriers are asymptomatic. Factor VII levels do not completely correlate with the severity of symptoms, and this may in part reflect heterogeneity in the molecular basis of factor VII deficiency or the tissue factor-containing reagents used to quantitate the factor VII activity.
level in patients. However, patients with levels of >10 to 15 IU/dl rarely manifest bleeding. Patients with levels between 5 and 10 IU/dl tend to have milder symptoms, such as epistaxis, gingival bleeding, or genitourinary and gastrointestinal bleeding. Patients with levels <1 IU/dl may have symptoms similar to patients with hemophilia A or hemophilia B, with spontaneous joint and deepmuscle bleeding, but some patients with factor VII levels of <1 IU/dl have been asymptomatic. Bleeding into the CNS is particularly common, being observed in 15% to 60% of patients with factor VII levels <2 IU/dl. CNS bleeds often present during the neonatal period, and the risk of recurrence is high enough that prophylaxis with factor replacement therapy should be considered in patients who present with this complication. The severity of bleeding after trauma or surgical procedures varies to a surprising degree in this disorder, with oral and urogenital cavity procedures being particularly troublesome, possibly reflecting the high local fibrinolytic activity in these regions of the body. Prior clinical bleeding symptoms are an important prognostic factor predicting surgical bleeding complications in patients with factor VII deficiency.

Some reports indicate that patients with factor VII deficiency may also be more prone to various thromboembolic manifestations. The explanation for this phenomenon is unknown, but thrombophilic markers have been observed in most of these cases.

Laboratory Diagnosis

In factor VII deficiency, normal results are obtained with coagulation tests that bypass the extrinsic pathway of coagulation and factor VII (Table 53.5), that is, the PTT, thrombin time, and, if tested, the Stypven (Russell viper venom) time. Thus, a diagnosis of factor VII deficiency is suspected in a patient with a life-long history of bleeding when there is an isolated prolonged PT and normal PTT. The PT will correct on 1:1 mixing of patient plasma with normal plasma, but a diagnosis of factor VII deficiency requires a specific factor VII assay for confirmation. Use of human thromboplastin in the PT assay is recommended. A factor VII mutation (factor VII Padua) has been described in African-American patients who are asymptomatic; this defect results in low factor VII activity levels when rabbit brain thromboplastin is used, but normal factor VII activity when human thromboplastin is used. Confirmation of low factor VII antigen level can be obtained by ELISA assay. Levels of factor VII in heterozygous carriers overlap the normal range. Before making a diagnosis of factor VII deficiency, one should exclude causes for acquired abnormalities such as vitamin K deficiency, liver disease, or warfarin therapy. Also, rare conditions such as combined deficiency of all vitamin K-dependent factors, and combined factor VII and factor X deficiency should be considered. Autoantibody directed to factor VII occurs, but few case reports have been published.

Phenotypically, patients have been characterized by evaluating plasma levels of factor VII antigen (or CRM). CRM-negative patients have low factor VII antigen as a result of the lack of synthesis or increased factor clearance, whereas CRM-positive patients produce factor VII that is detected antigenically but is structurally abnormal and with deficient function. CRM-reduced individuals presumably represent a combination of these two entities. Further complexity of the factor VII-deficient phenotype is introduced because of insensitivity of some factor VII activity assays to low levels of factor VII or from variability in assays that is introduced by the use of varying animal sources of tissue thromboplastin.

Treatment of factor VII deficiency with recombinant human factor VIIa, plasma, or PCCs is discussed later in this chapter. Although the necessity for correcting factor VII deficiency has been questioned, patients who have factor VII deficiency and a history of excessive clinical bleeding should be given replacement therapy before surgery. Numerous clinical reviews confirm that the patient’s clinical bleeding history is the best predictive parameter of bleeding risk. It has been reported that patients with factor VII deficiency who have factor VII levels >10% when assayed using human thromboplastin reagents have minimal bleeding symptoms.

FACTOR X DEFICIENCY

Inherited factor X deficiency, first described in the Prower and Stuart kindreds, is a rare autosomal recessive bleeding disorder with an estimated frequency of 1 in 1 million. Factor X deficiency represents ~10% of all rare bleeding disorders. To date, >100 mutations have been identified, with the majority being missense mutations. As with some of the other factor deficiencies, the frequency of factor X deficiency is greater in countries where consanguineous marriages occur. Phenotypically, factor X deficiency is classified as either type I, distinguished by reduced factor X activity and reduced factor X antigen, or type II, distinguished by reduced factor X activity but normal factor X antigen.

Pathophysiology
The CRM-negative form is a product of missense, insertion, or deletion mutations, and is characterized by a true deficiency of factor X, with a strong correlation between functional assays and immunoassays. The CRM-reduced and positive forms are products of missense mutations and are characterized by low to normal levels of antigenically competent factor X but with disproportionately reduced factor X activity. Deletion mutations result in premature termination and thus the loss of the factor X catalytic domain, whereas missense mutations may affect not only the catalytic domain, but phospholipid binding, activation, secretion, or even synthesis of factor X. By convention, these mutant factor Xs have been named according to the proband’s origin, e.g., factor X San Antonio I, factor X Friuli, and factor X St. Louis II.

Clinical Features

The symptoms of factor X deficiency tend to be the most severe of the inherited coagulation deficiencies. Epistaxis, menorrhagia, and posttraumatic bleeding are common complaints, and hemarthroses and hematomas have been reported in two-thirds of factor X-deficient patients. Umbilical stump, gastrointestinal, and CNS bleeding are also frequently observed. Heterozygotes generally appear asymptomatic, as hemostasis can be maintained by factor X levels >10% of normal. On the other hand, compound heterozygotes and homozygotes with factor X levels <1% of normal suffer from severe bleeding. Experiments utilizing factor X-knockout mice resulted in either neonatal death or postnatal death, caused by intraabdominal or intracranial bleeding.

Laboratory Diagnosis

A summary of laboratory findings in factor X deficiency is included in Table 53.5. Factor X deficiency is associated with normal thrombin times but prolonged PT, aPTT, and often Stypven (Russell viper venom) time, particularly among the CRM-negative variants. Unfortunately, factor X-deficiency variants have been described with isolated prolonged PT or aPTT values. Upon ruling out other inherited bleeding disorders, a factor X-specific assay can be used to verify factor X deficiency. Acquired factor X deficiency, caused by liver disease, warfarin therapy, amyloidosis, or antibodies to factor X, should be excluded before making the diagnosis of inherited factor X deficiency. Currently, FFP or PCCs are used to treat factor X deficiency, as outlined in Table 53.8.

FACTOR XI DEFICIENCY

Factor XI deficiency (plasma thromboplastin antecedent deficiency) was first recognized by Rosenthal et al. in 1953 and was called hemophilia C. Factor XI deficiency is transmitted as an incompletely recessive autosomal trait manifested either as a major defect in homozygous patients with factor XI levels <20 IU/dl or as a minor defect in heterozygous patients with levels ranging from 30 to 65 IU/dl. The incidence of this disorder varies widely, with estimates of frequency in the general population being 1 in 1 million persons. A particularly high frequency of the disorder exists in people of Jewish extraction, with an estimated gene frequency of 5% to 11% in Ashkenazi Jews. Up to 0.3% of this population is homozygous for factor XI deficiency.

Factor XI deficiency has been reported to result from three major types of mutations: Type I mutations result in disruption of splicing; type II mutations result in a stop codon and nonfunctional molecule; and type III mutations result in amino acid substitutions and a dysfunctional molecule. Patients with type II mutations have the greatest bleeding tendency. Type II and III mutations are most common in Ashkenazi Jews. The type II mutation is also common in Iraqi Jews, who may represent the ancient gene pool of Jews.

A more recent classification scheme for factor XI-deficiency cases that are CRM-negative includes three mechanistic categories: (a) Mutations that reduce or prevent polypeptide synthesis, (b) mutations resulting in polypeptides that fail to form intracellular dimers, and (c) mutations resulting in polypeptides that form dimers that are not secreted. Mechanism (c) may account for some kindreds with apparent autosomal dominant factor XI deficiency. In general, most factor XI mutations result in decreased factor XI protein proportionate to factor XI clotting activity. Over 100 factor XI mutations have been reported (database at isth.org).

Clinical Features

The clinical manifestations of factor XI deficiency are extremely variable and generally milder than those of hemophilia A or B. As a rule, spontaneous bleeding is rare, and hemorrhage usually occurs only after trauma or a surgical procedure. The extent of factor XI deficiency may not correlate with bleeding. Hemarthrosis is uncommon, but delayed bleeding is a particularly treacherous feature in some patients, especially for surgical procedures involving tissues rich in fibrinolytic activity. Mild factor XI deficiency may be associated with Noonan syndrome and Gaucher disease. Hemorrhagic manifestations may be absent in certain patients, especially in those with type I mutations. Approximately onehalf of heterozygous factor XI-deficient patients have a bleeding tendency.
deficiency should be considered in female patients with menorrhagia. In one study of women with menorrhagia, the prevalence of factor XI deficiency was 4%. Laboratory Diagnosis

In the homozygous form of factor XI deficiency, the PTT is prolonged. In most of these patients, factor XI levels in the plasma are in the range of 3 to 15 IU/dl. In people with the mild form of the disorder, the PTT often is normal because most PTT reagents are insensitive to mild factor XI deficiency. Abnormalities in the plasma of such mildly affected patients may be removed by freezing. Specific factor assays are used to diagnose factor XI deficiency. The bleeding time and thrombin time are normal. Factor XI deficiency has also been reported in combination with inherited factor IX deficiency (type VI familial multiple factor deficiency). Treatment of factor XI deficiency is discussed later in this chapter in the section "Plasma".

FACTOR XII DEFICIENCY

Factor XII deficiency was discovered by Ratnoff and Colopy during routine preoperative coagulation studies on John Hageman, an adult who had no evidence or history of abnormal bleeding. The disorder, subsequently named Hageman factor deficiency, is inherited as an autosomal recessive trait. Factor XII deficiency has been identified in 1.5% to 3.0% of a healthy blood donor population. Pathophysiology

The plasma of most patients with factor XII deficiency does not contain material that reacts with antibodies to this factor. Radioimmunoassays with heterologous antibodies have demonstrated antigenic material identical to normal factor XII in only 2 of 42 and 2 of 31 separate kindreds. One large study of 31 factor XII-deficient kindreds identified most mutations in the serine protease domain.

Clinical Features

Factor XII deficiency usually is not associated with hemorrhagic manifestations. It is noteworthy that myocardial infarction and thrombophlebitis have been observed in patients with severe factor XII deficiency, and that Hageman died of thromboembolic complications. It was originally thought that factor XII deficiency might actually predispose to thrombosis, possibly as the result of deficient activation of fibrinolysis. However, more recent surveys indicate that factor XII deficiency is not associated with an excessive risk of thrombosis; thrombotic events in factor XII-deficient patients may be explained by the presence of other prothrombotic gene defects in these patients.

In vitro experiments suggest that factor XII has a central role in the initiation of the intrinsic pathway of coagulation and mediates a variety of other processes such as fibrinolysis, complement activation, inflammation, and chemotaxis. The physiologic importance of these factor XII-mediated phenomena remains obscure, because patients with even severe deficiency of this proenzyme reveal no evidence of deficiency or aberrance of host defenses.

The discrepancy between in vitro evidence of grossly abnormal blood coagulation and the absence of hemorrhagic manifestations in factor XII deficiency poses a fundamental question regarding the role of the intrinsic coagulation pathway in hemostasis and the significance of laboratory measurements of coagulation. Alternative mechanisms for initiation of coagulation are discussed in Chapter 18.

Results of an animal model of arterial thrombosis have again raised the question of whether factor XII has a role in thrombosis. When factor XII-deficient mice were exposed to arterial vascular injury, defective platelet-rich thrombosis was observed, a defect that was corrected by administration of exogenous factor XII. Results from a mouse stroke model indicate that factor XII deficiency protects affected mice from ischemic brain injury. Although a large body of clinical evidence suggests that factor XII is not important for hemostasis, the animal model data suggest that factor XII is important for pathologic (arterial) thrombosis, perhaps by factor XII-mediated factor XI activation.

Laboratory Diagnosis

Factor XII-deficient patients typically present with a negative history of clinical bleeding and an isolated, prolonged PTT that corrects with mixing with normal plasma. The coagulant effects of contact activation are diminished or absent in plasma from subjects with factor XII deficiency. Normal levels of factor XII range from 50 to 150 IU/dl. As with factor XI, accurate assays of factor XII depend on a source of deficient substrate plasma. Laboratory demonstration of the heterozygous state is difficult. The mean level of factor XII in the plasma of carriers is “50% of normal, but observed values
are distributed in a bimodal manner, an observation interpreted as suggesting the presence of multiple abnormal alleles.

PREKALLIKREIN DEFICIENCY

An additional abnormality of the intrinsic pathway of coagulation was defined and named Fletcher factor deficiency by Hathaway in 1965. In 1972, Wuepper et al. established that Fletcher factor was identical to plasma prekallikrein, a protein that had been studied for many years in terms of its role in inflammation. The convergence of these two avenues of research demonstrated that prekallikrein, in addition to its role in inflammation and chemotaxis, is essential for the optimal activation and fragmentation of factor XII in the early steps of coagulation.

Pathophysiology

Prekallikrein deficiency apparently is inherited as an autosomal recessive trait, although genetic information is scanty. ~80 cases have been reported. Heterozygotes with ~50% of normal plasma levels of prekallikrein can be identified. The disorder is associated with the absence of antigenically competent prekallikrein in most cases.

Clinical Features

Prekallikrein deficiency, like factor XII deficiency, is not associated with abnormal bleeding. Studies of affected patients revealed variable deficiencies in stress-induced fibrinolysis, chemotaxis, immediate and delayed inflammatory responses, and responses to preformed permeability-enhancing activity. These abnormalities are not associated with any apparent deleterious effects. Most patients with prekallikrein deficiency are of African ancestry. Prekallikrein deficiency is not associated with an excessive risk of thrombosis.

Laboratory Diagnosis

Prekallikrein deficiency is associated with a moderate prolongation of the PTT. The PT and thrombin time are normal. The time required for release of vascular plasminogen activators in vivo after venous occlusion is prolonged. The disorder is characterized by abnormally slow contact activation. Thus, the PTT may be normalized by prolonged incubation (10 to 15 minutes) of plasma with particulate activators. This phenomenon appears to result from autoactivation of factor XII. Specific assays for prekallikrein are based on traditional coagulation techniques and chromogenic substrate assays.

HIGH-MOLECULAR-WEIGHT KININOGEN DEFICIENCY

A unique inherited coagulation abnormality associated with deficiencies of kinin formation and fibrinolysis was described in three unrelated kindreds in 1975. The disorder received the names of the affected families (Fitzgerald trait, Williams trait, Flaujeac trait, and Fujiwara trait) and has subsequently been found to be the result of deficiency of HMWK. Patients with this disorder are asymptomatic. The data suggest that HMWK functions in its nonactivated form as a cofactor, binding prekallikrein and factor XI to anionic surfaces, accelerating their activation by surface-bound factor XIIa (see Chapter 18).

Pathophysiology

Deficiency of HMWK appears to be inherited as an autosomal recessive trait. Mildly affected heterozygotes have been identified in some families. Detailed biochemical studies of five kindreds revealed considerable heterogeneity. Thus, HMWK levels in the plasma ranged from nil to 50 IU/dl. With the exception of the Fitzgerald kindred, associated deficiencies in low-molecular-weight kininogen have been demonstrated in all families. Variable deficiency of prekallikrein also was present in the Williams, Fitzgerald, and Fujiwara kindreds; prekallikrein levels were normal in the Flaujeac kindred. Immunologic studies revealed the absence of kininogen antigen in the homozygotes and 50% of normal levels in the heterozygotes. The associated prekallikrein deficiency also apparently is of the CRM-negative type. The absence of the stabilizing effects of HMWK may lead to accelerated degradation and deficiency of prekallikrein in this disorder. HMWK deficiency is not associated with excessive clinical bleeding or thrombosis. There is limited information on the genetic basis for HMWK deficiency.

Laboratory Diagnosis

Deficiency of HMWK is manifested by an isolated, prolonged PTT. The PTT assay results are abnormal whether particulate or soluble contact activators are used, and values are not normalized by prolonged incubation of the plasma with particulate activators.
MISCELLANEOUS INHERITED COAGULATION DISORDERS

Combined Defects

Of unusual interest are reports concerning the presence of combined deficiencies of two or more coagulation factors. Deficiency of factors V and VIII, and combined deficiency of various vitamin K-dependent factors appear to be the most common combined deficiency disorders. Several other combined coagulation defects have been described (Table 53.1).

Deficiency of Factors V and VII

Combined deficiency of factors V and VIII, reported in <200 patients, is inherited as an autosomal recessive trait. This combined defect manifests clinically with mild mucosal and cutaneous bleeding. Severe posttraumatic and postsurgical bleeding is common (e.g., after tooth extractions). Hemarthrosis is rare. Laboratory findings in homozygous patients include a prolonged PTT and PT and levels of factor VIIIc and Vc that average 15 IU/dl. Levels of factor VIIIAg (VIIIcAg) and VAg are low and are proportional to those obtained by coagulation measurements.

Linkage analysis of combined factor V and VIII deficiency to chromosome 18q excluded all known hemostasis proteins, suggesting that the basis for the disease is a defect affecting a process common to the biosynthesis of factors V and VIII. Indeed, subsequent studies by two groups identified the genetic basis for most patients with the disorder as mutations in the endoplasmic reticulum-Golgi intermediate compartment protein 53 (also known as lectin mannose-binding type 1 [LMAN1]). Other patients with this combined defect have mutations in another protein termed multiple coagulation factor deficiency-2 (MCFD2).

In addition to affecting levels of the vitamin K-dependent factors, skeletal abnormalities may also be seen, resulting from effects on bone Gla proteins. Levels of the vitamin K-dependent proteins range from <12% to 50% of normal; thus, clinical bleeding manifestations may vary widely. Both the PT and PTT are prolonged. Measurement of serum warfarin levels may be necessary to exclude surreptitious anticoagulant use. Mutations in the γ-glutamyl carboxylase gene have been identified in a few patients with this disorder, and another group has identified a second gene locus (vitamin K epoxide reductase complex, subunit 1 [VKORC1]) causing this defect. Some patients have clinical improvement and correction of the coagulopathy with vitamin K therapy.

Combined Deficiency of Factors II, VII, IX, and X

Combined deficiency of factors II, VII, IX, and X is an autosomal recessive coagulation disorder that has been identified in only a small number of patients. In addition to affecting levels of the vitamin K-dependent factors, skeletal abnormalities may also be seen, resulting from effects on bone Gla proteins. Levels of the vitamin K-dependent proteins range from <12% to 50% of normal; thus, clinical bleeding manifestations may vary widely. Both the PT and PTT are prolonged. Measurement of serum warfarin levels may be necessary to exclude surreptitious anticoagulant use. Mutations in the γ-glutamyl carboxylase gene have been identified in a few patients with this disorder, and another group has identified a second gene locus (vitamin K epoxide reductase complex, subunit 1 [VKORC1]) causing this defect. Some patients have clinical improvement and correction of the coagulopathy with vitamin K therapy.

ABNORMALITIES OF PROTEASE INHIBITORS

Rare abnormalities of three plasma antiproteases, which are associated with bleeding, are described in this section. Other, more numerous abnormalities of the components of the antiprotease system and the fibrinolytic enzyme system that may be associated with thrombosis are discussed in Chapter 55.

α2-Antiplasmin Deficiency

Severe bleeding, including hemarthrosis, was associated with deficiency of α2-antiplasmin in several kindreds. This disorder appears to be inherited as an autosomal recessive trait, in which heterozygotes have detectable deficiencies of this antiprotease but only mild bleeding. CRM-positive and CRM-negative forms have been identified. A report published in 2008 identified 15 cases; seven cases had genetic abnormalities defined.

Most cases had mutations in exon 10, which is the location of the active site, and the plasminogen-binding site. Bleeding presumably is the result of premature lysis of hemostatically important fibrin plugs caused by unregulated plasmin activity. The laboratory findings are variable. Hypofibrinogenemia and increased clot solubility in urea have been reported. Fibrinogen degradation product levels and platelet counts were normal in most cases. When assayed qualitatively by fluorometric or photochromogenic techniques, α2-antiplasmin levels usually are <10 IU/dl. Treatment of bleeding episodes with tranexamic acid and other antifibrinolytic agents may be helpful.

Plasminogen Activator Inhibitor-1 Deficiency

Deficiency of plasminogen activator inhibitor (PAI)-1 is associated with a moderate bleeding disorder. Only 10 to 20 families have been reported. One study investigated a large kindred with multiple family members who were homozygous for this disorder. Homozygous patients, but not heterozygous patients, exhibited clinical bleeding. The null gene mutation responsible for PAI-1 deficiency was identified in this kindred. Other cases have been described. The basis of the bleeding is similar to that described for α2-antiplasmin deficiency: Excessive plasmin activity, caused in this case by excessive activation of plasminogen.

2680
Laboratory screening studies are typically normal, but the euglobulin clot lysis time is shortened. It is recommended that measurement of PAI-1 antigen and activity in both serum and plasma be done to screen for PAI-1 deficiency. The in vitro activities and clinical relevance of PAI-1 have been reviewed.

α₁-Antitrypsin Pittsburgh

A life-long hemorrhagic diathesis in a 14-year-old boy was associated with a unique qualitatively abnormal form of α₁-antitrypsin (antithrombin III Pittsburgh). This disorder is the result of the substitution of a single amino acid (arginine for methionine at position 358 in the α₁-antitrypsin molecule). This site corresponds to the P1 residue or “bait” amino acid of the molecule, and the substitution produced a mutation of α₁-antitrypsin, a weak antiprotease with little affinity for thrombin, into a potent antithrombin that impaired blood coagulation to a significant degree. The mutant molecule also is a potent inhibitor of factor Xla, factor XIf, and kallikrein, a property lacking in the normal molecule. The plasma concentration of the abnormal molecule increased after trauma, possibly as the result of an acute-phase response. The patient ultimately died of bleeding. A second family was reported with the disorder; it is inherited in an autosomal dominant manner. Other amino acid substitutions at position 358 have been produced artificially by genetic engineering.

TREATMENT OF INHERITED COAGULATION DISORDERS

The principal treatment for the inherited coagulation disorders is replacement therapy—that is, the intravenous administration of the required factor in the form of blood products derived from normal people or animals, or recombinant coagulation proteins. Estrogens may be useful in treating female patients with vWD. Topical hemostatics (thrombin) may be temporarily effective in small injuries or nose bleeds, and certain other treatments such as DDAVP and inhibitors of fibrinolysis are useful adjunctive therapy under specific circumstances such as dental surgery.

Replacement Therapy

The objective of replacement therapy is to obtain a concentration of the required factor at the bleeding site such that coagulation may become hemostatically effective. The pharmacokinetic (PK) properties of the various coagulation factors (Table 53.9) and clinical assessment of the severity of the hemorrhagic risk are important considerations in determining appropriate doses and duration for therapy. Replacement products are dosed on the basis of actual body weight (Tables 53.8 and 53.10) or plasma volume. This latter method may be more precise in patients who do not have a normal plasma volume because of bleeding. In one such method, blood volume is considered to be 7% of body weight; plasma volume is then calculated using the patient’s hematocrit. Next, the therapeutic objective is assessed (e.g., the desired incremental increase in factor VIII level). For example, if a patient with severe hemophilia A (<1% factor VIII) has a plasma volume of 3,000 ml and requires major surgery, the target factor VIII level should be 100% of normal. Infusion of 3,000 IU of factor VIII would result in a calculated peak factor VIII level of 1 IU/ml (100% of normal). Peak factor levels should be monitored to determine whether the expected response was achieved, and then further dosage adjustments can be calculated if necessary. Subsequent doses are scheduled according to the predicted half-life of the factor, with laboratory tests to verify actual levels when appropriate. Case reports and clinical experience detailing management of hemophilia A during surgery have been published.

* Patients undergoing major surgery or experiencing major bleeding should receive dosages to achieve higher factor levels; for example, patients with hemophilia A should have replacement such that factor VIII levels approach 100% of normal. For patients with factor XIII deficiency and major trauma, plasma factor XIII levels of at least 25% should be achieved.

Hemostatic Levels

The hemostatic level may be defined as the lowest plasma concentration of a given coagulation factor that is required for normal hemostasis (Table 53.9). This value was determined by purely empiric means—that is, by measurement of the blood levels of the deficient factor at which bleeding appeared to stop in patients with one of the inherited coagulation disorders during the course of replacement therapy. Such estimates obviously may be inaccurate. In patients with hemophilia A, the hemostatic level of factor VIIIc is 25 to 30 IU/dl; in those with hemophilia B, values range from 20 to 60 IU/dl. However, for patients with major trauma or those undergoing surgery, higher plasma levels of these coagulation proteins should be achieved (i.e., 100% for factors VIII or IX; 25% to 50% for factor XIII).

In Vivo Recovery and Survival of Infused Coagulation Factors

When a coagulation factor is infused intravenously into a recipient who is deficient in that factor, the levels present in the circulation after intravascular mixing usually are significantly lower than those that would be expected from mere dilution in the recipient’s plasma. That this initial in vivo recovery of infused coagulation factors (Table 53.9) is <100% presumably is the result of loss of these proteins from the intravascular space. The adsorption of coagulation factors by platelets and various cell and vascular surfaces may also be involved. The initial recovery of infused coagulation factors is difficult to quantify and ranges from nearly 100% for factor XI to as low as 30% for factor IX. Typically, because the range of in vivo recovery in a population is so variable, clinicians will determine the in vivo recovery for each individual by laboratory testing of blood samples drawn 10 to 20 (peak level) minutes after the therapeutic infusion.

Note: Because weight-based calculations may not correctly predict plasma volumes in bleeding patients, confirmation of the hemostatic level of the coagulation factor being replaced should always be performed for patients with major bleeding indications, with appropriate dosage adjustments performed based on these results.

- Single dose of 15 IU/kg or equivalent amounts of concentrated product usually are sufficient.

- Recommended only if purified factor replacement therapy is not available. Antifibrinolytic therapy should not be used with prothrombin complex concentrates.

- Initial in vivo recovery of active factor varies somewhat depending on preparation.

- Recombinant factor IX may require higher doses.

After in vivo mixing is complete, the activity of most coagulation factors in the plasma declines in a biphasic manner—that is, an initial rapid loss of activity is followed by a more gradual decline (Fig. 53.10). The first or rapid phase presumably is the result of diffusion into extravascular pools. This diffusion half-life ranges from minutes for factor VII to several hours for factor VIII. In general, it is the rapidity of this first phase, together with the initial in vivo recovery of the particular factor, that determines the necessity for and the size of the preliminary or loading dose of therapeutic product.

The second or slow phase of the survival curve presumably is the result of degradation and reflects the true biologic half-life of the infused factor (Table 53.9; Fig. 53.10). This parameter, together with the hemostatic level for the factor of concern, is the main determinant of the frequency of administration and the size of the maintenance dose of therapeutic product. For example, ~80% of factor VIII infused is initially recovered in the circulation; its initial (diffusion) and subsequent (biologic) half-lives are ~6 and 12 hours, respectively. Thus, in the treatment of patients with hemophilia A, doses are administered every 8 to 12 hours. In patients with hemophilia B, the initial recovery of factor IX is 50% or less; its initial and subsequent half-lives are ~3 and 24 hours, respectively. Hence, larger doses are required initially, but dosing is usually once a day to maintain adequate hemostasis. After a large loading dose or after several courses of therapeutic product have been administered, the survival curves of infused coagulation factors become nearly monophasic, presumably because extravascular spaces and the other mechanisms that remove infused coagulation factors from the circulation are saturated. New factor VIII and factor IX products currently in small phase III clinical trials have extended half-lives, so it will be important during these clinical trials to determine the appropriate initial dosing and dosing intervals for each of the new products.
FIGURE 53.10. Biodynamics of factor VIII. A hypothetical survival curve obtained in a patient with severe hemophilia A after transfusion of sufficient factor VIII to increase the plasma factor VIIIc level to 100 IU/dl is shown. $T_{1/2}$, half-life.

Products

Before 1960, plasma was the only agent generally available for the treatment of the inherited coagulation disorders. Tremendous progress has been made in treating congenital coagulation disorders, primarily through development of effective therapeutic products. It should be noted that the life expectancy of a boy born in 1960 with severe hemophilia A was approximately 20 years, and now the life expectancy is essentially normal with modern therapeutic products and the comprehensive care of hemophilia treatment centers.\textsuperscript{454} Tables 53.11, Tables 53.12, Tables 53.13, Tables 53.14, Tables 53.15 and 53.16 summarize therapeutic choices available to treat certain inherited bleeding disorders.

Plasma

Although most current replacement therapies of coagulation factor deficiencies involve sterile purified concentrates or recombinant proteins, plasma therapy is still important in treating some deficient states such as factor XI deficiency. FFP is usually preferred for therapeutic purposes. For factor VIII and fibrinogen deficiencies, and vWD, the appropriate coagulation factors are concentrated in cryoprecipitate. Both the rate of administration and the total dose of plasma administered are limited by the possibility of acute or chronic circulatory overload. The volume expansion resulting from even moderate doses of plasma also limits the blood levels of the missing coagulation factor that can be attained. As a consequence, therapy with plasma alone can be expected to increase the levels of a deficient factor no
more than 20 IU/dl above baseline values. When plasma is the only therapeutic agent available, plasmapheresis may be of adjunctive value. A sterile solvent-detergent-treated plasma preparation is available, but activity of certain coagulation proteases and inhibitors in this product is not equivalent to that of FFP. Better preparations of solvent-detergent-treated plasma are available in Europe and are in clinical trials for the U.S. A British guideline for the use of FFP and cryoprecipitate has been published.

Purified or Concentrated Coagulation Factors

Cryoprecipitate

A major advance in the therapy of hemophilia A was the demonstration by Pool et al. that cold insoluble material obtained from plasma contains high concentrations of factor VIII and fibrinogen. Cryoprecipitate, which for many years was discarded during clarification of plasma, is prepared by slowly thawing rapidly frozen plasma at 2-4°C, then harvesting the precipitate by centrifugation. Cryoprecipitate prepared from 200 ml of fresh plasma (1 unit) contains 50 to 120 units of factor VIII, ~250 mg of fibrinogen, and therapeutically useful amounts of factor XIII and vWF that are rich in high-molecular-weight multimers. Cryoprecipitation provides 7- to 20-fold purification of factor VIII with respect to plasma and can be carried out by means of a closed double-bag system, even in small blood banks without special equipment. With the widespread availability of modern therapeutic products to treat hemophilia A and vWD, cryoprecipitate is now used primarily to treat hypofibrinogenemia.

Purified Factor VIII

Among the many methods developed to purify factor VIII, several are suitable for the large-scale production of concentrates of the human protein for therapeutic use, and sufficiently robust to attain in vivo factor VIIIc levels as high as 100 IU/dl in hemophilic patients without significant expansion of the plasma volume. Most plasma-derived factor VIII concentrates contain vWF but lack the high-molecular-weight vWF multimers found in cryoprecipitate or plasma.

Nearly all individuals with severe or moderate hemophilia require frequent therapeutic intravenous infusions and therefore, as the concentrated factor products became available in the late 1970s most patients learned how to administer these infusions themselves at home.

Unfortunately, before the mid-1980s, the risk of viral transmission accompanied the use of these concentrated preparations, because they were prepared from large plasma pools and specific virucidal treatment was not used. The risk of virus transmission has been greatly diminished by serologic testing of the plasma for viruses and by sterilization of the concentrate by solvent-detergent treatment and/or heat sterilization. High-potency preparations of factor VIII can be obtained by affinity chromatography using monoclonal antibodies. Therapeutic products of r-FVIII, activated factor VII, and factor IX are available for clinical use. The initial (first-generation) r-FVIII products contain human albumin. Second-generation products eliminated albumin, but human and/or animal protein components are utilized in the manufacturing process. Third-generation products have removed all exogenous human and animal proteins from the manufacturing process. Other recombinant factor products are in development or in clinical trials in 2013, including products with extended half-life for factors VIII, IX, and VII.

Although modern production methods have reduced the risk of transmitting lipid-enveloped viruses (e.g., human immunodeficiency virus [HIV] and hepatitis B and C), transmission of non-lipid-enveloped viruses, such as hepatitis A and parvovirus B19, has been reported with sterilized plasma-derived products. Tables 53.11, 53.13, and 53.14 summarize information on currently available products used to treat hemophilia A and hemophilia B.

Prothrombin Complex Concentrates, Factor IX, and Factor VII (VIIa)
The vitamin K-dependent factors (prothrombin; factors VII, IX, and X; and proteins C and S) are avidly absorbed by aluminum hydroxide or barium sulfate and can be readily concentrated by elution therefrom. This simple procedure is the starting point for several methods of preparing therapeutically useful concentrates of these proteins (Table 53.15).

Concentrates of vitamin K-dependent coagulation factors contain small but significant amounts of activated coagulation factors that may be thrombogenic when administered in large doses or for extended periods of time. The thrombogenicity of such concentrates varies from preparation to preparation and from lot to lot and has been variously attributed to thrombin, factor VIIa, factor Xa, factor IXa, and coagulant phospholipids. Attention has been directed to the serious and even fatal thromboembolic complications of these products, including disseminated intravascular coagulation. Such complications are particularly common in infants and in patients with liver disease, as discussed in Chapter 54. The availability of monoclonally purified and recombinant factor IX products has led to decreased use of PCCs in the treatment of hemophilia B. PCCs are now used primarily to treat patients with inhibitors to factor VIII, a condition in which the presence of thrombogenic proteins is clinically useful. PCCs are also useful in treating deficiencies of prothrombin and factors VII and X. PCCs also are used for reversal of the anticoagulation effects of warfarin or the new oral anticoagulants when bleeding occurs, although their usefulness with the latter is controversial.

When treating hemophilia B with replacement factor IX products, it should be noted that factor IX distributes to both intravascular and extravascular compartments. Consequently, loading doses required to achieve 100% of the normal plasma factor IX level are usually 1.5 to 2.0 times greater than those calculated from the patient's plasma volume. Thus, when purified factor IX products are used, twice the calculated amount of factor IX should be given for the initial dose. On the other hand, PCCs are thrombogenic, and when these products are used to treat patients with hemophilia B, the dosage should be reduced below that given when the purified products are used.

Recombinant factor VIIa is being used primarily for treatment of bleeding episodes in patients with hemophilia with inhibitors, but also in patients with bleeding due to refractory thrombocytopenia, platelet dysfunction, factor VII deficiency (discussed in the section Factor VII Deficiency), or severe liver disease (discussed in Chapter 54).

Detailed summaries of prior and current coagulation factor products have been published recently. A summary of the biologic properties of the new factor products in clinical trials in 2013 has also been published.

Adjunctive Therapies

A congener of vasopressin, DDAVP, was originally developed for the treatment of diabetes insipidus. Its extrarenal actions stimulate vascular endothelial cells to release several proteins, including vWF in amounts sufficient to raise the plasma levels of this protein and associated factor VIII two to five times (Fig. 53.11). This effect is therapeutically useful in most patients with type 1 vWD and in some patients with mild hemophilia A, and it is particularly useful because the biohazards of blood products are avoided. Excellent responses were obtained in the prevention of bleeding after minor surgical procedures, such as tooth extractions, and in some major surgical procedures. It has been noted that young boys with mild to moderate hemophilia A have a lower response rate to DDAVP; the response rate of these patients improves later in life, and nonresponder children are candidates for retesting when they are older.
The vWF released in response to DDAVP is rich in high-molecular-weight multimers that increase adhesion and spreading of platelets at injury sites. This effect may explain the therapeutic efficacy of the drug in several disorders of platelet function, including uremia.

DDAVP has also been reported to be clinically useful in patients with hemophilia B. Although factor IX levels are minimally increased by DDAVP, the improved PTT values in hemophilia B patients given DDAVP associated with increases
in factor VIII and vWF activity probably account for drug efficacy. Another group found DDAVP useful in hemophilia B patients when combined with antifibrinolytic therapy. 495

DDAVP also induces the release of endothelial cell-derived plasminogen activators and has produced exaggerated fibrinolytic phenomena in several rare cases. For this reason, it is sometimes given with e-aminocaproic acid (EACA) or other fibrinolytic enzyme inhibitors. Compared to vasopressin, DDAVP is markedly less potent as a pressor agent, but does retain significant antidiuretic activity. Neither effect has proved to be a major problem in its therapeutic use, but most experienced clinicians use caution when treating patients with hypertension or congestive heart failure. Reports of hyponatremia and seizures in children less than 2 years of age have led to cautious use of DDAVP in this population. Serum sodium should be monitored in adults who receive more than 3 or 4 sequential doses of DDAVP because of the side effect of hyponatremia, and in these patients water restriction is advised. DDAVP should not be administered more than once a day, and repeated doses of DDAVP may produce progressively diminishing amounts of vWF (tachyphylaxis), presumably because of exhaustion of stored vWF. DDAVP is available in a formulation for parenteral use or by the nasal spray Stimate. 490, 496 DDAVP can be given parenterally (0.3 µg/kg, up to a maximal dose of 20 to 24 µg). 497 Physicians should be aware that two DDAVP nasal sprays are available, and that only the nasal spray with the higher DDAVP concentration (Stimate, 1.5 mg/ml) is effective in treating vWD. DDAVP should be used cautiously in older patients with vascular disease because of the potential risk of drug-induced thrombosis. 497, 498, 499

Increasing use of DDAVP has revealed certain limitations of this hemostatic drug. One report in adult patients indicated that 2%-20% of patients experienced toxicity with DDAVP, including nausea and headache, and symptomatic hyponatremia was seen in 7%-5% of patients. 496 These side effects may be minimized with water restriction. Limitations of DDAVP in the pediatric population have been summarized. 500

Inhibitors of fibrinolysis, such as EACA or tranexamic acid, may diminish bleeding from mucosal membranes where the concentrations of fibrinolytic enzymes are high, in patients with inherited coagulation disorders: For example, with bleeding in the mouth, tongue, tonsils, and pharynx, and with bleeding associated with operative dental procedures. 501

These drugs act to protect labile hemostatic plugs from fibrinolytic degradation. The use of EACA alone has been effective in the treatment of patients with mild hemophilia A (plasma levels of factor VIII >5 IU/dl) 502 and those with other mild inherited coagulation disorders such as vWD or factor XI deficiency. Some clinicians have used EACA as an adjunct to single-dose 503 or various other factor replacement regimens. EACA should be administered in oral doses (pills or syrup) of 6 g every 6 hours to adults and 100 mg/kg every 6 hours to children, for 3 to 4 days after tooth extraction. Doses of as little as 1 g every 6 hours may be as effective in most adult patients. The drug can be given intravenously (1 g/hour) for patients who cannot swallow. Hematuria or abnormal renal function is a contraindication to the use of this drug because of the hazard of intrarenal or ureteral obstruction by blood clots. 504 EACA also should not be given to patients with disseminated intravascular coagulation or active hepatitis, or to patients receiving PCCs, although an EACA mouthwash can be used with these latter drugs. 501, 505

Tranexamic acid is now available; the recommended adult dosage is two 650 mg tablets orally three times daily. These drugs may be teratogenic and should be used with caution in pregnant women.

MAJOR AND MINOR BLEEDING

General treatment guidelines for patients, including newborns with hemophilia and other bleeding disorders, have been published. 73, 505, 506 Additional detailed guidelines are available on the National Hemophilia Foundation’s website, www.hemophilia.org, under Medical and Scientific Advisory Council (MASAC) recommendations.

For purposes of replacement therapy, the various bleeding manifestations commonly encountered in the inherited coagulation disorders are often divided subjectively into major and minor bleeding. Manifestations falling into the minor category include bleeding associated with uncomplicated hemarthrosis, symptomatic hematomas in noncritical areas, and minor traumatic injuries, as well as such therapeutic procedures as minor dental procedures, arthrocentesis, and dressing changes. Small cuts and scratches, removal of stitches or drains, superficial ecchymoses, and small hematomas may require no replacement therapy.

Major bleeding is by definition life-threatening and includes hematomas in critical locations and bleeding resulting from traumatic injuries, particularly those in which external blood loss is significant. Major bleeding occurs in surgical procedures, including tonsillectomy and the extraction of molar teeth. In the treatment of major bleeding, general guidelines recommend that the in vivo levels of the missing factor should be maintained above 60% to 80% to provide effective hemostasis until bleeding has stopped and appropriate healing has occurred so that there is no risk of
rebleeding. In bleeding of a particularly critical nature, such as intracranial hemorrhage, or for the prevention of excessive bleeding during neurosurgery, factor levels should be maintained at 100% of normal.

Hemophilia A Minor Bleeding

DDAVP is effective in the treatment of minor bleeding manifestations in individuals with hemophilia A with baseline factor VIIIc levels >5 IU/dl, if patients have been previously demonstrated to respond to DDAVP with therapeutic levels of factor VIIIc after administration of DDAVP. Side effects are more prominent if the total dose exceeds 24 µg. Both parenteral and intranasal administration produce significant increases in factor VIIIc and vWF. Repeated doses of DDAVP at approximately daily intervals may produce useful increments of factor VIII in many patients. At least 24 hours should elapse before repeat administration of the drug in order for the endothelial cell stores of vWF to be replenished. Patients should be tested before surgery for their response to DDAVP by documenting adequate hemostatic levels of factor VIII levels 30 to 60 minutes after treatment, to ensure that the drug will be effective in appropriate responders. Only small amounts of factor VIII are produced by DDAVP in persons with severe hemophilia, and the use of this drug in patients with factor VIII levels <5 IU/dl is seldom useful and therefore is not recommended, even for minor bleeding manifestations. EACA (6 g orally every 6 hours) or tranexamic acid (25 mg/kg orally every 6 to 8 hours) has been administered together with DDAVP in an attempt to minimize fibrinolysis. For maximal effectiveness, antifibrinolytic drugs should be started 24 hours prior to surgical procedures.

Although effective in minor bleeding, plasma or cryoprecipitate is not currently recommended for use in the treatment of patients with hemophilia A. Factor VIII concentrates are widely available and are the most useful therapeutic products. The regimens summarized in Table 53.10 illustrate one approach to treating hemophilia A. For some minor bleeding manifestations, treatment for a minimum of 3 days is required, but in most cases, a single dose of 10 to 15 IU/kg of factor VIII is usually sufficient. In the treatment of minor bleeding, loading doses are not required, and laboratory monitoring of in vivo factor VIII levels is unnecessary. The minor bleeding treatment regimens summarized in Table 53.10 typically result in peak factor VIII levels of ~30%. Occasionally, if the minor bleeding episode is not treated promptly and bleeding is prolonged, then a hematoma may form, and often additional doses of factor products at higher doses are needed to prevent continued bleeding around the hematoma and potential pseudocyst formation. It is generally recommended in such cases of delayed treatment that full (100%) doses be administered to maintain adequate hemostatic levels until the hematoma is completely resolved.

Hemophilia A Major Bleeding

To treat major bleeding in patients with hemophilia A, sufficient factor VIII must be given often enough to ensure that the blood level does not fall to <30 to 50 IU/dl for any length of time. Most experienced clinicians target trough levels of more than 50% IU/dl until bleeding has stopped and substantial healing has taken place. Maintenance doses usually are administered every 8 to 12 hours. Regimens of continuous infusion of factor VIII are being used with increasing frequency during hospitalization, and have been shown to save total factor use by as much as 30%. The administration of 2 IU/kg/hour of factor VIII produces a mean factor VIIIc level in the plasma of ~50 IU/dl and appears to be more cost-effective than twice-daily intravenous bolus treatments. Continuous infusion also has the advantage of maintaining a consistent, therapeutic factor level. It is important to note that the treatment of postsurgical or major traumatic hemorrhage in patients with mild hemophilia A requires nearly as much therapeutic product as is needed for the severely affected patient. Many authors recommend treatment for 10 to 14 days after major surgical procedures, whereas others administer the full doses indicated in Table 53.10 for 10 days and continue half-doses for longer periods as healing continues and the patient is undergoing increasingly active physical therapy, especially after major orthopedic surgeries.

Determination in the laboratory of the in vivo levels of factor VIIIc is recommended during the treatment of patients with major hemorrhage. Incidents of unexpected subtherapeutic responses to infused factor VIII have been reported. The use of the PTT to guide factor VIII replacement therapy is not recommended, because the results of these tests may be normal at levels of factor VIII that do not provide adequate hemostasis.

von Willebrand Disease

In a disease as heterogeneous as vWD, decisions about treatment begin with accurate diagnosis (including vWD subtype) and complete evaluation. Fortunately, in many patients with vWD, bleeding manifestations are mild, and replacement therapy is seldom required. Unlike the situation in hemophilia, in which there is a close correlation between factor levels and clinical outcome, treatment decisions are more complicated in vWD because it is unclear which measurement (vWF, factor VIII, or platelet function) correlates best with the severity of bleeding or clinical outcome. Many experts recommend following vWF:RCo and factor VIII levels, but little information exists about the level of vWF:RCo that is
critical for control of mucosal bleeding or the prevention of surgical bleeding. Bleeding times may not normalize, but a normal bleeding time is not required for a satisfactory response, and monitoring of bleeding time is not recommended. Therapeutic goals include resolution of active bleeding and prevention of excessive bleeding in response to invasive procedures or trauma.

P.1179

Unlike the situation with hemophilia A or B, chronic prophylaxis therapy is rarely required, but should be considered in patients with type 3 vWD who have recurrent gastrointestinal or joint hemorrhage.

The spectrum of therapeutic interventions in vWD includes desmopressin (DDAVP), concentrate infusion, and adjunctive therapy with medications that modulate bleeding symptoms by affecting either menstrual pattern or fibrinolysis. Dosing recommendations in vWD are empiric. In the case of a patient with major surgery or trauma, one recommendation is that clinicians attempt to bring the vWF (and factor VIII) level to near 100 IU/dl, and maintain it >40 to 50 IU/dl for the first 3 to 5 days, after which one recommended goal is to maintain the factor VIII level at >40 IU/dl for a total of 7 to 10 days or until healing is completed. In surgical settings, monitoring of factor levels seems prudent, but monitoring of the bleeding time is discouraged, as surgeries have been done successfully in patients with type 3 vWD in the face of only partial correction of bleeding time.

DDAVP is the mainstay of treatment for patients with mild forms of type 1 vWD. The dosage, route of administration, and contraindications described under the discussion of hemophilia A also apply to the use of the drug in vWD. vWF and factor VIII levels generally increase by two- to fourfold over baseline. Because responsiveness to therapy between patients is variable, a test dose given at the time of diagnosis or before elective surgery is advised. Obtaining both vWF:RCo and factor VIII levels 1 hour after DDAVP administration is recommended in order to confirm a patient’s responsiveness. It may also be informative to obtain a second sample between 2 and 4 hours after DDAVP to confirm that vWF has the expected 8- to 10-hour half-life after release. Concerns regarding tachyphylaxis, hyponatremia, and rare thrombotic complications are similar to those when treating patients with hemophilia A. Note that whereas patients with type 1 vWD are likely to have a satisfactory response, patients with non-type 1 vWD respond poorly or unpredictably to DDAVP. Type 3 patients have essentially no endogenous vWF synthesis, and are DDAVP-nonresponsive. In one large series of patients with type 2B vWD, the platelet count fell from an average of 86,000 to 60,000/μl after administration of this drug. Because thrombocytopenia may worsen after administration of DDAVP to patients with type 2B vWD and the platelet-type form of the disorder, patients with these variants should not be treated routinely with DDAVP. However, some authors report good-responder type 2B vWD patients who received DDAVP. Response in type 2A vWD is variable and may be of shorter duration than in type 1 patients, because of increased vWF proteolysis. Similarly, factor VIII levels may rise in response to DDAVP in patients with type 2N vWD, but because of the deficient factor VIII-stabilizing activity of vWF in this variant, levels of factor VIII then fall at an accelerated rate. Because of interindividual variability, a documented therapeutic response to DDAVP should be obtained before surgical prophylaxis with the drug, to ensure adequate hemostasis postoperatively. It is recommended that this DDAVP trial be performed at the time of diagnosis of vWD.

Transfusion therapy with plasma-derived products is the therapy of choice in DDAVP-unresponsive patients who require factor support. In order to treat both the factor VIII deficiency and the defect in primary hemostasis seen in patients with severe vWD, it is generally necessary to give a product with factor VIII activity that also contains high-molecular-weight multimers of vWF. The concentrations of vWF and factor VIII in FFP are insufficient for appropriate therapy. Cryoprecipitate contains ~80 to 100 units/bag, 5 to 10 times the concentration of these factors compared to plasma. Cryoprecipitate has a small residual risk of viral transmission and is not currently suited for virus-inactivation therapy; consequently, pathogen-inactivated, intermediate-purity factor VIII concentrates with demonstrated preservation of vWF multimers are the preferred replacement product. At the time of this writing, three commercial plasma-derived products were licensed in the United States for this indication (Humate-P, manufactured by CSL Behring and known as Haemate-P in Europe; Wilate, manufactured by Octapharma; and Alphanate SD/HT, manufactured by Grifols) (Table 53.12). Several other commercial products have been developed and are currently licensed in other countries. A Canadian multicenter study confirmed “excellent” or “good” outcomes in 97% of patients treated with Humate-P, with a median recovery of 1.23 IU/kg per IU/kg infused. Similarly, Alphanate was shown to ultimately control all bleeding episodes in one large multicenter trial. Alphanate is currently not licensed for treatment of vWD; it is labeled only in factor VIII units, but vWF:RCo has been reported to be “50% lower than the labeled factor VIII content.” A PK clinical trial compared Wilate vs Humate-P and found similar PK parameters for the two products; however, Wilate achieved a 1:1 ratio for vWF:factor VIII, suggesting simpler dosing of Wilate. A chromatographically purified vWF concentrate with minimal factor VIII (Wifactin) has been evaluated in type 3 vWD. After infusion, factor VIII levels rise slowly and peak ~6 to 8 hours later. These data
imply that if type 3 patients are to be pretreated for surgery with a pure vWF-containing concentrate, either concomitant factor VIII will need to be administered, or the surgery should be scheduled for 6 to 8 hours after the vWF administration. Very-high-purity plasma-derived factor VIII concentrates and r-FVIII concentrates are essentially devoid of vWF, and they should not be used to treat vWD.

Suggested doses and target factor levels for treatment of vWD patients have been published. Recommended doses in ristocetin cofactor units are similar to factor VIII doses, because both have similar in vivo recovery (2 IU/dl rise in plasma concentration for each IU/kg of factor administered). Monitoring response to therapy with both factor VIII and vWF:RCo is appropriate. Although vWF levels can be expected to fall between doses of vWF-containing concentrate, which has a half-life of 8 to 10 hours, factor VIII levels may continue to rise in response to the patient's endogenous factor VIII production. Avoidance of unusually high factor VIII levels is suggested in order to minimize venous thrombotic risk.

Platelets are estimated to contain ~15% of the total body vWF. Some authors suggest using platelet transfusion in patients with severe vWD who exhibit bleeding despite plasma factor VIII concentrate therapy. Thrombocytopenia may be exacerbated by the administration of normal exogenous vWF in platelet-type (pseudo) vWD, but not in type 2B vWD. Patients with platelet-type vWD should receive platelet transfusions for significant bleeding or surgery.

Adjunctive therapy for vWD patients with menorrhagia usually takes the form of oral contraception or other hormonal intervention. Antifibrinolytic therapy and DDAVP have also found a role in control of menorrhagia and oral bleeding. Doses of intranasal DDAVP administered every 12 to 24 hours for up to 3 days, or ε-aminoacapric acid up to 5 g three times per day, or tranexamic acid, have been reported to be useful in control of menorrhagia, but toxicity profiles should also be considered. Failure of medical therapy may lead to surgical approaches, such as endometrial resection or even hysterectomy.

Pregnancy is a special situation for patients with vWD. vWF levels generally improve in patients with type 1 vWD as pregnancy proceeds, but improvement is less likely in type 2A vWD, and thrombocytopenia may actually worsen in patients with type 2B and platelet-type (pseudo) vWD variants. Current information indicates that the patient's factor VIIIc at delivery predicts the risk of bleeding, with a factor VIII level <50% of normal at term being associated with excessive bleeding. If sufficient factor VIII levels are achieved, aggressive surgical hemostasis and efficient uterine contraction should prevent peripartum bleeding. Thus, factor levels should be determined before delivery. If sufficient P.1180

Factor VIII levels are not achieved before delivery and the patient is known to respond to DDAVP, this drug can be given to the mother immediately postpartum. If the patient does not respond to DDAVP, then vWF/factor VIII concentrate should be administered peripartum. Although endogenous vWF levels rise during pregnancy in patients with type 1 vWD, the vWF levels fall quickly after parturition, and patients should be advised to report late bleeding. DDAVP or replacement therapy may be useful to prevent late bleeding in patients with vWD. Finally, unlike type 1 vasopressin agonists, DDAVP has little or no oxytocic activity, and some authorities have advocated prophylactic use before invasive diagnostic or surgical interventions in pregnant vWD patients.

Alloantibodies to vWF develop in a minority of patients with type 3 vWD after replacement therapy. The risk appears to be highest in patients with large gene deletions. Administration of vWF-containing concentrates to these allosensitized patients has been associated with anaphylactic reactions. Alternative therapies that have been successful include high-dose r-FVIII administered by continuous infusion at doses of 700 to 900 IU/kg/day, or recombinant factor VIIa. Patients with acquired vWD (see Chapter 54) have broader therapeutic options, because DDAVP and replacement therapy may have some efficacy, as would treatment of the underlying disease process.

Hemophilia B Treatment

Most of the guidelines for replacement therapy of patients with hemophilia A apply to the treatment of those with hemophilia B (Table 53.10). Because of the low initial in vivo recovery and the rapid initial disappearance of factor IX from the circulation, higher initial doses are recommended, even for the treatment of minor bleeding. In patients with hemophilia B, purified factor IX concentrates or recombinant factor IX products are recommended for the treatment of major or minor hemorrhage because of the thrombogenic potential of PCCs (Table 53.14). One disadvantage of recombinant factor IX compared to plasma-derived factor IX is a lower in vivo recovery of recombinant factor IX (~30% lower than predicted), perhaps related to different posttranslational modifications of the recombinant protein. Higher doses of recombinant factor IX need to be given routinely to achieve similar therapeutic levels, and monitoring factor IX levels with this product should be done routinely, especially in young children. These concerns about in vivo recovery do not seem to apply to the new extended half-life factor IX products in clinical trials in 2013.
An unusual complication of hemophilia B therapy is anaphylaxis. These patients typically have severe factor IX deficiency with complete gene deletions. The anaphylaxis typically occurs with the first or second administration of factor IX, and essentially never with subsequent infusions if the initial doses are tolerated well. These patients rarely respond to immunetolerance induction, and should be treated with either PCCs or recombinant factor VIIa (see Chapter 54).

Gene Therapy for Hemophilia

Gene therapy for the inherited bleeding disorders is now promising, after many years of frustrating failures. A major success was recently published involving patients with severe factor IX deficiency. Six of six subjects with severe hemophilia B were treated with adeno-associated viral vector carrying a normal factor IX gene, and have had factor IX levels of 2% to 4% for many months. While this is encouraging, there need to be additional studies with more subjects to evaluate safety and efficacy of gene therapy in hemophilia. Work with the factor VIII gene for viral delivery is more complex because of its much larger size. Viral and nonviral constructs containing genes for factor VIII or factor IX have been used, as well as modified retrovirus, adenovirus, or adeno-associated virus vectors. Sustained partial correction of factor VIII or factor IX deficiency has been seen with gene transfer in animal models, and it is expected that with additional work, these encouraging results will be seen in patients also. A major focus of gene therapy research is to develop a gene delivery system that is efficient, safe, nonimmunogenic, and provides longterm gene expression. The promise for gene therapy lies in the fact that if gene therapy could increase endogenous factor VIII or factor IX levels only from <1% to 1 to 2 IU/dl, this incremental change would dramatically alter the clinical course and treatment of patients with severe hemophilia. Significant questions about potential risks associated with gene therapy, including inflammatory responses, inhibitor development, oncogenesis, and germine mutations will need to be addressed as further clinical trials are undertaken.

Factor VII Deficiency

Unlike in patients with severe hemophilia A or B, bleeding in a patient with factor VII deficiency undergoing surgery is variable, so multiple issues should be considered in the perioperative care of factor VII-deficient patients, including the individual patient’s prior experiences and symptomatology: Patients with a history of hemarthrosis or CNS hemorrhage are at a higher risk for bleeding complications. The oral and urogenital tracts are areas of high local fibrinolytic activity. The minimum factor VII level required for surgical hemostasis is not known; patients with levels <3 IU/dl are at high risk for bleeding, whereas patients with levels of 15 to 25 IU/dl are less likely to develop bleeding complications associated with surgery. Finally, one should consider the logistics of therapy, because factor VII has a short half-life, possibly as short as 3.5 hours. Volume overload is likely, as plasma is commonly used as a source for factor replacement, and the safety profile of the various factor VII-containing products varies.

Traditionally, FFP, PCCs, or plasma-derived factor VII concentrate has been used for factor VII replacement therapy, and more recently, recombinant human activated factor VIIa (rFVIIa) has been the recommended product. In general, doses of between 15 and 30 µg/kg of rFVIIa were administered at intervals of 4 to 6 hours. The half-life of recombinant factor VIIa is between 2.5 and 3 hours, and the roles of continuous factor infusion and laboratory monitoring remain to be defined in treating factor VII-deficient patients. Antibody to factor VII has developed in response to therapy in some individuals with congenital factor VII deficiency. Although serious thrombotic events have been reported when rFVIIa has been used in an attempt to control bleeding in the setting of acquired coagulopathy, only three reports of serious thrombotic complications were collected in a recent review of rFVIIa use to treat congenital factor VII deficiency. Furthermore, at least two of those three cases were managed using higher doses of rFVIIa than are recommended here. The risk of thrombosis should be considered when rFVIIa is being used, especially when treating a condition that itself is associated with thrombosis, such as orthopedic surgery.

Although the half-life of factor VII is short, both factor VII and, more recently, rFVIIa infusions have been successful in chronic infusion prophylaxis programs to prevent spontaneous CNS and joint bleeding. Factor VIIa was administered every other day or twice weekly, suggesting that an additional mechanism of action independent of the short plasma half-life was operative in these cases.

Although it is no longer the “product of choice,” plasma can be used for replacement therapy for factor VII in emergency situations when other products are not available. Plasma has the disadvantage of posing a large volume load and has potential for viral transmission. For patients treated with plasma, a loading dose of 15 to 20 ml/kg, followed by 4 to 6 ml/kg every 6 hours for 7 to 10 days has been recommended. Plasma exchange therapy has been used in some patients to avoid volume overload. PCCs

P.1181
have been used, but they too are not the product of choice. PCCs carry some thrombotic risk, which may be associated with the generation of unnecessarily high levels of other activated vitamin K-dependent coagulation proteins.\textsuperscript{555} This is especially a problem with extended PCC use or use of PCCs in the setting of liver disease. Those products are not generally labeled with their factor IX content, but the factor VII content is usually available from the manufacturer. Recovery studies indicate that an administered factor VII dose of 1 IU/kg will raise the patient’s plasma factor level by \textasciitilde 2 IU/dl. If it is available, the use of purified factor VII concentrate might decrease the thrombotic risk associated with the use of less-specific PCCs. A heat-treated intermediate-purity factor VII concentrate (manufactured by Immuno A.G.) had been used for treatment of acute bleeds, perioperative prophylaxis, and for prevention of recurrent CNS hemorrhage. Factor VII levels rose \textasciitilde 2.33 IU/dl for each IU/kg infused, and the factor VII half-life was \textasciitilde 6 hours. Despite the short half-life of factor VII, infusions as infrequent as once per week were successful in preventing recurrent intracranial bleeding.\textsuperscript{536} For replacement therapy in a surgical setting, factor-level monitoring is recommended, to ensure that perioperative factor levels are >25 IU/dl.

Factor XIII Deficiency Treatment

Therapy for congenital factor XIII deficiency is based on the principle that only a small quantity of factor XIII must be present in human plasma to promote normal hemostasis.\textsuperscript{556} The long half-life of factor XIII (estimated as being between 9 and 19 days in the literature\textsuperscript{557}) makes prophylactic therapy both practical and highly advisable given the high frequency of intracranial hemorrhage.\textsuperscript{284} This long half-life may not be present in some situations in newborn infants with severe FXIII deficiency.\textsuperscript{588} FFP and factor concentrates have been used successfully to prevent factor XIII-associated bleeding, and these remain the treatment of choice. Pasteurized factor XIII concentrate that contained only the A subunit prepared from human placenta has been replaced by plasma-derived preparations that contain both A and B subunits.\textsuperscript{559} A plasma-derived factor XIII preparation is available (Corifact, CSL Behring, Table 53.16) to treat congenital factor XIII deficiency. Recommended dosing is 40 IU/kg every 4 weeks with dose adjustments based on achieving a trough level of 5% to 20%. Two other preparations that have been used therapeutically are Fibrogammin-P, which is licensed in several countries (but not the United States or Canada), and a factor XIII preparation from Bio Products Laboratory that has been used in the United Kingdom. Kinetic studies with Fibrogammin-P indicate a mean recovery of 65% and a plasma half-life of \textasciitilde 5 to 11 days.\textsuperscript{560, 561} A recombinant factor XIII concentrate composed of the A subunit has been developed and is currently undergoing clinical investigation.\textsuperscript{562} Recommended dosing for factor XIII concentrate is 10 to 20 IU/kg body weight every 4 to 6 weeks for prophylaxis against unprovoked bleeding. It is strongly recommended that all patients with severe factor XIII deficiency be placed on life-long prophylaxis in order to prevent the devastating complication of intracranial hemorrhage. Prophylactic therapy of affected patients undergoing surgery may actually require more intensive replacement therapy. If concentrates are unavailable, patients can be given either FFP or cryoprecipitate.\textsuperscript{563} A typical plasma dose is 10 to 20 ml/kg body weight, every 4 to 6 weeks. Cryoprecipitate at a dose of 1 bag per 10 to 20 kg of body weight every 3 to 4 weeks is an alternative therapy that has the advantage of requiring transfusion of a smaller volume. It is recommended that factor XIII levels be kept between 25% and 50% of normal to achieve normal hemostasis following major trauma in these patients; doses of concentrate recommended are 35 IU/kg preoperatively, followed by 10 IU/kg/day for 5 more days. Affected patients with a history of spontaneous abortions can complete a normal pregnancy when they are managed with prophylactic FFP or factor XIII concentrates. Factor XIII levels fall during pregnancy, and replacement therapy is recommended every 21 days.\textsuperscript{564} Monitoring of factor XIII trough levels may also be helpful. Formation of antibody inhibitors to factor XIII after replacement therapy appears to be rare.

In acquired factor XIII deficiency, >50% of patients need aggressive therapy. The most useful therapy for patients who have acquired inhibitors to factor XIII remains plasma exchange with or without immunosuppression with cytotoxic drugs. In addition, infusions of platelets can be given with occasional success, because platelets contain large amounts of factor XIII. Alternatively, replacement therapy with a factor XIII concentrate can be considered.

Treatment Considerations for Miscellaneous Disorders

Therapeutic regimens recommended for the treatment of patients with any of the less common inherited coagulation disorders are summarized in Table 53.8.

The management of major bleeding caused by deficiencies of prothrombin and factor X has been facilitated by the availability of PCCs (Table 53.15). The majority of these plasma-derived products contain three factors (prothrombin, factor IX, and factor X), but four-factor concentrates are also available.\textsuperscript{481} Factor IX content has generally been used to label the potency of these concentrates, but factor content of the other vitamin K-dependent factors relative to the factor IX content is often available, either in published reports\textsuperscript{181} or from the manufacturer. The currently available PCC products are subjected to virus-attenuation steps to inactivate hepatitis B, hepatitis C, and HIV. However, the thrombogenicity of
these products remains a concern, and concomitant use of antifibrinolytics may increase that risk. In the absence of a specific factor concentrate, plasma transfusion may also be used to replace vitamin K-dependent coagulation factors.

There are few data on which to base recommendations on treating the rare bleeding disorders. It is estimated that 1 IU/kg of infused PCC will raise the prothrombin level by 1 IU/dl. Relatively low levels of prothrombin are required for normal hemostasis, and target values of 40 to 50 IU/dl are recommended for surgery. The half-life of prothrombin is ~72 hours, so infrequent postoperative infusions, every 2 to 3 days, is reasonable. Guidelines for the treatment of factor X deficiency vary. The biologic half-life of factor X is 20 to 40 hours. Calculation of the factor X dose is based on the empiric observation that for each 1 IU/kg infused, factor X levels rise ~1.5 IU/kg. Factor X levels varying from 5 IU/dl to as high as 40 IU/dl have been recommended for surgery; however, levels >20 IU/dl were suggested by the United Kingdom Haemophilia Centre Doctors' Organisation. Monitoring of the factor level achieved is prudent.

There are currently no factor V concentrates, so patients with factor V deficiency who require replacement therapy are treated with transfusions of plasma. Target levels of factor V recommended before surgery vary. The United Kingdom Haemophilia Centre Doctors' Organisation recommend target levels >15 IU/dl, whereas others have suggested levels of 25 to 30 IU/dl. The half-life of plasma factor V is reported to be 12 to 36 hours. In the United States, some blood collection organizations are moving away from production of FFP, toward production of plasma that is separated and frozen within 24 hours after collection (FP-24). Although factor V has been called “labile factor,” levels of factor V in FP-24 are only modestly reduced compared to those in FFP. In addition, factor V appears to be relatively stable in “thawed plasma” held up to 5 days in transfusion service refrigerators at 0-4°C. Loading plasma doses of 20 ml/kg are often given, followed by maintenance infusions of 3 to 6 ml/kg every 12 hours. Cryoprecipitate does not contain sufficient factor V to be used as an alternative to plasma. If adequate factor V levels cannot be achieved by simple transfusion, exchange transfusion may be tried. Finally, in the setting of acquired factor V autoantibody, platelet transfusion has been used successfully. Similarly, platelet transfusion might hold some promise in treatment of a patient with congenital factor V with alloantibody.

Patients with factor XI deficiency usually respond well to FFP. A solvent-detergent plasma preparation has been developed and may be the desired therapy not only for factor XI deficiency, but for other factor deficiencies for which sterile concentrates are not available. Unfortunately, some of the factor XI concentrates were shown to be thrombogenic in early clinical studies, and their clinical utility may be limited by this toxicity.

Cryoprecipitate is used in replacement therapy for afibrinogenemia, hypofibrinogenemia, and dysfibrinogenemia. When a sterile, nonthrombogenic fibrinogen concentrate becomes routinely available, it should replace cryoprecipitate for treating these latter disorders. Such a product is in clinical trial. Fibrinogen replacement therapy has been reviewed.

SPECIAL ASPECTS OF TREATMENT

Hemarthrosis

All patients with hemarthrosis should receive adequate replacement therapy in order to prevent the development of permanent disability due to repeated bleeding into a joint. Pain usually is relieved promptly and is a reliable index of the therapeutic response. Supportive therapy follows the acronym of RICE: Rest through immobilization, ice to cool the inflammation and reduce the swelling, compression to reduce the swelling and bleeding, and elevation to reduce the swelling. The administration of analgesics that do not interfere with platelet function is appropriate to relieve the pain of bleeding into the joint.

Arthrocentesis usually is unnecessary if therapeutic infusion is accomplished early, but it may be of significant benefit when the joint is severely distended or when resolution of the hemarthrosis is delayed despite adequate replacement therapy. Large volumes of blood seldom can be aspirated, but even a small volume may relieve symptoms. If arthrocentesis is performed, it should be done immediately after the administration of a therapeutic dose of factor.

Early physiotherapy aimed at restoring the full range of motion of the affected joint should be instituted as soon as the acute stage of hemarthrosis has resolved. More energetic physiotherapeutic techniques should be carried out only in conjunction with an adequate course of replacement therapy. Various orthopedic devices (orthotics), such as braces and removable bivalve plaster casts, which provide additional support for chronically injured joints, have proved useful in reducing the frequency of recurrent hemarthrosis, particularly in the knee and ankle joints. For pain management of hemophilic arthropathy, nonsteroidal antiinflammatory agents may be helpful. In particular, salsalate (Disalcid) or...
choline magnesium trisalicylate (Trilisate) or the newer cyclo-oxygenase-2 inhibitors (Celebrex) may be useful in patients with bleeding disorders, because these drugs have antiinflammatory activity but do not impair platelet function. Regular infusions of factor concentrates may prevent or significantly delay progression of hemophilic arthropathy. A randomized clinical trial in boys demonstrated the markedly better results of a prophylaxis program versus episodic treatment on long-term joint function. This study demonstrated a significant reduction in joint damage and other bleeding episodes in the prophylaxis group. Similar results would be expected in adult patients also, but have not yet been demonstrated in a rigorous clinical trial.

Prophylaxis therapy is regarded as optimal treatment for patients with severe hemophilia. One report compared two prophylaxis regimens for hemophilia A—standard prophylaxis (20 to 40 IU/kg every other day) vs. PK-tailored prophylaxis (20 to 80 IU/kg every third day). Annualized bleeding rates, factor consumption, and adverse events were similar.

Reconstructive surgical procedures are available to improve the function of chronically damaged joints. Favorable results have been reported with total knee arthroplasty in several series. Long-term follow-up (>5 years) indicates adequately functioning prostheses and persistent pain relief in most patients. Synovectomy is effective in reducing the frequency of hemarthrosis that cannot be controlled by replacement therapy. Radioisotopic synovectomy is also effective therapy for hemophilic arthropathy. A review of the literature on radioisotopic synovectomy indicates that 80% of patients benefit from the procedure, but an updated safety review identified two patients who subsequently developed acute lymphocytic leukemia. While not statistically significant, this report raises a safety question, and until more data and long-term follow-up is obtained, radioisotopic synovectomy should be considered carefully in the context of each patient’s needs.

Hemophilic Cysts

Hemophilic cysts are very rare with modern treatment, but once were a serious complication that developed in patients with severe hemophilia A or B that had recurrent bleeding with inadequate treatment. Also known as hemophilic pseudotumors, such cysts are gradually expanding blood-filled loculations that apparently originate from hemorrhages into confined subperiostal, tendinous, or fascial spaces. The osmotic pressure created by breakdown products of blood in such confined spaces may produce further influx of fluid; this, together with recurrent bleeding, explains the progressive increase in the size of the cyst and its ability to erode contiguous structures. Such cysts most commonly develop in the thigh and may destroy bone as well as the soft tissues as they increase in size. Hemophilic cysts are readily prevented, but difficult to treat. Although long-term replacement therapy combined with x-ray treatment has been successful in a few cases, hemophilic pseudocysts may require radical surgical procedures such as extensive resections or amputations. Even with optimal supportive therapy, these procedures often are unsuccessful and may be complicated by infection. Surgical and nonsurgical approaches to manage pseudotumors have been reviewed. The modern use of home prophylaxis has made pseudotumors an unusual complication of hemophilia, although they still occur in parts of the world that do not have access to prophylaxis treatment of hemophilia.

Intracranial Bleeding

Despite the widespread use of prophylaxis programs, hemorrhage, including intracranial hemorrhage, remains a leading cause of death among persons with hemophilia. After the neonatal period, intracranial hemorrhage affects 3% to 10% of hemophilia patients not receiving prophylaxis. An estimate of the incidence of intracranial hemorrhage placed the risk at 1 in 200 per year, proportional to the time spent with factor levels below 1 IU/dl. A mortality survey for hemophilia A for the years 1995 to 1998 found that hemorrhage was the listed cause of death for 22% of hemophilia A patients who died during that time period. Approximately 50% of cases are associated with head injury; the etiology is not apparent in 38% of cases (spontaneous cases). Bleeding may be subdural, epidural, or intracerebral. Subarachnoid bleeding occurs least commonly, but it carries the best prognosis. Hemorrhage also may develop in the spinal cord or spinal meninges. In cases associated with head trauma, the presence of a lucid interval and the absence of localizing neurologic signs at the time of presentation are commonly seen.

Significant head injury must be treated early and intensively in patients with inherited coagulation disorders. Those with hemophilia A and B should immediately receive sufficient factor product to raise the plasma level of deficient factor to 100 IU/dl. Samples for essential coagulation studies should be drawn before administration of replacement therapy, but treatment should not be delayed while waiting for results of these studies. Radiologic procedures, such as computed tomography scanning, should be performed after the therapeutic product is administered. If it is performed expertly,
lumbar puncture usually can be carried out without serious risk, but many clinicians prefer to wait until replacement therapy has been given. In one series, replacement therapy given within 6 hours of head injury prevented any intracranial bleeding.

In cases involving major cranial trauma, if neurologic signs or symptoms develop, or if intracranial bleeding is confirmed radiologically or otherwise, the administration of factor VIII or factor IX concentrates should continue on a schedule in doses sufficient to keep the nadir levels of the deficient factor >30 IU/dl. Treatment should be maintained for 10 to 14 days. Before the widespread use of factor VIII concentrates, the mortality rate after intracranial bleeding was greater than 70%.

For treatment of patients who have suffered from an episode of spontaneous intracranial hemorrhage, most experts recommend prophylaxis therapy so that the factor level rarely is below 1 IU/dl, as the risk of recurrence is significantly higher in such patients. It is expected that the morbidity and mortality of intracranial bleeding will be reduced further with the increased use of the extended half-life factor products currently in phase 3 clinical trials.

Viral Transmission from Past Factor Concentrates: HIV and Hepatitis C

Acquired immunodeficiency syndrome (AIDS) was first recognized in 1978 and was found to be transmitted in blood products in the early 1980s, infecting approximately 70% of persons with severe hemophilia using factor concentrates prior to 1984. HIV transmission through factor concentrate was reduced to zero after 1985, through the development of factor concentrates including virucidal steps in the manufacturing process, the institution of stringent donor testing, and the availability of recombinant products. Improvements in therapy for HIV have allowed many persons with hemophilia to become long-term survivors, although there remain many seropositive patients who have not progressed to AIDS.

In the United States mortality survey of hemophilia A patients between 1995 and 1998, liver disease was listed as a cause of death in 15% of patients. It is estimated that approximately 90% of persons with severe hemophilia who used factor concentrates prior to 1984 were infected by the hepatitis C virus transmitted in the factor concentrate. Nearly 20% of these individuals were able to eradicate the virus, thus becoming hepatitis C antibody positive, but hepatitis C virus negative. However, for other patients, the hepatitis C virus has progressed inexorably with many dying from chronic liver disease. Liver biopsies confirmed the presence of chronic active hepatitis in many patients. The disorder is usually the result of persistent infection with the hepatitis C virus, but may be complicated in some individuals by coinfection with hepatitis B. A prospective study of U.S. hemophilia patients found that 66% of the hepatitis C-infected hemophilia patients also had HIV infection, and that coinfection was associated with a five- to sixfold increase in endstage liver disease. Modern manufacturing methods render factor concentrates free of hepatitis C virus and other lipid-enveloped viruses. No hepatitis C viral transmission has been connected with factor concentrates since 1986. Patients who are seronegative for the hepatitis A and B viruses should receive immunizations for these viruses. However, standard solvent-detergent-inactivated products may still transmit non-lipid-enveloped viruses such as parvovirus, hepatitis A, and other viruses. An unresolved issue is the transmission potential of the agent that causes Creutzfeldt-Jakob disease, but the manufacturers of plasmaderived factor concentrates have taken steps to reduce the risk of transmitting this agent also.

Antibodies to Coagulation Factors

A major problem with current therapeutic products in hemophilia A is the development of neutralizing antibodies (inhibitors) to factor VIII. This complication is less common in patients with hemophilia B and other inherited coagulation disorders. Such antibodies may seriously complicate the treatment of these patients (see Chapter 54).

Home Treatment Programs

In general, current recommended therapy of hemophilia is replacement therapy or prophylaxis treatment to prevent any spontaneous bleeding episodes, rather than treating bleeding episodes after they occur, termed “on demand.” A prospective randomized clinical trial has demonstrated that joint damage is minimized if treatment is begun immediately after the onset of symptoms. The availability of factor VIII concentrates that are stable in home refrigerators led to the development of various early home-care programs. Parents and patients are trained to administer the product at the first sign of bleeding. Such programs have resulted in decreased bleeding episodes and improved preservation of joint function. Typical prophylactic regimens are 25 to 40 IU/kg of factor VIII three times per week for hemophilia A, and 25 to 40 IU/kg of factor IX twice per week for hemophilia B. Such therapy usually maintains the trough factor level at or above 1% of normal. In older hemophilia patients with significant joint arthropathy, higher doses often are needed, while in younger patients with essentially normal joints, the lower factor doses are sufficient. A 30-year follow-up report confirmed the efficacy of prophylaxis. An economic analysis of prophylaxis found that although higher costs were associated with prophylaxis programs, the approach was justified on medical grounds. It is recommended that patients begin prophylaxis soon after the first joint bleed.
In 2013 there were at least 3 new factor VIII products and 3 factor IX products with extended half-lives in clinical trials. There have been no safety issues demonstrated so far in this clinical trial experience. These new products should dramatically improve the treatment of patients with hemophilia by simplifying prophylaxis regimens.

Dental Care

Special attention should be given to preventive dental care in patients with coagulation disorders, so as to minimize the complications, expense, and hazards of operative dental procedures. The extraction of even a single tooth usually requires replacement therapy. Most authorities recommend that dental procedures in patients with inherited coagulation disorders be carried out under cover of replacement therapy and antifibrinolytic therapy.502

THE FUTURE IN HEMOPHILIA TREATMENT

After the devastating epidemics in the hemophilia community caused by HIV and hepatitis C, it was a major step forward to have available recombinant products for treatment of hemophilia in the early 1990s. Now, 20 years later, several new products are in clinical trials that promise major advances in hemophilia treatment. Factor VIII and factor IX have been available as recombinant proteins for nearly 20 years, but due to their relatively short half-lives, still require frequent intravenous infusions in order to maintain clotting factor concentrations in plasma to avoid the risk of spontaneous bleeding. The longer half-life factor VIII and factor IX products will change treatment paradigms. In addition, there are efforts to provide other coagulation proteins as recombinant therapeutic products. Finally, there are renewed efforts in gene therapy for hemophilia, with better and safer viral vectors.

Chapter 54 Acquired Coagulation Disorders

Abnormalities in blood coagulation may complicate a large number of disorders (Table 54.1). In contrast to inherited disorders in which deficiency or abnormality of a single factor is characteristic, the acquired forms usually are associated with multiple coagulation abnormalities, and the disorder often is complicated by thrombocytopenia, deficient platelet function, and abnormal inhibitors of coagulation. Because of the compound nature of the hemostatic defect, the severity of bleeding often correlates poorly with the results of laboratory tests in patients with acquired coagulation disorders, and replacement therapy may be ineffective. With some notable exceptions, however, bleeding usually is less severe than in the inherited forms, and the clinical picture often is complicated by signs and symptoms of the underlying disease.

DEFICIENCIES OF VITAMIN K-DEPENDENT FACTORS

Prothrombin; factors VII, IX, and X; and proteins C and S are synthesized by the liver by a process that depends on vitamin K (see Chapter 18 and Fig. 54.1). When stores of this vitamin are deficient or abnormal, hypofunctional analogs of these factors are synthesized, which inhibit normal coagulation. These descarboxy analogs of the vitamin K-dependent factors
do not bind to cellular phospholipid surfaces and, therefore, do not participate in cell-associated coagulation reactions. This may occur in disorders in which intake or absorption of vitamin K is deficient and in disorders that impair the biosynthetic capacity of the liver (Fig. 54.1). A similar coagulation abnormality may be produced by anticoagulant drugs such as coumarin and indanediones, which antagonize the action of vitamin K (see Chapter 55).

**Vitamin K Deficiency Bleeding (Hemorrhagic Disease of the Newborn)**

Hemorrhagic disease of the newborn is the result of vitamin K deficiency in the neonate; this phrase was first used more than 100 years ago. The preferred term is vitamin K deficiency bleeding (VKDB) in infancy as proposed by a consensus committee. Formerly a major cause of bleeding, this disorder is now uncommon because of the routine administration of vitamin K at birth; however, it is still encountered in economically deprived populations.

**Pathophysiology**

The normal newborn has a moderate deficiency of the vitamin K-dependent coagulation factors. The plasma levels of these factors normally fall even further during the first 2 to 5 days of life, rise again when the infant is 7 to 14 days old, and attain normal adult levels later in life (see also Table 45.6). The deficiency of the vitamin K-dependent coagulation factors that is present at birth, as well as the slow rate at which adult levels are attained, presumably is the result of intrinsic “liver immaturity;” neither of these physiologic phenomena is affected by vitamin K administration. On the other hand, the diminution in levels of these factors that occurs at age 2 to 5 days is prevented by vitamin K administration because it is the result of a transitory physiologic deficiency of this vitamin. Factors that further diminish the amount of vitamin K available at this juncture and those that further impair the synthetic capacity of the liver predispose neonates to hemorrhagic disease of the newborn. These factors are (a) prematurity, (b) inadequate dietary intake, (c) delayed gut colonization by bacteria, (d) various obstetric and perinatal complications, and, possibly, (e) maternal deficiency of vitamin K.

Prematurity often has been associated with VKDB. Levels of the vitamin K-dependent factors at birth are approximately proportional to gestational age and birth weight. In premature infants, the physiologic immaturity of the liver is marked, and the response to vitamin K that is present is subnormal.

Most factors associated with deficient intake of vitamin K also delay the colonization of the gut by bacteria. These factors include delayed feeding, breast-feeding, vomiting, severe diarrhea, and antibiotics, including those present in maternal milk. Human milk and colostrum are poor sources of vitamin K, and reliance on breast milk as the sole source of nutrients in the neonatal period is an important factor in many cases of VKDB.

Coumarin and indanedione drugs cross the placenta and may produce hemorrhagic disease in the newborn. Infants born of mothers who were taking diphenylhydantoin or other anticonvulsants, including barbiturates, or salicylates have developed a syndrome similar to VKDB. Treatment of the mother with vitamin K during the last trimester may prevent this complication.

**Clinical Features and Laboratory Diagnosis**

VKDB etiology is considered idiopathic (no cause other than breast-feeding) or secondary (malabsorption of vitamin K, liver disease, drugs). VKDB can also be classified in terms of age of onset: Early (onset <24 hours of age), classic (onset usually between 3 and 5 days), and late (onset on or after 8 days). Early VKDB is uncommon and usually results from placental transfer of maternal drugs that antagonize vitamin K in the newborn. Late VKDB occurs almost exclusively in breast-fed infants who may also have hepatobiliary disease.

### TABLE 54.1 ACQUIRED COAGULATION DISORDERS

**Deficiencies of vitamin K-dependent coagulation factors**

Hemorrhagic disease of the newborn (vitamin K deficiency bleeding)

Biliary obstruction (gallstone, strictures, fistulas)

Malabsorption of vitamin K (sprue, idiopathic steatorrhea, celiac disease, ulcerative colitis, regional enteritis, gastrocolic fistulas, *Ascaris* infestation)
Nutritional deficiency

Drugs

1. Pharmacologic antagonists of vitamin K (coumarins, indandiones, others)
2. Those that alter gut flora (broad-spectrum antibiotics, sulfonamides)
3. Miscellaneous (cholestyramine)

Liver disease (see Table 54.3)

Accelerated destruction of coagulation factors

Disseminated intravascular coagulation (see Table 54.4)
Fibrinolysis (liver disease, thrombolytic agents, tumors, after surgery)

Inhibitors of coagulation

Specific inhibitors (antibodies) (see Table 54.6)
Antiphospholipid-protein antibodies (see Table 54.7)
Miscellaneous (antithrombins, paraproteinemias)

Miscellaneous

After massive transfusion
After extracorporeal circulation
Drugs (antibiotics, antineoplastic agents, others)
Other disorders (polycythemia vera, congenital heart disease, amyloidosis, nephrotic syndrome, Sheehan syndrome, Gaucher disease, leukemia, others)
Bleeding in classic VKDB is severe. The most common manifestations are melena, large cephalohematomas, and bleeding from the umbilical stump and after circumcision. Generalized ecchymoses, often without petechiae, intracranial bleeding, and large intramuscular hemorrhages also may develop.

Laboratory diagnosis is relatively simple (Table 54.2), but physiologic differences in the results of various coagulation tests in normal neonates must be kept in mind (see Table 45.6). In infants with VKDB, the prothrombin time (PT) always is prolonged. The partial thromboplastin time (PTT) is also prolonged. Specific factor assays reveal deficiencies of prothrombin; factors VII, IX, and X; and proteins C and S. The presence of normal antigenic levels of the vitamin K-dependent factors may be demonstrated by immunoassays. Factors V and VIII, as well as fibrinogen, are present in normal amounts. The consensus committee recommends diagnosing VKDB with a prolonged PT value, a normal fibrinogen level, and a normal platelet count.

The clinician should not assume that bleeding in the neonate is invariably the result of vitamin K deficiency. In the differential diagnosis of VKDB, virtually all causes of bleeding, particularly thrombocytopenia (see Chapter 46) and disseminated intravascular coagulation (DIC) must be considered. The inherited coagulation disorders (see Chapter 53) also may produce serious hemorrhage in the neonatal period, but significant prolongation of the PT is not found in the most common forms, for example, hemophilia A and hemophilia B. Umbilical bleeding and hemorrhage after circumcision are relatively less common in the inherited coagulation disorders than in VKDB.

Treatment

Vitamin K₁ (0.5 to 1.0 mg given intramuscularly) is dramatically effective in the treatment of VKDB; the 0.5-mg dose appears to be more than adequate. Shortening of the PT may be expected within 6 hours, and normal neonatal levels of the vitamin K-dependent factors usually are attained within 24 hours of administration. An American Academy of Pediatrics consensus report has summarized recommendations of vitamin K therapy for prevention of early and late VKDB. Larger (2 mg) or repeated (every 4 to 8 hours) doses of vitamin K₁ may be required to counteract the effects of coumarin drugs in infants. The response in premature infants to vitamin K₁ usually is incomplete. The administration of
large doses of vitamin K may produce hemolysis, hyperbilirubinemia, and even kernicterus in the neonate. These complications appear to be associated more commonly with the synthetic derivatives than with vitamin K₁, but even the latter may be dangerous in large doses.⁵

In severe cases of VKDB, the transfusion of plasma may be helpful.⁶ Concentrates of vitamin K-dependent coagulation factors are effective but have led to thrombosis and intravascular coagulation in some infants, particularly in premature infants. This result has been attributed to immaturity of the hepatic clearance functions and physiologic deficiency of antithrombin.

Because VKDB is primarily a disease of breast-fed infants,¹⁶ VKDB can be prevented by the administration of vitamin K to the mother before delivery. Most authorities, however, recommend administering vitamin K₁ to the infant. This procedure is now routine in most nurseries. Many pediatricians also recommend the prophylactic administration of vitamin K₁ to infants 1 to 5 months of age, especially those who are breast-fed or who have a disorder that may impair vitamin K absorption.¹⁷ The usual dosage in such older infants is 50 to 100 µg daily or 1 mg monthly.

Miscellaneous Tests

- Antithrombin: D, decreased; FDP, fibrin(ogen) degradation products; I, increased; N, normal; u, usually; v, variably; V, variable.
- May reveal effects of acute bleeding or abnormality characteristic of underlying disease.
- Results may differ from adult norms in normal neonates.
- One-stage assays may yield aberrant results.
- Hypofibrinogenemia may alter results.

The presence of immunoglobulin M rheumatoid factors in certain patients may lead to a false-positive result in latex-agglutination assays.

Most pediatricians would attribute the decrease in incidence of VKDB in recent years to the prophylactic administration of vitamin K. There is widespread consensus on continuing vitamin K prophylaxis to newborns. A prospective population study in the United Kingdom found that with prophylaxis, VKDB in newborns is rare, whereas in developing countries, prophylaxis is not frequently used, and VKDB is common.

Other Causes of Vitamin K Deficiency

Obstruction of the biliary tract, either intrahepatic or extrahepatic, produces vitamin K deficiency because of the absence of bile salts in the gut. Complete obstruction may lead to severe coagulation abnormalities and bleeding within 2 to 4 weeks. This was a major obstacle to surgical procedures on the biliary tract before the discovery of vitamin K.

Most malabsorption syndromes and various other chronic gastrointestinal disorders also may give rise to vitamin K deficiency. Such disorders include celiac disease, sprue, gastrointestinal fistulas, ulcerative colitis, regional enteritis, extensive gut resections, protracted diarrhea of any cause, Ascaris infestations, and cystic fibrosis. The last named disorder often is complicated by liver disease. Severe abnormalities of coagulation and bleeding are less common in association with these disorders than with biliary obstruction, presumably because absorption of vitamin K is seldom completely deficient.
Because vitamin K normally is available from two independent sources (Fig. 54.1), neither nutritional deficiency nor gut sterilization alone produces deficiency of a degree that results in significant coagulation abnormalities. In normal adults, the daily oral intake of vitamin K must be reduced to 20 µg or less for several weeks to produce significant hypoprothrombinemia. However, vitamin K deficiency is more common than is usually realized in hospitalized patients with poor or negligible oral food intake, especially if they are also taking antibiotics. Significant coagulation abnormalities may arise with surprising rapidity in such patients, and when unsuspected, they may be confused with DIC or may first be revealed by serious, unexpected postoperative hemorrhage. Antimicrobial agents presumably impair vitamin K production by inhibiting the synthesis of menadiones by gut bacteria, but they may also directly affect carboxylation reactions. Vitamin K deficiency also may result from use of drugs other than antimicrobial agents, such as cholestyramine, which acts by binding bile salts, or mineral oil and other cathartics when used for protracted periods. Vitamin E may antagonize the metabolic action of vitamin K and potentiate the action of coumarins. When taken in large doses, this vitamin may prolong the PT. Antibiotic therapy, poor diet, or any of the aforementioned disorders may predispose patients to coumarin toxicity (see Chapter 55). Large doses of aspirin, as given to treat rheumatic disorders or in amounts associated with overdosage of the drug, may also induce vitamin K deficiency.

Treatment

In adults, the parenteral administration of 10 mg of vitamin K₃ abolishes coagulation abnormalities within 12 to 24 hours if they are the consequence of a deficiency of this vitamin. Failure of vitamin K to normalize the PT is evidence for the presence of a complicating process, such as liver disease or DIC, or super-warfarin ingestion. The synthetic vitamin K₃ (menadiones) may be absorbed in the absence of bile salts and in various malabsorption syndromes. However, these congeners of vitamin K have a more transient effect than the natural forms of this vitamin and offer minimal therapeutic advantage in the usual case. Replacement therapy with fresh frozen plasma or prothrombin complex concentrates (PCCs) is effective in the treatment of emergent vitamin K deficiency.

Intravenous administration of vitamin K may produce hemolytic anemia in patients with inherited deficiencies of various red cell enzymes, and may be associated with a risk of anaphylaxis. Malnourished patients receiving broad-spectrum antibiotic therapy should receive vitamin K prophylactically, 5 mg twice weekly, orally or subcutaneously.

Commercially available rodenticides (super-warfarins) that exhibit long-acting vitamin K antagonism have been associated with significant bleeding disorders when these compounds have been ingested by humans. These drugs are chemically distinct from warfarin, are 100 times more potent than warfarin, and can induce vitamin K deficiency lasting for months. In 1995 alone, more than 13,000 people were exposed to these agents and treated. Initial treatment of these patients may require up to 100 mg of vitamin K daily to normalize vitamin K metabolism.

LIVER DISEASE

Virtually every hemostatic function may be impaired in patients with severe hepatic disease (Table 54.3) as the result of failure of both the biosynthetic and clearance functions of the liver. The pathophysiology of some of these abnormalities is tied to thrombocytopenia (see Chapter 46), platelet dysfunction (see Chapter 52), intravascular coagulation and fibrinolysis, and the effects of products of fibrinogen catabolism on hemostasis (see below).

Pathophysiology

Thrombocytopenia

Patients with significant liver disease have portal hypertension, splenomegaly, and splenic sequestration of platelets, contributing to thrombocytopenia. The liver is also the major site of production of thrombopoietin, the principal humoral factor involved in megakaryocyte maturation and platelet formation (see Chapter 15). Recent studies have evaluated whether deficient levels of thrombopoietin occur in liver disease. Results indicate that thrombocytopenia in liver disease is not explained by deficient hepatic production of thrombopoietin. However, there is a correlation between the extent of liver disease and platelet expression of the thrombopoietin receptor, c-Mpl, and this reduced expression may contribute to thrombocytopenia. Additionally, increased thrombopoietin degradation by platelets sequestered in the spleen may also contribute to thrombocytopenia in these patients.

TABLE 54.3 ABNORMALITIES OF HEMOSTASIS AND COAGULATION IN LIVER DISEASE
Deficient biosynthesis
Of fibrinogen; prothrombin; coagulation factors V, VII, IX, X, XI, XII, XIII; prekallikrein; high-molecular-weight kininogen
Of antithrombins, antithrombin, proteins C and S

Aberrant biosynthesis
Of abnormal fibrinogen, factor V
Of abnormal inhibitory analogs of prothrombin, factors VII, IX, and X

Deficient clearance
Of hemostatic “products” (e.g., fibrin monomers, fibrinogen degradation products, platelet factor-3)
Of activated coagulation factors (IXa, Xa, Xa, XIa)
Of plasminogen activators

Accelerated destruction of coagulation factors
Disseminated intravascular coagulation
Abnormal fibrinolysis

Thrombocytopenia
Hypersplenism (portal hypertension)
Folic acid deficiency
Chronic ethanol intoxication
Disseminated intravascular coagulation

Platelet dysfunction
Acute and chronic ethanol intoxication
Effects of products of fibrinogen degradation
Uremia

Miscellaneous
Inhibition of coagulation by products of fibrinogen degradation
Loss or consumption of coagulation factors in ascitic fluid

Deficient or Aberrant Synthesis of Coagulation Factors
In patients with liver disease, all coagulation factors except factor VIII may be deficient as a consequence of synthetic failure of the hepatic cells. Failure of biosynthesis of coagulation factors often correlates with the severity of hypoalbuminemia, but exceptions to this rule are common. Deficiencies of prothrombin; factors VII, IX, and X; and proteins C and S result mainly from synthetic incompetence. For example, factor VII expression in liver biopsies from patients with liver disease decreases as the severity of hepatic dysfunction increases. Impaired carboxylation of precursors may contribute to the defect. Superimposed vitamin K deficiency may result from a poor diet or malabsorption caused by insufficient production of bile salts or by exocrine pancreatic insufficiency. The failure of these coagulation abnormalities to respond to vitamin K administration provides good evidence of hepatic cell dysfunction.

Factors V, XI, and XIII are synthesized by the liver but are not vitamin K-dependent; all of these factors may be deficient in patients with severe liver disease. Plasma levels of factor XII, prekallikrein (Fletcher factor), and high-molecular-weight
kininogen (Fitzgerald factor) also may be low in association with liver disease. Deficiencies of these latter three factors do not contribute to a bleeding diathesis.

Hypofibrinogenemia rarely may result from deficient hepatic biosynthesis or DIC, as discussed subsequently. In many patients with liver disease, prolongation of the thrombin time can be significant in the absence of hypofibrinogenemia or increased levels of fibrinogen degradation products (FDPs). This apparently is the result of a qualitatively abnormal fibrinogen that is synthesized by the diseased hepatic cell. Such acquired dysfibrinogenemia has been reported in most forms of liver disease, ranging from mild acute hepatitis to acute hepatic necrosis and cirrhosis. Fibrin monomer polymerization is delayed, and the abnormal fibrinogen molecule acts as an antithrombin. Additionally, this hepatic disease dysfibrinogen may have an abnormally high content of sialic acids and may produce a structurally defective fibrin clot. Acquired dysfibrinogenemia, abnormal inhibitors of fibrinolysis, and the presence within the plasma of descarboxy analogs of prothrombin have been reported in patients with hepatomas. Hepatoma-associated dysfibrinogens have also been noted to have an increased carbohydrate content.

Plasma levels of factor VIIIc usually are elevated in both parenchymal and cholestatic liver disease. Studies in patients with cirrhosis indicate that elevated plasma factor VIII levels are not due to increased transcriptional activity of factor VIII in the liver, but instead likely result from increased liver synthesis of von Willebrand factor (vWF) and decreased levels of lipoprotein receptor-related protein. Both of these latter proteins regulate plasma factor VIII levels.

Fibrinogenolysis and Fibrinolysis

Endogenous plasminogen activators normally are removed from the circulation by the liver. In patients with severe liver disease, however, they may circulate for an abnormally long time and lead to the chronic or intermittent activation of the fibrinolytic enzyme system. This process may be a contributory factor in the pathogenesis of hypofibrinogenemia in patients with liver disease. It also leads to the production of large amounts of FDP, which persist in the circulation for abnormally long periods because of deficient hepatic clearance, and may impair blood coagulation and platelet function. Such proteolytic activity also may produce a shift in the mean molecular weight of circulating fibrinogen from the normal species to a less reactive species of lower molecular weight, thereby contributing to the “antithrombins of liver disease.”

The incidence of hyperfibrinolysis was surveyed in patients with cirrhotic and noncirrhotic liver disorders. Hyperfibrinolysis, as measured by a shortened euglobulin clot lysis time, was present in approximately 30% of cirrhotic patients but not present in noncirrhotic patients. The role of thrombin-activatable fibrinolysis inhibitor deficiency in liver disease in contributing to hyperfibrinolysis has been studied; thrombin-activatable fibrinolysis inhibitor levels are reduced in liver disease, with lower levels seen in more severe liver disease. However, there was no association of low thrombin-activatable fibrinolysis inhibitor levels with hyperfibrinolysis, even in cirrhotic patients. These studies suggest that hyperfibrinolysis is not common in liver disease, even in cirrhosis.

Plasma levels of antithrombin, antiplasmin, and plasminogen are subnormal in patients with liver disease. These abnormalities are of uncertain clinical importance.

Intravascular Coagulation

Severe liver disease theoretically predisposes individuals to the development of DIC because DIC is associated with deficient hepatic clearance of activated coagulation factors and other coagulant substances. The in vivo turnover rates of prothrombin, fibrinogen, plasminogen, and antithrombin often are accelerated in patients with cirrhosis. Plasma levels of fibrinopeptide A are elevated in most patients with cirrhosis. All of these abnormalities may be normalized in some cases by the administration of heparin. It has been hypothesized that accelerated catabolism of coagulation factors in these disorders is the result of DIC. The nature of the initiating process is unclear, but one suggestion is that DIC is activated by hypoperfusion of the congested portal bed. Indirect evidence suggests that in severe liver disease, activators of coagulation, possibly endotoxin, may originate in the gut.

Low-grade DIC or localized intravascular coagulation indeed may occur in association with severe liver disease, but overt DIC is responsible only rarely for bleeding in the absence of other etiologic factors that trigger this process, for instance, sepsis, shock, and cancer. This conclusion is supported by findings in patients with stable cirrhosis that demonstrated no increased levels of markers of activation of coagulation, such as prothrombin fragment 1+2, thrombin-antithrombin complex, and so forth.

Evidence for accelerated fibrinogen turnover in ascitic fluid suggests that the loss or consumption of coagulation factors in peritoneal fluid may be a contributory factor in the coagulopathy of chronic liver failure. Shunting of ascitic fluid into the venous circulation by means of LeVeen shunts consistently produces coagulation abnormalities consistent with DIC in
cirrhotic patients. Although this phenomenon usually is attributed to intravascular coagulation, evidence shows that it may result in part from the presence of plasminogen activators and active plasmin or collagen in peritoneal fluid.

A transitory coagulation disorder that resembles intravascular coagulation with active fibrinolysis has been documented during liver transplantation procedures. Coagulation abnormalities disappear promptly if the graft is successful. The complex coagulopathy seen with liver transplantation has been reviewed.

Clinical Manifestations

In view of the numerous hemostatic abnormalities associated with severe liver disease, it is surprising that many patients do not bleed abnormally. Gastrointestinal hemorrhage is the most common bleeding manifestation, but it almost always originates from a local lesion, such as esophageal varices, peptic ulcer, or gastritis. The degree to which coagulation abnormalities contribute to such bleeding is uncertain. In one large series, gastrointestinal bleeding was not significantly more severe or protracted in patients with coagulation abnormalities than in those without them. In another study, serious hemorrhage occurred only in patients with prolonged PTs and significant factor IX deficiency. Moderate generalized bleeding manifestations, such as recurrent ecchymoses and epistaxis, are not uncommon, and severe generalized bleeding may complicate surgical procedures, including biopsies, tooth extractions, and other minor procedures.

The above-mentioned paradox of the lack of bleeding in many patients with severe liver disease despite multiple hemostatic abnormalities has been explored. An emerging concept is that coagulation in liver disease patients is “rebalanced” due to parallel reductions in both procoagulant and anticoagulant factors. Standard coagulation tests (such as the PT) do not measure major in vivo regulators of coagulation such as thrombomodulin and may not adequately reflect hemostasis in these patients. This new paradigm has implications for managing the coagulopathy of liver disease.

Laboratory Diagnosis

The laboratory findings in liver disease vary with the cause and severity of the underlying disorder and range from a slight prolongation of the PT in anicteric hepatitis to the findings summarized in Table 54.2, which are seen in severe decompensated cirrhosis. In cirrhosis, coagulation abnormalities correlate with the presence of portal hypertension and may be minimal in inactive cirrhosis; thrombocytopenia alone is common in association with portal hypertension. Acute fibrinogenolysis is significantly more common in patients with cirrhosis than in those with acute hepatocellular disease, such as hepatitis, although elevations of FDP are consistently found in people with chronic aggressive hepatitis. Coagulation abnormalities are seldom marked in biliary cirrhosis, and some patients with this disorder have abnormally high levels of prothrombin and factors VII and X. Hemostatic abnormalities of any sort are rare in metastatic liver disease. In acute liver failure, the PT value has prognostic value and is indicative of the need for liver transplantation. The spectrum of coagulation abnormalities in liver disease has been reviewed.

Although screening tests of coagulation are almost invariably performed before liver biopsy, they apparently are of little value in predicting hemorrhage after this and other minor surgical procedures. Similarly, the bleeding time test is of little clinical use in predicting bleeding. Many physicians use the international normalized ratio (INR) as a substitute coagulation test for the PT. When measured with a sensitive thromboplastin, the INR can quantitate vitamin K deficiency due to liver disease, but it should not be interpreted as in patients receiving warfarin.

Treatment

Not all patients with the coagulopathy of liver disease require hemostatic correction before procedures such as liver biopsy. A retrospective study looked at the PT ratio (patient PT/mean of reference range PT) and degree of thrombocytopenia to determine the necessity of plasma and platelet transfusion. In patients with platelet counts of 50,000/µl or greater, there was no increased bleeding with liver biopsy compared with patients with normal platelet counts. With regard to elevated PT values, if the PT ratio was <1.5, no increased bleeding was observed. Therefore, patients with moderate thrombocytopenia and mild liver disease coagulopathy do not need routine hemostatic correction with blood products. One exception to this recommendation is patients with a diagnosis of malignancy, who may have a higher bleeding risk, possibly due to chronic DIC and elevated FDP levels. On the other hand, a British guidelines committee on the use of plasma products suggests that “patients with liver disease and a PT more than 4 seconds longer than control are unlikely to benefit from FFP.” This recommendation is based on expert opinion.
Elevated FDP levels may be a significant hemostasis risk factor in liver disease. High levels of FDP may impair platelet function and fibrin monomer polymerization. The thrombin time can screen for the latter defect. A prolonged thrombin time in a patient with a normal functional fibrinogen level and high FDP levels, who is not receiving heparin, may constitute a significant bleeding risk, especially in the setting of moderate thrombocytopenia.

Vitamin K, in a dose of 10 mg, produces some improvement in the coagulation abnormalities in approximately 30% of patients with liver disease, but the PT often becomes prolonged again after an initially favorable response. Patients with severe liver disease have minimal or no response to vitamin K therapy.

Replacement therapy with fresh frozen plasma is indicated only in the presence of serious bleeding or before surgical procedures, and its effect is often disappointing in patients with liver disease. Reasons for this may include the short in vivo half-life of factor VII, hypervolemia, the loss of transfused factors into ascitic fluid, and the fact that the in vivo recovery of transfused factor IX is significantly lower than that of other factors, even in the absence of liver disease. Concentrates of vitamin K-dependent coagulation factors (PCC) have been used in the replacement therapy of bleeding in patients with liver disease with variable success but, in several cases, have led to thromboembolic complications and DIC. Thrombosis presumably develops because such concentrates contain trace amounts of activated coagulation factors, particularly factors IXa and Xa, that normally are not cleared from the circulation by the diseased liver and because of antithrombin deficiency, which is commonly present. Newer PCCs are becoming available; these also contain proteins C and S in addition to the procoagulant vitamin K-dependent factors. These products have not been well studied in liver disease coagulopathy, but appear to be effective in reversing warfarin coagulopathy. Fresh frozen plasma is the preferable treatment option, but the effects of even maximum doses (20 to 30 ml/kg of body weight) often are transitory. Cryoprecipitate is useful to maintain fibrinogen levels over 100 mg/dl. A controlled trial found that 1-desamino-8-darginine vasopressin (DDAVP) is not helpful in management of variceal bleeding in cirrhotic patients.

Recombinant factor VIIa (rVIIa) is a potential therapy for liver disease patients with significant coagulopathy. However, the drug is not indicated for use in variceal bleeding, partial hepatectomy, or liver transplantation. Disadvantages of rVIIa include its high cost and risk of DIC and thromboembolic complications.

Even though heparin administration may normalize fibrinogen catabolism, little evidence is cited that it decreases the duration or severity of bleeding in patients with low-grade DIC and severe liver disease. However, heparin may be useful in conjunction with PCC therapy. In this setting, the addition of small amounts of normal plasma and heparin to vials of these thrombogenic concentrates inactivates activated proteases and minimizes the thrombotic risks of these concentrates.

Correction of thrombocytopenia may be difficult in patients with severe liver disease. One promising intervention is the use of synthetic thrombopoietins and thrombopoietin mimetic agents. Eltrombopag is approved to treat thrombocytopenia in chronic hepatitis C patients who receive interferon therapy.

For patients requiring liver biopsy who are deemed “high risk” from the hemostasis perspective, the transjugular approach should be considered.

**DISSEMINATED INTRAVASCULAR COAGULATION**

The syndrome of DIC (defibrination syndrome, consumption coagulopathy) has been one of the most intensively studied subjects in hematology. This large body of information has been summarized in many detailed reviews and monographs. A consensus definition of DIC has been proposed: “DIC is an acquired syndrome characterized by the intravascular activation of coagulation with loss of localization arising from different causes. It can originate from and cause damage to the microvasculature, which if sufficiently severe, can produce organ dysfunction.”

**Etiology and Incidence**

DIC has been well documented in association with the disorders summarized in Table 54.4. Several retrospective studies suggest that DIC remains a relatively uncommon entity, but in one large general hospital, its overall incidence was 1 in 1,000 admissions. The most prevalent etiologic factor was infection, but in another study, more than 50% of cases were obstetric patients. A Japanese study found that in a hospital population, 45% of DIC cases were associated with malignancy. In many of the disorders listed in Table 54.4, DIC develops only in an occasional case. Thus, it is rare in heatstroke, autoimmune disorders, and hemolytic anemias. DIC is present in most cases of venous snakebite, which is probably one of the most common causes of the disorder worldwide.
TABLE 54.4 ETIOLOGIES OF DISSEMINATED INTRAVASCULAR COAGULATION

**Obstetric complications**
Abruptio placentae, septic abortion and chorioamnionitis, amniotic fluid embolism, intrauterine fetal death, miscellaneous (degenerating hydatidiform moles and leiomyomas, postpartum hemolytic-uremic syndrome, abdominal pregnancy, tetracycline-induced hepatorenal failure, fetomaternal blood passage, saline- and urea-induced abortions)

**Infections**
Viral (herpes, rubella, smallpox, acute hepatitis, Reye syndrome, cytomegalic inclusion disease, various epidemic hemorrhagic fevers, others)
Rickettsial (Rocky Mountain spotted fever, others)
Bacterial (meningococcemia, septicemia, particularly that due to Gram-negative organisms, many others)
Mycotic (histoplasmosis, aspergillosis)
Protozoal (malaria, kala-azar, trypanosomiasis)

**Neoplasms**
Carcinomas (prostate, pancreas, breast, lung, ovary, many others)
Miscellaneous (metastatic carcinoid, rhabdomyosarcoma, neuroblastoma, others)

**Disorders of the hematopoietic system**
Acute leukemia (promyelocytic, other types)
Intravascular hemolysis (transfusion of incompatible blood, paroxysmal nocturnal hemoglobinuria, fresh-water submersion)
Histiocytic medullary reticulosis

**Vascular disorders**
Malformation (giant hemangiomas [Kasabach-Merritt syndrome], aneurysms, coarctations of the aorta and other large vessels, Takayasu aortitis, large prosthetic arterial grafts, cyanotic congenital cardiac lesions)
Collagen-vascular disorders
Hypoxia and hypoperfusion, myocardial infarction, cardiac arrest, various forms of shock, hypothermia

**Massive tissue injury**
Large traumatic injuries and burns, extensive surgical intervention, extracorporeal circulation, fat embolism

**Miscellaneous**
Acute iron toxicity, head trauma, snakebite, anaphylaxis, concentrates of vitamin K-dependent coagulation factors, heatstroke, allograft rejection, graft versus host disease, severe respiratory distress syndrome, diabetic acidosis, status epilepticus, acute pancreatitis, homozygous deficiency of protein C

Pathophysiology

Mechanisms by Which Disseminated Intravascular Coagulation Is Initiated
The pathophysiology of DIC is complex. The mechanisms that activate or “trigger” DIC act on processes that are involved in normal hemostasis, namely, the processes of platelet adhesion and aggregation and contact-activated (intrinsic) and tissue factor-activated (extrinsic) pathways of coagulation (Fig. 54.2). These mechanisms have in common the capacity, in terms of either the magnitude or the duration of the activating stimulus, to exceed normal compensatory processes. Thrombin is persistently generated, and fibrin is formed in the circulating blood. Fibrinogen, various other coagulation factors, and platelets are consumed. The fibrinolytic mechanism is activated, and large amounts of FDP are produced, which further impair hemostatic function. Bleeding, shock, and vascular occlusion commonly supervene and produce profound alterations in the function of various organ systems. Normal compensatory processes may become impaired, creating a self-perpetuating “vicious cycle.” The ultimate outcome is determined by a dynamic interplay between the various pathologic processes and compensatory mechanisms, in other words, fibrin deposition versus fibrinolysis; depletion versus repletion of coagulation factors and platelets; and production versus clearance of fibrin, FDPs, and other products of coagulation (Fig. 54.3). In most forms of DIC, the initiating factors are multiple and interrelated. For example, in meningococcemia, endothelial cell injury may lead to expression of tissue factor and to collagen exposure; the latter then initiates platelet adhesion, aggregation, and thrombosis.
FIGURE 54.2. Initiating mechanisms of disseminated intravascular coagulation (DIC). The solid arrows indicate normal hemostatic pathways, and dotted arrows indicate pathways by which certain disorders associated with DIC initiate or promote the coagulopathy of DIC. Initiation of coagulation by expression of tissue factor activity is probably the most important mechanism triggering DIC.

Tissue Factor
The exposure of procoagulant tissue extracts to blood is a major contributory factor in most forms of DIC and is of major pathogenetic importance in cases associated with abruptio placentae, intrauterine fetal death, acute promyelocytic leukemia, amniotic fluid embolism, massive trauma, and various neoplasms. The active component of such extracts is tissue factor (thromboplastin); that is, tissue factor interacts with factor VIIa to activate the extrinsic pathway of coagulation.

In abruptio placentae decidual fragments, serum-containing activated coagulation factors, and other substances from the placental site enter the intervillous “maternal lake” and, hence, the venous circulation. This process is initiated by rupture of the basal decidual plate.

In amniotic fluid embolism, relatively weak thromboplastins that increase in potency with gestational age and large amounts of particulate matter enter the circulation suddenly. In intrauterine fetal death, thromboplastic substances from the dead fetus are slowly but continuously absorbed, producing a picture of chronic but progressive DIC.

FIGURE 54.3. Pathophysiology of disseminated intravascular coagulation (DIC). The critical event in DIC is the generation of thrombin in an unregulated fashion. The clinical consequences of thrombin production depend on the rate of thrombin formation as well as underlying host factors (marrow reserve of platelet production, liver function). Patients with adequate compensatory responses (ability to enhance platelet or coagulation factor production, fibrinolysis, intact clearance mechanisms) may have minimal symptoms, whereas other patients with defective compensatory responses may bleed, thrombose, or both. Increased levels of cytokines occur (TNF, IL-1) that contribute to the proinflammatory state by down-regulating thrombomodulin activity; this leads to enhancement of intravascular fibrin formation and organ dysfunction. Major compensatory factors that influence clinical events are indicated in colored blocks. The zig-zag line indicates interruption of an adverse clinical event by a compensatory factor. FDP, fibrin(ogen) degradation product; IL-1, interleukin-1; PAI-1, plasminogen activator inhibitor-1; TNF, tumor necrosis factor.
In neoplasms, tumor microemboli and tumor “vesicles” are thought to enter the circulation and act as thromboplastins. Tumor cell surface expression of tissue factor has been demonstrated. Some neoplasms may secrete a factor X activator.

DIC in association with acute leukemia presumably results from the formation or release of tissue factor by leukemic cells. Additional leukocyte enzymes such as elastase may contribute to DIC and fibrin(ogen)olysis by proteolysis of coagulation zymogens and fibrinogen. Malignant promyelocytes, as seen in promyelocytic leukemia, express high levels of annexin II, a phospholipid-binding protein and receptor for plasminogen and tissue plasminogen activator. This overexpression of annexin II results in enhanced plasmin production and increased fibrinolytic activity. The granules of various “blast” forms contain tissue factor, with the promyelocyte containing particularly high concentrations.

In DIC associated with massive trauma, major surgical procedures, or large burns, damaged tissue expressing tissue factor activity presumably is a major initiating factor. In such cases, additional abnormalities and complications are important contributory factors, such as “hypercoagulability,” azotemia, shock, intravascular hemolysis, massive transfusions of stored blood, sepsisemia, and hypoxia. Cerebral trauma of sufficient magnitude to produce significant brain destruction induces a brief episode of DIC, which, although transitory, may be significant in that it may perpetuate cerebral bleeding.

Monocyte-associated Procoagulants

It has been known for many years that monocytes and tissue macrophages may, when suitably activated, express substances capable of initiating blood coagulation. This phenomenon is thought to be of importance in inflammation and in tissue localization of infectious agents and tumors. It has become apparent that “recognition-coupled” responses of the monocyte-macrophage system may be important in triggering DIC in association with meningococcemia and other forms of septicemia, certain forms of leukemia, major transfusion reactions, and anaphylaxis. The best defined model of this process is the induction of tissue factor by monocytes exposed to endotoxin or immune complexes.

Other substances that may induce monocyte procoagulant activity include anaphylatoxins and cytokines. Most of these substances induce the formation of monocyte coagulants only in the presence of T lymphocytes. A prothrombinase-like activity and a specific activator of factor X also are formed by appropriately conditioned monocytes.

Vascular Endothelium

In addition to monocytes or macrophages, vascular endothelium can be induced to express tissue factor activity in the setting of experimental DIC. Endothelium can also be down-regulated in terms of anticoagulant properties (e.g., thrombomodulin activity, fibrinolysis) by stimuli relevant in the pathogenesis of DIC (see Chapter 19). This altered endothelium is referred to as activated; properties of activated endothelium include conversion of the normally anticoagulant phenotype to a procoagulant phenotype, expression of adhesion molecules, production of inflammatory mediators, and production of vasoactive agents. Many of these pathologic events are amplified by endothelial cell proteaseactivated receptors (PARs) (see Chapter 19). Vascular endothelium may also promote coagulation by formation of thrombogenic microparticles, which express anionic phospholipid. Microparticles in DIC may also originate from platelets or granulocytes. Thrombin generation caused by activation of factor XII in DIC appears to be less important than that initiated by tissue factor. Contact activation, instead, appears critical in mediating DIC-associated hypotension.

Role of Cytokines

Although there are numerous etiologies for DIC (Table 54.4), a common pathway for activation of coagulation by these disorders is cytokine release. Important mediators include endotoxin, interleukin-1 (IL-1), IL-6, IL-8, platelet activating factor, and tumor necrosis factor (TNF). TNF and IL-1 both increase monocyte and endothelial cell tissue factor activity and inhibit protein C activation. Elevated levels of IL-8 correlate with sepsis mortality and DIC.

Infections

DIC often accompanies sepsisemia as a result of bacteria that possess potent endotoxins. This correlation has led to the intensive study of the effects of endotoxin on the hemostatic mechanism. Purified endotoxin produces several effects that may lead to DIC, namely, activation of factor XII, platelet aggregation, inhibition of fibrinolysis, leukocyte aggregation, direct endothelial injury, cellular induction of tissue factor activity, and impairment of compensatory clearance.
functions. Many of these phenomena may be mediated by the interaction between endotoxin and monocytes, as discussed earlier.

Shock, Hypoperfusion, and Hypoxemia

Shock may favor the development of DIC by potentiating various activating stimuli that ordinarily would not exceed the capacity of compensatory processes and may perpetuate DIC after a transient activating stimulus has been dissipated. Hypoperfusion, even of normal vessels, acidosis, and hypoxemia produce hypercoagulability and favor intravascular platelet aggregation. Furthermore, splanchnic hypoperfusion impairs reticuloendothelial and hepatic clearance functions and is present in virtually all forms of shock. Shock also may impair hepatic synthesis of coagulation factors and thus contribute to the coagulation defect in DIC. Activated neutrophils may generate oxygen radicals and proteases to alter vascular permeability. Vascular injury may also occur with ischemia/reperfusion that elicits inflammatory responses.

DIC in association with giant hemangiomas (Kasabach-Merritt syndrome)\(^ {130} \) or with aneurysms of the aorta or other large vessels\(^ {131} \) has been attributed to hypoperfusion and stasis in local vascular beds. In Kasabach-Merritt syndrome, large gaps in the endothelium that expose subendothelial collagen and other fibers, together with the induction of thromboplastic substances by poorly supported, recurrently injured vessels within the tumor, also may be important factors leading to the initiation of DIC.

Miscellaneous Activating Stimuli

Snake venoms contain enzymes that may trigger coagulation in unique ways. Such venoms may produce defibrination without affecting other coagulation factors, such as ancrad, an enzyme purified from the venom of the Malayan pit viper (Agkistrodon rhodostoma). Other venoms contain thrombinlike enzymes or substances that specifically activate factor X or prothrombin.\(^ {132} \) Crude venoms also contain substances that act as thromboplastins and produce intravascular red cell hemolysis and massive vascular damage.\(^ {133} \) An inventory of the biochemical properties of snake venoms and their constituent enzymes has been summarized elsewhere.\(^ {134} \)\(^ {135} \)

Consumption of Coagulation Factors and Impaired Anticoagulant Pathways

DIC constitutes a model of accelerated turnover of various coagulation factors, the levels of which at any time are determined by the size of the plasma pool and the differences between the rates at which they are being destroyed and replenished. Results of quantitative studies have demonstrated accelerated turnover rates for platelets, fibrinogen,\(^ {136} \) and prothrombin. Numerous factors complicate a simple kinetic approach. For example, the depletion of plasma fibrinogen induces a compensatory release of large amounts of fibrinogen into the circulation, possibly from the hepatic-lymphatic system, and also increases the rate of fibrinogen synthesis. Other complexities include impaired hepatic synthesis of coagulation factors and the phenomenon of postdepletion “rebound” and “overshoot.”\(^ {137} \)

Generalizations based on the consumption of coagulation factors during in vitro coagulation are not always consistent with laboratory findings in patients with DIC. Plasma levels of factors that are normally consumed, such as fibrinogen, prothrombin, and factors V and XIII, often are reduced in severe DIC, but factors that normally are not consumed also may be deficient, such as factors VII, IX, and X. Prothrombin, which is consumed completely during coagulation in vitro, often is at a normal level in patients with DIC. Significant hypoprothrombinemia must reflect either massive and protracted activation of coagulation or complicating factors, because in animals, severe depletion of platelets, fibrinogen, and factors V and VIII results from activation of only 10% of plasma prothrombin.\(^ {138} \)

Proteins other than coagulation factors may be depleted as a result of DIC; those of potential importance include antithrombin,\(^ {139} \)\(^ {140} \)\(^ {141} \) α2-antiplasmin, and plasminogen.\(^ {141} \) Plasminogen has great avidity for fibrin and may co-precipitate in fibrin thrombi. In experimental animals, depletion of tissue plasminogen activator, as well as plasminogen, can be produced by the protracted infusion of tissue factor.

Antithrombin is the principal inhibitor of thrombin activity; low levels of antithrombin in DIC result from consumption due to persistent neutralization of thrombin, degradation by elastase released from activated neutrophils, and decreased hepatic synthesis. Other natural anticoagulant pathways—the protein C pathway and tissue factor pathway inhibitor—are also diminished in DIC.\(^ {142} \) Proinflammatory cytokines (TNF, IL-1) down-regulate endothelial cell thrombomodulin activity, resulting in decreased levels of activated protein C (APC). Low levels of APC not only fail to inhibit activation of coagulation (by inactivating factors Va and VIIIa), but also contribute to failure to down-regulate inflammation. Thus, impairment of the protein C pathway in DIC contributes to the procoagulant and inflammatory phenotype seen in the disorder.

The numerous and diverse defense processes that are mediated by factor XIIa are activated in DIC, including the complement system and the kallikrein system. It has been suggested that the hypotensive effects of bradykinin may
explain the conspicuous presence of hypotension in patients with DIC triggered by activation of factor XII, for example, that associated with endotoxemia.

Consumption of Platelets
In DIC, the platelet count often is depressed out of proportion to the severity of coagulation abnormalities. Thrombocytopenia may result from processes other than the consumption of platelets in thrombotic lesions. These processes include adhesion to denuded or damaged endothelial cell surfaces and intravascular aggregation with subsequent sequestration, which may be caused by endotoxin, antigen-antibody complexes, thrombin, particulate matter, and, possibly, fibrin-FDP complexes.

All of these agents initiate the platelet release reaction, which may produce a population of partially activated platelets that are depleted of storage nucleotides (acquired storage pool disease). Partially activated platelets may contribute to impairment of clearance functions. Epinephrine and serotonin are released from the platelets and may reach extremely high concentrations in hypoperfused vascular beds. This process may produce sustained constriction of the afferent renal arteriole and may predispose to cortical necrosis. Serotonin also may produce pulmonary and cerebral hypoperfusion.

A mouse model of DIC investigated the role of PARs in mediating the endothelial cell and platelet response to activation of coagulation. In this model of endotoxemia, activation of coagulation occurred, but knockout of PARs failed to improve survival or thrombocytopenia. Although this model may not be extrapolated to human DIC, the possibility is suggested that PARs may not mediate the DIC response, and that thrombocytopenia in DIC may result from mechanisms other than thrombin activation.

Intravascular Fibrin Formation
The formation of fibrin, in the form of small strands and “microclots”, is the immediate result of DIC; the ultimate consequence of this process is determined by a balance between the rate of fibrin formation and the rate of its clearance from the circulation or lysis by the fibrinolytic enzyme system.

Erythrocytes are injured mechanically during passage through fibrin networks in the microcirculation. Such microangiopathic hemolysis leads to the production of schistocytes and microspherocytes. Erythrocyte damage in metastatic carcinoma appears to be caused mainly by fibrin strands that form around tumor cell emboli as a result of low-grade DIC. It should be noted that red cell fragmentation is not seen in all patients with DIC.

Fibrinolysis
Fibrinolysis is present in virtually every patient with DIC, but it generally plays a homeostatic rather than a pathologic role. In the setting of DIC, this “secondary fibrinolysis” is an appropriate response to persistent thrombin generation. Fibrinolysis may be activated by several mechanisms. The major endogenous source of plasminogen activators is in the vascular endothelium of the microcirculation, and in DIC, such activators, especially tissue plasminogen activator, are apparently released as a result of thrombin formation and fibrin deposition on endothelial surfaces, endothelial injury, or hypoxia. Many of the thromboplastic substances that initiate DIC, such as tumor tissues and extracts of leukemic cells, also contain plasminogen activators. The release of plasminogen activators from platelets and leukocytes also may be significant. Finally, factor Xlla activates plasminogen by interacting with normal proactivators and the kinin system.

Fibrinolysis must be distinguished clearly from the process of fibrinogenolysis, in which fibrinogen and other coagulation factors are proteolytically destroyed in the circulation. Fibrinogenolysis may be an inappropriate response in DIC associated with amniotic fluid embolism, heatstroke, and, rarely, carcinoma. It is uncommon in other forms of DIC; when present, it is usually transitory and overshadowed by marked fibrinolysis. Disorders in which fibrinogenolysis arises in the absence of DIC (primary fibrinolysis) are discussed elsewhere in this chapter.

Following the initial enhanced fibrinolytic response to DIC, suppression of fibrinolysis occurs due to elevated levels of plasminogen activator inhibitor-1; this inhibition of fibrinolysis was associated with a poorer clinical outcome.

Fibrin(ogen) Degradation Products
The stepwise process by which fibrin is degraded proteolytically and the biologic effects of the various products of the process (FDPs) are discussed in Chapter 18. These protein fragments act as antithrombins, inhibit fibrin polymerization, produce a structurally defective fibrin polymer, and may impair platelet and reticuloendothelial
clearance functions. The presence of large amounts of FDP in the circulation is a major factor in the production of hemorrhage in many patients with DIC.

The infusion of large amounts of FDP (fragment D) into rabbits produces changes that resemble the posttraumatic respiratory distress syndrome in humans. This observation suggests that large amounts of FDP may directly damage the pulmonary vasculature, leading to respiratory distress syndrome, which has been reported in association with DIC and the use of thrombolytic agents. The smallest FDPs are peptides of 3,000 to 4,000 molecular weight that inhibit smooth muscle contractility, an effect that may explain the frequency of uterine inertia in abruptio placentae.

In DIC, a large amount of fibrin remains in a soluble state as a consequence of the formation of complexes between fibrin monomers, various FDPs, and fibrinogen. This solubility has been regarded as a final defense against vascular occlusion. In vitro, the complexes dissociate in the presence of alcohol or protamine sulfate to form gels or precipitates of various types (paracoagulation).

Impairment of Clearance Mechanisms

The numerous processes that normally remove procoagulant material from the circulation are of the utmost importance in DIC because of the presence of massive amounts of both activators and products of coagulation. Most of the products of intravascular coagulation (prothrombinase, platelet factor-3 activity, various types of FDPs and complexes thereof), as well as various initiators of the process (tissue fragments, endotoxin, antigenantibody complexes, tissue factor, and red cell stroma), are removed from the circulation by the reticuloendothelial system (Fig. 54.3). The Kupffer cells of the liver and splenic macrophages are of particular importance. In certain forms of DIC, large amounts of relatively inert particulate matter (e.g., amniotic fluid embolism) place an additional burden on the reticuloendothelial system. The hepatic cells are of primary importance in the clearance of activated coagulation factors (IXa, Xa, and XIa).

Investigators have suggested that various substances saturate and produce an “autoblockade” of reticuloendothelial and hepatic clearance functions in DIC in a manner comparable to that produced experimentally in the Shwartzman reaction. This blockade may be an important pathophysiologic factor, particularly in perpetuating DIC after a transient activating stimulus. Shock and endotoxemia, both of which produce significant hepatic hypoperfusion, may contribute indirectly to autoblockade of clearance functions.

Chronic or “Compensated” Disseminated Intravascular Coagulation

Certain forms of DIC result from a weak or intermittent activating stimulus. In such patients, destruction and production of coagulation factors and platelets are balanced. The pathophysiology of such chronic, subacute, or “compensated” DIC is fundamentally the same as that in the acute case. Nevertheless, the distinction is valuable because the clinical picture and laboratory findings in the chronic form are quite variable and may be diagnostically confusing.

Chronic DIC has been described in many patients with intrauterine fetal death or giant hemangiomas (Kasabach-Merritt syndrome) and in many cases of adenocarcinoma. Other etiologic factors that may produce chronic DIC include various forms of vasculitis, acute leukemia, aneurysms, hemangiomatous transformation of the spleen, and renal allograft rejection.

In cancer patients, a virtually continuous spectrum of clinical and laboratory features has been described; these range from recurrent venous thrombosis or arterial embolism with high levels of platelets and coagulation factors to acute DIC with severe hemorrhage. The clinical and experimental study of hypercoagulability, is associated with an increased propensity for the development of DIC. Indeed, even normal pregnancy has been suggested as a form of low-grade “physiologic” DIC, which, at term, becomes overt for a short time. Thus, transitory but significant elevations of FDP and corresponding diminution in fibrinogen levels are observed regularly during the first 4 hours after delivery. This may be triggered, in part, by the release of tissue factor into the circulation.

Clinical Features

The major clinical features of DIC are bleeding, often of serious magnitude and abrupt onset; a variable element of shock that is often out of proportion to apparent blood loss; and symptoms of hypoperfusion of various vascular beds. Acute renal failure is common, and thromboembolic manifestations often are noted. Any of these features or signs and symptoms of the underlying disorder may predominate in a given case.
Evidence of major organ dysfunction is a common finding in patients with DIC, most often including signs, symptoms, and laboratory evidence of abnormal pulmonary, renal, hepatic, and central nervous system function. Although virtually all of these manifestations have been attributed to the underlying DIC, the clinical manifestations that have been described usually were the result of the underlying disorder. For example, one study observed that patients with DIC due to aortic aneurysm had laboratory features of DIC but minimal clinical manifestations. Patients with DIC due to obstetric disorders all had bleeding, but only 20% had organ dysfunction. In contrast, of patients with DIC due to sepsis, only 15% had bleeding, but 76% had organ failure. These results suggest that marked heterogeneity exists in clinical manifestations of DIC, and that the etiology of DIC is a major predictor of clinical events.

In this section, the clinical manifestations and diagnosis of DIC are discussed in general terms. Various specific clinical features and details regarding treatment of the most common forms follow in a separate section.

Acute Disseminated Intravascular Coagulation

Bleeding manifestations of virtually every kind have been described, and they may evolve rapidly in the patient with acute DIC. Generalized ecchymoses, petechiae, and bleeding from previously intact venipuncture sites or around indwelling intravenous needles or catheters are noted in many patients. Large, spreading, hemorrhagic skin lesions often are superimposed on familiar exanthems in patients with rickettsial and viral infections. “Geographic” acral cyanosis is a prominent feature in some patients. Large, sharply demarcated ecchymotic areas may result from thrombotic occlusion of dermal vessels and may progress to skin infarction. Such infarcts are particularly common in patients with purpura fulminans (Fig. 54.4) and are seen also in coumarin-induced skin necrosis and inherited homozygous deficiency of protein C (see Chapter 55). In patients with meningococcemia, cutaneous hemorrhage may be striking. Bleeding from apparently normal gingivae, epistaxis, gastrointestinal bleeding, pulmonary hemorrhage, and hematuria are common. In patients who develop DIC after surgical procedures, alarming hemorrhage may develop around drains and tracheostomies, and accumulations of blood may be concealed in serous cavities.

Chronic Disseminated Intravascular Coagulation

Superficial but extensive ecchymoses of the extremities, often without petechiae, may develop intermittently or may persist. Recurrent episodes of epistaxis or more serious internal mucosal bleeding may punctuate the course. Trousseau sign (recurrent migratory thrombophlebitis in association with cancer) in most instances is a manifestation of chronic DIC. More serious hemorrhagic manifestations may develop as the underlying disease progresses or may arise with dramatic suddenness after surgical procedures such as a prostatectomy. Acute DIC may be heralded by further thrombophlebitis or pulmonary emboli. In some patients, evidence of vascular obstruction (e.g., impairment of renal function, confusion, transient neurologic syndromes, or repeated episodes of cerebral thrombosis) may develop with minimal bleeding.
FIGURE 54.4. Purpura fulminans in infection-associated disseminated intravascular coagulation. Early lesions (A) are circumscribed; progressive lesions (B) may become necrotic. (From Dudgeon DL, Kellogg DR, Gilchrist GS, et al. Purpura fulminans. Arch Surg 1971;103: 351-358; copyright 1971, American Medical Association.)

Laboratory Diagnosis

The laboratory findings in DIC are summarized in Table 54.2. Contrary to what is commonly assumed, they may be quite variable. The plasma fibrinogen level, PTT, PT, platelet count, and estimates of FDP or D-dimer are the cornerstones on which the diagnosis of DIC is based. These simple tests should always be performed first. Additional information may
confirm, but seldom refutes, the diagnosis of DIC if typical abnormalities are demonstrated by these tests. Laboratory data may change with remarkable rapidity in DIC, based on disease progression or therapy.

Laboratory data must be interpreted with caution. Levels of platelets and various coagulation factors, fibrinogen, and factor VIII, in particular, may be elevated in many of the conditions associated with DIC, including pregnancy. Thus, a fibrinogen level of 200 mg/dl, although within the normal range determined in healthy subjects, may represent a significant decrease in a patient whose baseline level was 800 mg/dl due to acute-phase changes.

The best test for diagnosing DIC is the D-dimer assay. The semiquantitative method is sensitive, and D-dimer values >2,000 ng/ml have been reported to be consistent with DIC. More sensitive, quantitative D-dimer assays are now available; one study reported that a sensitive D-dimer assay result <8.2 µg/ml optimized sensitivity and negative predictive value in patients with DIC.

A new test, measurement of the biphasic waveform in the PTT assay, has been reported to precede development of DIC and to predict DIC better than the D-dimer assay. The biphasic waveform results from the formation of a precipitate on plasma recalcification; the precipitate contains very-low-density lipoprotein complexed with C-reactive protein. If confirmed in clinical outcome studies, this assay may be a useful addition to laboratory tests for DIC.

Basic Blood Examinations

In patients with DIC, routine hematologic tests may reveal evidence of acute bleeding, accelerated red cell destruction, or signs of the underlying disease. Examination of the blood smear reveals schistocytes in approximately 50% of cases, but the degree of schistocytosis bears no necessary correlation with other facets of the disorder. More subtle evidence of intravascular hemolysis often is found, such as increased serum levels of lactic acid dehydrogenase and diminished haptoglobin levels. Rarely, massive intravascular hemolysis with hemoglobinemia and hemoglobinuria is noted.

Thrombocytopenia is an early and consistent sign of acute DIC, and the consideration of this diagnosis in the presence of a persistently normal platelet count is difficult. Platelet counts in the range of 50,000 to 100,000/µl are the usual finding, but thrombocytopenia may be severe.

Coagulation Defect

The PTT, PT, and thrombin time are prolonged in most patients with acute DIC. Early in the course of the disorder and in chronic DIC, the PTT may be normal or even shorter than normal, which may be the result of the procoagulant effects of activated coagulation factors or elevated factor VIII levels.

Occasionally, one can follow the process of DIC from its inception, and specific assays for various coagulation factors obtained at the time of diagnosis reveal a variable and rapidly changing picture. The plasma levels of fibrinogen and of factors V and XIII usually are significantly depressed; fibrinogen and factor V are the most consistently affected. The level of factor X may be lower than that of other “stable” factors (factors VII, IX, and XI), which usually are present in normal amounts. In many patients, particularly those with abruptio placentae, normal prothrombin levels are maintained, but marked hypoprothrombinemia often is present in those with septic DIC.

The levels of factors VIII, IX, and XI as determined by onestage assays may fluctuate widely as the result of the presence of activated factors such as thrombin and factor Xa. This problem is minimized in two-stage assays. Levels of factor VIIIC often are normal or increased, particularly when assayed by twostage techniques. In many patients, the levels of coagulation factors tend to “overshoot” after repletion. As a consequence of the inhibitory effects of FDPs, the thrombin time may be prolonged out of proportion to the reduction in the fibrinogen level.

Tests for Fibrinolysis: Fibrin Monomers, Fibrinogen Degradation Products, and D-Dimer

In most patients with DIC, FDP levels as determined by quantitative methods, such as red cell hemagglutination inhibition or latex agglutination, are 25-µg fibrinogen “equivalents”/ml or higher. All methods are most sensitive to large or “early” FDPs. These fragments, particularly fragment X, retain thrombin-binding sites or may form a complex with fibrinogen and consequently be removed during the preparation of serum for FDP tests. This phenomenon or the presence of only small FDPs may explain the normal levels of FDPs in some patients with otherwise typical DIC. Fibrinopeptide A and certain fibrinogen fragments that are formed by the lysis of cross-linked fibrin, such as the DD-dimer and the DD-dimer-E complex, can be demonstrated by using special techniques. These latter FDPs provide direct evidence
of the action of thrombin on fibrinogen and provide a means of differentiating fibrin degradation products from fibrinogen degradation products. 171 172

The simplicity, specificity, and sensitivity of the D-dimer test have led many laboratories to replace less sensitive or less convenient tests for DIC with the D-dimer test. Because false-positive results may be seen with FDP latex agglutination tests in patients with dysfibrinogenemia, the D-dimer test may be more specific in diagnosing DIC, especially in distinguishing the coagulopathy of liver disease from DIC. 65 163 173 False-positive D-dimer latex agglutination tests may occur in patients with elevated levels of immunoglobulin M (IgM) (rheumatoid factor).

“Paracoagulation” techniques are simple to perform, but they are less specific than tests for FDPs. The results of the ethanol gelation test, in particular, often are negative in DIC. To the contrary, results of protamine gelation tests usually are positive, 174 but abnormal results are obtained in numerous other disorders, including many that commonly are associated with DIC.

Other Laboratory Findings

Plasma levels of fibrinopeptide A 175 and the rate of incorporation of 14 C-labeled glycine ethyl ester into soluble “circulating fibrin” 176 are exceptionally sensitive indicators of DIC and may be abnormal even in patients with normal levels of FDP. Levels of antithrombin, 177 α2-antiplasmin, and proteins C and S may be diminished in some cases.

Other parameters of activation of coagulation and fibrinolysis have been studied in DIC, especially in sepsis. Thrombin-antithrombin III (TAT) complexes and plasmin-α2-antiplasmin (PAP) complexes are often elevated in sepsis-associated DIC. Assays such as TAT and PAP complexes may have prognostic significance in DIC, as may other coagulation parameters, including plasminogen activator inhibitor type-1, vWF antigen, and α2-antiplasmin. 178 In a primate model of Gram-negative sepsis, a number of molecular markers of coagulation were investigated for their use in monitoring DIC. 179 Markers such as soluble thrombomodulin and soluble fibrin monomer are useful in assessing the status of microvascular injury.

The clinical role of these assays in diagnosing or managing DIC patients at this time is uncertain. The best test for diagnosis and monitoring DIC appears to be a sensitive D-dimer assay; the PTT waveform analysis may also prove to be a useful test. The International Society on Thrombosis and Haemostasis (ISTH) has proposed clinical and laboratory criteria to better define the spectrum of DIC cases. 90 180

Differential Diagnosis

The syndrome of DIC is seldom difficult to recognize. Problems arise when the diagnosis simply is not considered or in chronic forms, when the underlying coagulation disorder may be masked by features of the basic disease or by thromboembolic complications. 181

Two disorders, however, produce laboratory abnormalities that resemble DIC: Severe liver disease, which is common, and primary fibrinogenolysis or “pathologic” fibrinolysis, which is rare (Table 54.2).

In patients with primary fibrinogenolysis, the following conditions may be evident: Hypofibrinogenemia; increased levels of FDP; abnormalities of the PTT, PT, and thrombin time; and deficiencies of factors V and VIIIc. The euglobulin lysis time is significantly and persistently shortened, often in association with plasminemia. However, the platelet count usually is normal, the D-dimer level should be normal or only minimally elevated, and protamine sulfate tests should be negative. Hypoprothrombinemia and deficiencies of stable coagulation factors VII, IX, X, and XI are rare. Thus, routine coagulation tests should be able to distinguish DIC from primary fibrinogenolysis.

In patients with liver disease, coagulation abnormalities and thrombocytopenia may originate from many pathologic processes (Table 54.3). Chronic or intermittent fibrinogenolysis with high levels of FDP is common, particularly in patients with cirrhosis. In such patients, the exclusion of the diagnosis of DIC may be difficult. Factor VIIIc levels usually are elevated when liver disease is severe, and the levels of factors VII and IX typically are low. A helpful test in discriminating between the coagulopathy of liver disease and DIC is the D-dimer test, the results of which should be abnormal in DIC but normal in liver disease (unless additional disorders coexist 65 173).

DIC, particularly that associated with carcinoma, may be confused with various microangiopathic hemolytic anemias, such as thrombotic thrombocytopenic purpura and hemolytic-uremic syndrome; in these disorders, the clinical picture may resemble that of DIC in many respects. High levels of FDP may be encountered in patients with microangiopathic hemolytic anemias, but significant coagulation abnormalities are not commonly present. Many other disorders may produce slight to moderate elevations of FDP: For example, pulmonary embolism and chronic renal disease with uremia.
Moderate thrombocytopenia is a common consequence of the use of extracorporeal circulatory devices, and coagulation abnormalities often are noted immediately after their use because of the presence of residual heparin. Heparin levels also may rise several hours later (the rebound phenomenon). In such patients, the presence of thrombocytopenia together with the effects of heparin may be confused with DIC; similar difficulties may arise after hemodialysis. Even the small amounts of heparin required to irrigate indwelling catheters, or to contaminate Hickman catheters, are a common cause of “pseudo-DIC.”

**Treatment**

DIC always is the end result of a serious underlying disorder. Although the patient may benefit greatly from the replacement of depleted coagulation factors and platelets, correction of the syndrome depends on prompt and energetic treatment of the primary disorder. This—not the therapeutic measures described in this section—remains the cornerstone of therapy.

**Anticoagulants**

Heparin is a specific activator of the physiologic antithrombin system and thereby inhibits a number of proteolytic enzymes, including factors IXa and Xa and thrombin (see Chapter 55). The therapeutic efficacy of heparin is unquestionable in some animal models of DIC, but assessment of its effectiveness in humans has proved more difficult. In view of the complexity of DIC, inhibition of coagulation alters only one facet, albeit a fundamental one, of the pathophysiologic cycle. Recent appreciation of the role of anticoagulation and inflammatory pathways has led to consideration of novel therapies, including replacement of anticoagulant proteins such as antithrombin and APC.

In patients with chronic DIC, the results of heparin therapy usually are favorable and may be dramatic. In most patients, heparin would not be expected to alter ultimate mortality because of the nature of the underlying diseases; however, this drug typically does reduce the severity of bleeding and thromboembolic manifestations and produces parallel improvement in the abnormalities of laboratory test values. Elevated levels of D-dimer and FDPs drop rapidly, and accelerated fibrinolysis, if present, disappears after the administration of heparin, often before the coagulation defect has been alleviated. The response of the platelet count to heparin therapy for DIC is slow and often erratic.

In patients with acute DIC, particularly that associated with sepsis, the results of heparin therapy have been less encouraging. Most clinicians are reluctant to use heparin in patients with acute DIC. Because baseline PTT values are usually prolonged in acute DIC, heparin levels may be required to monitor therapy (see Chapter 55).

**Replacement Therapy with Platelets and Coagulation Factors**

Many patients with DIC ultimately receive large amounts of blood products, even though evidence is only anecdotal that they are necessary or therapeutically effective. The major aim of replacement therapy with blood products in DIC is to replenish fibrinogen. This goal is best accomplished by the administration of cryoprecipitate, each unit of which contains approximately 250 mg of fibrinogen. The amount of cryoprecipitate given should be sufficient to elevate the plasma fibrinogen level to at least 100 to 150 mg/dl. As a general guide, 3 g of fibrinogen can be expected to raise the plasma level of an adult patient approximately 100 mg/dl. Fibrinogen administration probably should be restricted to the occasional patient with hypofibrinogenemia and significant bleeding, in whom DIC is self-limited or has been controlled by heparin therapy (e.g., in intrauterine fetal death before surgical intervention). Sterile fibrinogen concentrates are not yet available for routine therapeutic use in the United States.

Patients with DIC, bleeding, and platelet counts <50,000/µl should be considered for platelet transfusion. Due to the acquired storage pool defect seen with DIC, as well as FDP inhibition of platelet function, DIC patients may require a higher platelet count for adequate hemostasis than patients with thrombocytopenia in the absence of platelet dysfunction.

The availability of purified, sterile antithrombin concentrates has led to its investigation in treating DIC. As seen in most studies, although antithrombin concentrates can normalize plasma levels of this protein in patients with DIC and improve hemostasis parameters, consistent clinical benefit in terms of survival is not evident. A large clinical trial demonstrated that high-dose antithrombin therapy in patients with sepsis had no effect on mortality. A post hoc analysis of this clinical trial indicated that high-dose antithrombin therapy may be effective in improving survival in the subset of patients with severe sepsis and high risk of death, especially if concomitant heparin treatment is avoided. Prospective studies will be important to confirm this subgroup analysis.

**Other Therapeutic Measures**
Treatment of shock should be immediate and vigorous in all patients with DIC. Packed erythrocytes should be given promptly if indicated. The indiscriminate use of epsilon-aminocaproic acid (EACA) and other antifibrinolytic drugs should be discouraged. Because of the potential risks, fibrinolytic enzyme inhibitors should be administered only to carefully selected patients, that is, those in whom DIC has resulted from a transitory stimulus or has been arrested by heparin administration and in whom fibrinogenolysis or inappropriate fibrinolysis, hypofibrinogenemia, and adequate renal function have been clearly documented. The therapeutic use of EACA in fibrinogenolysis and appropriate dosage schedules are discussed elsewhere in this chapter.

Specific Features of Various Forms of Disseminated Intravascular Coagulation

Obstetric Disorders

Abruptio Placentae

DIC complicates abruptio placentae in approximately 10% of cases in which fetal compromise occurs. Shock develops rapidly, but vaginal bleeding may be minimal or absent for a time and bears little relationship to the extent of abruption. Brisk external hemorrhage may originate from episiotomies and lacerations, and large amounts of blood may be concealed behind the placenta and within the wall of the uterus. Severe placental abruption associated with fetal death is often linked with DIC.

Hemorrhage is the major factor leading to shock and renal complications in abruptio placentae, and the most essential therapeutic measures are the vigorous treatment of blood loss and the prompt evacuation of the uterus. Extensive replacement therapy seldom is required. Often, fibrinogen replacement is given if immediate surgical treatment is necessary. Fibrinogen replacement may be most useful in patients with fetal death requiring cesarean delivery. If the coagulation defect and thrombocytopenia are severe or persist for an unusually long time, the administration of platelets, fibrinogen in the form of cryoprecipitate, and fresh frozen plasma may reduce hemorrhage. Most obstetricians do not administer heparin because it may increase bleeding and because rapid spontaneous remission of DIC is usual when the uterus is evacuated.

Intrauterine Fetal Death

In the event of intrauterine fetal death, definite laboratory abnormalities are not seen until the dead fetus has been retained for ≥5 weeks; plasma levels of FDPs then begin to rise, and the platelet count and fibrinogen level gradually decline. Bleeding may be inconspicuous, but a progressive loss of renal function is not uncommon. In most women in whom delivery of the dead fetus is induced promptly according to usual obstetric practice, bleeding is not serious, even in the presence of low-grade DIC. Operative intervention is dangerous when hypofibrinogenemia is severe, and such patients should receive heparin until safe fibrinogen levels are restored. If immediate surgery is imperative, heparin administration should be followed by platelet replacement and enough fibrinogen, in the form of cryoprecipitate, to produce plasma fibrinogen levels of 150 mg/dl or greater.

Amniotic Fluid Embolism

In women who survive amniotic fluid embolism (mortality rate of up to 80% in early studies), DIC with severe hemorrhage may develop within 1 to 2 hours. More recent surveys indicate a mortality rate of 20% to 30%; 50% of patients with amniotic fluid embolism had DIC. Often, the syndrome is complicated by significant fibrinolysis and even fibrinogenolysis. Hypoxia and other sequelae of pulmonary vascular obstruction dominate the clinical picture and usually determine the outcome. The release of serotonin and other vasoactive substances from platelets may contribute to the profound pulmonary vasoconstriction.

Miscellaneous Obstetric Disorders

Intravascular coagulation has been documented after abortions induced by intra-amniotic injection of hypertonic saline solutions and hypertonic urea, but it apparently does not complicate abortions performed by suction curettage or those induced by prostaglandin F₂α.

Disseminated Intravascular Coagulation in Neonates and Infants

Several disorders unique to the neonate and infant may be associated with DIC (Table 54.2). The transplacental passage of thromboplastins or other procoagulant substances has been the apparent cause of DIC in neonates born of mothers...
affected with DIC owing to abruptio placentae, eclampsia, or septicemia. Asphyxia may be a common precipitating factor for DIC in these disorders.\textsuperscript{197} Bacterial infection and generalized viral infections (e.g., herpes simplex, cytomegalic inclusion disease, and rubella), acidosis, and hypoxia are more common causes of DIC in infants than in adults.\textsuperscript{198} DIC secondary to giant hemangiomas and purpura fulminans has been reported in neonates.

Management of septic DIC in the neonate should emphasize treatment of underlying infection. A controlled study that compared treatment with heparin, extensive replacement therapy with blood products, and supportive care only revealed no significant differences in outcome for the three groups.\textsuperscript{199} A more recent study confirms that clinical trials in neonatal sepsis have not identified a beneficial therapy.\textsuperscript{200}

The diagnosis seldom is difficult, but DIC must be distinguished from septic shock, endotoxin shock, or simple thrombocytopenia, all of which may develop independently of DIC in severe infections.\textsuperscript{201}

In many patients, no additional measures other than treating infection and shock (if present) are required. No evidence has been cited that heparin has diminished mortality.\textsuperscript{168} In one series, the alleviation of septic shock appeared to be more important in the ultimate prognosis than did correction of the coagulation abnormalities.\textsuperscript{168} Recombinant APC (r-APC) was demonstrated in one study to reduce mortality in adult patients with sepsis\textsuperscript{202}; however, a Cochrane database review of the effects of r-APC in neonates with sepsis concluded that there were insufficient data to support the use of the drug in the pediatric setting.\textsuperscript{203} Subsequent studies in adult patients demonstrating no clinical benefit of r-APC in sepsis led to withdrawal of this drug.

Purpura Fulminans

The hemorrhagic manifestations of purpura fulminans develop several days after an acute infection; these are most commonly scarlet fever or various viral respiratory diseases. Purpura fulminans is most common in children but is also well documented in adults. The most common manifestations are symmetric ecchymoses of the lower extremities and buttocks, sharply circumscribed infarcts of the skin and genitalia, and gangrene of the extremities that often involves the digits symmetrically.\textsuperscript{204} These ecchymotic lesions often become necrotic, ultimately forming blood-filled bullae (Fig. 54.4). Petechiae are rare. Fever and prostration are seen, but visceral lesions, including renal involvement, are relatively uncommon.

The mortality rate associated with purpura fulminans ranges from 18\textsuperscript{205} to 40\textsuperscript{206} to 70\textsuperscript{207}. Heparin in therapeutic doses has often proved therapeutically effective, and it has been suggested that poor results obtained previously with this anticoagulant reflect late treatment of moribund patients. In patients with purpura fulminans, relapses are particularly common after cessation of heparin therapy,\textsuperscript{205} and the administration of this anticoagulant, possibly in reduced doses, should always be continued for 2 to 3 weeks. The subject of purpura fulminans diagnosis and treatment has been recently reviewed.\textsuperscript{207} Evidence that purpura fulminans may be a manifestation of homozygous protein C deficiency is discussed in Chapter 55. The efficacy of protein C in patients with sepsis and purpura fulminans is discussed below.

Neoplastic Disorders

Carcinoma

In patients with DIC associated with carcinoma, the clinical picture is quite variable and often consists of a combination of bleeding and thromboembolic phenomena, including arterial embolism.\textsuperscript{98, 102, 203} The association of chronic DIC, thromboembolism, and cancer is often called Trousseau syndrome.\textsuperscript{98} Laboratory findings are variable. Evidence of chronic DIC, hypercoagulability, or acute DIC may be found. In a study of more than 1,000 patients with solid tumors, 7\textsuperscript{208} were diagnosed with DIC using standard coagulation tests (platelet count, fibrinogen, D-dimer, FDPs). Risk factors associated with the occurrence of DIC included older age, male gender, advanced disease, breast cancer, and necrosis of the tumor specimen.\textsuperscript{208}

One reason for the variability in cancer patients having venous thromboembolism relates to the histology of the malignancy. Analysis of a very large database of Medicare patients with cancer identified tissue-specific differences in thrombotic risks among cancers.\textsuperscript{209} Those cancers with a high risk of thrombosis included uterine, brain, leukemia, ovary, and pancreas (twofold or greater risk), whereas prostate, liver, head or neck, bladder, and breast cancer had less than a onefold risk (compared to noncancer patients).\textsuperscript{209}

DIC in association with carcinoma resolves with effective treatment of the underlying tumor. Heparin or low-molecular-weight heparin (LMWH) in therapeutic doses has proved effective in controlling the hemorrhagic and thromboembolic
symptoms. There is a suggestion in the literature that the use of LMWH therapy is associated with improved mortality in cancer patients. A large European study of patients with incurable solid tumors evaluated the survival effects of a LMWH (nadroparin) given in therapeutic dose for 2 weeks followed by half-dose for 4 weeks. There was significant improvement in survival in the LMWH group with minimal toxicity. The basis for this antithrombotic activity of LMWH may not relate to anticoagulant activity. A recent Cochrane literature review of the effects of anticoagulation on cancer patient survival found improved survival after 24 months, but not 12 months.

A significant minority of patients with cancer and thrombosis will experience recurrent thrombosis with oral anticoagulation and will benefit from long-term heparin or LMWH. Based on these data, optimal anticoagulant therapy for cancer patients with thrombosis is LMWH. In the case of DIC associated with prostate cancer, adjunctive therapy with ketoconazole or antiandrogens may be useful.

An animal model of cancer has provided evidence that tumors may activate coagulation through overexpression of the MET oncogene. When MET-induced carcinogenesis was established in mice, a hypercoagulable state resulted. Inhibition of the activated MET oncogene may be a potential therapeutic target in patients with cancer and DIC. The spectrum of mechanisms of thrombosis in Trousseau syndrome has been reviewed.

Acute Promyelocytic Leukemia

DIC has been reported in association with all forms of acute leukemia, but it is most common in the “hypergranular” promyelocytic variety, in which it may occur in 60% to 100% of cases. The cause of the coagulopathy is multifactorial: Tissue factor is present in the granules of the abnormal promyelocytes as well as leukocyte proteases, including elastase. Enhanced fibrinolysis also results from increased promyelocyte expression of annexin II, a receptor for plasminogen and tissue plasminogen activator. Additionally, the malignant promyelocytes contain plasminogen activators. The clinical picture usually is one of chronic progressive DIC with a significant fibrinolytic component that may antedate the other manifestations of the disease. Acute fulminant DIC may develop spontaneously or may be triggered by the administration of chemotherapeutic agents, which cause the release of thromboplastic contents of the promyelocytes.

In some patients with acute leukemia, accelerated fibrinolysis is a conspicuous finding. In one study, depletion of α2-antiplasmin developed during induction of chemotherapy, a finding that was more predictive of bleeding complications than traditional indices of DIC, such as levels of fibrinogen, antithrombin, and plasminogen. This study suggests that “unregulated” fibrinolysis, by destroying functional hemostatic plugs and depleting fibrinogen, may be more important than DIC in some cases.

In the past, heparin has produced clear-cut remissions in patients with chronic forms of DIC associated with acute leukemia. An earlier approach recommended fibrinogen replacement therapy for fibrinogen levels <100 mg/dl and platelet transfusion for platelet counts <20,000/µl. Fresh frozen plasma is given to patients with prolonged PT and PTT values who are bleeding. If the fibrinogen level is difficult to maintain over 100 mg/dl, or if FDP levels are rising, heparin is infused at 500 U/hour. When α2-antiplasmin levels are below 30% of normal, EACA or another antifibrinolytic agent should be added to this regimen, and α2-antiplasmin levels should be monitored during induction of chemotherapy.

A newer approach that has virtually replaced the need for heparin and antifibrinolytic agents in the treatment of acute promyelocytic leukemia is the early administration of all-trans retinoic acid. However, these patients still may require replacement therapy for hypofibrinogenemia and thrombocytopenia. Current protocols for acute promyelocytic leukemia combine all-trans retinoic acid and combination chemotherapy (or arsenic trioxide) to ameliorate the coagulopathy; all-trans retinoic acid is more effective than chemotherapy alone in improving the coagulopathy.

Kasabach-Merritt Syndrome (Giant Hemangiomas)

The severity and incidence of DIC tends to parallel the size of the vascular tumors in the Kasabach-Merritt syndrome. Platelet consumption, activation of coagulation, and microangiopathic red cell destruction take place mainly within the hemangioma (“sequestered” or localized intravascular coagulation), but laboratory evidence of DIC in the general circulation usually is clearcut. Recurrent bleeding from the surface of the tumor is the major hemorrhagic manifestation; in the presence of DIC, this bleeding may be intractable. Periodic swelling of the lesions often is observed. This phenomenon may be a consequence of intermittent obstruction of blood outflow from the hemangioma and may provoke serious hemorrhage. Irradiation and corticosteroids have produced favorable results in a few cases, but surgical removal of the tumors has ultimately been required in most patients. Interferon-α has been successful in large numbers of patients; this cytokine probably acts as an antiproliferative/antiangiogenic agent. Antifibrinolytic therapy has been reported to be useful in controlling the coagulopathy. Other useful therapies include cryoprecipitate and platelets for replacement therapy to correct a severe coagulopathy. The use of heparin therapy is uncertain.
For patients with aneurysms associated with DIC, LMWH has been reported to be useful in resolving the coagulopathy.\textsuperscript{228}

Shock and Massive Trauma

Heparin therapy may be hazardous for patients with massive injuries. Even in the face of DIC, intensive supportive care and replacement therapy with plasma and platelets are the mainstays of treatment.\textsuperscript{229}

Hemolytic Transfusion Reactions

DIC is present in many patients with hemolytic transfusion reactions. Severe, acute hemolytic transfusion events are triggered by antigen-antibody reactions that initiate complement activation and activation of coagulation. These reactions are usually a result of ABO incompatibility. These patients may experience not only DIC, but also shock and renal failure. Primary therapy is directed to control of hypotension and restoration of renal blood flow. Fluid, diuretics, and dopamine may be useful therapies. Heparin therapy for DIC in hemolytic transfusion reactions is controversial.\textsuperscript{230}

Snakebite

DIC associated with snakebite differs from the usual form of the syndrome in several respects. Hemorrhage may be relatively inconspicuous,\textsuperscript{231} even in the presence of incoagulable blood. When present, it is mainly the result of a vascular toxin. Platelets often are spared, although the venom of the timber rattlesnake (Crotalus horridus horridus) contains a unique serine protease that acts as a potent platelet activator.\textsuperscript{232} In some cases, a disorder manifested mainly by brisk fibrinolysis in the absence of evidence of DIC has been described.\textsuperscript{233} The specific coagulopathy seen in individual patients in large part depends on venom constituents present in the particular snake species. Detailed lists of venom constituents affecting hemostasis have been published.\textsuperscript{132, 134, 135}

The treatment of snakebite involves the administration of specific antivenom and intensive supportive care. Heparin therapy has proved marginally effective at best.\textsuperscript{231, 234} In general, it is not indicated when specific antivenom is available. Cryoprecipitate should be given to maintain the fibrinogen level over 100 mg/dl.

Pathology

The fatality rate associated with DIC is up to 60%.\textsuperscript{235} In many cases, death is attributed to bleeding or thrombosis. Mortality increases with age, underlying co-morbidities, the number of clinical manifestations, and the severity of laboratory abnormalities.

The deposition of fibrin in small vessels represents the ultimate result of DIC. In many patients, fibrin can be formed and lysed without significant vascular occlusion. Indeed, at autopsy, fibrin thrombi in some subjects were absent or were demonstrated only with special stains or by electron microscopy. This may result from postmortem lysis or from deposition of thin films of fibrin on the vast endothelial surface and on the erythrocytes. The localization of fibrin thrombi varies somewhat with the cause of DIC. The kidney is the single most common site of fibrin thrombi. Renal lesions range from patchy tubular necrosis to massive bilateral cortical necrosis and have been attributed to a sieving effect of the renal microvasculature. Nonthrombotic endocarditis and pulmonary hyaline membranes have been found in many patients,\textsuperscript{98, 236} especially those with cancer.

Emerging Therapies for Disseminated Intravascular Coagulation

The recognition of pathogenic mechanisms critical in initiation or progression of DIC has led to investigation of new therapeutic agents in animal models of DIC and clinical trials in humans. For example, protease inhibitors such as aprotinin\textsuperscript{237} or gabexate\textsuperscript{238} have been studied. However, survival advantages have not been shown with these agents. Similarly, high-dose antithrombin replacement therapy had no effect on mortality in patients with severe sepsis.\textsuperscript{186}

The key role of tissue factor in triggering DIC\textsuperscript{239} has led to studies in which neutralizing antibodies to this procoagulant were found to prevent lethal septic shock in animal models.\textsuperscript{240, 241} Two published clinical trials in sepsis patients used tissue factor pathway inhibitor as therapy; there was no significant benefit observed.\textsuperscript{242}

The role of protein C in ameliorating the mortality of sepsis has also been demonstrated; neutralization of protein C activity in an animal model exacerbated the lethal response,\textsuperscript{243} and infusion of protein C\textsuperscript{244} or APC\textsuperscript{245} prevented the lethal response in humans with meningococcemia or in a primate model, respectively. APC had previously been demonstrated to improve survival in sepsis\textsuperscript{202}; subsequent studies demonstrated no clinical benefit of the drug, and it is no longer available.
PRIMARY FIBRINOLYSIS (FIBRINOGENOLYSIS)
Fibrinolysis is an appropriate response to thrombosis and necessary in the re-establishment of blood flow. This localized response, termed physiologic fibrinolysis, is discussed in Chapter 18. The term pathologic fibrinolysis has been used indiscriminately to refer to any situation in which in vitro evidence of fibrinolysis was associated with bleeding. In retrospect, it seems probable that fibrinolysis in many cases was secondary to DIC and that in others it represented an essentially physiologic response to anoxia, shock, or stress. In fibrinogenolysis, on the other hand, the proteolytic destruction of fibrinogen and other proteins occurs in the general circulation, and severe bleeding may develop. The pathophysiology of fibrinogenolysis may represent a disproportionate or “inappropriate” response to underlying DIC or may result from a defective fibrinolytic mechanism that may be inherited or acquired.

Etiology
Fibrinogenolysis may complicate various disorders, among which severe liver disease is the most common. Fibrinogenolysis is a predominant laboratory feature in several patients with disseminated neoplasms, especially urogenital neoplasms. The mechanism for enhanced fibrinolysis in these patients is probably increased tumor cell secretion of plasminogen activators such as urokinase. Fibrinogenolysis and marked fibrinolysis rarely complicate the immediate puerperium, and they have been reported in association with acute promyelocytic leukemia. Enhanced fibrinolysis has also been associated with cardiac bypass surgery and aortic clamping during vascular surgery. Inherited deficiency of plasminogen activator inhibitor type-1 or α2-plasmin inhibitor also results in hyperfibrinolysis and a bleeding tendency.

Pathophysiology
Fibrinogenolysis is a consequence of the generation of plasmin within the general circulation (plasminemia). Potent plasmin inhibitors (antiplasmins) normally neutralize free plasmin rapidly (see Chapter 18); the result is that the proteolytic effects of this enzyme normally are restricted to fibrin. Fibrinogenolysis occurs only when the neutralizing capacity of the antiplasmins is exceeded.

The proteolytic action of plasmin is nonspecific. In addition to fibrin and fibrinogen, this enzyme may degrade factor VIIIc, factor XIII, other coagulation factors, and a wide variety of other plasma proteins, such as complement and various hormones. Free plasmin also may activate bradykinin, a phenomenon that may underlie the marked hypotension present in some patients with fibrinogenolysis. Thus, pathologic proteolysis is an appropriate synonym for fibrinogenolysis.

Fibrinogenolysis is activated by mechanisms that are remarkably similar to those that initiate DIC. Therefore, tumor tissue contains plasminogen activators in addition to tissue factor. The secretion of these activators into the circulation may rapidly activate most of the circulating plasminogen.

Hypoxia and hypoperfusion may lead to plasminogen activation and, occasionally, to fibrinogenolysis. However, in many of these patients, bleeding is minimal; when present, it cannot be clearly related to the presence of fibrinogenolysis. In these patients, fibrinogenolysis probably is a nonspecific, essentially physiologic response. Fibrinogenolysis may also result from therapy with thrombolytic agents, as discussed in Chapter 55.

Clinical Features and Laboratory Diagnosis
The clinical picture in most reported cases of fibrinogenolysis is similar to that of DIC. The usual laboratory findings are P.1202

summarized in Table 54.2 and are discussed in an earlier section of this chapter. Hypofibrinogenemia may be seen. The PT, PT, and thrombin time may be prolonged because of the anticoagulant effects of FDPs. Moderate concentrations of EACA (4 × 10^-4 mol/L) inhibit plasminogen activators but not free plasmin. Thus, the euglobulin lysis time, which invariably is shortened in patients with fibrinogenolysis, is unaffected by the addition of EACA if free plasmin is present. Among the coagulation factors, factors V and VIIIc are the most sensitive to the proteolytic action of plasmin; factor XIII also is deficient in some patients. The plasma levels of other factors (e.g., factors VII and IX), including some that are degraded by plasmin in vitro, usually are normal in patients with fibrinogenolysis. Depletion of plasminogen and α2-antiplasmin and the presence of α2-antiplasmin-plasmin complexes in the plasma also may be demonstrated in many patients with fibrinogenolysis and in those with DIC and active fibrinolysis.

The standard FDP test does not discriminate between fibrinogen degradation products and fibrin degradation products. Measurements of fibrinopeptide A and the D-dimer, which is a specific indication of degraded cross-linked fibrin, yield normal results in fibrinogenolysis. Thus, patients with hypofibrinogenemia, prolonged PT and PTT values, elevated FDP
levels, and a normal D-dimer may have primary fibrinogenolysis. In the absence of intravascular coagulation, paracooagulable complexes containing fibrin monomers do not form in plasma; thus, plasma protamine gelation tests are negative in fibrinogenolysis. Assays for plasminogen and for the various inhibitors of the fibrinolytic enzyme system may reveal a pattern of depletion. In addition to normal results for D-dimer, patients with fibrinogenolysis have normal platelet counts or mild thrombocytopenia with bleeding out of proportion to the reduction in platelet count.246

Treatment

Antifibrinolytic agents would seem therapeutically desirable in the treatment of fibrinogenolysis; however, these drugs are hazardous in the presence of DIC. EACA and tranexamic acid are specific and potent inhibitors of fibrinolysis and fibrinogenolysis.254 In low concentrations (10^4 mol/L), EACA inhibits plasminogen activation competitively; in high concentrations (0.06 M), it inhibits plasmin directly in a noncompetitive manner. The clinical effectiveness of this drug is dramatic in carefully selected patients.255 For severe bleeding, EACA should be administered intravenously (0.1 g/kg every 6 hours, up to 24 g/day), or intravenous doses of 1 g/hour, after a 5-g loading dose. The drug can also be given orally. The total dosage should not exceed 24 g in a 24-hour period. Tranexamic acid is a newer antifibrinolytic agent that, like EACA, possesses the ability to bind to the lysine-binding sites of plasminogen, thereby preventing plasmin that is generated from binding to fibrin. The oral dosage of tranexamic acid is 25 mg/kg, three or four times daily. The intravenous dosage is 10 mg/kg given three or four times daily.

Because antifibrinolytic agents are potentially dangerous drugs in the presence of DIC,256 the diagnosis of DIC should be excluded in these patients using a specific test, such as D-dimer, before administering these agents. Patients with DIC and a substantial secondary fibrinolytic component should be considered for heparin therapy before administration of antifibrinolics.248

Patients with hormone-refractory prostate cancer and fibrinogenolysis have been reported to benefit from docetaxel, with resolution of bleeding symptoms and laboratory evidence of hyperfibrinolysis.257

Pathologic Inhibitors of Coagulation

Circulating anticoagulants are pathologic endogenous inhibitors that can act at any stage in the process of coagulation. Most are antibodies that act as specific inhibitors, inactivating a single coagulation protein. The clinical and laboratory manifestations resemble the corresponding inherited coagulation disorders in many respects. Antibody disorders with wider effects on the coagulation system are sometimes seen, especially in the antiphospholipid-protein antibody (APA) disorders. Other inhibitors of coagulation often have heparinlike activities and are much less common.

Antibodies to Factor VIII

Factor VIII is the most common target of monospecific acquired anticoagulant antibodies. Conditions that are associated with monospecific factor VIII antibodies are outlined in Table 54.5. Factor VIII inhibitors are termed alloantibodies when they appear in treated hemophilia patients and autoantibodies when they appear in nonhemophilia patients.

Alloantibodies in Hemophilia A

Frequency of Inhibitors

Prospective studies suggest a higher incidence of inhibitors than that historically appreciated258,259,260 (up to 45%), even in patients treated with traditional factor VIII concentrates. However, many patients have only transient inhibitors, and perhaps only 5% to 10% of hemophiliacs have persistent inhibitors.261 As a consequence, initial concerns based on historical prevalence controls suggesting that newer factor VIII concentrates, such as those purified by monoclonal antibody affinity chromatography or produced by recombinant technology, might be inducing an increased percentage of inhibitors appear to be allayed. In fact, continued longitudinal surveillance of patients receiving such products indicates a similar or perhaps lower incidence of clinically significant persistent inhibitor induction.262,263 Those at high risk of development of inhibitors include patients with severe hemophilia A whose factor VIII mutation prevents factor VIII synthesis (nonsense mutation or intron 22 inversion), or patients with mild or moderate hemophilia A whose factor VIII mutation in the A2 domain or near the junction of the C1-C2 domains results in an abnormal factor VIII molecule.264 This latter mutation results in a factor VIII molecule identified by the patient’s immune system as abnormal. Other factors affecting the risk of inhibitor development include the patient’s human leukocyte antigen (HLA) class II haplotype, the type of factor VIII therapy used,265 African-American ancestry,264,265 periods of intensive therapy,266 and early use of factor VIII at the time of a major bleed or surgery.267
Additional reports have confirmed these conclusions in patients with mild to moderate hemophilia. A more recent literature metaanalysis observed that use of recombinant factor VIII products was associated with an almost twofold increase in inhibitor development compared to plasma-derived factor VIII products, and an initial study identifies an increased risk of inhibitor development with second-generation full-length recombinant products. A provocative study reported that patient age at initiation of therapy was an independent risk factor for inhibitor development. Patients beginning therapy before 6 months of age had three times the rate of inhibitors than patients beginning therapy after 1 year of age. If these data are confirmed, exposure of hemophilia A patients to factor VIII should be delayed, and patients should be treated with other products during the first year of life (such as rVIIa). A United Kingdom epidemiology study reported that there is a biomodal distribution of factor VIII antibodies in hemophilia A patients, with peaks in early childhood and >60 years of age. The genetic and immunologic aspects of induction of antifactor VIII alloantibodies have been reviewed.

### TABLE 54.5 CONDITIONS ASSOCIATED WITH MONOSPECIFIC FACTOR VIII ANTIBODIES

**Alloantibodies in hemophilia A**

**Autoantibodies in nonhemophilic patients**
Autoimmune disease
Systemic lupus erythematosus
Rheumatoid arthritis
Inflammatory bowel disease
Dermatologic conditions
Psoriasis
Pemphigus vulgaris
Pregnancy (peripartum)
Malignancy
Lymphoproliferative disorders
Plasma cell dyscrasias
Medications: penicillin, sulfa antibiotics, chloramphenicol, phenytoin
Idiopathic

**Induced Antibody Titer**

It is recognized, particularly in patients with mild hemophilia, that 50% to 75% of inhibitors are subclinical, occur relatively early (median of 10 days) after product exposure, are of low titer, are transient, and often resolve even with continuing product exposure. Hemophiliacs with inhibitors can be categorized as either strong or weak responders to administered factor VIII. Once an antibody has developed in a hemophilic, further administered factor VIII may act as an inducing antigen. Additionally, it has been appreciated that certain factor VIII products, depending on the manufacturing process, may be immunogenic in hemophilia A patients.

**Autoantibodies to Factor VIII in the Nonhemophilic Patient**

It is estimated that acquired factor VIII autoantibodies are seen in 1 to 2 persons per million population annually. Monospecific antibodies to factor VIII can arise spontaneously in association with various autoimmune and chronic inflammatory diseases, such as systemic lupus erythematosus (SLE), rheumatoid arthritis, and ulcerative colitis. Antibodies to factor VIII can develop in the puerperium, usually appearing at term or within several months after parturition in association with a first pregnancy. The antibody may disappear spontaneously in postpartum patients after 12 to 18 months. Reappearance during subsequent pregnancy seems to be very unusual, and in those patients who have persistent antibodies, remission can occur during a subsequent pregnancy. Acquired hemophilia may also be seen in association with hematologic malignancies and solid tumors; certain medications such as penicillin, sulfa antibiotics, chlorpromazine, and phenytoin; and dermatologic conditions such as psoriasis and pemphigus vulgaris.
Most often, acquired factor VIII antibodies are idiopathic, particularly in older persons without apparent underlying disease. Pathophysiology of Development of Antibodies to Factor VIII

The immunologic mechanism that underlies inhibitor induction in a select minority of patients with hemophilia A and the corresponding presumed lack of immunologic tolerance is unclear. Although inhibitor induction is more common in more severely affected patients, inhibitors are also seen in mild hemophilic patients. In patients with severe hemophilia, major deletions, the intron 22 inversion, nonsense mutations, and early initiation of replacement therapy are risk factors for antibody development. Underlying genetic susceptibility factors have been suggested by studies of brother pairs with a significant predisposition to the development of inhibitors. Specific associations between factor VIII genotype and HLA class II phenotype have been made, but the associations are weak. Genetic influences on inhibitor development are postulated to be additive and polygenic. Mutations resulting in a major loss of factor VIII gene coding information and a lack of circulating factor VIII antigen are associated with a high incidence of inhibitor formation. For example, a high frequency (70%) of inhibitor development is seen in patients with either large, multidomain deletions or nonsense mutations in the factor VIII A3 domain. Fewer patients with other gene defects (missense point mutation) form inhibitors. However, the presence of inhibitors is not consistent, even in a given family with similar factor VIII mutations, suggesting that other factors contribute to induction of factor VIII antibodies. A clinical prediction score to identify the risk of untreated hemophilia A patients to develop an inhibitor has been reported.

Another hypothesis as to how inhibitors to factor VIII might occur is that these antibodies arise from the expansion of preexisting natural factor VIII clones that possess neutralizing properties; such antibodies have been identified from the IgG fraction of plasma from normal people. Clonal expansion of antifactor VIII antibodies may be modulated by the presence of anti-idiotypic antibodies.

Characteristics of Factor VIII Inhibitory Antibodies

The majority of antibodies to factor VIII are IgG immunoglobulins that appear to be specific for the coagulant subunit of the factor VIII complex (VIIIc). Common epitopes for allo- and autoantibodies include those in the A2 domain, the C2 domain, or both. Typically, hemophilic alloantibodies recognize both domains, whereas autoantibodies recognize the C2 domain more frequently than the A2 domain. Circulating factor VIII immune complexes have been identified in plasma from patients with acquired hemophilia A with autoantibodies. IgA or IgM inhibitors are rare, as are antibodies that inhibit both VIIIc and vWF. The factor VIII inhibitory antibody subunits in hemophilia A show limited heterogeneity but are not truly monoclonal. In nonhemophiliacs, antibodies to factor VIII more often reveal normal heterogeneity of their subunits. Antibodies to factor VIII are disproportionately often of the IgG4 subclass and do not fix complement.

Antibodies inactivate factor VIII in a time- and temperature-dependent process, the kinetics and stoichiometry of which are variable. Two types of antibody inhibition are described: Type I inhibitors completely inhibit factor VIII activity following secondorder kinetics (linear time course of inactivation); these antibodies are seen in hemophilia patients. Type II inhibitors have complex kinetics and do not completely inhibit factor VIII activity; these are autoantibodies seen in nonhemophilic patients. The type II inhibition phenomenon may produce aberrations in the assay system and may explain certain puzzling laboratory features in atypical cases, such as detectable factor VIII clotting activity in a patient with a high-titer inhibitor. A report on alloantibody inhibition of factor VIII activity indicated that certain alloantibodies possess catalytic activity that can proteolyze factor VIII.

Laboratory Evaluation

Simple mixing techniques based on the PTT usually suggest the presence of an inhibitor. Factor VIII levels usually are undetectable in severely affected patients but may be detectable in patients with autoantibodies. Specific tests for antibodies involve the demonstration of progressive and time-dependent inactivation of factor VIII in vitro by the plasma or serum of the patient. Methods for detecting low-titer inhibitors and for quantifying the levels of antibody have been devised, and standardized inhibitor units (the Bethesda unit in the United States and the Oxford unit in Britain) have been defined. In the Bethesda assay, in vitro tests are performed at 37°C using 2-hour incubation mixtures of various dilutions of patient plasma with normal plasma. The inhibitor titer is the reciprocal of the dilution of inhibitor plasma that neutralizes 50% of normal factor VIII activity. Because the Bethesda assay may underestimate the inhibitor titer in acquired hemophilia, it is recommended that the titer should be calculated from the lowest dilution that results in 50% residual factor VIII activity.
after the incubation period. The New Oxford method measures residual activity at 37°C after a 4-hour incubation. A Bethesda unit is generally equivalent to 1.21 Oxford units. The standard Bethesda assay does not control pH, permitting variable low-level inactivation of factor VIII by nonimmunologic mechanisms. The Nijmegen modification controls pH, thus improving classification of positive and negative samples. The Nijmegen modification of the Bethesda assay has been endorsed by the ISTH. Additional improvements in this assay have been described. Although an inhibitor unit does not imply that any specific number of factor VIII units infused into the patient will neutralize any specific number of inhibitor units, the titer provides a general estimate of the initial likelihood of response to infusion of factor VIII products.

Clinical Manifestations

The bleeding manifestations resulting from antibodies to factor VIII are often similar to those seen in hemophilia A. Prolonged or unexpectedly severe hemorrhage may occur after comparatively trivial trauma, postoperatively, or postpartum. Soft tissue or muscle hematomas, hematuria, and spontaneous and intractable epistaxis seem relatively common. For unknown reasons, hemarthrosis is relatively less common in acquired hemophilia than in congenital hemophilia A. Figure 54.5 illustrates soft tissue hematomas occurring in a nonhemophilic patient with an acquired inhibitor to factor VIII. When antibodies arise in patients with mild hemophilia A, bleeding typical of severe deficiency may develop; more significantly, the bleeding may be refractory to replacement therapy. This condition may have serious consequences, and fatal events are seen in 10% to 20% of clinically symptomatic patients. Antibodies to factor VIII arising during pregnancy may cross the placenta.

Treatment

The treatment of bleeding in patients with antibodies to factor VIII presents several challenges. No adequate randomized trials have been conducted to evaluate different forms of therapy or to investigate the timing and sequence of their application; therefore, practical treatment decisions are somewhat arbitrarily based on estimates of benefits and risks deduced from retrospective literature review and consideration of each patient’s circumstances and co-morbidities. A consensus group from the United Kingdom and an international panel have published guidelines on treatment of inhibitors in patients with hemophilia, and a literature review of acquired hemophilia therapy options has summarized treatment recommendations. An algorithm that has some general applicability is shown in Figure 54.6. As a first step, basic clinical information should be obtained, including whether the inhibitor arose in the setting of hemophilia or is acquired; the severity of bleeding; anticipated surgical procedures; inhibitor titer and persistence; prior inhibitor response and relation in time to previous factor infusions; possible triggering events such as recent medication exposure or pregnancy; and the presence of other diseases. For example, the mere presence of an inhibitor may in itself not warrant immediate therapy because many inhibitors are present in low titer and are often transient. Spontaneous remissions may occur in a significant number of patients, particularly if the inhibitor develops during the puerperium. At the other end of the spectrum, an unfortunate clinical scenario might involve significant spontaneous clinical hemorrhage, a persistent high-titer inhibitor, and incidental co-morbidities such as cardiac, hepatic, or renal insufficiency. Principles of management include stopping bleeding using bypass therapy, eradication of the inhibitor with immunosuppression, and recognizing and treating any underlying disorder that may have triggered autoantibodies to factor VIII.
FIGURE 54.5. Soft tissue hemorrhage in a 76-year-old man with a high-titer factor VIII inhibitor. This patient has a history of ischemic cardiomyopathy and diabetes and developed spontaneous extremity bruising as shown. The antihuman factor VIII antibody titer was 10 Bethesda units. (Courtesy of Alan Grosset.)

In patients with low-titer inhibitors who do not have any clinical bleeding and for whom no surgical procedures are foreseen, the most reasonable approach may be to monitor the abnormal laboratory finding. Steroids and cytotoxic therapy (usually cyclophosphamide) are usually ineffective when inhibitors arise in patients with congenital hemophilia A, but they are effective in the setting of nonhemophilic patients. Cyclosporin has also been used to treat acquired antibodies to factor VIII. Procedures or medications (antiplatelet drugs) that would increase hemostatic risks should be avoided, and ancillary local therapeutic measures to control minor bleeding are recommended and may in themselves be sufficient. For patients with minor bleeding who have residual factor VIII activity >5% of normal, DDAVP therapy may be helpful (0.3 µg/kg, up to 24 µg maximal dose). Antifibrinolytic therapy, such as the administration of EACA or tranexamic acid, may be helpful, especially for oral or nasal bleeding; however, this therapy should be used cautiously in muscle bleeds because it appears to be less effective, and it should not be used in conjunction with PCCs, activated PCCs (APCCs), or rVIIa.

The inhibitor titer and its prior response to factor VIII infusion may be of particular use in guiding therapeutic decisions (Fig. 54.6). As a rule, replacement therapy with factor VIII in the usual doses is ineffective. If clinical bleeding mandates active therapy, patients with a low Bethesda titer (<5 U/ml), particularly if they are known to be low responders, usually respond to highpurity or recombinant human factor VIII given as a large initial 150 U/kg bolus followed by a continuous infusion of 1,000 U/hour. The therapeutic response to human factor VIII should be clinically assessed; factor VIII levels and repeat assays of inhibitor titer response may be helpful. Therapy with human factor VIII is seldom successful in patients with high-titer antibodies (>5 Bethesda U/ml), high-affinity antibodies, and infinite coagulation times. As an alternative, particularly in patients with high-titer inhibitors or a history of an anamnestic response, or routinely in medical centers that prefer to reduce the uncertain risk of inducing an increased inhibitor titer, the use of inhibitor-bypassing products may be useful. These include the PCCs, APCCs, and rVIIa. The best-studied treatment options are FEIBA (factor VIII inhibitor bypassing activity) and rVIIa. There is no consensus as to the best therapeutic approach between these options.
A literature review of efficacy and safety of FEIBA and rVIIa in treating bleeding events in acquired hemophilia indicates “indistinguishable” efficacy between the two products; if one agent is not successful in stopping bleeding, the other agent should be used. A typical dose for FEIBA in this indication is 75 U/kg every 8 to 12 hours. Both therapies (FEIBA, rVIIa) are associated with thrombosis.

**FIGURE 54.6.** A strategy for management of factor VIII inhibitors in hemophilic and nonhemophilic patients. Key decisions are based on antihuman and antiporcine factor VIII inhibitor titers. Multiple options for patients not responding to human or porcine factor VIII are available. BU, Bethesda units; DDAVP, 1-desamino-8-D-arginine vasopressin; PCC/APCC, prothrombin complex concentrate/activated prothrombin complex concentrate. The underlined options are preferred. Immunosuppression options include rituximab, steroids, and cytotoxic drugs. *As of early 2013, porcine factor VIII was not routinely available, so testing porcine inhibitor titers should not be done. If a recombinant porcine product becomes available, then these tests will be relevant. (Information in this figure is from the literature, including Morrison AE, Ludlam CA. Acquired haemophilia and its management. Br J Haematol 1995;89:231-236.)

rVIIa is a treatment option for inhibitor patients. This drug was originally thought to exert activity by binding to tissue factor at sites of vascular injury to initiate coagulation. More recent data indicate that at the pharmacologic concentrations of factor VIIa achieved during rVIIa therapy, there may be platelet-dependent, tissue factor-independent mechanisms to mediate hemostasis. The standard dose of rVIIa is 90 µg/kg every 2 hours for serious bleeding or 90 µg/kg every 3 hours for mild to moderate bleeding in home treatment. Recent trial data indicate that a single rVIIa dose of 270 µg/kg is effective home treatment for hemarthroses. Continuous infusion of rVIIa is also effective, targeting
factor VII levels to 30 to 40 U/ml.\textsuperscript{326} rVIIa, like FEIBA therapy, is associated with potential thrombotic complications; a comparative evaluation of the thrombotic event rate of rVIIa versus FEIBA revealed that rVIIa was associated with approximately threefold more thrombotic events than APCC.\textsuperscript{327} FEIBA has been successfully used as a prophylaxis therapy for hemophilia patients with inhibitors.\textsuperscript{328}

There are few studies directly comparing the efficacy of rVIIa versus FEIBA or other activated PCCs in inhibitor patients with serious bleeding. These products have similar efficacies,\textsuperscript{316,329,330} and consensus recommendations generally include multiple treatment options.\textsuperscript{331,332} For patients refractory to both drugs used as single agents, sequential therapy with FEIBA and rVIIa has been reported.\textsuperscript{333}

Another potentially useful product in inhibitor patients is porcine factor VIII. Obtaining an antiporcine antibody titer is useful, but as a rule of thumb, the initial antiporcine titer is often 5% to 10% of the antihuman titer. However, the antiporcine titer may rapidly rise after administration of porcine factor VIII. For these reasons, porcine factor VIII is usually reserved for one-time use.\textsuperscript{332} Some investigators consider porcine factor VIII to be the therapy of choice for patients with factor VIII antibodies in which the antibody has minimal cross-reactivity to porcine factor VIII,\textsuperscript{334} and consensus groups consider porcine factor VIII an appropriate treatment option.\textsuperscript{314,331} Porcine factor VIII is currently unavailable in the United States; however, a recombinant B-domain-deleted porcine factor VIII product is in clinical trials.

Long-term eradication of antibodies to factor VIII requires immunosuppressive therapy. Numerous treatment options exist.\textsuperscript{316} A literature review\textsuperscript{335} of the efficacy of intravenous Ig in the treatment of acquired factor VIII antibodies found a cumulative response rate of only 12%, suggesting that other modalities should be attempted first for these patients.

Standard immunosuppression should be reserved for patients with autoantibodies because this therapy is rarely beneficial in the alloimmune setting. Corticosteroids (e.g., prednisone in doses of 1.0 to 1.5 mg/kg/day) produced improvement in approximately 50% of patients when administered on a long-term basis,\textsuperscript{275} with the best results obtained with nonhemophilic patients. Similar therapeutic responses have been reported when immunosuppressive drugs, such as cyclophosphamide (2 to 3 mg/kg/day), were administered alone or with prednisone.\textsuperscript{316,336} Remission of bleeding and reduction of antibody titer have been well documented, but total suppression of the antibody is rare.

Rituximab, a monoclonal antibody to the CD20 antigen on B cells, has been reported to be effective in case series of patients with acquired factor VIII antibodies,\textsuperscript{316,337,338} and a United Kingdom practice guideline recommends rituximab as second-line therapy if patients have not responded to steroids and cyclophosphamide.\textsuperscript{324}

One aggressive treatment regimen for acquired hemophilia combined protein A immunosorption, factor VIII, intravenous IgG, and immunosuppression; this regimen resulted in abolition of antibody levels within 3 days and a complete response rate of 88%.\textsuperscript{339} This aggressive regimen should be considered for patients with severe, life-threatening bleeding.\textsuperscript{316} Cyclosporin A has been reported to be useful in patients failing first-line eradication therapy.\textsuperscript{316}

In many patients with hemophilia A who have developed alloantibodies to factor VIII, infused factor VIII provokes a rapid increase in the antibody titer. However, in many of these patients, the administration of large doses of factor VIII for periods of months to years may produce immune tolerance (IT) to factor VIII. An international registry of patients treated with this approach reported that approximately 70% of patients achieved long-lasting tolerance.\textsuperscript{340} A 1997 update of this registry indicated that 52% of patients were successfully treated with IT.\textsuperscript{341} Several IT regimens have been summarized.\textsuperscript{342} The registry data suggest that success of inducing tolerance is greatest in patients given more than 100 U/kg/day factor VIII who had an initial inhibitor titer of <10 Bethesda U before starting IT.\textsuperscript{340,341} Data from the North American Immune Tolerance Registry have been reported; the overall success rate was 70%.\textsuperscript{343} The cost effectiveness of IT therapy has been demonstrated.\textsuperscript{344}

The International Immune Tolerance Study compared highdose (200 U/kg daily) versus low-dose (50 U/kg daily) factor VIII. Both dosage regimens were equivalent in terms of inducing tolerance; however, the low-dose regimen was associated with more bleeding.\textsuperscript{345} The use of factor VIII products that contain VWF may be more effective in IT induction.\textsuperscript{346} The topic of IT induction in hemophilia A and B patients has been recently reviewed.\textsuperscript{347}

Monospecific Antibodies to Other Coagulation Factors

Table 54.6 summarizes certain conditions associated with antibodies to other coagulation factors.

Factor IX
Inhibitors of factor IX have been demonstrated in approximately 5% of patients with hemophilia B and rarely in previously normal persons (acquired hemophilia). Hemophilia B patients who acquire antibodies to factor IX often have gross gene deletions. In contrast to antibodies to factor VIII, factor IX antibodies act instantaneously. One series of eight hemophilia B inhibitor patients found that antibodies typically were IgG1 and IgG4, and that the antibodies targeted the Gla domain and protease domain epitopes of factor IX. rVIIa or IT therapy has been used to treat these patients, although IT for hemophilia B inhibitor patients may be less effective than for hemophilia A inhibitor patients. PCCs are also a treatment option. Patients with antibodies to factor IX may experience anaphylaxis when treated with factor IX-containing products; rVIIa may be the appropriate therapy for this patient group. A British consensus group has published guidelines on treating factor IX inhibitor patients, and an ISTH registry of factor IX inhibitor patients has been established.

Evidence suggests these inhibitors are antibodies. In patients with inherited deficiencies of the various factors, their development usually is related to transfusion of blood or blood products.

Factor V

Inhibitors of factor V have developed spontaneously in previously normal older persons after administration of streptomycin, gentamicin, or penicillin and after surgical procedures. More rarely, factor V inhibitors have been associated with tuberculosis, femoral fracture, and bullous pemphigoid. These antibodies are usually of IgG isotype. An Australian survey estimated the annual incidence of factor V inhibitors at 0.29 cases per million population, and a Singapore incidence rate was 0.09 cases per million person years. Alloantibodies to factor V may occur in factor V-deficient patients who receive blood products.

Over the past 30 years, an iatrogenic coagulopathy has been identified: The occurrence of antibodies to thrombin and factor V in patients treated with bovine thrombin during surgery. The antithrombin antibody neutralizes bovine thrombin and therefore can prolong the thrombin time when bovine thrombin is used for this test. However, no clinically significant hemostatic defect appears to result from this single laboratory abnormality. Some patients acquire additional antibodies to human factor V, which may result in significant factor V deficiency and bleeding. In a large surgical series of patients exposed to bovine thrombin, more than 95% of patients developed antibodies to bovine thrombin or factor V, and 50% of these patients had antibodies cross-reacting to human coagulation proteins. These latter patients have a bleeding risk.

In contrast to most other specific inhibitors, antibodies to factor V seldom produce serious hemorrhage. Patients with alloantibodies to factor V typically have significant bleeding. Patients with antibody recognition of the C2 domain of factor V have also been reported to have a significant bleeding risk. A literature review identified a bleeding mortality rate of 12% in patients with factor V antibodies not due to exposure to bovine factor V or noninherited acquired factor V antibodies. In several patients with severe hemorrhage, platelet transfusions were therapeutically more effective than plasma. This clinical benefit of platelet transfusions likely relates to platelet α-granule content of factor V which is released at sites of bleeding to improve local hemostasis. Plasmapheresis, immunosuppression, and intravenous IgG have been reported to be effective in resolving antibodies to factor V. In some cases, these antibodies resolve spontaneously.

A small number of patients have been described with thrombosis symptoms associated with factor V antibodies. These patients may have coexisting antiphospholipid antibodies.

von Willebrand Factor

Acquired von Willebrand disease (vWD) has been reported in association with a variety of disorders, primarily including patients with lymphoproliferative disorders, myeloproliferative disorders, solid tumors, autoimmune disease, aortic stenosis, and artificial heart devices. An international registry identified lymphoproliferative and myeloproliferative disease as accounting for more than 60% of acquired vWD. A literature review concluded that most cases of acquired vWD result from an antibody that recognizes high-molecular-weight multimers of vWF and mediates subsequent antigen-antibody clearance. Another mechanism for the development of this disorder includes adsorption of vWF by tumor cells or platelets. Acquired vWD has also been reported in patients with aortic stenosis and in patients with ventricular-assist devices and artificial hearts. In these cardiac conditions, vWF is subjected to shear stress and proteolysis.

Ristocetin co-factor activity is usually decreased, whereas factor VIII activity may be normal. In most patients, the hemostatic abnormalities disappear when the underlying disorder is treated. For patients with acquired vWD resulting from a lymphoproliferative disorder or monoclonal gammopathy, intravenous Ig may be effective. The consensus group recommends a trial of DDAVP as initial therapy; DDAVP failures are then treated with vWF concentrates (e.g., Humate-P or Wilate). Intravenous Ig is reserved for those patients having no success with DDAVP and vWF concentrates. For patients with acquired vWD associated with monoclonal gammopathy of uncertain significance, a trial comparing DDAVP and vWF concentrates versus intravenous Ig found that the latter treatment provided a sustained response compared to DDAVP/vWF concentrates.

Factor XIII

Inhibitors of factor XIII have been described after transfusions in patients with inherited deficiency of this proenzyme and in previous normal persons. Many of the latter group had received isoniazid, and it was suggested that this drug may alter factor XIII in such a manner that it becomes antigenic. These inhibitors may recognize the zymogen, impair the activation of factor XIII by thrombin, or be directed against the cross-linking sites of fibrin, or to the B-subunit. Therapeutic options include factor XIII replacement therapy (plasma, cryoprecipitate), rVIIa, as well as inhibitor
eradication options (steroids, cyclophosphamide, rituximab, etc.). A factor XIII concentrate, Fibrogammin, if available, may also be useful. A survey of hemophilia treatment centers reported that “38% of inherited factor XIII-deficient patients developed antibodies as a treatment complication”; these patients may require bypassing agents to treat bleeding.

Fibrinogen and Prothrombin
A precipitating antibody to fibrinogen has been demonstrated after transfusions in patients with hereditary afibrinogenemia. Acquired hypofibrinogenemia is usually seen in acute DIC. Dysfibrinogenemia may occur in patients with liver disease or hepatoma, or in plasma cell disorders (discussed in the section “Deficient or Aberrant Synthesis of Coagulation Factors”). Antibodies to prothrombin have also been reported. An unusual case of an autoantibody to prothrombin was described; the antibody induced protease activity from the zymogen, leading to neutralization by antithrombin. Acquired hypoprothrombinemia usually occurs in the setting of the lupus anticoagulant (LA) when patients have antibodies to prothrombin that clear prothrombin activity from blood.

Factor XI
A survey of prevalence of acquired inhibitors to factor XI in patients with inherited factor XI deficiency found that “5% of patients with severe deficiency developed antibodies after plasma therapy.” Of those factor XI-deficient patients homozygous for a null allele, one third developed antibodies. A combination of low-dose rVIIa and tranexamic acid was reported to be safe and effective for such patients requiring surgery. Specific inhibitors of factor XI have been described primarily in association with autoimmune disease.

Factor X
Antibodies to factor X are very uncommon and may be associated with upper respiratory tract infections, either viral or mycoplasma; however, in these cases, inhibitors to factor X have been directly proved infrequently. Bleeding has been controlled using PCCs, or ivIgG and steroids. Acquired factor X deficiency has been frequently reported in amyloidosis (discussed below).

Factor VII
Antibodies to factor VII are rare, with fewer than 20 cases reported in the English literature. They have been reported in lung cancer and human immunodeficiency virus infection, and with no apparent disorder. Immunosuppression has been used successfully in anecdotal case reports of autoantibodies to factor VII.

Tissue Factor
Antibodies to tissue factor are very uncommon, with one group reporting two patients who developed antitissue factor antibodies after liver surgery. Similar to patients who acquire antithrombin and antifactor V antibodies after use of topical bovine thrombin, the patients who developed antitissue factor antibodies were both treated with a topical hemostatic agent prepared from bovine tissue that contained tissue factor. The antibodies to bovine tissue factor did not cause clinical bleeding but did prolong PT values.

Antiphospholipid-Protein Antibodies: Lupus Anticoagulants and Anticardiolipin Antibodies

Historical Considerations and Nomenclature
The two best-known clinical types of APAs are traditionally called LA and anticardiolipin (aCL) antibodies. These antibodies are associated in some patients, but not in others, with clinical illness of varying severity. Individual patients may manifest arterial or venous thromboembolic disease, recurrent pregnancy loss, thrombocytopenia or other cytopenias, and neurologic and skin abnormalities. The clinical importance, particularly of the LA or higher-titer aCL antibodies, has been increasingly recognized; these antibodies or their functional consequences are found in approximately 10% of patients with venous thromboembolic events. Bleeding is quite uncommon, and when present, it is usually the result of severe thrombocytopenia, platelet dysfunction, hypoprothrombinemia, or the effects of an underlying disease. On the other hand, thrombosis and its many manifestations are common.

Synonyms for LA and aCL antibodies include antiphospholipid (aPL) antibodies, APAs, and autoantibodies to phospholipidbinding plasma proteins. The associated clinical manifestations including thrombosis are variously called the LA syndrome, antiphospholipid syndrome (APS), or antiphospholipid-protein syndrome. APS without a known well-
defined autoimmune disease is termed primary APS (PAPS). A few patients with APA develop an acute, severe, multiple-organ APS illness. These patients are designated as having catastrophic APS (CAPS).

The existence of these antibodies was first detected more than 50 years ago when it became apparent that approximately 15% of patients with active SLE have a false-positive Venereal Disease Research Laboratory (VDRL) test. The VDRL test assesses antibody reactivity to "reagin" (antigen), an acidic-phospholipid complex that is chemically extracted from bovine heart tissue. Reagin consists of a mixture of lecithin, cholesterol, and cardiolipin. A nonspecific antibody reaction to reagin is also seen less often in other autoimmune disorders and in some apparently healthy patients. Other laboratory assays discussed in this section identified a family of antibodies that were initially thought to have direct specificity to various phospholipids, although it is now known that the antibodies recognize phospholipid-protein complexes. The proteins often serve a critical cofactor role, and the antibodies collectively are thus most accurately called APAs.

Coagulation assays are sensitive to some of these antibodies. Plasma samples from some patients with SLE, often those with the abnormal VDRL tests, show an in vitro inhibitor effect in several coagulation assays. This association gave rise to the term LA. Most often, a prolonged PT result that is not corrected on mixing with normal plasma is observed; other phospholipid-dependent assays, including the modified Stypven time (dilute Russell viper venom time [DRVVT]), are also affected. Despite persistent clinical use, it is now known that most patients with an LA phenomenon do not have SLE. Moreover, clinical thrombosis is much more often seen than is bleeding with APS antibodies. Patients with SLE occasionally have inhibitors to other hemostatic factors, but these inhibitors are not considered LAs.

In addition to the biologically false-positive VDRL results and the paradoxic in vitro lupus-anticoagulant effect, laboratory studies found a third phenomenon, initially detected by radiomimunoassay: Antibodies to cardiolipin. In aCL-antibody assay systems, serum Igs bind to various anionic phospholipid-protein complexes, most commonly to cardiolipin in a coated microwell enzyme-linked immunosorbent assay (ELISA). The sensitivity and specificity of this assay are substantially higher than those of the VDRL. A phospholipid-binding protein, \( \beta_2 \)-glycoprotein I (\( \beta_2 \text{gpI} \)), has been identified, and antibodies to this antigen can also be demonstrated in patients with APS. Thus, the most useful assays to evaluate patients for antiphospholipid antibodies include the LA, aCL antibodies, and antibodies to \( \beta_2 \text{gpI} \).

**Epitope Specificity**

In these disorders, the antibodies were initially thought to react with anionic phospholipids directly, but the presence of specific plasma proteins associated with phospholipids is now known to be of great importance. In the case of LAs, the seemingly paradoxical discordance between laboratory screening test results and clinical symptoms is frequently the consequence of antibodies that bind to a complex of phospholipid-protein complexes. This antibody binding impairs the function of the standard prothrombin-binding synthetic anionic phospholipid that are used routinely in the laboratory to replace platelets in phospholipid-dependent coagulation assays, such as the PTT. Other more natural phospholipids, or platelets themselves, are less affected by this phenomenon and are used in some assays as correction factors in mixing studies.

In the case of aCL antibodies, especially in autoimmune and drug-induced aCL, \( \beta_2 \text{gpI} \) serves as a mandatory protein cofactor. Patient-derived antibodies directed against \( \beta_2 \text{gpI} \) that have LA activity have also been reported. \( \beta_2 \text{gpI} \) is a 57-kD plasma protein with an uncertain physiologic role, but it is often considered a noncomplement member of the complement-control family of proteins, with structural similarity to complement factor H. A recent study reported that \( \beta_2 \text{gpI} \) inhibited complement activation at the level of C3. \( \beta_2 \text{gpI} \) has a number of anticoagulant activities, but inherited deficiency of \( \beta_2 \text{gpI} \) has no thrombophilic association. The antibodies in these settings are often of the IgG isotype, are relatively persistent and high in titer, are associated with an LA phenomenon in approximately 60% of patients, and are clearly associated with the clinical syndromes.

Discussed subsequently. IgM and IgA antibodies occur less often. aCL antibodies are not directed primarily against cardiolipin itself, but against epitopes formed after \( \beta_2 \text{gpI} \) binds to anionic phospholipid membranes or anionic synthetic surfaces. One study observed that pathogenic antibodies targeted an epitope in domain 1 of \( \beta_2 \text{gpI} \), and that these antibodies had LA activity. \( \beta_2 \text{gpI} \) may also mediate aCL binding to endothelial cell membranes. Other proteins have been occasionally implicated as possible obligatory cofactors, including annexin A5, annexin A2, factor Xa, protein C, protein S, and vimentin. Anti-\( \beta_2 \text{gpI} \) antibodies have been reported to induce acquired resistance to APC.

It was previously thought that APA recognized neoeptopes of the above phospholipid-binding proteins expressed on cellsurface binding. Another hypothesis is that the true antibody target is an appropriate density (“clustering”) of proteins bound to phospholipid surfaces, which is necessary for antibody recognition. For example, based on in vitro data, it has
been proposed that β₂gpI acts as an antigen in vivo only when the antigen (β₂gpI) clusters on membrane surfaces such as endothelium. When clustering occurs, this increased antigenic density allows antibody recognition to occur, leading to antibody binding and endothelial cell activation and potentially triggering cellular events resulting in thrombosis. Figure 54.7 illustrates how this phenomenon might occur. Additional studies found that β₂gpI undergoes a conformational change (circular to “fishhook”) upon cell binding to anionic phospholipids, leading to clustering and antibody binding. Involvement of the MyD88 signal transduction pathway in antibody-mediated endothelial cell activation has been described, and others have reported involvement of the p38 mitogen-activated protein kinase pathway. Receptors that have been described that could possibly mediate the APA response include a toll-like receptor on endothelium, annexin A2, and apoER2'. The latter receptor has been demonstrated to promote leukocyte-endothelial cell adhesion and thrombosis by inhibition of endothelial cell nitric oxide synthase activity. Other investigators have identified cell signaling through the toll-like receptor 4 mediated by a multiprotein complex as a pathway for endothelial cell activation by APS antibodies.
allows for efficient antibody binding, resulting in endothelial cell activation and promotion of thrombosis (C).

In other settings, particularly those related to infection, the aCL antibodies are often of IgM isotype, are often of low titer and relatively transitory, and have no identified co-factor protein.\textsuperscript{409} Although β2gpl is an absolute protein co-factor requirement for aCL activity in autoimmune settings, it may, in contrast, be inhibitory in the infection-related circumstance.\textsuperscript{409} The clinical association of IgM antibodies with thrombophilia is less strong,\textsuperscript{439} particularly thrombosis occurring after drug administration,\textsuperscript{440} although exceptions to this generalization have been noted.\textsuperscript{441} The detection of subgroups of aPLs has been reviewed.\textsuperscript{403}

Another key question related to the pathogenesis of APS is, how are antiphospholipid antibodies generated? One report found that only β2gpl bound to phospholipids could be successfully presented to T lymphocytes to elicit a pathogenic immune response.\textsuperscript{442} Oxidation of β2gpl increases its immunogenicity, and patients with APS have increased amounts of oxidized β2gpl.\textsuperscript{443}

Mechanism of Thrombosis

Potential mechanisms to explain how aPL induces thrombosis\textsuperscript{405} include (a) endothelial cell activation, (b) oxidant-mediated vascular injury, (c) interference with the function of phospholipid-binding proteins in regulating coagulation, and (d) complement activation.\textsuperscript{404} In the first hypothesis, aPL antibodies directly bind to endothelium to up-regulate expression of adhesion molecules and cytokine secretion.\textsuperscript{403} In the second hypothesis, autoantibodies to oxidized low-density lipoprotein occur with aCL antibodies, and aCL antibodies recognize oxidized phospholipids and phospholipid-binding proteins.\textsuperscript{404} In the third hypothesis, aPL antibodies may interfere with the anticoagulant functions of protein C or annexin V or enhance procoagulant activity.\textsuperscript{403} 427 428 In the fourth hypothesis, complement activation by aPL antibodies leads to neutrophil expression of tissue factor.\textsuperscript{445}

Immunologic studies lend strong support for a direct pathophysiologic role of these antibodies in the clinically observed thrombotic syndromes.\textsuperscript{446} In animal models using standardized vessel injury to induce thrombosis, either passively conferred APA\textsuperscript{447} or active induction of antibody with either APA or β2gpl\textsuperscript{448} resulted in thrombosis; this suggested that APAs are not merely epiphenomena of thrombi arising for other reasons but, in some cases, play a direct role in initiation, propagation, or maintenance of thrombosis. Immunization of mice or rabbits with β2gpl produces two populations of antibodies: One with specificity for β2gpl alone without binding to phospholipids and the other with specificities for both cardiolipin and β2gpl.\textsuperscript{449} This dual specificity of antibodies is also seen with those aPLs that are present in patients with autoimmune diseases.

The concept of hexagonal phase configuration has been popularized. This configuration is thought to arise in vivo in response to membrane damage.\textsuperscript{450} 451 Normally, polar heads of phospholipids exist on the external surface, whereas in the hexagonal phase, lipid cylinders exist with internal aqueous channels formed by polar head groups.\textsuperscript{452} LA and aCL may represent antibodies generated in response to these neoantigens. APAs have been generated in mice immunized with hexagonal phase phospholipid;\textsuperscript{453} these antibodies reacted with cardiolipin and possessed functional LA activity.

The precise cause of thrombosis in APS is uncertain, and is likely multifactorial. Presumably, APAs act by interfering with coagulation,\textsuperscript{404} possibly involving dysfunction or apoptosis\textsuperscript{454} of endothelial cells, platelets, and coagulation proteins, and affect pregnancy outcome by interfering with embryo implantation and fetal development.\textsuperscript{403}

Epidemiology and Clinical Associations

Young, apparently healthy control subjects are reported to have a prevalence of 1% to 5% of aPL antibodies.\textsuperscript{458} In patients with systemic lupus, aPL occurs in 12% to 34%. After prolonged followup, APS may develop in more than 50% of patients with systemic lupus.\textsuperscript{403}
LA and aCL antibodies have been reported in a variety of clinical disorders, including SLE and other autoimmune and connective tissue diseases, and in disorders that are unrelated to SLE (Table 54.7). The presence of phospholipid-binding antibodies could in some cases be an epiphenomenon. In other cases, APAs may be of profound direct etiologic relevance. In general terms, although there are individual patient exceptions, clinical symptoms are seen less often with aCL than with LA, particularly when APAs are associated with infection or medication, are of low titer, and are of IgM isotype. Interpretation of estimates of APA frequency must consider the sensitivity of the diverse assay systems that have been used by investigators. Different LA assay systems have been tested with plasma samples from a rigorously defined group of patients with the antiphospholipid-protein syndrome, confirming the importance of variables such as the concentration and composition of phospholipids used in the assay, phospholipid reagent conformation, and so forth.

**Neurologic disorders**

**Liver disease**

**Valvular heart disease**

**Peripheral arterial disease**

**Chronic renal failure**

**Sickle cell disease**

**Ethylenediaminetetraacetic acid-dependent pseudothrombocytopenia**

In a large series of internal medicine patients, 7% were APA positive, and 2% fulfilled the criteria of antiphospholipid antibody syndrome. The most commonly associated diseases were cancer and chronic or acute alcoholic intoxication. In another study, elevations of APA were found in approximately 20% of an unselected autopsy population, 10% of age- and sex-matched controls, and 2% of healthy normal subjects.

Inhibitors of the lupus type originally were recognized in association with SLE. The prevalence of LA in patients with SLE strongly depends on the type of LA assay system used; three standard PTT reagents detected LA in only 10% of SLE patients. A modified PTT with a reduced concentration of phospholipid detected LA activity in approximately 50% of SLE patients. The kaolin clotting time, a test similar to the PTT, detected LA in 70% of patients with SLE. LA activity was associated with higher mortality in SLE patients. APAs have been seen in other connective tissue disorders, including rheumatoid arthritis and Behçet syndrome. APAs are present in many patients with malignancy. APAs have been associated with monoclonal gammapathy of undetermined significance and Waldenström macroglobulinemia. APAs have been identified in liver disease, the prevalence increasing significantly as the liver disease progresses; APA positivity was as high as 80% in patients with alcoholic hepatitis or cirrhosis. The antibodies have been found in many infections, including hepatitis C, infection with human immunodeficiency virus, human T-cell lymphotrophic virus-1-associated tropical spastic paraparesis, Q fever, and malaria. Children with viral infections often acquire a transient LA effect. Perhaps as a result of the structural changes in the red cell membrane with increased hexagonal-phase content, APAs are common in sickle cell disease. Patients with transient ischemic attacks and cardiac valve lesions had a high incidence of APAs. APAs have
been seen in a variety of unrelated neurologic disorders. Patients with essential thrombocytosis have an increased prevalence of APA and increased risk of thrombosis.

Several medications are associated with APA, most often, phenothiazines such as chlorpromazine, procainamide, quinine and quinidine, hydralazine, and penicillin. APAs were common in patients with ethylenediaminetetraacetic acid-dependent pseudothrombocytopenia. aCL antibodies can occur in both active and quiescent Crohn disease, usually without concomitant LA expression, but their role in the thrombotic complications that can occur in the active phase of this disease is uncertain.

APA positivity is a common finding in patients with idiopathic thrombocytopenic purpura, with either LA or elevated aCL antibodies in almost one half of patients. Moreover, APA levels were not influenced by immunosuppressive therapy with steroids and are not related to the activity of idiopathic thrombocytopenic purpura.

aCL antibodies and, less often, LA are seen in apparently healthy people, especially in the elderly. In studies of normal blood donors, 5% to 10% have aCL antibodies, often present transiently and in relatively low titer without a concomitant LA effect; these donors do not have an increased risk of developing thrombosis. An inherited predisposition to the development of lupus inhibitors was suggested by their presence in two pairs of siblings and in familial studies. Further investigations have suggested associations with certain HLA types.

Clinical Manifestations

Although LAs are immunologically distinct from aCL antibodies, clinical manifestations associated with each antibody appear to be similar. Clinical experience suggests that venous thrombosis is more likely associated with the LA, and arterial thrombosis is more likely associated with high-titer aCL antibodies. However, a literature meta-analysis found that the LA was a stronger risk factor for all thrombosis.

The antiphospholipid-antibody syndrome is characterized by the clinical events of pregnancy morbidity or thromboembolic disease (arterial, venous, or small vessel), or both (Table 54.8). These clinical features are most highly associated with aPL antibodies in prospective studies. Older definitions included immune thrombocytopenia as a clinical event, but the newer classification omits thrombocytopenia. A wide variety of clinical features may be seen with APA. However, many patients with APA are asymptomatic. A proportion of asymptomatic patients develop SLE or other disorders. The diverse clinical manifestations of APA are listed in Table 54.9.

Arterial and Venous Thromboembolic Disease

The most common clinical presentation of patients with LA or aCL antibodies, or both, is arterial or venous thromboembolism, affecting up to 70% of patients in some series but averaging approximately 30% to 40% of patients in most studies. The most common site is extremity deep vein thrombosis, but occasionally, unusual sites are involved, such as the axillary, retinal, and hepatic veins and cerebral venous sinus thrombosis. Cerebral thrombosis, often heralded by repeated transient ischemic attacks, is a common arterial lesion. Mesenteric artery occlusion, adrenal infarction, gastrointestinal ischemia or ulceration, and subclavian thrombosis with “pulseless” disease also have been described. Multiple cerebral infarcts with dementia in addition to coronary occlusions have occurred in unusually young age groups. A paradoxic syndrome of cerebral infarction with concurrent severe thrombocytopenia and bleeding has been reported in several cases. Antibodies to β,γpl are highly associated with venous thrombosis, and in other studies, assays for the LA correlated best with thrombosis, compared with assays for other APAs. Another unusual ischemic syndrome associated with APA is avascular osteonecrosis.

Positive $\beta_2$gpI antibody test (titer >99th percentile, IgG or IgM antibodies)

and

Laboratory abnormality should persist for two or more occasions at least 12 wk apart

or

Complications of pregnancy

One or more unexplained deaths of normal fetuses at or after 10 wk of gestation with normal fetal morphology

One or more premature births of normal neonates before 34 wk of gestation

Three or more unexplained consecutive spontaneous abortions before 10 wk of gestation, excluding anatomic, hormonal, and chromosomal abnormalities

Note: A diagnosis of definite APS requires the presence of at least one clinical event and at least one laboratory abnormality.

Ig, immunoglobulin.

TABLE 54.9 CLINICAL MANIFESTATIONS OF ANTIPHOSPHOLIPID ANTIBODIES

Asymptomatic

Arterial and venous thromboembolism

Avascular osteonecrosis

Hematologic

Cytopenias: thrombocytopenia, autoimmune hemolytic anemia, leukopenia

Coagulopathy: platelet dysfunction, prothrombin deficiency, lupus anticoagulant

Neurologic

Acute ischemia (cerebrovascular accident, transient ischemic attack, encephalopathy); severe migraine; multiple infarct dementia; cognitive dysfunction; seizures

Dermatologic

Livedo reticularis; acrocyanosis (distal cutaneous ischemia, ulceration, gangrene); widespread cutaneous necrosis; pyoderma gangrenosum-like skin lesions; anetoderma

Cardiopulmonary

Marantic endocarditis; myocardial ischemia and infarction; intracardiac thrombotic mass; peripheral arterial disease; thromboembolic and nonthrombotic pulmonary hypertension

Obstetric

Recurrent spontaneous abortion; intrauterine growth restriction; preeclampsia; chorea gravidarum; low
Apgar scores; prematurity

Catastrophic antiphospholipid syndrome

Thrombocytopenia

Moderate immune thrombocytopenia is noted in approximately 50% of patients with lupus inhibitors, but in many cases, it apparently is the result of the underlying disorder. Immune thrombocytopenia is no longer considered a clinical criterion for diagnosis of APS. When bleeding occurs in patients with aPLs, this is generally attributed to co-existent thrombocytopenia, platelet dysfunction, prothrombin deficiency, or other underlying coagulopathies. Other cytopenias may be associated with APA, including autoimmune hemolytic anemia and leukopenia.

Neurologic Syndromes

Various neurologic disorders have been linked with APA, including dementia, migraines, chorea, seizures, transverse myelopathy, Guillain-Barré syndrome, mononeuritis multiplex, transient global amnesia, and myasthenia gravis. Many of these disorders are not associated with ischemia or thrombosis, and the pathologic relationship of these disorders with APA is uncertain. A consensus statement on stroke and APS proposed criteria to determine the likelihood that APA is associated with ischemic stroke. A literature survey determined that the presence of APA in patients with ischemic stroke did not predict recurrence of stroke or differential response to treatment, and that routine screening for APA in these patients was not warranted.

Dermatologic Disorders

A variety of ischemic-dermatologic syndromes have been associated with aCL antibodies, including livedo reticularis, acrocyanosis (distal cutaneous ischemia, ulceration, gangrene), widespread cutaneous necrosis, and pyoderma gangrenosum-like skin lesions. Livedo reticularis is more prevalent among APS patients with systemic lupus, and in females.

Cardiac Disorders

A high incidence of APA is seen in patients with peripheral arterial disease who experience an associated increased risk of early graft thrombosis. This may justify routine testing for APA before reconstructive vascular surgery, with consideration of perioperative antiplatelet agents or anticoagulation. Some reports have noted the presence of APA in survivors of myocardial infarction. A variety of valvular heart lesions is associated with APS. The consensus group recommends that patients with biopsy-proven myocardial small-vessel thrombosis or those with intracardiac thrombi be considered for meeting criteria for APS. Coronary artery disease also fulfills the APS thrombosis criterion.

Pulmonary Disorders

Ischemic and thrombotic pulmonary disease is linked to APA, including pulmonary embolism, pulmonary hypertension, intraalveolar pulmonary hemorrhage, and adult respiratory distress syndrome. The latter syndrome has been reported in patients with CAPS.

Obstetric Aspects

APAs are associated with obstetric complications, including intrauterine growth restriction, preeclampsia, chorea gravidarum, and, primarily, recurrent spontaneous fetal loss (RSFL). Pregnancy losses in women with aPLs are often caused by fetal death despite normal fetal karyotypes. Spontaneous fetal loss is perhaps most common in the first trimester, but paradoxically, early first-trimester pregnancy losses are relatively less common than in other patients with recurrent fetal loss. The international consensus statement listed obstetric criteria for diagnosis of APA: (a) One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation (with normal fetal morphology); (b) one or more premature births of a morphologically normal neonate before the 34th week of gestation because of preeclampsia, eclampsia, or placental insufficiency; or (c) three or more unexplained consecutive spontaneous abortions before the 10th week of pregnancy (with maternal anatomic or hormonal abnormalities, and paternal and maternal chromosomal causes excluded). There is a significantly increased incidence of elevated APA in women with a history of two or more miscarriages in the first trimester of pregnancy. Women with a history of RSFL should be tested for both LA and aCL antibodies. Repeat testing is important because only 66% of LA-positive, 37% of IgG aCL-positive, and 36% of IgM aCL-positive women had a
positive test result on repeat evaluation. Laboratory screening for LA is confounded in pregnancy because altered coagulation factor concentrations in normal pregnancy may change the observed normal range of coagulation tests, including the PTT. In two studies, the DRVVT was the most frequently positive test for the LA in this population. Rigorous adherence to diagnostic criteria is particularly appropriate in pregnancy because treatment may require potentially hazardous antithrombotic therapy. Elevated maternal serum levels of α-fetoprotein or human chorionic gonadotrophin are common in women with aPLs and are significantly associated with fetal loss. Maternal APA testing may be appropriate if prenatal screening reveals an elevated human chorionic gonadotrophin level and ultrasonography demonstrates an otherwise normal singleton gestation.

It is generally considered not appropriate to screen for APA in asymptomatic pregnancies without a history of RSFL. APAs were identified at the first prenatal visit in almost 25% of healthy pregnant women. LA appears to be much rarer than aCL antibodies in pregnancy. It appears that women with isolated IgM aCL or with low levels of IgG aCL are a distinct group that is not at risk for APA-related complications beyond the risk conferred by their medical histories.

Although the mechanism by which APA causes recurrent pregnancy loss has not been fully explained, these antibodies may induce intervillosus thrombosis and intravillosus infarctions, resulting in poor placental perfusion, and have been shown to affect cytotrophoblast tissue in vitro. The thrombotic phenomenon may be mediated by aPL antibodies interfering with trophoblastic annexin V.

The role of inflammation and the complement pathway in APS-associated pregnancy complications was reported. Anticoagulants that prevented complement activation (unfractionated or LMWH) were successful in preventing pregnancy loss in an animal model of APS; anticoagulants that did not inhibit complement activation (fondaparinux, hirudin) did not prevent pregnancy loss. These data suggest that the beneficial effects of anticoagulants in APS-associated pregnancy loss result from inhibition of complement activation.

Catastrophic Antiphospholipid-antibody Syndrome

Some patients with APA develop an acute, severe, multiorgan illness characterized by diffuse small vessel ischemia and occlusion with extensive tissue damage, including myocardial infarction, limb ischemia, DIC, and a high mortality rate of 50%. The patients present with a dramatic illness, often without an obvious precipitating event, that prompts consideration of a wide differential diagnosis including severe lupus vasculitis, thrombotic thrombocytopenic purpura, or severe DIC. The syndrome is defined by clinical involvement of at least three different organ systems with histologic evidence of thrombosis. Typically, small vessel thrombotic lesions occur, with common sites of involvement including the kidney, lung, central nervous system, heart, and skin. In a larger series of CAPS patients, nearly one half of the cases had systemic lupus, and 40% had PAPS. Precipitating factors for development of CAPS included infections, trauma/procedures, cancer, and subtherapeutic anticoagulation. LA activity and, particularly, high aCL antibody titers are usually present. Central nervous system symptoms and hypertension are common, and leukocytosis and a significantly elevated sedimentation rate are often also present. The clinical manifestations of this syndrome can include all the symptoms and signs indicated in Table 54.9. Preliminary criteria for the classification and diagnosis of CAPS have been published. Effective therapies include therapeutic anticoagulation, steroids, ivIgG, plasma exchange, and cyclophosphamide. A literature review of rituximab use in CAPS found encouraging results. A summary of CAPS registry cases reported that anticoagulation with steroids ± plasma exchange/ivIgG was associated with at least a 70% success rate.

Laboratory Diagnosis of Antiphospholipid-Protein Antibodies

LA and high-titer aCL antibodies have similar clinical implications, although studies suggest a higher thrombotic risk in patients with the LA. In patients with SLE, the LA is the best predictor for both venous and arterial thrombosis. The laboratory should perform both fibrin-based coagulation assays to detect LA and solid-phase ELISA assays for aCL and β2gpl antibodies in patients suspected of having APA.

A considerable array of phospholipid-responsive laboratory tests, such as the PTT, dilute PTT, kaolin clotting time, and DRVVT, may serve to screen for the LA. LA may be defined as an immunoglobulin (IgG, IgM, IgA, or a mixture) that interferes with one or more of these in vitro, phospholipid-dependent coagulation tests. A more recent definition of the LA would be antibodies to β2gpl or to prothrombin that prolong phospholipid-dependent coagulation assays. Coagulation tests that are phospholipid independent are not affected by LA. Unless concurrent additional factor deficiencies are present, the standard PT is usually normal because of the large amount of phospholipids in this reagent.
No individual test seems to have a universal detection rate; this observation may reflect LA subtypes with distinct activities or the requirement of various co-factors. Consequently, it is recommended to perform at least two independent assays for the LA. A simplified algorithm approach for diagnosis of the LA has been described that uses two assays, the DRVVT and a hexagonal phase assay. Comparative studies suggest that activated PTT reagents with reduced levels or different types of phospholipids are more sensitive than routine PTT reagents. Platelet-poor plasma should be used in these screening assays, particularly if frozen plasma samples are to be tested. A recent update of LA guidelines has reviewed these issues. Table 54.10 indicates some of the clinical and laboratory differences between specific anticoagulant antibodies to particular factors, such as factor VIII and LA. Other nonspecific anticoagulants are uncommon but include the heparinlike anticoagulants discussed in the section “Other Acquired Coagulation Disorders.” Confirmatory tests for LA based on activated PTT or DRVVT include abnormal mixing studies with normal plasma and correction with mixing using phospholipids, such as lysed washed platelets (platelet neutralization procedure), or with added hexagonal-phase phospholipids. A high concentration of liposomes prepared from rabbit brain extracts may achieve the most efficient correction of the defect, but this method is not widely used. The College of American Pathologists has published detailed recommendations for LA testing, and testing issues affecting the LA have been reviewed.

Several clinical points are worth stating. The search for LA or aCL antibodies should not be abandoned even if normal plasma in a mixing study corrects the test patient plasma, particularly in a human immunodeficiency virus-positive population. It is sometimes important for the clinician to discern the possible effect that heparin in the test patient plasma can have on the confirmatory laboratory assay; satisfactory correction procedures should be resistant to heparin, and many commercial LA reagents have heparin neutralizers. The ideal test to identify the LA is controversial; some investigators have reported the kaolin clotting time to be the most sensitive test. On the other hand, some DRVVT assays are more able to identify LA associated with thrombosis. A subgroup of patients with unexplained thrombosis with antibodies to phosphatidylethanolamine as the only abnormal APA test has been identified. Optimal detection of the LA requires more than one of the phospholipid-dependent assays described earlier. This latter suggestion is supported by reports that different phospholipid-dependent coagulation tests detect different populations of LA antibodies. Table 54.11 summarizes the recommendations of an ISTH consensus group on laboratory diagnosis of LA.

Ig, immunoglobulin.

aPLs may also be detected by ELISA or by radioimmunoassay. Commercial ELISA systems are reasonably well standardized. The aCL-antibody assay used to improve sensitivity and specificity has undergone several modifications. Using anti-β2-gpI-dependent assay systems is useful to discriminate between transiently positive aCL antibodies that are associated with infection, which characteristically do not have a β2-gpI cofactor requirement, and those aCL antibodies associated with an increased risk of thrombosis. IgA aCL antibodies should not be considered a laboratory criterion for diagnosis of APS.

Definitional standardization of the criteria for clinical and laboratory APA has been published. For the diagnosis of APS, in addition to a clinical event (e.g., at least one venous, arterial, or small-vessel thrombosis, pregnancy morbidity/mortality), positive laboratory tests for LA, aCL, or β2-gpI antibodies (in medium or high titer) should be found on two occasions at least 12 weeks apart (Table 54.8). It is recommended that aCL antibodies be measured by a standardized ELISA for β2-gpI-dependent antibodies.

Although consensus criteria require persistence of the laboratory abnormality for at least 12 weeks, in clinical practice, a functional definition taking into account the number of clinical manifestations and the titer of aCL antibodies or positivity for the LA on even a single occasion may help categorize patients as having definite, probable, or doubtful APS and may direct immediate treatment options. A “triple positive” profile (positive results for all three assays: LA, aCL antibodies, and β2-gpI antibodies) has been identified as a strong independent risk factor for thrombosis.

**TABLE 54.11 LABORATORY DIAGNOSIS OF LUPUS ANTICOAGULANT: INTERNATIONAL SOCIETY ON THROMBOSIS AND HAEMOSTASIS CRITERIA**

- Prolongation of at least two phospholipid-dependent coagulation tests with the use of platelet-poor plasma (e.g., the activated partial thromboplastin time, dilute prothrombin time, dilute Russell viper venom time, kaolin clotting time). The DRVVT should be the first test considered.
- Failure to correct the prolonged coagulation time by mixing patient and normal plasma.
- Confirmation of lupus anticoagulant by demonstrating correction of the prolonged coagulation time by addition of excess phospholipids or freeze-thawed platelets.
- Exclusion of alternative coagulopathies using specific assays (e.g., factor VIII antibodies).

Even if the patient is asymptomatic, lupus inhibitors should always be identified correctly when discovered, even though costly and time-consuming laboratory study is required. If the cause for a prolonged PTT is not identified, the necessity for definitive laboratory evaluation almost invariably arises again, often in the context of an emergency. This may result in the unnecessary use of blood products and a delay of required surgical procedures.

**Treatment of Antiphospholipid-Protein Antibody Syndrome**

The optimal treatment of patients with APA syndrome is undefined, although randomized treatment trials are providing useful therapy recommendations. Depending on the clinical symptoms, patients with APA may need no treatment or may need anticoagulant or immunosuppressive therapy. Although spontaneous remissions are uncommon and aCL antibodies and LA can be associated with life-threatening thromboembolic events, only 10% to 15% of asymptomatic patients with APA develop these complications. Based on the uncertainty of predicting when thrombotic events might occur, as well as
the risks of anticoagulation, most investigators do not treat asymptomatic patients prophylactically, with the possible exception of short-term intervention when additional thrombophilic hazards such as immobilization or surgery are anticipated.

Patients with significant thrombotic events (e.g., deep vein thrombosis, arterial ischemia, or fetal loss) are appropriate candidates for antithrombotic therapy. Two randomized trials investigated the optimal intensity of warfarin therapy in APS patients. Both studies found that high-intensity warfarin (INR 3.1 to 4.0 or 4.5) was not superior to standard intensity warfarin (INR 2.0 to 3.0). Long-term treatment with oral anticoagulation therapy is advised because of the high rate of recurrence even if the venous or arterial occlusion occurred many years previously. Patients receiving oral anticoagulants had no recurrence over 8 years, whereas patients in whom anticoagulant drugs had been discontinued had a 50% probability of a recurrent venous thromboembolic episode after 2 years and an almost 80% probability of recurrence after 8 years. This strategy is supported by a study that found that APS patients with thrombosis benefited from prolonged oral anticoagulation because persistent elevation of aCL levels predicted an increased risk of thrombosis recurrence and death. Many investigators follow this approach, unless all laboratory evidence of LA and aCL in patients in whom high titers were initially detected or in whom a thrombotic risk was attributed to APA has been continually absent for at least 6 months; no other thrombophilic risk is present; and close surveillance is feasible. An emerging treatment strategy in APS patients is to consider single-positive test results for β2GPI or aCL antibodies as a lesser risk for recurrent thrombosis, and perhaps less-intense or shorter duration treatment periods.

A literature review of treatment for APS patients with ischemic stroke concluded that treatment with either aspirin or low-intensity warfarin (INR 2.0 to 3.0) is effective. For noncerebral arterial thrombosis, combined therapy with low-intensity warfarin (INR 2.0 to 3.0) plus aspirin (81 mg) was recommended. A relatively new therapy for APS is hydroxychloroquine, an immunosuppressive agent used to treat patients with SLE. Hydroxychloroquine therapy decreases thrombosis risk in SLE patients, perhaps by interfering with aPL antibody binding to phospholipid.

Patients with the uncommon LA hypoprothrombinemia syndrome who either have bleeding or need surgery may benefit from steroid therapy or intravenous IgG.

Patients with the LA and acute thrombosis pose difficulty in terms of monitoring heparin anticoagulation. The usually prolonged PTT value seen with the LA renders this test unreliable. These patients can be monitored using heparin assays, which are available by automated methodology (see Chapter 55). Alternatively, patients can be treated using a LMWH, without the necessity for laboratory monitoring (see Chapter 55).

In those patients with an LA and hypoprothrombinemia, or an LA that affects the PT, the use of the INR to monitor anticoagulation has been questioned. These patients may require monitoring with a test that is insensitive to the LA, such as a prothrombin-proconvertin assay or a chromogenic factor X assay.

Corticosteroid use often diminishes or abolishes the coagulation abnormalities and immune thrombocytopenia of APA syndrome within a short time. However, for most patients, the role of steroids, other immunosuppressive agents, or aspirin is uncertain. Although immunosuppression with cyclophosphamide in pulse form is effective in reducing elevated antibody levels, there is often a rapid rebound to pre-treatment levels shortly after discontinuation of the therapy. Consequently, additional therapies with aspirin or steroids or more aggressive immunosuppression are not used unless recurrent thrombotic or ischemic events are seen despite optimal warfarin therapy. High-dose corticosteroid therapy has equivocal efficacy and considerable toxicity and is reserved for treatment of underlying co-morbid conditions such as active lupus and not for the laboratory phenomena of the antiphospholipid antibody syndrome itself.

In patients with CAPS who experience multisystem involvement, intensive treatment with corticosteroids, immunosuppression, intravenous IgG, or plasmapheresis may be useful. In one literature analysis of CAPS therapy, the highest response to therapy occurred in patients treated with anticoagulation and steroids (64%). Immune thrombocytopenia and autoimmune hemolytic anemia in patients with APA are treated similarly as in patients without APA.

Obstetric Treatment

Because the risk of pregnancy loss in women with APS and prior pregnancy loss may exceed 60%, a history of recurrent fetal loss is an indication for treatment during pregnancy. Antiplatelet agents such as aspirin 80 mg/day, low-dose immunosuppressive agents such as prednisolone 10 mg/day, or anticoagulants (heparin or LMWH) have all been used in an attempt to improve pregnancy outcome. Several randomized studies have provided information about useful treatment strategies in pregnancy-associated APS (reviewed in References 403 and 564). Intravenous IgG is of no benefit.
in these patients, and heparin may be more effective than aspirin. A meta-analysis recommends that a combination of unfractionated heparin (5,000 U s.c. twice daily) and low-dose aspirin be used, and a recent consensus guideline recommends “prophylactic or intermediate-dose unfractionated heparin or prophylactic LMWH combined with low-dose aspirin (75 to 100 mg/day)”.

Transfusion-associated Coagulation Abnormalities
The administration of blood products in a volume >1.5 times the patient’s estimated blood volume or replacement of total blood volume in <24 hours constitutes massive blood transfusion. Traditional resuscitation efforts were initiated with large volumes of crystalloid and packed red cell transfusions; a new paradigm is termed “damage control resuscitation” which includes administration of tranexamic acid for cases of uncontrolled hemorrhage, use of a massive transfusion protocol with fixed blood product.

P.1215

ratios, avoidance of large-volume crystalloid use, and usage of permissive hypotension.

The importance of core body temperature on hemostasis parameters has been demonstrated; at a temperature of 33°C, platelet function is impaired. Below 33°C, both coagulation factor activity and platelet function are reduced.

Bleeding Associated with Extracorporeal Circulation
Defective hemostasis with cardiopulmonary bypass is associated with multiple contributory causes, including hemodilution of coagulation factors, inadequate neutralization of heparin, acquired platelet dysfunction, and thrombocytopenia. These latter two defects are further discussed in Chapter 52. In general, extracorporeal-circulation-induced hemostatic defects may be ascribed to activation of platelets and coagulation proteins by artificial surfaces.

Platelet dysfunction (acquired storage pool defect) is considered the major hemostatic insult induced by bypass. Although DDAVP was shown to reduce bleeding and transfusion requirements in these patients in earlier studies, subsequent trials indicated no benefit from DDAVP, and routine DDAVP therapy may be hazardous in older patients with significant vascular disease. Aprotinin should not be used in this setting.

Drug-induced Coagulation Abnormalities
Broad-spectrum antibiotics, such as the β-lactam antibiotics, may induce a coagulopathy by inhibition of vitamin K synthesis by gut bacteria and direct inhibition of essential carboxylation reactions. A number of antibiotics may also inhibit platelet function (see Chapter 52).

L-Asparaginase produces hypofibrinogenemia and deficiency of other coagulation factors. Hematin produces a complex coagulopathy. Valproic acid therapy has been associated with acquired vWD.

Acquired Deficiencies of Single Coagulation Factors
An uncommon phenomenon is the development of deficiency of a single coagulation factor during the course of an acquired disorder (Table 54.6). Isolated deficiency of factor X is well documented in patients with primary amyloidosis and amyloidosis associated with multiple myeloma. Factor X levels in these patients do not rise even after massive replacement therapy, and studies using 131I-labeled factor X suggest that this proenzyme is bound to subendothelial amyloid fibrils in blood vessels. A combined deficiency of factors IX and X in amyloidosis also has been reported. In many patients, the hemostatic defect is complicated by other abnormalities, such as vascular infiltration, liver disease, high levels of antithrombins, and azotemia with platelet dysfunction. Splenectomy abolished the factor X deficiency and produced complete remission of bleeding in several cases, presumably because of extensive amyloid infiltration in the splenic vasculature. Chemotherapy with melphalan and prednisone may also resolve factor X deficiency in amyloidosis. High-dose chemotherapy with stem cell transplantation is also effective therapy. Factor X deficiency has also been associated with upper respiratory tract infections. A detailed literature review of acquired factor X deficiency has been published.

Hypoprothrombinemia has been reported as an isolated finding, most commonly in association with LAs, as discussed previously. Deficiencies of prothrombin, factors IX and XII, plasminogen, and antithrombin have been reported in some patients with the nephrotic syndrome, presumably as the result of massive protein loss in the urine. In one patient with Sheehan syndrome, a selective deficiency of factor IX responded to treatment with corticosteroids and thyroid replacement. Isolated deficiency of factor IX in several patients with Gaucher disease also has been documented. Acquired factor VII deficiency has been reported with aplastic anemia and liposarcoma.
Factor XIII deficiency has been associated with chronic myelocytic leukemia and with various forms of acute leukemia. Factor XIII deficiency has also been associated with inflammatory bowel disease, and isoniazid-induced antibodies to factor XIII have been reported. Factor XII deficiency has been described in association with chronic myelocytic leukemia and antiphospholipid antibodies. Factor XI deficiency has been linked to Gaucher disease and Ehlers-Danlos syndrome. Factor V deficiency has been reported in chronic myeloid leukemia and in celiac disease. Acquired vWD was discussed earlier in the section on vWF.

Other Acquired Coagulation Disorders

Heparinlike anticoagulants have been reported in patients with hematologic malignancies (e.g., plasma cell dyscrasias or leukemias, or solid tumors). A prolonged thrombin time and normal reptilase clotting time are typically seen in these patients. Significant clinical bleeding may occur with heparinlike anticoagulants; a titrated protamine sulfate infusion may be helpful in these patients.

Malignancy may also be associated with other inhibitors of coagulation, including FDPs and paraproteins, dysfibrinogenemias, and specific antibodies to coagulation factors (discussed earlier). A monoclonal antithrombin antibody associated with bleeding has been reported in a patient with myeloma.

Thrombosis and Antithrombotic Therapy

Robert C. Pendleton

George M. Rodgers

The term thrombosis refers to the formation, from constituents of the blood, of a mass within the venous or arterial vasculature of a living animal. Hemostatic thromboses, namely, self-limited and localized thromboses that prevent excessive blood loss, represent the body’s natural and desired response to acute vascular injury. Pathologic thromboses such as deep venous thrombosis (DVT), pulmonary embolism (PE), coronary arterial thrombosis leading to myocardial infarction (MI), and cerebrovascular thrombotic occlusion represent the body’s undesired response to acute and chronic perturbations of the vasculature, blood, or both. The terms coagulated blood and clot are not synonymous with thrombosis and refer to the formation of a solid mass of blood components outside of the vascular tree. Examples of clots include soft tissue, body cavity (e.g., peritoneal), and visceral hematomas. Coagulated blood best describes clots formed ex vivo.

Thrombosis of the veins and arteries, together with complicating embolic phenomena, is perhaps the most important cause of sickness and death in the developed countries of the world at the present time. Deaths from MI and thrombotic stroke consistently represent the major causes of death in the United States, numbering >700,000 people annually.
Venous thromboembolic disease is the third most common cardiovascular disease, after atherosclerotic heart disease and stroke. It has been estimated that between 500,000 and 2 million venous thromboembolic events (VTE) including calf vein thrombosis, proximal DVT (e.g., lower extremity and pelvic veins), and PE occur annually in the United States alone. The incidence of pathologic thrombosis, prevalence of disorders that predispose an individual to thrombosis, and morbidity and mortality associated with thrombotic events all reflect the magnitude of the importance of the study of thrombotic mechanisms and development of effective antithrombotic and thrombolytic therapies.

In this chapter, the pathophysiology of arterial and venous thrombosis and mechanisms of action of antithrombotic pharmacologic agents including antiplatelet drugs, anticoagulants, and fibrinolytic agents are summarized and discussed. Inherited conditions that predispose an individual to thrombosis, also termed hypercoagulable states, and the management of venous thromboembolic disease are covered. The management of arterial thrombotic events is beyond the scope of this chapter, and the reader is referred to several excellent recent review articles.

PHYSIOLOGY AND PATHOPHYSIOLOGY OF THROMBOSIS

The human hemostatic system consists of multiple independent, yet integrally related, cellular and protein components that function to maintain blood fluidity under normal conditions and promote localized, temporary thrombus (hemostatic thrombus) formation at sites of vascular injury. A normal hemostatic system is the human physiologic defense against exsanguination. An abnormal hemostatic system can result in pathologic bleeding, vascular thrombosis, or both.

The hemostatic system is comprised of six major components: Platelets, vascular endothelium, procoagulant plasma protein “factors,” natural anticoagulant proteins, fibrinolytic proteins, and antifibrinolytic proteins. Each of these six hemostatic components must be present in fully functional form, in adequate quantity, and at the proper location to prevent excessive blood loss after vascular trauma and, at the same time, to prevent pathologic thrombosis. The hemostatic system is highly regulated and maintains a delicate balance between a prohemorrhagic state and a prothrombotic state. Any significant acquired or congenital imbalance in the hemostatic “scales” can lead to a pathologic outcome.

Normal hemostasis in response to vascular injury can be divided into two major processes of equal importance, known as primary and secondary hemostasis. Primary hemostasis comprises the reactions needed to form a platelet plug at a site of vascular damage, whereas secondary hemostasis comprises a series of reactions (coagulation cascade) needed to generate cross-linked fibrin required to stabilize the platelet plug and form a durable thrombus. Natural anticoagulants (antithrombin [AT] and activated protein C [APC]) function to confine thrombus formation to the sites of vascular injury and limit thrombus size to prevent vessel occlusion and flow interruption in the affected vessel. The activity of AT is greatly enhanced by endothelial cell heparan sulfate and pharmacologic heparins. The function of APC is enhanced by its cofactor, protein S. Physiologic fibrinolysis is initiated by endothelial-cell-derived tissue-type plasminogen activator (t-PA), which converts plasminogen to plasmin. Plasmin can degrade cross-linked fibrin, limit thrombus size, and help dissolve a thrombus once the vascular injury has been repaired. The fibrinolytic system is regulated and localized by antiplasmin and PA inhibitor (PAI)-1. Details of the hemostatic mechanisms and endothelial cell regulation of hemostasis are given in Chapters 18 and 19.

Specific alterations in the quantitative and qualitative status of any hemostatic cellular or protein element can lead to pathologic thrombosis. A marked increase in the platelet count (thrombocytosis) and accentuated platelet aggregation (“sticky platelet syndrome”) are associated with thromboembolic events. Elevated levels of procoagulant factors such as fibrinogen, factors VIII, IX, XI, and VII, as well as resistance to inactivation of factor Va by APC, are recognized risk factors for vascular disease and thrombosis. Deficiency of a natural anticoagulant protein such as protein C, protein S, or AT is associated with venous thromboembolic disease. Deficiency of a fibrinolytic cascade component, such as t-PA or plasminogen, and excess plasma levels of the fibrinolytic inhibitor PAI-1 have been linked to hypercoagulability and thrombosis. It is the net balance between the participating and, at times, opposing groups of proteins and not the level of any individual factor that is most critical to hemostatic regulation.

VIRCHOW TRIAD

In the mid-19th century (1854), German pathologist Rudolph Virchow postulated that vascular obstruction was precipitated by, and thrombosis resulted from, three interrelated factors:

P. 1219

(a) “Decreased blood flow” (stasis of blood flow), (b) “inflammation of or near the blood vessels” (vascular endothelial
injury), and (c) “intrinsic alterations in the nature of the blood itself” (hypercoagulability). Many students of coagulation medicine, though, do not realize that Virchow actually recognized his “triad” as being the result of vascular occlusion, not necessarily as the original precipitant of vascular thrombosis. Nonetheless, the vascular, rheologic, and hematologic aspects of thrombosis known as the Virchow triad remain relevant and instructive today (Fig. 55.1).

Abnormalities of Blood Flow

Arterial thrombosis initially occurs under conditions of rapid blood flow (high shear stress), a condition in which von Willebrand factor (vWF) is critical for platelet adhesion. Arterial thrombi usually are composed of tightly coherent masses of platelets, which contain small amounts of fibrin and a few erythrocytes and leukocytes. These thrombi are the classic “white thrombi,” which resemble, in many respects, normal hemostatic plugs. As arterial thrombi enlarge, progressive or intermittent deposition of new layers of platelets and fibrin produces the characteristic lines of Zahn; partial or complete obstruction of blood flow may produce a “tail” of “red thrombus.” The most serious consequences of arterial thrombosis are vascular occlusion with resultant ischemia and infarction of tissue and distal thrombus embolization.

FIGURE 55.1. Pathophysiology of thrombosis. Factors implicated in the pathogenesis of arterial thrombosis (left) and venous thrombosis (right) are depicted. Examples of disorders leading to platelet activation and arterial thrombosis include atherosclerosis, the myeloproliferative disorders, heparin-associated thrombocytopenia/thrombosis syndrome, thrombotic thrombocytopenic purpura, and certain platelet polymorphisms. Examples of disorders leading to venous thrombosis in the category of deficiency of physiologic inhibitors include the inherited disorders, factor V Leiden, proteins C and S deficiencies, and AT deficiency. Many patients with thrombosis may have more than one of the risk factors listed. Estrogen therapy is a risk factor for venous thrombosis; its use is associated with activation of coagulation.

Hypertension, turbulent blood flow at arterial branch points and at sites of focal atherosclerosis, and hyperviscosity may be contributory factors in certain forms of arterial thrombosis. Causes of plasma hyperviscosity that can precipitate thrombosis and exacerbate ischemia include acute myeloid leukemia, myeloproliferative syndromes such as polycythemia rubra vera, cryoglobulinemia, and the plasma cell dyscrasias, including multiple myeloma and Waldenström macroglobulinemia. Immunoglobulin (Ig) paraproteins produced by plasma cell dyscrasias can increase viscosity, and promote red blood cell agglutination.
Venous thrombosis typically develops under conditions of slow blood flow (low shear stress) and is augmented by further retardation and stagnation of flow caused by the developing thrombus itself. Right-sided heart failure, pre-existent venous thrombosis, extrinsic vascular compression by tumor, and chronic venous insufficiency all promote venous stasis, blood pooling, and a concentration of procoagulant factors. The anatomic structure of venous valves results in retrograde eddy currents, which produce pockets of stasis even in normal veins. The venous arcades in the soleus muscles of the calves may represent another site of physiologic venous stasis. These structures may enlarge and lose vascular tone with aging. These facts may partially explain why DVT most commonly occurs in the valve cusps and veins of the pelvis and lower extremities, and why older age is an important risk factor for venous thrombosis.

Venous thrombi are composed of large amounts of fibrin containing numerous erythrocytes. In these loose, friable masses (the red thrombus), the platelets and leukocytes are enmeshed in random fashion. Venous thrombi resemble blood clots formed in vitro, and they usually produce significant obstruction to blood flow from the outset, but their most serious consequence is embolization. Blood flow obstruction secondary to venous thrombosis itself promotes the further formation of thrombus. Results of studies of clots formed in a thromboviscometer at varying rates of shear suggest that the differences in the structure of venous and arterial thrombi may be mainly the result of the velocity of blood flow. The many and complicated rheologic factors that may be involved in thrombosis have been reviewed. Although traditional teaching holds that risk factors for arterial and venous thrombotic disease are distinct, new epidemiologic data suggest that common risk factors exist for both disorders, and that appropriate management of thrombosis patients should address secondary prevention of both arterial and venous thrombosis.

Vascular Injury

Permanent and transient vascular injuries play major roles in the development of arterial thrombosis. Intraluminal vascular endothelial cell injury, atherosclerotic plaque rupture, hyperhomocysteinemia, arterial outflow obstruction, aneurysm formation, and vessel dissection are among the recognized risk factors for arterial thrombosis. Arterial thrombosis usually begins with platelet adhesion to an abnormal vascular endothelial surface or exposed subendothelial constituent such as collagen. The adherent platelets become activated, leading to the release of α- and dense granule contents. Platelet-dense granules (dense bodies) release adenosine diphosphate (ADP), adenosine triphosphate (ATP), calcium, and serotonin into the surrounding milieu, resulting in the recruitment and activation of additional platelets. This release reaction and platelet synthesis of thromboxane A2 (TxA2) and other agonists induce the aggregation of more platelets and enlargement of the temporary platelet plug. In addition to the recruitment of additional platelets, the original nidus of adherent platelets provides a phospholipid surface rich in phosphatidylerine to support and concentrate the generation of thrombin and fibrin necessary to reinforce and stabilize the platelet plug.

New insights into arterial thrombus formation have been gleaned from experiments using confocal and wide-field microscopy to image real-time thrombus formation in live-mouse cremaster muscle arterioles. Thrombosis is precipitated by laser-induced endothelial injury. These experiments demonstrated that the initiation of blood coagulation in vivo involves the initial accumulation of tissue factor (TF) on the upstream and thrombus-vessel wall interface of the developing thrombus. The TF is biologically active and is associated with intrathrombus fibrin generation. TF density is highest at the thrombus-vessel wall interface and is eventually observed throughout the thrombus. Leukocyte rolling is noted approximately 2 minutes after endothelial cell injury and correlates with P-selectin expression on the outer aspect of the thrombus. Minimal TF and fibrin are detected in platelet thrombi formed in mice lacking P-selectin or the P-selectin glycoprotein ligand, PSGL-1.

In venous thrombosis, the luminal surface of the vessel wall is usually histologically normal, and factors extrinsic to the vessel appear to have a major pathophysiologic role. Exceptions to this generalization are direct venous trauma, extrinsic venous compression, and vascular endothelial cell injury resulting from the toxic effect of cancer chemotherapy and excess levels of homocysteine. A limited quantity of activated platelets likely serves as a phospholipid surface to support local thrombin and fibrin formation. A generalized reduction in venous tone may be an important pathophysiologic factor in venous thrombosis in pregnant women and in women taking oral contraceptives. VWF-mediated platelet adhesion was shown to be essential for venous thrombosis in an animal model. Additional mechanisms may contribute to a prothrombotic state, including up-regulation of stress-response genes, endothelial cell activation, formation of neutrophil extracellular traps, and activation of the intrinsic coagulation pathway.

2811
Studies indicate that human platelets express TF pre-mRNA, and when activated, splice this message into mature mRNA which is expressed. These results suggest that both platelets and the vessel wall may contribute to initiation of thrombosis.

Abnormalities of the Blood: Hypercoagulability

The term hypercoagulable state and its synonym thrombophilia refer to any inherited or acquired abnormality of the hemostatic system that places an individual at increased risk for venous or arterial thrombosis (or both). Blood from patients with active thrombosis or with a hypercoagulable state may clot at an abnormally rapid rate in vitro. The concept of hypercoagulability has gained widespread acceptance, and it is generally appreciated that these hemostatic changes are important in the pathogenesis of thrombosis; however, whether testing for these disorders may be helpful in patient management is uncertain.

Platelet Abnormalities

Although platelets may be incorporated into virtually any thrombus, they appear to be pathogenetically most important in arterial thrombosis. Increased platelet turnover (shortened platelet survival, compensated platelet destruction) occurs in vascular disease and thrombosis, including arterial and venous thrombosis, coronary artery disease, vasculitis, hyperhomocysteinemia, and valvular heart disease. Increased platelet turnover can also be seen in patients with risk factors for vascular disease, including those who use tobacco and those with hyperlipidemia. Increased platelet turnover and activation can reflect thromboembolic disease and also probably contribute to an exacerbation of thrombotic events.

As a consequence of platelet-vessel wall interactions in patients with vascular disease, platelet adhesion, activation, and aggregation occur, resulting in acquired storage pool disease and the presence in the blood of platelet-granule-derived proteins such as platelet factor-4 (PF4) and β-thromboglobulin. Although elevated blood levels of these proteins indicate increased platelet turnover, improper blood collection technique may artifactually result in abnormal levels, and the clinical value of such testing is uncertain.

Vascular endothelium possesses multiple antiplatelet properties that may be important in preventing platelet adhesion, promoting vasodilation, and inhibiting platelet aggregation. However, interruption of endothelial cell prostacyclin synthesis by aspirin does not result in a net thrombotic tendency. The potential role of hyperactive platelets in patients with thrombosis, as well as the use of platelet function testing in this setting, is somewhat controversial.

Because of the importance of vWF in mediating platelet adhesion to subendothelium, the role of vWF in human vascular disease has been a topic of investigation. An association between elevated plasma vWF levels and recurrent MI has been demonstrated, and vWF antigen is an independent predictor of coronary artery disease.

Platelet polymorphisms have been evaluated as risk factors for arterial thrombosis. These include polymorphisms for glycoprotein (gp) Ila (PIA2), gpIb (807 T allele), and gpIbα. The PIA2 polymorphism is linked with coronary artery disease; PIA2-positive platelets exhibit a lower threshold for activation and also have variable aspirin sensitivity.

Coagulation Abnormalities

Coagulation disorders that can contribute to hypercoagulability can be divided into three risk-factor categories: Transient, inherited, and acquired. Transient risk factors represent well-defined, temporary clinical circumstances that are associated with increased thrombosis risk both while they are present and for a short period after they have resolved. Examples include surgery, prolonged immobilization, oral contraceptive pill (OCP) use, hormone replacement therapy (HRT), pregnancy, cancer chemotherapy, and heparin-induced thrombocytopenia (HIT). Inherited risk factors represent genetic mutations and polymorphisms that result in deficiency of a natural anticoagulant (e.g., protein C, protein S, or AT), procoagulant factor accumulation (e.g., prothrombin G20210A), or coagulation factor resistance to inactivation by a natural anticoagulant (i.e., factor V G1691A, also known as factor V Leiden). These conditions are characterized by a disruption in the normally highly regulated coagulation mechanism, resulting in greater thrombin generation and an increased risk of clinical thrombosis. Acquired risk factors result either from medical conditions or from nonfamilial hematologic abnormalities that interfere with normal hemostasis or blood rheology. Examples include cancer, inflammatory bowel disease, nephrotic syndrome, vasculitis, antiphospholipid antibodies, myeloproliferative syndromes, paroxysmal nocturnal hemoglobinuria, and hyperviscosity syndromes. These acquired risk factors are distinct from
transient risk factors by the fact that they represent alterations in hemostatic homeostasis as a result of disease or, for the most part, nonreversible processes. In contrast, transient risk factors result from either a therapeutic intervention or an adverse reaction to such an intervention. Hyperhomocysteinemia and increased factor VIII functional activity are examples of thrombosis risk factors that can be acquired in nature or have a genetic predisposition.\textsuperscript{41, 42} Age defies categorization but remains the single most predictable risk factor for thrombosis. The estimated baseline annual age-associated risk of VTE is 1 in 10,000 people <40 years of age, increasing to 1 in 100 people >75 years of age.\textsuperscript{43, 44, 45}

Recent reports have focused on elevated levels of various coagulation factors, particularly fibrinogen and factors V, VII, VIII, X, and XI, that have been documented in patients with thrombosis and prethrombotic disorders, including pregnancy and use of estrogen-containing contraceptives.\textsuperscript{46} Fibrinogen and factors V and VIII are acute-phase reactants, and their plasma levels may rise in patients with virtually any disorder associated with tissue damage or inflammation, including most thrombotic processes. Whether increased because of a genetic factor or an acute-phase reaction, excess procoagulant factor concentrations may tilt the hemostatic scales in favor of hypercoagulability and may be associated with an increased risk of thrombosis. Epidemiologic studies have identified dose-dependent elevations in plasma levels of vWF, fibrinogen, factor VII, factor IX, and factor XI as independent risk factors for cardiovascular disease.\textsuperscript{47, 48, 49, 50}

Fibrinolytic Abnormalities

Abnormal fibrinolysis has also been linked to vascular disease. Low fibrinolytic activity (measured by dilute clot lysis) was a significant determinant of coronary artery disease in the Northwick Park Heart Study, and elevated PAI-1 activity was associated with major ischemic events in other studies.\textsuperscript{51, 52} In the European Concerted Action on Thrombosis and Disabilities study, an increased incidence of vascular events was associated with higher baseline PAI-1 antigen concentrations (p = .02) and PAI-1 activity (p = .001).\textsuperscript{53} Defects in endogenous fibrinolytic capacity have also been found in young patients with severe limb ischemia or unexplained arterial thromboembolism. Deficient t-PA release was found in 45% of such patients, and elevated levels of PAI-1 were found in 59%.\textsuperscript{54} Excess PAI-1 resulting in impaired endogenous fibrinolysis has also been associated with venous thrombosis in select cases.\textsuperscript{55}

ACTIVATION OF COAGULATION

Mechanisms leading to activation of coagulation in patients with thrombosis have been proposed. TF is thought to be the primary initiator of in vivo coagulation.\textsuperscript{56, 57} In the absence of TF expression, endothelial cells actively maintain thromboresistance. TF may be expressed in trace amounts during various physiologic processes, such as during normal parturition and after even minimal trauma, including minor head injuries. Immunologic injury of endothelium may lead to the exposure of TF.\textsuperscript{58} Antibodies formed to exogenous heparin may bind to heparan sulfate on the endothelium, resulting in cell injury, the expression of TF, and the initiation of coagulation.\textsuperscript{59} In a similar manner, endothelial cells may be induced to express TF by interleukin-1, homocysteine, tumor necrosis factor, and endotoxin.\textsuperscript{60, 61, 62, 63} TF antigen expression by endothelium has been demonstrated in pathologic primate and human tissues.\textsuperscript{64, 65, 66, 67} Activation of coagulation may also occur on monocytes, and platelets can be activated to mediate factor-Xa-catalyzed prothrombin conversion to thrombin.\textsuperscript{67, 68} Deficient hepatic clearance of activated coagulation factors may represent an important thrombogenic factor in premature infants and in patients with liver disease, especially after administration of prothrombin complex concentrates that contain trace amounts of activated vitamin-K-dependent coagulation factors.

Various other mechanisms may be responsible for low-grade in vivo coagulation under certain conditions. Certain tumor cells can promote thrombin generation directly, by producing TF, expressing the coagulation factor X activator known as cancer procoagulant, or displaying surface sialic acid residues that can support nonenzymatic factor X activation.\textsuperscript{69, 70} Tumor cells can also promote thrombin generation indirectly, by eliciting TF expression by monocytes and endothelial cells. Tumor-associated coagulation cascade activation can result in the generation of thrombin that can promote angiogenesis by signaling through protease-activated receptors PAR-1, PAR-3, and PAR-4. In addition to its normal role in coagulation, evidence is mounting that TF plays a direct role in growth, invasion, dissemination, and angiogenesis of tumors.\textsuperscript{71, 72} Clotting-independent signaling through the TF cytoplasmic tail can lead to vascular endothelial growth factor (VEGF) up-regulation. Because VEGF can promote TF up-regulation, the potential for a self-perpetuating proangiogenic amplification loop exists. The TF:factor VIIa complex can also activate PAR-2 directly in a manner that results in gene expression related to angiogenesis and cell migration.\textsuperscript{72} Selected tumors may mediate an accentuation of platelet activation and accumulation, whereas other tumor cells may express surface phospholipid species such as phosphatidylserine, which can support prothrombin and factor X activation.\textsuperscript{73}

A laboratory picture similar to that described in the hypercoagulable state may also be seen in patients with nonovert (compensated or chronic) disseminated intravascular coagulation (DIC).\textsuperscript{74} In such patients, the prothrombin time (PT) and the activated partial thromboplastin time (aPTT) may be shortened because of the presence of traces of thrombin or other
activated coagulation factors. These activated factors affect one-stage, but not two-stage, clot endpoint coagulation assays. High levels of factor V and factor VIII activity may reflect the presence of thrombin-activated forms of these factors in the circulation. Pregnancy, which can be regarded as a hypercoagulable state, has also been described as a physiologic form of nonovert DIC by some clinicians. Pregnancy increases the risk of venous thromboembolism (VTE) approximately fivefold among the general population, and female patients who have experienced prior venous thrombosis have a threefold risk of venous thrombosis during pregnancy. The use of estrogen-containing oral contraceptives and estrogen HRT is clearly associated with an increased risk of VTE. A prospective study of these patients indicates that estrogens induce activation of coagulation as well as reduction in levels of natural anticoagulants such as AT and protein S. However, many patients who experience VTE while taking oral contraceptives have a common inherited thrombotic disorder, APC resistance (APC-R), or prothrombin G20210A. Another report indicated that oral contraceptives induced “acquired APC-R” in women. The relative risk of VTE in postmenopausal women using estrogen replacement is 2.14, and the risk is highest during the first year of use. The thrombotic risk imparted by pharmacologic estrogens appears to dissipate following medication discontinuation. One study found that transdermal estrogen products were safer than oral estrogens in women receiving HRT. One literature review of hormonal therapy and venous thrombosis concluded that all oral estrogen-containing products used for contraception or HRT, as well as therapeutic doses of progesterone-only products increased thrombosis risk. The risk of venous thrombosis is not clearly increased for the levonorgestrel-containing intrauterine device, transdermal estrogen, and tibolone. Regarding the risk of thrombotic stroke and MI, a very large Danish study found that use of ethinyl estradiol increased risk by 0.9 to 2.3, depending on drug concentration in the contraceptive pill. Table 55.1 summarizes acquired etiologies that predispose to thrombosis.

INHERITED THROMBOTIC DISORDERS

Several monographs and reviews have covered the topic of inherited thrombotic disorders in detail. Table 55.2 summarizes the prevalence of selected inherited and acquired hypercoagulable states in different populations, whereas Table 55.3 summarizes the clinical presentations of venous thrombosis that may be suggestive of particular hypercoagulable states. Many patients who experience thrombosis are found to have a combination of defects, for example, APC-R plus use of oral contraceptive agents, or a combination of inherited defects. Although people with inherited hypercoagulable states are at a greater risk for developing a thrombotic event than those without such disorders, not all people with a well-defined hypercoagulable state develop an overt thrombosis, and not all people with thrombosis have an identifiable hypercoagulable state. Testing for an inherited hypercoagulable state is likely to uncover an abnormality in >60% of patients presenting with idiopathic (i.e., spontaneous or unprovoked) venous thrombosis. Although the remaining 30% to 40% have unremarkable test results, this does not imply a true absence of a hypercoagulable state. Some of these individuals may have an acquired condition such as cancer or antiphospholipid antibodies, whereas others may have a disorder or genetic defect that has not yet been discovered or characterized.

TABLE 55.1 ACQUIRED DISORDERS PREDISPOSING TO THROMBOSIS

**Vascular disorders**

- Atherosclerosis
- Diabetes
- Vasculitis
- Prosthetic materials (grafts, valves, indwelling vascular catheters)

**Abnormal rheology**

- Stasis (immobilization, surgery, congestive heart failure)
- Hyperviscosity (polycythemia vera, Waldenström macroglobulinemia, acute leukemia, sickle cell disease)
Other disorders associated with hypercoagulability

Cancer (Trousseau syndrome)
Cancer chemotherapeutic agents, thalidomide, bevacizumab
Oral contraceptives, estrogen therapy, selective estrogen-receptor modulators
Pregnancy
Infusion of prothrombin complex concentrates and recombinant factor VIIa
Nephrotic syndrome
Myeloproliferative disorders
Paroxysmal nocturnal hemoglobinuria
Inflammatory bowel disease
Thrombotic thrombocytopenic purpura
Disseminated intravascular coagulation
Antiphospholipid antibody syndrome
Heparin-induced thrombocytopenia/thrombosis
Human immunodeficiency virus infection

thrombocytemia, antiphospholipid antibodies, antithrombin deficiency, PT G20210A mutation

Intra-abdominal vein thrombosis (inferior vena cava, renal vein, portal vein, mesenteric and hepatic veins)

Antiphospholipid antibodies, paroxysmal nocturnal hemoglobinuria, myeloproliferative syndromes, cancer, antithrombin deficiency

Warfarin skin necrosis

Protein C, protein S deficiencies

Unexplained recurrent fetal loss

Antiphospholipid antibodies; factor V Leiden

Recurrent superficial thrombophlebitis

Factor V Leiden, polycythemia vera, protein C, protein S, or antithrombin deficiency

Migratory superficial thrombophlebitis (Trousseau syndrome)

Adenocarcinoma (particularly of the gastrointestinal tract)

Neonatal purpura fulminans

Homozygous protein C or protein S deficiency

PT, prothrombin.

**Antithrombin Deficiency**

AT, formally known as AT-III, deficiency was first described by Egeberg in 1965. AT, a serine protease inhibitor, regulates coagulation by inactivating thrombin and other procoagulant enzymes, including factors Xa, IXa, Xla, and XIIa. As are most inherited thrombotic disorders, AT deficiency is inherited as an autosomal dominant disorder. A blood bank survey reported that 1 in 600 people has AT deficiency. The interactions of unfractionated and low-molecular-weight heparin (LMWH) with AT are discussed in the section “Heparin.”

**Pathophysiology and Genetics**

Patients with AT deficiency may have either type I (quantitative deficiency) or type II (qualitative abnormality) disease. Type I AT-deficient patients usually have concordant reductions in AT measured by both immunologic and functional assays. Type II patients have reduced functional AT activity associated with normal amounts of AT protein. Plasma concentrations of the thrombin activation peptide, prothrombin fragment 1+2, are elevated in patients with AT deficiency, indicating persistent activation of coagulation as a result of deficient neutralization of factor Xa in these patients.

The genetic basis for type I AT deficiency is either deletion of a gene segment or the occurrence of point mutations or deletions, resulting in a nonsense mutation and an incomplete protein. The genetic basis for type II AT deficiency is the occurrence of point mutations that do not impair synthesis of the protein, but that result in a dysfunctional protease inhibitor. A summary of AT mutations (>100) has been reported. A database of AT mutations is located at: http://www1.imperial.ac.uk/departmentofmedicine/divisions/experimentalmedicine/haematology/coag/AT/. In general, mutant AT molecules exhibit deficient heparin binding, deficient protease inhibition, or both.

**Clinical Aspects**

AT deficiency is manifested primarily by recurrent VTE. Almost every vein site has been reported to be involved with thrombosis in AT-deficient patients, including unusual sites such as mesenteric vessels. Thrombosis may occur in the absence of precipitating factors or may result from events such as pregnancy, estrogen use, trauma, or surgery. AT deficiency can result in heparin resistance manifesting as a normal to minimally increased aPTT in patients receiving large doses of heparin. However, most patients with AT deficiency do not exhibit heparin resistance, and most cases of heparin resistance are not due to AT deficiency. In family studies, venous thrombosis occurred in 85% of AT-deficient relatives before 55 years of age. The estimated increased lifetime relative risk of venous thrombosis has been reported to be up to 40-fold. An annual absolute risk of venous thrombosis of 27.5% has been reported in female carriers of AT deficiency who also use OCPs. Early studies reported pregnancy-related venous thrombosis rates as high as 70% for AT-deficient women. Most AT-deficient patients are heterozygotes and possess ~50% of normal activity levels. Although homozygotes have been reported in consanguineous kindreds, in general, homozygous type I AT deficiency is believed to be fatal in utero.

**Laboratory Diagnosis**

Results of the PT and aPTT are normal in AT-deficient patients. A variety of commercial assays is available to measure AT levels, including functional and immunologic assays. Functional assays are preferable because they detect both type I and
type II patients. One report found that 2% of patients with AT deficiency had type II disease. Functional assays for AT measure heparin cofactor activity using a chromogenic substrate method to quantitate thrombin or factor Xa neutralization. A potential disadvantage of functional AT assays is that plasma AT levels may be overestimated because of the presence of heparin cofactor II (HCII) in the sample. The use of bovine thrombin and a low heparin concentration (3 U/ml) in the assay system can minimize this problem.

Immunologic assays for AT use Laurell rocket immunoelectrophoresis, microlatex-particle immunoassay, radial immunodiffusion, or enzyme-linked immunosorbent assay (ELISA) methods. Ideally, patients should be evaluated for AT deficiency at a time when they are not receiving therapeutic heparin or oral anticoagulants, because heparin depresses AT levels, whereas long-term warfarin therapy increases plasma AT levels in some patients. Laboratory tests for AT deficiency have been summarized.

Treatment

Some AT-deficient patients may experience heparin resistance, requiring the administration of AT by using virally inactivated, plasma-derived, or transgenic AT concentrates, or fresh-frozen plasma. Supplemental AT may make it easier to achieve therapeutic anticoagulation with heparin in these patients. Patients with recurrent thrombosis should receive long-term warfarin therapy at a dosage to maintain an international normalized ratio (INR) value of 2.0 to 3.0 (discussed in the section "Warfarin"). Patients with a single thrombotic event should receive at least 3 to 6 months of warfarin therapy and, because of an increased recurrence rate, should be considered for long-term therapy beyond 6 months. Patients with massive venous thrombosis or PE may be candidates for thrombolytic therapy. AT-deficient patients who become pregnant or who will undergo general surgery should be considered for anticoagulant prophylaxis, including AT concentrate administration. Most asymptomatic patients should not be treated. The avoidance of estrogens should be considered in AT-deficient patients, who are not therapeutically anticoagulated.

Acquired Antithrombin Deficiency

AT deficiency is also associated with numerous disorders, including DIC, liver disease, nephrotic syndrome, and preeclampsia, and is seen in patients taking oral contraceptive agents and during pregnancy. Although logic suggests that correction of AT deficiency might be clinically useful in disorders such as DIC or liver disease, there are no conclusive data supporting AT replacement therapy outside the setting of prophylaxis of high-risk patients, such as pregnant, AT-deficient patients.

Heparin Cofactor II Deficiency

HCII is another heparin-dependent thrombin inhibitor, differing from AT in that a glycosaminoglycan other than heparin, dermatan sulfate, catalyzes this inhibitor of coagulation. HCII deficiency is inherited as an autosomal dominant trait. Although there have been anecdotal studies of thrombosis associated with HCII-deficient kindreds, a larger study has concluded that HCII deficiency by itself may not be an inherited risk factor for thrombosis. Commercial assays to measure HCII levels are available, but the clinical utility of such assays in routine evaluation of patients for inherited thrombosis is uncertain.

Protein C Deficiency

Protein C is a vitamin-K-dependent plasma protein that, when activated by the thrombin-thrombomodulin complex to APC, inactivates factors Va and VIIIa to inhibit coagulation. APC also possesses profibrinolytic activity that results from neutralization of PAI-3 activity. Inherited deficiency of protein C and its association with thrombosis were first described by Griffin and coworkers in 1981. Protein C deficiency was believed to be inherited in an autosomal dominant pattern with incomplete penetrance. More recent studies have suggested that protein C deficiency may be an autosomal recessive disorder and that coinheritance of another defect (particularly factor V Leiden) results in a high degree of penetrance that appears as the dominant inheritance in double-heterozygous carriers.

Pathophysiology and Genetics

As with AT deficiency, patients with protein C deficiency may have type I (quantitative deficiency) or type II (qualitative abnormality) disease. Most patients are heterozygotes with ~50% of normal protein C levels. A hypercoagulable state can be demonstrated in nonanticoagulated protein-C-deficient patients using activation peptide (fragment 1+2) assays.
In type I protein C deficiency, more than half of the gene mutations identified are missense mutations. Point mutations affecting protein function appear to be common in patients with type II protein C deficiency. At least 195 different gene abnormalities have been associated with both types of protein C deficiency.127 Despite the clear association of protein C deficiency with thrombosis in large epidemiologic studies, there are also definitive data indicating that many protein-C-deficient patients are asymptomatic.128 For example, one report found that heterozygous protein C deficiency occurred in approximately 1:250 subjects, whereas a large Scottish study estimated the prevalence to be approximately 1:500.124,129 No patient in either study had a history of symptomatic venous thrombosis. These findings indicate that additional risk factors—acquired, genetic, or both—are necessary to provoke thrombosis in heterozygous protein-C-deficient patients. Indeed, in one study, up to 20% of symptomatic protein-C-deficient patients also had APC-R, supporting the concept that many patients with recurrent thrombosis have more than one risk factor.125

Clinical Aspects

Three clinical syndromes are associated with protein C deficiency: VTE in heterozygous adults, neonatal purpura fulminans in homozygous newborns, and warfarin-induced skin necrosis in certain heterozygous adults. The predominant clinical symptom of protein-C-deficient patients is recurrent VTE, although arterial thrombotic events, including stroke, have been reported.130,131 As mentioned above, many patients are found to have risk factors other than inherited protein C deficiency on investigation, such as APC-R, use of oral contraceptive agents, and pregnancy. Protein C deficiency has also been linked to fetal loss.132

Neonatal purpura fulminans is seen in homozygous newborns of heterozygous parents. These children develop DIC at birth, associated with extensive venous or arterial thrombosis (or both) and very low levels of protein C (<5% of normal).133 Warfarin-induced skin necrosis is an unusual syndrome seen in certain patients with heterozygote protein C deficiency.134 Most patients who develop this syndrome have received large doses of warfarin in the absence of concomitant overlapping therapeutic parenteral anticoagulation. The basis for this syndrome is that warfarin therapy, especially in large loading doses, reduces protein C levels more rapidly than the vitamin-K-dependent procoagulant factors, leading to exacerbation of the basal hypercoagulable state and thrombosis.

In family studies, venous thrombosis occurred in 50% of protein-C-deficient relatives of affected probands before 40 years of age.135 The estimated increased lifetime relative risk of venous thrombosis has been reported to be up to 31-fold.136 As stated above, other studies did not detect an increased thrombosis risk in carriers of protein C deficiency. Differences in risk between family- and population-based studies can be in part explained by greater difficulty in obtaining reliable population-based estimates because of the overall low prevalence of this and other natural anticoagulant deficiencies. In studies of unselected patients with venous thrombosis, the odds ratio (OR) of having protein C deficiency is increased six- to ninefold compared to controls.40,135,136,137 An annual absolute risk of venous thrombosis of 4.3% has been reported in women carriers of a natural anticoagulant deficiency such as protein C deficiency who also use OCPs.138

Laboratory Diagnosis

Patients with heterozygous protein C deficiency have normal PT and aPTT values, whereas patients with homozygous protein C deficiency have abnormal coagulation tests consistent with DIC. Because both type I and type II disorders may occur, functional assays are suggested to optimize identification of affected patients. Some investigators prefer the clot endpoint-based assay, because it measures complete function of the protein C molecule, including those patients with abnormal protein C molecules that possess normal activity by a chromogenic substrate assay. However, therapeutic heparin levels affect the clot-based assay. A College of American Pathologists’ consensus conference on thrombophilia recommends use of the chromogenic substrate assay.139 One report indicated that measurement of the ratio of protein C to protein S antigen was useful in identifying carriers of protein C deficiency.140

Protein C levels can also be measured by immunologic methods, including Laurell rocket immunoelectrophoresis and ELISA. However, immunologic assays may not detect type II patients and may overestimate protein C levels in warfarin-treated patients. Immunologic assays may be more useful in evaluating patients with homozygous deficiency and DIC.

Age-related changes occur with protein C levels.141 Consequently, it is important to consider this when testing younger patients (<30 years); otherwise, normal subjects may be misclassified as protein C deficient.

A common problem faced by laboratories is measuring protein C levels in patients taking oral anticoagulants. Many clinicians forget that protein C is a vitamin-K-dependent molecule, and that otherwise hemostatically normal people taking warfarin may have low protein C levels.142 Griffin and coworkers suggested that protein C data be normalized against the level of another vitamin-K-dependent protein to distinguish inherited protein-C-deficient patients from normal subjects taking warfarin.123 One author reported that using a ratio between protein C and prothrombin optimally categorized patients.142 However, for this method to be useful, patients must be stably anticoagulated for at least 2...
weeks, and the laboratory must obtain plasma samples and reference ranges from patients taking warfarin for reasons other than recurrent thrombosis. The consensus conference did not recommend assaying protein C levels in patients on oral anticoagulants. Laboratory tests for protein C deficiency have been reviewed.

Treatment

Many patients with protein C deficiency are asymptomatic, especially those identified in screening studies. Asymptomatic patients should not be treated but should be considered for prophylaxis when they experience high-risk procedures, such as surgery. Symptomatic protein-C-deficient patients should be anticoagulated with heparin and then considered for long-term secondary prophylaxis with warfarin at an INR of 2.0 to 3.0. Those patients with a single thrombotic event should receive at least 3 to 6 months of warfarin. Patients with more than one thrombotic event, patients with a single life-threatening thromboembolic event, and those with a significant family history of thrombosis should be considered for long-term anticoagulation. Patients with massive thrombosis or PE may be candidates for thrombolytic therapy.

Infants with neonatal purpura fulminans should be treated with protein C replacement therapy. Protocols using a purified protein C concentrate or prothrombin complex concentrates have been described. Use of the purified concentrate normalizes activation of coagulation in these homozygous patients.

Acquired Protein C Deficiency

Because protein C is a vitamin-K-dependent protein, any disorder associated with vitamin K deficiency may result in protein C deficiency, including warfarin use, liver disease, and malnutrition. Protein C levels are also reduced in DIC, presumably reflecting thrombin activation of the zymogen and consumption of APC. Protein C levels may also be reduced in renal disease, especially the nephrotic syndrome.

Protein S Deficiency

Protein S is a vitamin-K-dependent plasma protein that facilitates the anticoagulant activity of APC. Protein S deficiency in association with inherited thrombotic disease was first described by two groups in 1984. As with AT and protein C deficiencies, protein S deficiency is inherited as an autosomal dominant trait. Many patients with a previous diagnosis of protein S deficiency actually have APC-R. This diagnostic error results from interference in the functional protein S assay of patients with the inherited disorder, APC-R, and misclassification of patients. These patients have a “pseudo” protein S deficiency, often display a type II deficiency pattern, and have protein S activity levels that correlate with the APC ratio. Based on these reports and the high incidence of APC-R in the general population, the true importance of protein S deficiency in inherited thrombosis is uncertain.

Pathophysiology and Genetics

As described for AT and protein C deficiencies, patients with protein S deficiency may have quantitative or qualitative disorders. Under normal circumstances, protein S exists in plasma in two forms: Bound to C4b-binding protein (60% of total protein S) and free (40% of total). Because only free protein S has APC co-factor activity, a revised classification system has been proposed for protein S deficiency. Type I protein S deficiency is a quantitative disorder in which protein S functional activity, total antigen, and free antigen levels are equally reduced to ~50% of normal. Type IIa protein S deficiency is a deficiency of free protein S with preserved normal levels of total protein S. In type IIb protein S deficiency, the levels of both total and free protein S antigen are normal. Apparent type IIb protein S deficiency has been described in patients with APC-R. An acquired type IIa protein S deficiency may result from excess levels of C4b-binding protein or the presence of free protein S inhibitory and clearing autoantibodies. Almost 200 different mutations have been identified in the gene that codes for protein S. A full listing of protein S gene mutations and polymorphisms can be found at www.ISTH.org.

As with protein C deficiency, many patients with protein S deficiency and thrombosis have additional risk factors. In one study, among patients with protein S deficiency, ~40% also had APC-R; of family members with thrombosis, 72% had both defects, whereas <20% of patients with single defects experienced thrombosis.

Clinical Aspects

Like AT and protein-C-deficient patients, most patients with protein S deficiency and thrombosis have experienced VTE. However, unlike most other inherited thrombotic disorders, up to 25% of patients with protein S deficiency may experience arterial thrombosis, including stroke. As mentioned previously, many patients with protein S deficiency...
and thrombosis have other risk factors, including APC-R, estrogen use, or pregnancy. Neonatal purpura fulminans, fetal loss, and warfarin-induced skin necrosis have also been associated with protein S deficiency. In family studies, venous thrombosis occurred in 100% of protein-S-deficient relatives of affected probands by 70 years of age. The estimated lifetime increased relative risk of thrombosis has been reported to be as high as 36-fold for protein S deficiency.

Laboratory Diagnosis

Patients with heterozygous protein S deficiency have normal PT and aPTT values. The laboratory diagnosis of protein S deficiency is complicated by four factors: The levels of C4b-binding protein, the coexistence of APC-R in certain patients, elevated factor VIII activity levels, and warfarin therapy. C4b-binding protein is an acute-phase-reactant protein-S-binding protein, often elevated in thromboembolism, resulting in reduced free protein S levels from the patient’s true baseline. Consequently, measurement of protein S levels in patients with acute thrombosis may yield misleading results. Similarly, false-positive results may be seen when functional protein S assays are performed on patients who have APC-R or factor VIII activity levels ≥250%. Patients should not be assumed to have protein S deficiency (diagnosed by functional assay) until APC-R has been excluded. Lastly, because protein S is a vitamin-K-dependent protein, warfarin therapy and vitamin K deficiency pose the same difficulty as described for patients evaluated for protein C deficiency. Protein S levels may also be decreased in the setting of pregnancy but are not necessarily associated with thrombotic events.

Both functional and immunologic assays are commercially available to quantitate plasma protein S levels. Functional assays may be PT- or aPTT-based, measuring inhibition of factor Va by APC. These assays have the advantage of measuring free protein S activity. Immunologic assays to measure either total (free plus C4b-binding-protein bound) or free protein S levels are available.

Immunologic assays may be useful in evaluating patients who have co-existing APC-R. Total protein S levels are measured by Laurell rocket immunoelectrophoresis or ELISA. In the interpretation of immunologic assays, one should consider the report that the mean plasma level of protein S antigen in males is higher than it is in females.

Treatment

Asymptomatic patients should not be treated but should be considered for prophylaxis when they experience high-risk procedures such as surgery. Symptomatic protein-S-deficient patients should be anticoagulated as described for protein-C-deficient patients.

Protein Z Deficiency

Protein Z is a vitamin-K-dependent plasma protein that serves as a co-factor for activated factor X inhibition by the protein-Z-dependent protease inhibitor. Reduced circulating levels of protein Z have been implicated in thrombosis. Protein Z deficiency has also been linked to early and late fetal demise and intrauterine growth restriction. Protein Z deficiency has also been found in the setting of acute coronary syndromes, whereas a deficiency state and the presence of a series of protein Z variants that modulate protein Z plasma levels have been associated with stroke. Further data are required before routine protein Z testing can be recommended.

Activated Protein C Resistance (Factor V Leiden)

Before 1993, most patients with idiopathic venous thrombosis evaluated for inherited thrombosis were not given a diagnosis.
inactivation of factor Va, APC cleavage at this site is necessary for subsequent proteolytic events. This “partial resistance” is explained by the fact that cleavage of factor Va by APC at Arg306 continues to occur, albeit at a slower rate. In fact, factor Va Arg506Gln (factor V Leiden) is inactivated 10 times more slowly than normal factor Va. This provides a pathophysiologic explanation for why factor V Leiden, although common, is a relatively weak risk factor for VTE. Because factor Va functions as a cofactor in the conversion of prothrombin to thrombin, the mutation results in greater amounts of factor Va being available for coagulation reactions, “shifting” the hemostatic balance toward greater thrombin generation.

APC-R due to factor V Leiden is the most common inherited predisposition to hypercoagulability in Caucasian populations of northern European background. Factor V Leiden follows a geographic and an ethnic distribution: The mutation occurs most frequently in northern and western Europe (the highest prevalences, 10% to 15%, have been reported in Cyprus, Sweden, and Turkey) but is rare in the Asian and African continents as well as in ethnic groups of Asian descent, such as Inuit Eskimos, Amerindians, Australian Aborigines, and Polynesians. In the United States, factor V Leiden is most commonly seen in Caucasians (6.0%), with lower prevalences in Hispanics (2.2%), African and Native Americans (1.2%), and Asian Americans (0.45%).

Factor V Leiden accounts for 92% of cases of APC-R, with the remaining 8% of cases resulting from pregnancy, oral contraceptive use, cancer, selected antiphospholipid antibodies, plasma glucosylceramide deficiency, and other factor V point mutations. Therefore, the terms factor V Leiden and APC-R should not be considered synonymous; in fact, APC-R is an independent risk factor for VTE even in the absence of factor V Leiden. It is estimated that the mutation arose in a single Caucasian ancestor some 21,000 to 34,000 years ago, well after the evolutionary separation of non-Africans from Africans (~100,000 years ago) and of Caucasoid (white Caucasians) from Mongoloid (Asians) subpopulations (~60,000 years ago).

Clinical Aspects

Heterozygous carriers of factor V Leiden have a 2- to 10-fold increased lifetime relative risk of developing VTE. This risk is further increased in combination with pregnancy (9-fold), OCP use (36-fold), and HRT (13- to 16-fold). VTE is the most common clinical symptom of APC-R in patients who experience thrombosis. In general, there is a notable lack of association of APC-R with arterial thrombosis (exceptions discussed below). Another clinical association with APC-R is recurrent miscarriage, with one study reporting that 20% of patients with second-trimester pregnancy loss have APC-R. Factor V Leiden does not appear to be a cause of recurrent pregnancy loss occurring late in the first trimester. Neonatal purpura fulminans has been reported in a patient with factor V Leiden who did not have protein C or S deficiency. APC-R is also a common inherited risk factor for cerebral venous thrombosis.

The factor V Leiden mutation has also been identified in children who experience thrombosis. However, this mutation does not appear to play a major role in the hypercoagulability of cancer. An intriguing report has demonstrated that the factor V Leiden mutation is a risk factor for MI in young women; the combination of factor V Leiden with smoking increased the risk of MI more than 30-fold. Factor V Leiden has also been associated with MI in individuals with coronary artery thrombosis in the absence of evidence of underlying fixed atherosclerotic lesions.

There are conflicting data on the role of factor V Leiden heterozygosity as an independent risk factor for VTE recurrence. Two studies ("positive studies") have found an increased risk of VTE recurrence compared to control subjects, with relative risk of 4.1 and 2.4, respectively. Six other studies ("negative studies") have found no such association. The positive studies by Ridker et al. and Simioni et al. were prospective but included a small number of patients with factor V Leiden heterozygosity (14 and 41, respectively). The Physicians' Health Study (by Ridker et al.) included only men. Among the negative studies, four were prospective and two were retrospective. Three of the prospective studies and the large retrospective cohort study by De Stefano et al. each included 80 to 112 patients with factor V Leiden heterozygosity. A recent re-evaluation of the study by Simioni et al. did confirm the original study findings of increased relative risk of recurrent VTE in heterozygous carriers of factor V Leiden. The PREVENT trial later demonstrated equivalent rates of recurrent VTE in patients with and without factor V Leiden.

Homozygous carriers of the factor V Leiden mutation are estimated to have an 80-fold increased lifetime relative risk of VTE. A more recent estimate, derived from a pooled analysis of a larger population, has confirmed an increased risk of VTE but of lower magnitude (10-fold). The discrepancy is likely due to the very low prevalence of factor V Leiden heterozygosity found in the healthy controls from the general population. Most homozygous carriers present with VTE before 40 years of age, but some can live thrombosis-free until the sixth or seventh decade of life or even remain asymptomatic for life. The majority of VTE is situational, and women appear more likely to develop VTE than men, suggesting an important role of OCP use and pregnancy in triggering thrombosis. Based on data from the first
prospective Duration of Anticoagulation trial, the risk of VTE recurrence is significantly increased in homozygous factor V Leiden carriers (36.4% at 48 months) when compared to heterozygous carriers (16.1%) and controls (12.4%).

Laboratory Diagnosis

The intense interest in this common inherited thrombotic disorder has focused substantial attention on laboratory methods for its diagnosis. Laboratory aspects of its discovery have been reviewed by Dahlback. The disorder can be evaluated by coagulation assays that have as their basis inhibition of factor Va by APC and prolongation of the clotting time. Typically, APC is added to patient plasma, and a clotting assay is performed (usually the PTT), with results expressed as a ratio:

\[
\frac{\text{Patient PTT + APC}}{\text{Patient PTT}}
\]

Reference ranges are established for normal patients with and without addition of APC. Affected patients with mutant factor V have clotting times prolonged to a lesser extent (lower ratio) than normals. Alternatively, a DNA test can be done to look specifically for the Arg506Gln mutation; this highly conserved point mutation is present in most patients with APC-R.

With properly collected plasma samples, the APC-R clotting test can correctly classify nearly 100% of patients, when normalized to a control plasma pool. Predilution of the patient sample with factor-V-deficient plasma has improved the performance characteristics of most currently available commercial assays. Samples from patients with baseline abnormal coagulation studies (e.g., anticoagulant therapy, lupus anticoagulants, liver disease) yield uninterpretable results. A TF-dependent factor V assay has been described that is useful in patients taking oral anticoagulants or with the lupus anticoagulant. The polymerase chain reaction test for factor V Leiden uses the restriction enzyme MnlI to digest a 267-base pair amplified fragment of patient DNA. Consensus recommendations on methodologies to assay for factor V Leiden and APC-R have been presented.

Treatment

Therapy of VTE in patients with APC-R is similar to that described for patients without an identified hypercoagulable state. Long-term secondary prophylaxis is not necessary for heterozygotes unless they experience more than one thrombotic event or experience life-threatening thromboembolism. Asymptomatic patients with APC-R should not be treated, but female patients with this disorder should be informed about the additional thrombotic risk associated with oral contraceptive use, pregnancy, and HRT. Prophylaxis for high-risk situations, such as surgery, should be given. Homozygotes who experience VTE should be considered for long-term anticoagulation.

Prothrombin Mutations

The prothrombin G20210A mutation is the second most common inherited predisposition to hypercoagulability. Heterozygous prothrombin G20210A has been found in 18% of probands of thrombophilic families, 6% of unselected patients with deep vein thrombosis (DVT), and 2% of normal Caucasian individuals.

More recently, a novel single-point mutation of the prothrombin gene at position 20209 has been reported in four unrelated patients, two of whom had a history of VTE and one of whom had a history of stroke. Although the clinical significance of the prothrombin C20209T mutation is unknown, it may be underrecognized because it is not detected by the polymerase chain reaction/digestion assay commonly used for prothrombin gene mutation testing. Interestingly, all four reported individuals with prothrombin C20209T were African-Americans.

Pathophysiology and Genetics

Prothrombin G20210A is a single-point mutation (G-to-A substitution at nucleotide 20210) in the 3’ untranslated region of the prothrombin gene. This autosomal dominant mutation results in elevated concentrations of plasma prothrombin. In fact, the VTE risk increases as the plasma prothrombin level increases, with levels >115 IU/dl leading to a 2.1-fold increased relative risk of VTE. The G20210A mutation leads to a “gain of function” of the prothrombin gene, perhaps by
The mutation appears to follow a geographic and ethnic distribution, with the highest prevalence occurring, unlike factor V Leiden, in Caucasians from southern Europe (3%). This prevalence is nearly twice that observed in northern Europe (1.7%). Similar to factor V Leiden, the prothrombin G20210A mutation is also found in the Middle East and Indian regions, but it is virtually absent in individuals of Asian and African backgrounds. These distributions provide support to the estimate that both mutations (factor V Leiden and prothrombin G20210A) originated relatively recently in the European founding population, after the evolutionary divergences of subpopulations. An evaluation of patients in northeast Ohio who underwent hypercoagulability evaluations revealed an equivalent prevalence of prothrombin gene mutations in whites and blacks.

Clinical Aspects

Heterozygous prothrombin G20210A is associated with a two- to sixfold increased lifetime relative risk of VTE. The risk appears to be further increased in combination with pregnancy (15-fold) and OCP use (16-fold). The relative risk of cerebral vein thrombosis is increased 10-fold in women with this mutation who are not on OCPs, as opposed to 150-fold in OCP users. Homozygosity for prothrombin G20210A has an estimated population prevalence of 0.014%, and homozygous carriers appear to have greater predisposition to develop early (before 40 years of age) idiopathic recurrent VTE than heterozygotes.

The role of prothrombin G20210A as a risk factor for VTE recurrence is less controversial than it is for factor V Leiden, but data are also somewhat conflicting. Simioni et al., re-evaluating a prospective study from 1997, retrospectively determined patients’ prothrombin G20210A mutation status and found that the hazard ratio of VTE recurrence was 2.4. However, three prospective studies, which each included 28 to 52 patients, found no increased risk of recurrent VTE in heterozygous prothrombin G20210A carriers.

A fourfold increased risk of MI has been demonstrated, particularly in young women carriers of this mutation. A large case-control study of >14,000 men, though, revealed no increased risk of stroke or MI associated with this abnormal prothrombin gene. The reasons for this apparent male/female disparity are unknown.

Laboratory Diagnosis

The prothrombin G20210A and C20209T mutations can only be reliably and routinely identified using molecular biologic techniques. Measurements of functional prothrombin activity do not sufficiently differentiate between carriers and noncarriers of this gene mutation. Testing can be performed accurately despite concomitant treatment with any form of anticoagulation.

Treatment

Treatment paradigms for patients with prothrombin G20210A heterozygosity parallel those for patients with heterozygous factor V Leiden. Patients with concomitant prothrombin G20210A heterozygosity and factor V Leiden heterozygosity should be considered for long-term anticoagulation following a first thrombotic event.

Hyperhomocysteinemia

Homocysteine is a sulfhydryl amino acid formed during the conversion of methionine to cysteine. Hyperhomocysteinemia results when homocysteine metabolism is abnormal. Hyperhomocysteinemia has been identified as an independent risk factor for stroke, MI, peripheral arterial disease, and venous thrombotic disease. Even mild to moderate hyperhomocysteinemia is a significant risk factor for vascular disease. However, lowering homocysteine levels with vitamin therapy has not resulted in improved outcomes in vascular disease and thrombosis.

Pathophysiology and Genetics

The amino acid homocysteine is normally metabolized via the transsulfuration pathway by the enzyme cystathionine-β-synthase (CBS), which requires vitamin B₆ as co-factor, and via the remethylation pathway by the enzymes methylenetetrahydrofolate reductase (MTHFR), which is folate dependent, and methionine synthase, which requires vitamin B₁₂ as co-factor. Inherited severe hyperhomocysteinemia (plasma level >100 µmol/L), as seen in classic homocystinuria, may result from homozygous MTHFR and CBS deficiencies and, more rarely, from inherited errors of cobalamin metabolism. Inherited mild to moderate hyperhomocysteinemia (plasma
level >15 to 100 µmol/L) may result from heterozygous MTHFR and CBS deficiencies, but most commonly results from the thermolabile variant of MTHFR (tlMTHFR) that is encoded by the C677T gene polymorphism. Acquired hyperhomocysteinemia may be caused by folate deficiency, vitamin B₆ or B₁₂ deficiency, renal insufficiency, hypothyroidism, type II diabetes mellitus, pernicious anemia, inflammatory bowel disease, advanced age, climacteric state, carcinoma (particularly involving breast, ovaries, or pancreas), and acute lymphoblastic leukemia, as well as methotrexate, theophylline, and phenytoin therapy. The precise mechanisms underlying the thrombogenicity of homocysteine remain unclear. Several diverse mechanisms have been proposed, including endothelial cell desquamation, low-density lipoprotein (LDL) oxidation, promotion of monocyte adhesion to endothelium, and factor V activation and promotion of thrombin generation. Homocysteine also enhances platelet aggregation and adhesiveness as well as turnover, presumably as a result of endothelial cell injury. One study found that moderate hyperhomocysteinemia does not impair the activation of protein C by thrombin and does not impair the inactivation of factor V by APC.

Severe homocysteinemia usually results from homozygous CBS deficiency. The incidence of this disorder is ~1 in 335,000 live births. Classic symptoms for homozygous patients include premature vascular disease and thrombosis, mental retardation, ectopic lens, and skeletal abnormalities. Heterozygous homocysteinemia has been recognized as a disease entity; this disorder may affect 0.3% to 1.0% of the general population.

Clinical Aspects

Heterozygous carriers of the tlMTHFR mutation have normal plasma homocysteine levels unless folate levels are reduced. More important, the majority of case-control studies have not demonstrated an increased VTE risk in homozygous carriers of the tlMTHFR, and the majority of individuals with hyperhomocysteinemia do not have the tlMTHFR polymorphism. Thus, characterization of the tlMTHFR polymorphism is not useful to determine an individual's VTE risk. VTE risk is most closely related to elevated fasting plasma homocysteine levels, regardless of etiology. Hyperhomocysteinemia (plasma level >18.5 µmol/L) has been associated with a two- to fourfold increased VTE risk. It is interesting that, in the Physicians' Health Study, hyperhomocysteinemia (plasma level above the 95th percentile; 17.2 µmol/L) did increase the risk of idiopathic VTE (relative risk, 3.4) but not the risk of all (transient and idiopathic) VTE.

The majority of reports linking hyperhomocysteinemia to thrombosis have focused on venous thromboembolic disease. Kottke-Marchant et al. compared 23 patients with documented arterial peripheral thrombosis to age- and sex-matched controls. Elevated homocysteine levels (>13 µmol/L) conferred an OR of 7.8 for thrombosis. Elevated homocysteine levels were found in 73% of cases versus 28% of controls. Only smoking and homocysteine level were independent risk factors for arterial thrombosis. Currie et al. evaluated homocysteine and cardiovascular risk factors in 66 adult patients with vascular disease. Hyperhomocysteinemia was identified in 29% of patients and was an independent risk factor for the failure of vascular procedures (p = 0.006).

Laboratory Diagnosis

The initial step in the evaluation of the patient with suspected hyperhomocysteinemia involves measurement of fasting total plasma homocysteine (the sum of nonprotein-bound and protein-bound). Many laboratories report homocysteine values in reference to published “normal” ranges such as 5 to 15 µmol/L, but, ideally, a local, laboratory-specific normal range should always be established. A normal value in the nonfasting setting does not normally require repeating. Testing 2 to 8 hours after an oral methionine load (100 mg/kg) increases the sensitivity of detecting occult vitamin B₆ deficiency and obligate heterozygotes for CBS deficiency, but methionine loading is not routinely recommended. Vitamin B₁₂ and folate deficiency do not affect post-methionine loading homocysteine values. In patients found to have elevated levels of homocysteine, testing for vitamin B₁₂ deficiency is advocated to avoid missing subclinical deficiency before beginning oral folic acid therapy. Methodologies to measure homocysteine levels have been reviewed.

Treatment

Folic acid supplementation is the mainstay of effective hyperhomocysteinemia therapy. A recent meta-analysis of 1,114 patients enrolled in 12 randomized studies of vitamin supplementation to lower homocysteine levels demonstrated a 25% reduction in homocysteine levels, with similar effects across a dosage range from 0.5 to 5.0 mg daily. The usual recommended dose is 0.4 to 1.0 mg daily. Whether patients who are not responsive to one dose benefit from an escalation in dose is unclear. Because patients with subclinical vitamin B₁₂ deficiency may be prone to developing peripheral neuropathy if they receive folic acid supplementation alone, additional treatment with 0.5 mg/day of oral vitamin B₁₂ has been advocated. In the same meta-analysis, an additional 7% reduction of homocysteine levels was noted with vitamin B₁₂ supplementation. Vitamin B₁₂ administration results in normalization of homocysteine levels in B₁₂-
deficient individuals. In these patients, a monthly intramuscular injection of 200 to 1,000 µg of vitamin B<sub>12</sub> is considered adequate replacement. Vitamin B<sub>6</sub> supplementation did not appear to have any effect on homocysteine levels. Betaine, a nutritional supplement derived from beets, functions as an alternative methyl donor in the remethylation of homocysteine to methionine. Betaine has been used in individuals with homocystinuria and may facilitate homocysteine reduction in individuals who are not responsive to folate and vitamin B<sub>6</sub>.<sup>256</sup>

Thrombotic events in hyperhomocysteinemic patients should be treated as described for other inherited disorders. An additional treatment strategy is to lower plasma homocysteine levels, with the hope of alleviating a risk factor for recurrent thrombosis. However, results of the Heart Outcomes Prevention Evaluation (HOPE)-2 trial and Norwegian Vitamin (NORVIT) trial do not support the utility of homocysteine lowering in patients with arterial disease.<sup>257</sup>,<sup>258</sup> In patients with a history of coronary artery, cerebrovascular, or peripheral artery disease, or diabetes with at least one risk factor for atherosclerosis, lowering plasma homocysteine levels with folic acid and B vitamins did not reduce risk for the composite endpoint of MI, stroke, or death from cardiovascular causes more than placebo despite a 22% reduction in plasma homocysteine.<sup>257</sup> In NORVIT, folic acid and vitamin B<sub>12</sub>, with or without vitamin B<sub>6</sub>, did not reduce risk for the composite endpoint of MI, stroke, or death from coronary artery disease in patients with an index MI. Other clinical trials have also failed to show a cardiovascular benefit of lowering homocysteine levels.<sup>239</sup>,<sup>240</sup> Secondary analysis of the HOPE-2 trial regarding effects of vitamin therapy on VTE risk found that there was no significant risk reduction in VTE with vitamin therapy.<sup>259</sup> These trials yielding negative results with vitamin therapy raise questions about the utility of testing and treating homocysteinemia.

P.1229

Increased Factor VIII Activity

It is now appreciated that elevated levels of procoagulant coagulation factors, in addition to deficiencies of natural anticoagulant proteins, are risk factors for VTE. Factor VIII levels >1.5 IU/ml (150%) are associated with a threefold and a sixfold greater relative risk of VTE when compared to levels <1.5 IU/ml (150%) and <1.0 IU/ml (100%), respectively.<sup>260</sup> VTE risk is increased 11-fold with levels >200%, but it does not appear to be accentuated by concomitant OCP use.<sup>261</sup>,<sup>262</sup> Elevated activity levels of factor VIII associated with VTE risk seem to be persistent and not solely attributable to acute-phase response.<sup>263</sup> Transiently elevated factor VIII levels associated with acute-phase protein release, though, may in part explain the hypercoagulability associated with inflammatory disorders such as inflammatory bowel disease and cancer. Individuals with plasma factor VIII activity >234% (above the 90th percentile cutoff point for the study population) have a 6.7-fold increased relative risk of recurrent VTE compared to those with activity levels of <120%.<sup>264</sup>

Because factor VIII is indeed an acute-phase reactant and its levels can be affected by many factors, including blood type and WVF concentration, determination of the true meaning of an elevated factor VIII level in an individual patient with VTE is challenging. In the study by Koster et al., in which blood samples for factor VIII activity were obtained a minimum of 6 months after the VTE, it was impossible to distinguish completely between inherited elevation and postthrombotic, transient elevation of factor VIII.<sup>265</sup> Nonetheless, the fact that an increased factor VIII level is prevalent in persons with VTE may, in fact, imply that elevated factor VIII is not only frequent, but also an important risk factor for VTE.<sup>214</sup> More recent studies support the concept that elevated factor VIII levels are a significant risk factor in asymptomatic individuals for both arterial and venous thrombosis.<sup>264</sup>,<sup>264a</sup> The College of American Pathologists' consensus conference recommendations are not to routinely measure factor VIII levels in patients with venous or arterial thrombosis.<sup>265</sup>

Increased Levels of Factors IX, X, XI, and XIII

The Longitudinal Investigation of Thromboembolism Etiology study investigated the possible role of elevated factors IX, X, XI, and XIII in VTE risk.<sup>266</sup> and found that of these coagulation proteins, only elevated factor XI levels were associated with VTE risk. Elevated factor XI levels have also been linked to stroke<sup>267</sup> and coronary disease.<sup>268</sup> This effect of elevated factor XI levels may be mediated by increased fibrin formation and decreased fibrinolysis.<sup>269</sup>

Impaired Endogenous Fibrinolysis

The endogenous fibrinolytic system is comprised of plasminogen, PAs, and antifibrinolytic regulatory proteins. Intravascular plasminogen is converted to the active fibrinolytic enzyme plasmin primarily by t-PA derived from vascular endothelial cells and by urokinase-type PA (u-PA) from leukocytes. The principal physiologic inhibitor of t-PA is PAI-1, whereas plasmin itself is inactivated by circulating and thrombus-bound α<sub>2</sub>-antiplasmin, and to a lesser extent, α<sub>2</sub>-macroglobulin. Decreased endogenous fibrinolytic activity as a result of qualitative and quantitative abnormalities of
plasminogen, an inadequate release of t-PA in response to vascular injury, and excessive production of PAI-1, such as is found in inflammatory and malignant diseases, can result in impaired endogenous fibrinolysis and accumulation of pathologic thrombus.

Abnormal fibrinolysis was previously thought to account for a large proportion of patients with inherited thrombosis. However, the discovery of APC-R as a common inherited disorder and a literature review that concluded that a causal relationship between abnormal fibrinolysis and inherited thrombosis had not been clearly demonstrated diminished enthusiasm for routinely evaluating patients with recurrent thrombosis for abnormal fibrinolysis. However, newer data from the Leiden Thrombophilia Study indicate that reduced plasma fibrinolytic potential is a risk factor for venous thrombosis,

Two reports have suggested that quantitative plasminogen deficiency and dysplasminogenemia may not be risk factors for thrombosis, and a recent large series of 50 patients with quantitative plasminogen deficiency found the major clinical manifestation to be ligneous conjunctivitis; venous thrombosis was not observed. The College of American Pathologists Consensus Conference on Thrombophilia does not recommend routine assay for plasminogen deficiency in thrombophilia patients.

Tissue Plasminogen Activator Deficiency
Defective synthesis or release of t-PA from the vessel wall represents a potential mechanism for thrombosis. Plasma t-PA activity is unstable, and for accurate assays, citrated plasma samples must be immediately acidified and red blood cells removed. Addition of a platelet activation inhibitor to the blood collection tube may help reduce the release of platelet-derived PAI-1, which can interfere with t-PA activity quantification. A plasminogenchromogenic substrate assay is used to measure t-PA activity; t-PA antigen can be measured by ELISA using citrated plasma. The CAP Consensus Conference on Thrombophilia does not recommend routine assay for t-PA deficiency in thrombophilia patients.

Increased Plasminogen Activator Inhibitor-1 Levels
Increased levels of PAI-1 have been associated with venous or arterial thrombosis. Plasma PAI-1 activity is measured in citrated plasma using a back-titration method with single-chain t-PA. Because blood fibrinolytic activity exhibits a diurnal rhythm (decreased fibrinolysis in the morning as a result of peak PAI-1 levels; increased fibrinolysis in the evening as a result of low PAI-1 levels), plasma samples should be obtained at standardized times, such as between 8:00 and 9:00 a.m. In addition, because fibrinolytic component levels can be affected by acute-phase changes, patients should not be evaluated for abnormal fibrinolysis until 2 to 3 months after an acute thrombotic event.

In the European Concerted Action on Thrombosis and Disabilities study, an increased incidence of vascular events was associated with higher baseline PAI-1 antigen concentrations (p = .02) and PAI-1 activity (p = .001). Elevated levels of PAI-1 may effectively reduce t-PA activity levels, thereby blocking the activation of plasminogen to plasmin and inducing impaired fibrinolysis that may ultimately lead to thrombosis. Theoretically, markedly elevated levels of PAI-1 might also impair attempts at pharmacologic thrombolysis in the setting of acute arterial and venous thrombosis.

Defects in endogenous fibrinolytic capacity have also been found in young patients with unexplained arterial thromboembolism. Deficient t-PA release was found in 45% of such patients, and elevated levels of PAI-1 were found in 59%. It has been noted that patients who have undergone major surgical procedures might experience a transient “fibrinolytic shutdown” as a result of elevated PAI-1 levels as part of an acute-phase response.

Avoidance of obesity and associated insulin resistance, correction of hypertriglyceridemia, cessation of smoking, and exercise may improve the innate fibrinolytic status. Treatment of hypertension with angiotensin-converting enzyme inhibitors or angiotensin II receptor antagonists has been associated with significantly reduced PAI-1 production. The lipid-lowering agent gemfibrozil has also been shown to decrease the PAI-1 synthesis rate.
Modest alcohol consumption and hormone replacement treatment in postmenopausal women also seem to be beneficial.  

Dysfibrinogenemia

The clinical and biochemical aspects of dysfibrinogens are reviewed in Chapter 53. In general, dysfibrinogens associated with thrombosis have as their molecular defect generation of an abnormal fibrin that is resistant to fibrinolysis. An updated summary of dysfibrinogen molecular abnormalities is presented at www.ISTH.org. Dysfibrinogenemia as a cause of inherited thrombosis is uncommon.

Certain patients with dysfibrinogenemia may have a prolonged PT; more typically, these patients are detected by prolonged thrombin and reptilase times, suggesting a defect in the conversion of fibrinogen to fibrin. Confirmation of a dysfibrinogen can be done by simultaneous measurement of functional and immunologic fibrinogen levels. Typically, immunologic levels are found to be higher than levels measured by functional assay. Published data for the healthy population indicate that for fresh plasma samples, the ratio of immunologic to functional fibrinogen ranges from 1.12 to 1.65; ratios >1.65 are suggestive of dysfibrinogenemia.

Another potentially useful test to evaluate patients for dysfibrinogenemia is the fibrinogen lysis time. This test requires partial purification of the patient’s fibrinogen, followed by clotting and lysis in a standardized assay. Dysfibrinogens may also result in a false positive test for fibrinogen degradation products (FDPs) as assayed by latex agglutination, because residual fibrinogen remains in serum after clotting and is detected by the antibody-coated latex beads. An algorithm for the laboratory diagnosis of dysfibrinogenemia has been reported.

Thrombomodulin Deficiency

Thrombomodulin is a transmembrane protein that reacts with thrombin to activate protein C. Thrombomodulin deficiency may be an important cause of dysfibrinogenemia as a primary defect or be a consequence of other causes such as atherogenesis and vaso-occlusive disease.  

Lipoprotein(a)

Lipoprotein(a) (Lp[a]) is a lipoprotein moiety similar to LDL cholesterol in core lipid composition, and it has apolipoprotein (apo) B-100 as a surface apolipoprotein. In addition, Lp[a] has a unique glycoprotein, apo(a), which is bound to apoB-100. Apo(a) is structurally similar to plasminogen but lacks fibrinolytic activity. Lp(a) has both atherogenic and thrombogenic properties. Its thrombogenic effect is derived from stimulation of PAI-1 synthesis, promotion of intercellular adhesion molecule-1 expression by vascular endothelium, inhibition of both plasminogen and t-PA binding to fibrin, inhibition of plasminogen activation by t-PA, and competition with plasminogen for binding sites on endothelial cells and fibrin. The cumulative effect is impaired activation of plasminogen to plasmin at the vessel wall, inhibition of fibrinolysis, and increased risk for thrombosis.

The exact mechanisms that control Lp(a) levels are unknown, but genetic factors that regulate hepatic synthesis of apo(a) are likely important. One's plasma Lp(a) level is stabilized during infancy and maintained throughout life. Plasma concentrations >20 mg/dl seem to increase the risk of coronary artery disease, peripheral arterial occlusive disease (PAOD), and stroke. Lippi et al. evaluated Lp(a) in 68 patients subjected to vascular and endovascular surgery. Significant restenosis or reocclusion occurred in 23 (34%) patients. Lp(a) concentrations were significantly higher in those with restenosis and reocclusion compared with those in the no-restenosis group. Occlusive complications were unlikely to occur in patients with Lp(a) concentrations <5 mg/dl. Different isoforms of the apo(a) component of Lp(a) have different atherogenic potential and possibly different thrombogenic potential.

Measurement of Lp(a) should be considered mainly in individuals with atherosclerosis in the absence of classic risk factors, rapidly progressive atherosclerotic lesions despite aggressive risk factor modification, and individuals with acute arterial thrombosis. Because it is an acute-phase reactant, an elevated Lp(a) level must be carefully interpreted if drawn shortly after surgery, acute thrombosis, or acute coronary syndromes.

Patients with elevated Lp(a) benefit most from aggressive LDL cholesterol lowering. Although hepatic 3-methylglutaryl coenzyme A reductase inhibitors ("statins") may be the ideal agents for LDL lowering and atherosclerotic plaque stabilization, this class of drug does not appreciably lower Lp(a) levels themselves. Nicotinic acid (niacin), usually in high
the suggested tests are not recommended by the College of American Pathologists' consensus panel, and there are no

A consensus panel of the International Society on Thrombosis and Haemostasis has recommended that pediatric patients be routinely tested for inherited and acquired disorders in a comprehensive fashion. However, many of the suggested tests are not recommended by the College of American Pathologists' consensus panel, and there are no
data to indicate that patients with a genetic predisposition to thrombosis—children or adults—should be treated differently from those without risk factors (discussed in the following section).

Perspective on Laboratory Testing for Inherited Thrombotic Disorders

Increased availability of hypercoagulable-state test “panels” and enhanced ability to identify an abnormality in tested patients has prompted widespread testing of thrombosis patients. Testing for acquired and inherited hypercoagulable states uncovers an abnormality in >50% of patients presenting with an initial VTE but may have minimal actual impact on management in most of these patients. Such laboratory screening should be reserved for patients for whom the results of individual tests significantly affect the choice of anticoagulant agent, intensity of anticoagulant therapy, therapeutic monitoring, family screening, family planning, prognosis determination, and, most of all, duration of antithrombotic therapy. Testing “just to know” is neither cost-effective nor clinically appropriate. Table 55.4 lists situations in which hypercoagulable-state testing should be considered, but not necessarily performed, unless an a priori use of the test results has been determined. Table 55.5 lists potential elements of an initial battery of tests to detect a defined hypercoagulable state.

Patients should be considered for evaluation of these disorders if they are young (<45 years of age) with recurrent thrombosis, or if they have had a single idiopathic thrombotic event and have a positive family history. This recommendation is based on the fact that, with the exception of hyperhomocysteinemia and qualitative abnormalities of plasminogen, inherited thrombotic disorders, especially the five most common (APC-R, prothrombin G20210A, protein C deficiency, protein S deficiency, and AT deficiency), are autosomal dominant disorders, and most patients with these disorders (but not all) have supportive family histories. Patients without a family history of thrombosis should be evaluated for common acquired etiologies for thrombosis, including malignancy, myeloproliferative disorders, PNH, and antiphospholipid antibodies. Because thrombosis may induce an acute-phase response that may affect functional coagulation assays, testing is ideally done when the patient has fully recovered from the acute event and is not receiving anticoagulants. Functional assays are preferred over immunologic assays, so that both type I and type II disorders can be detected. An important exception to this recommendation is APC-R, which can be screened for using a DNA test that is not affected by acute-phase responses or anticoagulant therapy. Diagnosis of protein C or S deficiency in patients already anticoagulated with warfarin can be facilitated by parental testing, testing symptomatic family members who are not receiving anticoagulation, referral to a reference laboratory that has standardized assays for these natural anticoagulants in anticoagulated patients, or temporary cessation of warfarin therapy (minimum of 3 to 4 weeks). Patients with arterial thrombosis should be considered for testing for hyperhomocysteinemia, Lp(a), and, possibly, protein S deficiency and antiphospholipid antibodies.

- Activated protein C resistance (diluting patient plasma with factor V-deficient plasma)
- Prothrombin G20210A mutation testing by polymerase chain reaction
Activity assays for antithrombin, protein C, and protein S
Activated partial thromboplastin time, mixing studies, and dilute Russell viper venom time
Fasting total plasma homocysteine level
Anticardiolipin and β2-glycoprotein 1 antibody testing by enzyme-linked immunosorbent assays
Factor VIII activity
Assays should not be done at the time of acute thrombosis or while the patient is anticoagulated.
Cardiovascular disease was reported to be the underlying cause of death in ~30% of all deaths in the United States in 2010. Every year 750,000 new strokes occur in the United States, of which 85% are ischemic in nature. Acute limb ischemia secondary to peripheral arterial thrombosis and thromboembolism involving native and prosthetic vessels is a relatively uncommon but ominous form of vascular accident. National databases suggest a rate of 16 events annually per 100,000 population. In a fashion similar to coronary artery thrombosis, acute peripheral arterial thrombosis typically develops at sites of pre-existing peripheral atherosclerotic occlusive disease (PAOD). PAOD has been diagnosed in as many as 17% of men and 20% of women >55 years of age and is highly predictive for the coexistence of coronary and cerebral vascular disease. It has been estimated that PAOD progresses to critical limb ischemia in 15% to 20% of patients.

Acute VTE, including DVT and PE, is a common, potentially life-threatening, often preventable vascular condition associated with trauma, major surgery, advanced congestive heart failure, pregnancy, HRT, malignancy, and inherited hypercoagulability. Proximal lower-extremity DVT can result in venous limb gangrene (phlegmasia cerulea dolens), chronic stasis changes related to the postthrombotic syndrome (PTS), and symptomatic PE. PE in its most severe presentation can result in pulmonary hypertension, right-sided heart failure, cardiopulmonary collapse, and death.

A common feature of the management of all thromboembolic vascular diseases is the use of antithrombotic agents. Antithrombotic agents, including antiplatelet drugs, anticoagulants, and thrombolytic agents, are used to prevent thrombotic events, prevent or mitigate the complications of thrombotic events, and restore vascular patency to prevent loss of tissue, organ, and limb function, as well as life. Based on the pathologic basis of thrombosis involving different vascular beds, drugs that inhibit platelet activation and aggregation play a primary role in arterial disease management, whereas drugs that inhibit thrombin and fibrin generation play a primary role in venous disease.

management. The following sections describe the pharmacodynamics, pharmacokinetics, and clinical uses of select antithrombotic agents.

Antiplatelet Drugs

Given the important role of platelets in mediating arterial thrombosis and the significant morbidity and mortality of arterial thrombotic disorders, the safety and efficacy of antiplatelet drugs have been evaluated in numerous primary and secondary prevention trials. A 1988 meta-analysis indicated that antiplatelet treatment reduced overall mortality from vascular disease by 15% and that nonfatal vascular events were reduced by 30%. A 2002 update on this subject supports the original observation of the efficacy of antiplatelet therapy. The American College of Chest Physicians' consensus conference has summarized the status of clinical trials with aspirin and other antiplatelet drugs.

Numerous potential targets exist for antiplatelet therapy (Fig. 55.3). Platelet cyclo-oxygenase (COX) is the target of acetylation and irreversible inactivation by aspirin. ADP-induced platelet aggregation can be selectively inhibited by the thienopyridines, ticlopidine, clopidogrel, prasugrel, and by ticagrelor, a member of the cyclopentyltriazolopyrimidine class of drugs. Dipyridamole alters platelet function, in part, by inhibition of cyclic nucleotide phosphodiesterase to increase platelet cyclic AMP levels. Other potential targets for antiplatelet therapy include the platelet membrane receptor, gpIIb, mediator of platelet adhesion, and inhibitors to thrombin, the most potent stimulus to platelet activation. Interference with fibrinogen-mediated platelet aggregation by anti-gpIIb-IIIa antibodies and peptides is well established.
FIGURE 55.2. Algorithm for excluding deep vein thrombosis (DVT) using clinical criteria, D-dimer testing, and venous ultrasound. Clinical criteria are based on those of Wells PS, Anderson DR, Bormanis J, et al. Value of assessment of pretest probability of deep-vein thrombosis in clinical management. Lancet 1997;350:1795-1798. D-dimer methods are similar to those described by Hirsh J, Lee AY. How we diagnose and treat deep vein thrombosis. Blood 2002;99: 3102-3110. A: Based on clinical criteria fulfilled by the patient, the cumulative score is tallied. High probability is a score ≥3, moderate probability is 1 or 2, low probability is ≤0. B: The probability score is used with D-dimer assay and ultrasound to determine which patients may be excluded from DVT testing.

FIGURE 55.3. Targets for antiplatelet agents. This diagram summarizes certain aspects of platelet function relevant to antiplatelet therapy. Platelet metabolic pathways, membrane receptors, and enzymes are depicted with specific therapeutic targets enumerated. Four target categories for antiplatelet drugs are the arachidonic acid pathway, which
regulates production of prostaglandins (PGs) and thromboxanes; the cyclic adenosine monophosphate (cAMP) mechanism, which modulates important metabolic events; platelet membrane glycoproteins (GPs), which act as receptors for platelet agonists; and thrombin, a key stimulus to platelet activation. Specific targets for antiplatelet therapies include the following: (1) COX is the target of acetylation and irreversible inactivation by aspirin, as well as reversible inactivation by the nonsteroidal anti-inflammatory agents; (2) inhibitors to thromboxane synthetase prevent generation of thromboxane A₂ (TXA₂); (3) an example of a TXA₂ receptor antagonist is BM 531; (4) infusion of PGE₁, or stable analogs of prostacyclin (Iloprost) increases platelet concentrations of cAMP via stimulation of adenylate cyclase; (5) dipyridamole increases platelet cAMP concentrations by inhibition of cyclic nucleotide phosphodiesterase (PDE), and cilostazol inhibits PDE3 to increase platelet cGMP concentrations; (6) because thrombin is the most potent stimulus to platelet activation, inhibitors of thrombin (heparin, argatroban, and bivalirudin) are important agents in preventing platelet-dependent thrombosis; (7) ticlopidine, clopidogrel, prasugrel, and ticagrelor inhibit platelet activation by inhibition of adenosine-diphosphate (ADP)-induced aggregation; (8) monoclonal antibodies or peptides directed against the GPIIb-IIIa complex inhibit fibrinogen binding to platelets and subsequent platelet aggregation; (9) inhibitors to the von Willebrand factor receptor (GPIb) are being developed to prevent platelet adhesion; and (10) inhibitors to protease-activated receptors 1 and 4 (PAR 1 and 4) such as vorapaxar antagonize thrombin activation of platelets. ATP, adenosine triphosphate.

P.1235

Aspirin

Aspirin (acetylsalicylic acid) is the prototypical antiplatelet drug, exerting its antithrombotic action by irreversibly inactivating (by acetylation) the COX activity of platelet prostaglandin H synthase-1 (COX-1) and prostaglandin H synthase-2 (COX-2). This COX inhibition leads to the prevention of TXA₂ synthesis and impairment of platelet secretion and aggregation. A variety of nonsteroidal anti-inflammatory drugs can inhibit TXA₂-dependent platelet function via competitive reversible inhibition of COX-1. A lesser degree of COX-1 inhibition may explain why long-term use of nonaspirin nonsteroidal anti-inflammatory drugs is not protective against first MIs in postmenopausal women. Aspirin is the least expensive, most widely studied, and most widely used antiplatelet drug.

Aspirin (when not enteric-coated) is rapidly absorbed from the upper gastrointestinal tract; plasma salicylate concentrations peak within 1 hour of ingestion. The effects of aspirin on platelet function occur within 1 hour and last for the duration of the affected platelets’ lifespan (~1 week). The toxicity of aspirin is dose-related, explaining why clinical studies have focused on finding the lowest effective antithrombotic dose of the drug. Toxicities include gastrointestinal discomfort and blood loss, and the risk of systemic bleeding. Clinical trials suggest that aspirin doses as low as 75 mg/day or 30 mg/day are antithrombotic.

In addition to reducing aspirin toxicity, lower aspirin doses also inhibit vascular endothelial cell prostacyclin production to a lesser extent, because inhibition of endothelial cell COX is of shorter duration and requires higher aspirin doses than does platelet COX inhibition. The inhibitory effects of chronic low-dose aspirin administration are cumulative. However, even when taken chronically in large doses, aspirin is not believed to be thrombogenic.

The 2012 consensus conference statement on antiplatelet therapy indicates that aspirin has been convincingly demonstrated to be effective in treatment of the following thrombotic disorders: Stable and unstable angina, acute MI, transient ischemic attack and incomplete stroke, stroke after carotid artery surgery, atrial fibrillation (low risk), and prosthetic heart valves (in combination with warfarin). The minimum effective aspirin dose for these indications is 75 to 325 mg/day. Aspirin has also been shown to reduce mortality post-coronary-artery bypass surgery and to be effective for primary prevention of cardiovascular events, although more recent meta-analysis data of aspirin use for primary prophylaxis show less-certain benefits.

Data from the Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance (CHARISMA) trial highlight aspirin’s pre-eminent antiplatelet role in cardioprevention. CHARISMA assessed whether adding clopidogrel (75 mg/day) to aspirin therapy (75 to 162 mg/day) provided any benefit over aspirin monotherapy in preventing MI, stroke, or death from cardiovascular disease. The study involved 15,603 patients aged 45 years or older who were at high risk for these events. The study showed that the addition of clopidogrel to aspirin did not result in a significant lowering of risk of the primary composite endpoint. In addition, the rate of severe bleeding was 1.7% and 1.3% for the clopidogrel-plus-aspirin and aspirin-only groups, respectively. Clopidogrel in addition to aspirin did reduce the
relative risk of a recurrent MI, stroke, or cardiovascular death by 12.5% in the subgroup of patients with established atherothrombotic disease. The subgroup of patients with multiple risk factors but no clearly established vascular disease did not benefit from the addition of clopidogrel and actually had nonstatistically significant increases in cardiovascular events and bleeding. Clopidogrel plus aspirin remains an approved and standard therapy in conjunction with coronary artery stenting.

Aspirin may modify the natural history of intermittent claudication from lower-extremity arteriosclerosis. Because these patients are at high risk for future cardiovascular and cerebrovascular atherothrombotic events, life-long aspirin therapy is recommended.\textsuperscript{357} Similar therapy is advisable after peripheral arterial bypass surgery and carotid endarterectomy.

The Pulmonary Embolism Prevention trial was a large-scale, double-blind, multicenter study of 13,356 patients undergoing surgery for hip fracture and an additional 4,088 patients undergoing elective knee or hip arthroplasty.\textsuperscript{358} Patients were assigned to a regimen of 160 mg of aspirin or placebo once daily for 5 weeks, with the first dose given before surgery. Other forms of prophylaxis were allowed, and 40% of patients received unfractionated heparin (UFH) or LMWH in addition to the aspirin. The study demonstrated that aspirin reduced the incidence of fatal PE (58% risk reduction) and symptomatic nonfatal DVT or PE (36% risk reduction) in patients with hip fracture.\textsuperscript{358} Although beneficial when compared to placebo, aspirin cannot be recommended as first-line VTE prophylaxis in hip fracture patients, because the benefit of aspirin is less than with anticoagulants.\textsuperscript{359} The potential role of aspirin in treating VTE has been resurrected by the results of a VTE treatment trial that demonstrated that aspirin therapy, begun after 6 to 18 months of oral anticoagulant treatment, reduced VTE recurrence by ~40% compared to placebo.\textsuperscript{360} Aspirin, used as prophylaxis for VTE recurrence, would have the advantage of being an active drug to also prevent arterial thrombosis.\textsuperscript{360a}

The concept of “aspirin resistance” has been popularized. This term refers to persistent platelet activation that occurs in patients treated with aspirin who experience treatment failure. There are numerous reasons for aspirin resistance;\textsuperscript{361} current recommendations are to not test routinely for aspirin resistance and to not change therapy based on such test results.\textsuperscript{362} One literature review concluded that the most common cause for aspirin resistance was noncompliance.\textsuperscript{363} Routine laboratory monitoring for aspirin resistance is not recommended.\textsuperscript{364}

**Thienopyridines**

Ticlopidine and clopidogrel are structurally related compounds that selectively inhibit ADP-induced platelet aggregation and likely ADP-mediated amplification of the platelet response to other agonists.\textsuperscript{365} A lack of in vitro platelet aggregation inhibition suggests that in vivo hepatic transformation to an active metabolite is necessary for an antiplatelet effect. Both agents were initially used as aspirin substitutes in aspirin-intolerant patients. Enthusiasm for ticlopidine has been dampened by associated hematologic complications. Ticlopidine has been associated with neutropenia, thrombocytopenia, aplastic anemia, and thrombotic thrombocytopenic purpura.\textsuperscript{366, 367, 368, 369}

Clopidogrel, an irreversible inhibitor of the P2Y\textsubscript{12} ADP receptor, is rapidly absorbed and extensively metabolized. The plasma half-life of the main systemic metabolite, SR 26334, is roughly 8 hours.\textsuperscript{370} Platelet function returns to normal approximately 7 days after the last dose of clopidogrel. The Clopidogrel Versus Aspirin in Patients at Risk of Ischemic Events trial compared clopidogrel to aspirin in patients who had experienced a recent stroke or a recent MI and in those presenting with symptomatic peripheral arterial disease.\textsuperscript{371} A modest difference in efficacy was observed. The annual ischemic event rate for aspirin was 5.83% compared to 5.32% for clopidogrel. The majority of the difference in efficacy occurred in the patients who entered the trial because of symptomatic peripheral arterial disease, with a 23.8% relative risk reduction.\textsuperscript{371} The Clopidogrel in Unstable Angina to Prevent Recurrent Events trial has demonstrated an advantage of clopidogrel plus aspirin over aspirin alone in patients with acute coronary syndromes.\textsuperscript{372} Clopidogrel, like ticlopidine, can rarely precipitate thrombotic thrombocytopenic purpura.\textsuperscript{373}

Despite the current standard antiplatelet regimen of aspirin and clopidogrel (with or without glycoprotein IIb/IIIa inhibitors) in percutaneous coronary intervention (PCI) patients, peri-procedural and postprocedural ischemic events continue to occur. Prasugrel, a newer potent thienopyridine P2Y\textsubscript{12} receptor antagonist, can achieve more rapid and higher levels of inhibition of ADP-induced platelet aggregation than clopidogrel.\textsuperscript{374} However, although a major clinical trial with prasugrel found that it did not reduce overall mortality, it did increase major bleeding (reviewed in Reference 344).

Ticagrelor, a new antiplatelet agent of the cyclopentyltriazolopyrimidine class, reversibly inhibits the P2Y\textsubscript{12} ADP receptor in platelets.\textsuperscript{375} An international trial that compared clopidogrel versus ticagrelor in patients with an acute coronary
syndrome found that although the overall trial results demonstrated that ticagrelor was the superior drug, the results for United States’ patients showed the opposite, with clopidogrel associated with better outcomes. Major bleeding rates between the two drugs were similar.\textsuperscript{346} Perioperative management of patients on antiplatelet therapy has been reviewed.\textsuperscript{374a}

Integrin $\alpha_\text{IIb}\beta_3$ (Glycoprotein IIb/IIIa) Receptor Antagonists

Because of the multitude of pathways that lead to platelet aggregation, it is not surprising that the clinical efficacy of the antiplatelet agents described above is only partial. Even combination therapy with clopidogrel and aspirin, resulting in partial inhibition of TxA$_2$- and ADP-mediated platelet aggregation, leaves platelets susceptible to agonists such as thrombin and collagen.\textsuperscript{341} Because expression of functionally active gpIIb/IIIa on platelet surfaces is the final common pathway of platelet aggregation regardless of initial stimulus, it is logical to target this glycoprotein receptor with antiplatelet agents for maximal platelet inhibition.

gpIIb/IIIa is a member of the integrin family of receptors. These receptors recognize the amino acid sequence arginine-glycine-aspartate (Arg-Gly-Asp [RGD]), which represents the cell attachment regulation sequence present in certain adhesive proteins such as fibrinogen.\textsuperscript{375} Inhibitors of fibrinogen binding to gpIIb/IIIa, called the disintegrins, include a chimeric monoclonal antibody against the receptor, naturally occurring RGD sequence-containing peptides from snake (pit viper) venoms, synthetic RGD peptides, synthetic Lys-Gly-Asp (KGD) peptides, peptidomimetics, and nonpeptide RGD mimetics.\textsuperscript{344, 376, 377, 378}

Three parenteral gpIIb/IIIa inhibitors have been extensively studied, primarily in the settings of PCI, unstable angina, and non-Q-wave MI. These are abciximab, eptifibatide, and tirofiban.\textsuperscript{344, 346} Abciximab (c7E3 Fab) is a chimeric Fab fragment of human and murine protein that binds to gpIIb/IIIa. Abciximab is unique among the gpIIb/IIIa antagonists because it also blocks the $\alpha_\text{IIb}\beta_3$ receptor.\textsuperscript{379} Eptifibatide is a synthetic cyclic heptapeptide with a KGD sequence that is more specific for gpIIb/IIIa than the RGD sequence.\textsuperscript{344, 376} Tirofiban is a synthetic peptidomimetic based on the RGD sequence.\textsuperscript{380} Oral gpIIb/IIIa inhibitors have been generally unsuccessful. Current and emerging antiplatelet therapies have been reviewed.\textsuperscript{346}

Anticoagulant Drugs

Anticoagulant drugs are ubiquitous in medical and surgical practice. Anticoagulants are used to prevent and treat thrombosis. Traditionally, short-term anticoagulation is provided in the form of an intravenous infusion or subcutaneous injection whereas more chronic anticoagulation is facilitated by the use of oral agents. However, narrow-spectrum (single-protein-target) oral anticoagulants (e.g., dabigatran, rivaroxaban, and apixaban) are beginning to supplant more broad-spectrum anticoagulants (e.g., heparin and warfarin) and this trend will likely continue. The 2012 version of the American College of Chest Physicians Clinical Practice Guidelines has been published.\textsuperscript{381}

\begin{figure}

Heparin

Heparin is a naturally occurring, highly sulfated glycosaminoglycan that is normally present in human tissues (Fig. 55.4). McLean first isolated heparin from ox liver and identified its anticoagulant properties.\textsuperscript{382} Commercial UFH is obtained from either bovine lung or porcine intestinal mucosa and consists of a heterogeneous mixture of polysaccharides (glycosaminoglycans) with molecular weights ranging from 4,000 to 30,000 D, with a mean molecular weight of approximately 15,000 D (approximately 45 saccharide units). UFH molecules possessing anticoagulant activity constitute approximately one third by weight of commercial heparin products.\textsuperscript{383} Sodium and calcium salts of heparin are available, and most commercial heparin preparations have specific activities of 150 U/mg. Heparin structure consists of alternating residues of uronic acid and glucosamine that are variably sulfated.\textsuperscript{384} Sulfation of residues in heparin is a major
determinant of the anticoagulant activity of a given heparin preparation; the heparin molecules with anticoagulant activity exhibit high-affinity binding to AT.

UFH molecules contain a randomly distributed unique pentasaccharide sequence that binds to AT. Once bound to UFH, the natural anticoagulant effect of AT is potentiating, resulting in the accelerated binding and inactivation of serine proteases in general, and factor Xa and thrombin in particular. The inhibition of these factors affects the common pathway of coagulation, resulting in decreased formation of thrombin and fibrin.

Heparin's interaction with AT is thought to occur as follows and is depicted in Figure 55.5. A ternary complex with heparin, thrombin, and AT first occurs; this association permits inactivation of thrombin by the active site inhibitor domain of AT. Lastly, heparin dissociates from the AT-thrombin complex to subsequently catalyze additional AT-mediated reactions. A pentasaccharide series interacts only with the AT-binding sequence and promotes factor Xa inhibition substantially but has minimal effect on thrombin inhibition. In this case, only the conformational change induced by the pentasaccharide is necessary for factor Xa inhibition to occur. Oligosaccharides of greater length (at least 18 residues) are necessary for enhancement of thrombin inhibition by AT. It is likely that in this latter case, a ternary complex of ATIII, thrombin, and heparin forms to mediate protease inhibition. In vitro experiments suggest that UFH exerts its major anticoagulant effect by promoting AT suppression of thrombin-independent amplification reactions.

In addition to its anticoagulant activity, heparin possesses other, unrelated biologic effects. Heparin hydrolyzes triglycerides from chylomicrons and very-low-density lipoproteins by release of endothelial cell lipoprotein lipase into the blood. Heparin can also activate platelets, suppress cell-mediated immunity, and affect metabolism of aldosterone and thyroxine. Heparin is active when given parenterally, either intravenously or subcutaneously. Because of its highly charged nature and inability to cross biologic membranes alone, oral use of heparin has historically been viewed as impossible. Recently, delivery systems have been developed that make oral heparin a possibility and when sufficient amounts of heparin are administered orally, a prophylactic intensity of anticoagulation can be achieved.

The half-life of heparin varies with the dosage given, with the half-life increasing with increasing dosage. A 100-U/kg intravenous dose is cleared with a half-life of ~1 hour. The clearance of heparin is also affected by the extent of thromboembolism, with extensive thrombosis decreasing heparin half-life. Heparin is cleared by the reticuloendothelial system and metabolized by the liver, and metabolic products are excreted in the urine. The anticoagulant effect of heparin is also altered by its nonspecific binding to plasma proteins and cells. Given these numerous variables affecting the plasma half-life of heparin, therapeutic use of this drug generally requires close laboratory monitoring to ensure attainment of a therapeutic effect and regulation of heparin levels within a targeted range to optimize safety and efficacy. When using intravenous heparin, the use of established nomogram-guided therapy is preferred. Table 55.7 illustrates an example of a weight-based nomogram for using UFH. This assumes that the hospital laboratory has calibrated the aPTT
values such that an aPTT range from 1.5 to 2.5 times the mean laboratory control aPTT is equivalent to plasma heparin levels of 0.3 to 0.7 U/ml, as measured by anti-factor Xa activity. Pharmacologic reversal of UFH anticoagulant activity can be achieved with protamine sulfate. Protamine is a positively charged moiety derived from salmon sperm that can interact with the negatively charged UFH to form a stable complex that lacks anticoagulant activity. One milligram of protamine can inactivate ~100 U of UFH. Protamine, in excess, can promote an anticoagulant state. Because of a clinically meaningful risk of anaphylaxis, protamine should be administered with caution and is normally reserved for use in case of life-threatening bleeding or UFH overdose and reversal of anticoagulation following cardiopulmonary bypass.

An additional challenge to the use of heparin to prevent and treat thrombosis is heparin resistance. “True” heparin resistance manifests as inadequate anticoagulant and antithrombotic responses from what would otherwise be perceived as an adequate, and probably weight-based, dose of heparin. Some have deemed a requirement of >35,000 U of heparin per 24-hour period, regardless of patient weight, to reflect this form of heparin resistance. With true heparin resistance, both a measurement of anticoagulant activity such as the aPTT and a measurement of antithrombotic activity such as the anti-factor Xa activity assay demonstrate inadequate degrees of heparin activity. True heparin resistance most likely results from the nonspecific binding of heparin to mononuclear white cells, vascular endothelial cells, and acute-phase proteins such as histidine-rich glycoprotein, vitronectin, and PF4, resulting in an inadequate quantity of free or AT-bound heparin. Another potential cause of heparin resistance is acquired AT deficiency such as can be seen in cancer patients.

Patients can also manifest an “apparent” heparin resistance characterized by dissociation between the aPTT and heparin assays. In these patients, the aPTT may be normal or near normal, whereas the anti-factor Xa activity assay reveals an appropriate target heparin activity level between 0.3 and 0.7 U/ml. Simply escalating the dose of heparin to achieve the desired aPTT without checking a heparin assay may result in a pronounced bleeding risk. Dissociation between the aPTT and aPTT, activated partial thromboplastin time.

Low-molecular-weight Heparins

LMWH is derived from the enzymatic or chemical cleavage of UFH to produce a mixture of low-molecular-weight glycosaminoglycan molecules with a mean molecular weight of ~5,000 D (~15 saccharide units). For example, enoxaparin sodium is produced by benzylation followed by alkaline hydrolysis, dalteparin sodium is produced by controlled nitrous acid depolymerization, and tinzaparin sodium is produced by enzymatic digestion with heparinase. LMWH binds AT via the same pentasaccharide sequence as UFH. However, because of the predominance of molecules <18 saccharide units in length, LMWH has limited anti-thrombin (IIa) activity compared to its anti-factor Xa activity.
Whereas UFH has an anti-factor Xa to anti-IIa activity ratio of 1:1, LMWHs have reported ratios of 1.9:1 to 4.1:1. Because of limited thrombin inhibition, LMWH therapy cannot be monitored using the aPTT. Other differences between LMWH preparations include the degree of TF pathway inhibitor release, degree of sulfation, and degree of stimulated vWF release. These differences form the basis for many medical organizations’ stating that LMWHs are unique drugs and not therapeutically interchangeable.

At low doses, subcutaneous LMWH has 90% bioavailability, compared to 30% for UFH. LMWHs have limited nonspecific binding to plasma proteins and platelets, endothelial cells, and macrophages compared to UFH, as well as a predictable clearance and a longer half-life that facilitates once- or twice-daily administration. Unlike UFH, the half-life of LMWH is not dose-dependent. These characteristics make LMWH preferred in settings that may normally result in heparin resistance. These advantages of LMWH allow these drugs to be given subcutaneously, once or twice daily and without the need for laboratory monitoring. Similar to UFH, absolute contraindications for LMWH include active bleeding, HIT, or a history of HIT, and known sensitivity to LMWH, UFH, or pork products.

LMWHs have substantial renal clearance; therefore, multi-day therapeutic use of LMWH in patients with significant renal insufficiency (creatinine clearance <30 ml/minute) should be avoided. In the setting of less severe renal insufficiency, LMWH should be used with caution and with a reduced dosing frequency. Only ~60% of LMWH anticoagulant activity can be reversed after the administration of protamine sulfate.

**Heparinoids**

Heparinoids are low-molecular-weight glycosaminoglycans that are not derived from heparin. Heparinoids include dermatan sulfate and danaparoid sodium. Dermatan sulfate and low-molecular-weight dermatan sulfate act as anticoagulants by activating HCII. Danaparoid sodium is a glycosaminoglycan mixture derived from porcine intestinal mucosa and composed of heparan sulfate (84%), dermatan sulfate (12%), and chondroitin sulfate (4%). Danaparoid has an anti-factor Xa activity to anti-IIa activity ratio of greater than 22:1 (compared to a 1:1 ratio for heparin), which explains why it is minimally neutralized by protamine sulfate.

The largest collection of clinical experience with danaparoid is in the setting of HIT. Danaparoid may cross-react with 10% to 50% of HIT sera, but in vivo cross-reactivity, although reported, has not been commonly observed. Danaparoid has a relatively long half-life of ~24 hours, which may make its use less desirable in patients at high risk for developing bleeding or those likely to need surgery. Significant experience exists with the administration of danaparoid by both intravenous and subcutaneous routes. Danaparoid anticoagulation is monitored using an anti-factor Xa activity chromogenic assay calibrated with danaparoid standards. The drug is approved for deep vein thromboprophylaxis after orthopedic surgery at a dose of 750 U anti-Xa twice daily by subcutaneous injection. A common dose for the treatment of active thrombosis in patients with normal renal function is 1,500 U as an intravenous bolus followed by 1,500 U subcutaneously twice daily. The target therapeutic anti-factor Xa activity is 0.5 to 0.8 U/ml. Danaparoid’s potential for cross-reactivity and the longer half-life make it less desirable than a direct thrombin inhibitor (DTI) for the treatment of patients with HIT. The manufacturer of the drug has discontinued availability of danaparoid in the United States.

**Pentasaccharides**

Because factor Xa is situated at the start of the common pathway of coagulation and upstream of thrombin in the cascade, it is an attractive target for new anticoagulants. By not directly inhibiting thrombin activity, factor Xa inhibitors might allow small amounts of thrombin to be generated, facilitating hemostasis and theoretically leading to a more favorable bleeding-risk profile. Fondaparinux is an FDA-approved synthetic pentasaccharide (molecular weight, 1,728 D) that causes selective indirect (i.e., AT-mediated) inhibition of factor Xa. Fondaparinux is administered subcutaneously, has a half-life of ~17 hours, and does not require therapeutic monitoring. Fondaparinux elimination is prolonged in patients with renal impairment. The reduction in clearance increases as the creatinine clearance decreases. Elimination is also prolonged in patients >75 years of age and in those weighing <50 kg. Fondaparinux has been used with success to treat HIT. Fondaparinux is approved for the prevention and treatment of VTE.

A long-acting, hypermethylated pentasaccharide, idraparinux, and a similar compound with a biotin moiety at the reducing end unit allowing for neutralization with avidin, idrabiotaparinux, have a half-life of up to 130 hours, which may facilitate anticoagulation with once-weekly subcutaneous dosing. However, Phase III trials to date have been disappointing. In the VTE treatment studies, idraparinux was less effective than comparators, and in a large atrial fibrillation trial, idraparinux was equally effective as vitamin K antagonists, but caused more bleeding.
The parenteral DTIs have been studied for use in patients with acute coronary events, but are most widely utilized in patients with HIT. In these patients, elimination of all heparin exposure is the most essential element in the treatment. This includes discontinuing heparin intravenous catheter flushes, prophylactic subcutaneous heparin or LMWH, and heparin-coated indwelling catheters. Yet, despite heparin discontinuation and platelet count recovery, patients with isolated, serologically confirmed HIT have up to a 50% risk of developing a confirmed thrombotic event during the 30-day period after heparin cessation. The persistent prothrombotic tendency associated with HIT and the patient's original indication for heparin therapy warrant use of an alternative anticoagulant agent such as the DTIs after heparin cessation (Table 55.9).

Hirudins

Hirudin, a polypeptide originally isolated from the salivary glands of the medicinal leech, directly inhibits thrombin. Two recombinant forms of hirudin, lepirudin, and desirudin, are available for clinical use. Lepirudin is a recombinant hirudin analog that received FDA approval in 1998 for anticoagulant treatment in patients with HIT in the setting of thromboembolic disease to prevent further thrombosis. Lepirudin differs from native hirudin in that it lacks sulfation on the tyrosine at position 63 and has a leucine at position 1 rather than isoleucine. Lepirudin is a potent DTI that lacks any structural homology with heparin, does not cross-react with heparin, has a short half-life, is able to inactivate clot-bound thrombin, and can be monitored using the ubiquitous aPTT assay or the less readily available ecarin clotting time.

In composite, when compared to historical controls in patients with HIT with associated thrombosis, lepirudin (n = 389 patients, 3 cohorts) demonstrates a relative risk of 0.70 (95% confidence intervals [CIs], 0.27 to 1.8), 0.28 (0.15 to 0.52), and 2.31 (0.94 to 5.71) for limb amputation, new thrombosis, and major bleeding, respectively. 422

Current lepirudin dosing recommendations are an infusion of 0.15 mg/kg/hour (up to 110 kg) with or without an initial bolus of 0.4 mg/kg. 397 The target aPTT is 1.5 to 2.5 times the median value for the normal range. Monitoring during bypass requires performance of the less readily available ecarin clotting time with a target plasma lepirudin concentration of 2.0 µg/ml. 423 The activated clotting time (ACT) and point-of-care aPTT assays do not appear to be suitable for lepirudin therapeutic monitoring. 424 Outpatient subcutaneous lepirudin has been used to treat patients with HIT and thrombosis and patients who are refractory to other anticoagulant therapy. 425

The major challenges of lepirudin treatment are the lack of an antidote, the extreme care needed when treating patients with even mild renal insufficiency, and immunogenicity. In the event of lepirudin overdose or lepirudin-induced bleeding, infusions of prothrombin complex concentrates or recombinant factor VIIa may help promote hemostasis. 419 High-flux capillary hemodialysis membranes may facilitate the hemofiltration of lepirudin in some cases. 426 Partial-exchange transfusions, plasmapheresis, and immobilized thrombin affinity columns have also been tried to neutralize the effects of lepirudin. 419 Marked bolus and infusion rate reductions are necessary in patients with a creatinine clearance of <60 ml/minute (serum creatinine >1.6 mg/dl). Lepirudin is to be avoided completely or administered with extreme care in the settings of hemodialysis and acute renal failure and in patients undergoing continuous venovenous hemodialysis, even in the setting of a normal serum creatinine. Careful monitoring of both the aPTT and serum creatinine is indicated during lepirudin therapy. Approximately 40% of HIT patients treated with lepirudin develop antihirudin antibodies of the IgG class. 427 The antibodies seem to be capable of decreasing renal elimination of the drug rather than exerting any in vivo neutralizing effect. This paradoxical enhancement of the anticoagulant effect of lepirudin often warrants a significant reduction of infusion rate. Lepirudin is no longer available in the United States.

Desirudin is another recombinant form of hirudin that is approved in the United States for VTE prevention after elective hip replacement surgery. When used for thromboprophylaxis, desirudin is given subcutaneously at a dose of 15 mg twice daily. 397 More recently, a small open-label study comparing desirudin, dosed at 30 mg twice daily, to argatroban in patients with HITT has been reported. 428

Argatroban

Argatroban is a synthetic, small-molecule, L-arginine derivative that received FDA approval in June 2000 for prophylaxis and treatment of thrombosis in patients with HIT. Argatroban is a rapid and reversible DTI, in contrast to lepirudin, which is an irreversible thrombin inhibitor. Argatroban is capable of inhibiting both free and fibrin-associated thrombin. Argatroban exerts its antithrombotic effects by inhibiting thrombin-mediated reactions including fibrin formation; activation of coagulation factors V, VIII, and XIII; activation of the natural anticoagulant protein C; and platelet activation. 429 Like lepirudin, argatroban does not cross-react with heparin. Argatroban is metabolized by the liver with biliary excretion and has a half-life of only 40 minutes. Renal excretion has also been documented; however, renal impairment has been shown to have little adverse effect on drug clearance and half-life. Unlike lepirudin, argatroban does not require dose adjustment in the setting of renal insufficiency. Dose reduction is required in patients with significant hepatic disease. 429

In two cohorts (n = 419) of patients with HITT treated with argatroban and compared to historical controls who were followed for 37 days, the relative risk for death due to thrombosis, limb amputation, new thrombosis, and major bleeding
was 0.12 (95% CI, 0.05 to 0.34), 1.26 (95% [CI]; 0.53 to 2.99), 0.45 (95% [CI];0.28 to 0.71), and 3.70 (95% [CI]; 0.52 to 26.5), respectively. Argatroban is dosed based on patient weight. The recommended starting intravenous infusion rate is 2 µg/kg/minute with a target aPTT of 1.5 to 3.0 times the baseline value. Therapy may also be monitored by whole-blood ACT and the ecarin clotting time. Like lepirudin, argatroban prolongs the PT as well as the aPTT. This PT prolongation makes determination of an accurate INR during conversion to oral warfarin therapy a challenge. Holding the infusion of either DTI for several hours before INR determination is prudent. Argatroban has been shown to provide adequate anticoagulation with minimal bleeding risk while enabling procedural success in HIT patients undergoing PCI. Patients were given a 350-µg/kg bolus of argatroban followed by 25 µg/kg/minute infusion titrated to achieve an ACT of 300 to 450 seconds. This dosing regimen may provide satisfactory anticoagulation during cardiopulmonary bypass and allow intraoperative dose adjustments based on the readily available ACT.

Bivalirudin

Bivalirudin is a semisynthetic, bivalent DTI consisting of a dodecapeptide analog of the carboxy-terminus of hirudin. Bivalirudin has four glycine residues that connect the thrombin exosite 1 and thrombin active-site moieties. After binding to bivalirudin, thrombin cleaves a Pro-Arg bond at the amino-terminus of the molecule, making it a reversible thrombin inhibitor. The short half-life of bivalirudin (~25 minutes) may enhance its safety profile. Bivalirudin is used primarily during PCIs, in which it has been shown to be at least as effective as heparin with gpIIb/IIIa inhibition, but with an improved safety profile. Bivalirudin has also been evaluated in patients presenting with acute coronary syndromes as an alternate to heparin. In patients with moderate-or high-risk acute coronary syndromes who were undergoing invasive treatment including gpIIb/IIIa inhibition, bivalirudin was associated with rates of ischemia and bleeding similar to those in heparin-treated subjects. However, bivalirudin alone was associated with similar rates of ischemia and significantly lower rates of bleeding compared to heparin plus gpIIb/IIIa blockade. Bivalirudin has also been evaluated for the management of patients with HIT, especially those requiring cardiac surgery. The currently recommended dose of bivalirudin is a bolus of 0.75 mg/kg followed by an infusion of 1.75 mg/kg/h for the duration of the procedure. Bivalirudin is also recommended for anticoagulation in managing hemodialysis patients with HIT.

Warfarin

In the 1920s, cattle developed a bleeding disorder when they were fed spoiled sweet clover. Campbell and Link later identified the active agent as bishydroxycoumarin (dicoumarol). Drugs that inhibit the biosynthesis of the vitamin-K-dependent coagulation proteins are derived either from 4-hydroxycoumarin or 1,3-indanedione. Although the indanediones are used in Europe, a coumarin derivative, warfarin, is the major formulation used in the United States. Warfarin inhibits γ-carboxylation of select glutamic acid residues in the N-terminus of prothrombin and factors VII, IX, and X, as well as the vitamin-K-dependent natural anticoagulants, protein C and protein S. Warfarin inhibits the two enzymes critical for the generation of reduced vitamin K, namely, vitamin K epoxide reductase and vitamin K reductase. Reduced vitamin K is necessary for catalyzing γ-carboxylation of glutamic acid residues. Inhibition of γ-carboxylation by warfarin leads to synthesis of incomplete, hypofunctional coagulation proteins that are unable to bind to cellular surfaces to mediate coagulation reactions. The effect of warfarin on vitamin-K-dependent procoagulant protein production is depicted in Figure 55.6. Details of vitamin K metabolism are presented in Chapter 18. Commercially available warfarin is a racemic mixture of levorotatory and dextrorotatory forms of the drug. The half-life of warfarin in blood is ~36 hours. Laboratory monitoring of warfarin therapy is best done using functional coagulation tests, such as the PT. Plasma warfarin levels are most useful in evaluating the unusual patient who does not respond to standard warfarin dosages or in whom malabsorption, noncompliance, or inherited drug resistance is an issue.

Because factor X and prothrombin have half-lives >2 days, reduction of all vitamin-K-dependent coagulation proteins into the therapeutic range (~20% of normal) requires 4 to 5 days of therapy. This is the basis for the “parenteral anticoagulant overlap” period of 4 to 5 days during which patients receive therapeutic parenteral anticoagulant while waiting to achieve the therapeutic effects of warfarin. An animal study indicated that depression of both factor X and prothrombin levels by warfarin was important in the prevention of hypercoagulability.

Warfarin dosage is influenced by numerous variables, including the patient's age, body mass, dietary stores of vitamin K, liver function, co-existing medical disorders, concurrent medications, and presence or absence of cytochrome P-450 complex (CYP2C9) and vitamin K epoxide reductase complex subunit 1 (VKORC1) single-nucleotide polymorphisms that affect coumarin metabolism or sensitivity. Patients with liver disease, malnutrition, or other factors associated with sensitivity to warfarin should receive lower warfarin dosages. The most common adverse interaction of warfarin use occurs in a patient with marginal dietary vitamin K intake (postoperative state) who is given a broad-spectrum antibiotic, reducing enteric bacterial synthesis of vitamin K, resulting in increased sensitivity to warfarin. Starting warfarin therapy early after heparin therapy (day 1 or 2) has many advantages, including earlier hospital discharge on adequate oral anticoagulation and potential reduction in the incidence of HIT. The metabolism of warfarin may be affected by other drugs metabolized by the cytochrome P-450 enzyme complex, drugs that displace albumin-bound warfarin into the circulation, drugs that impair gastrointestinal absorption, and many antibiotics that alter the natural flora of the colon (an endogenous source of vitamin K). Certain genotypes for CYP2C9 and VKORC1 have a significant effect on the pharmacokinetic and pharmacodynamic response to warfarin dosing, respectively. Although there is a clear gene-dose relationship, it is uncertain if the routine use of genotype-guided warfarin dosing improves clinical outcomes. Yet, as clinical dosing algorithms are increasingly refined, the prospects for warfarin pharmacogenetics increase. Clinical outcome trials are underway to determine definitively the role of genetic testing in routine warfarin therapy.
Certain patients may require very large doses of warfarin (>50 mg/day) to achieve therapeutic anticoagulation; the term warfarin resistance has been applied. Patients who are difficult to anticoagulate with warfarin, either because they exhibit warfarin resistance or because they are very sensitive to the drug and cannot be safely regulated, may be candidates for long-term parenteral anticoagulants, or a novel oral anticoagulant.

Laboratory Monitoring of Warfarin Therapy

The PT assay is useful to monitor warfarin therapy, because this assay measures three vitamin-K-dependent coagulation proteins: Factors VII, X, and prothrombin. The PT is particularly sensitive to factor VII deficiency; with a half-life of 4 to 6 hours, the factor VII level may drop rapidly after only 1 day of warfarin therapy and prolong the PT value. However, because the other vitamin-K-dependent proteins have longer half-lives, therapeutic anticoagulation takes 4 to 5 days.

There is no advantage to giving larger loading doses of warfarin (e.g., >10 mg); this regimen only results in a more rapid drop in factor VII levels, delay in attainment of a stable PT, a precipitous fall in protein C levels, and predisposition to warfarin-induced skin necrosis.

To understand current recommendations for monitoring warfarin therapy, it is important to appreciate the concept of the INR, a method that standardizes PT assays. An international reference thromboplastin preparation has been adopted by the World Health Organization (WHO). Each new commercial thromboplastin is calibrated against the primary WHO reference preparation. These results are used to calculate the relative sensitivity of the unknown preparation compared with the WHO standard (international sensitivity index [ISI]). The method to determine the ISI for a particular thromboplastin is depicted in Figure 55.7. By adjusting for the ISI of a particular thromboplastin, an INR, defined as the PT ratio that would have been obtained if the WHO standard thromboplastin had been used, can be determined. The INR is calculated using the following formula: INR = (PT ratio)\(^{ISI}\) (Fig. 55.8).

The American College of Chest Physicians' consensus panel recommends low-intensity warfarin therapy (INR, 2.0 to 3.0) for all indications except prosthetic mechanical heart valves and prophylaxis of recurrent MI, for which higher-intensity warfarin therapy (INR, 2.5 to 3.5) is suggested.\(^{438}\)
FIGURE 55.7. Method for determination of an international sensitivity index (ISI) value for a laboratory's thromboplastin preparation. Log prothrombin time (PT) values are determined using a reference thromboplastin reagent and the commercial laboratory thromboplastin reagent on patients receiving stable (2 weeks) oral anticoagulant therapy and a group of normal, untreated volunteers. The best-fit line is determined, and the slope of this line multiplied by the ISI of the reference thromboplastin reagent is the ISI value for the commercial thromboplastin reagent. From Rodgers GM. Laboratory monitoring of anticoagulant and fibrinolytic therapy. In: Kjeldsberg C, McKenna R, Perkins S, et al., eds. Practical diagnosis of hematologic disorders, 2nd ed. Chicago, IL: ASCP Press, 1995:745-755, with permission.

Adverse Effects of Warfarin Therapy

Bleeding. A direct relationship exists between the risk of bleeding and the intensity of anticoagulation, with patients receiving higher-intensity (INR > 3.0) therapy having a fivefold greater risk of bleeding. Other major factors contributing to bleeding include co-existing conditions such as structural gastrointestinal lesions, hypertension, renal disease, and cerebrovascular disease. Investigation of patients who experience visceral bleeding while on warfarin therapy often results in identification of structural disease. Highest bleeding rates occur early in the course of warfarin therapy and in patients with cerebrovascular disease. For patients given low-intensity warfarin therapy for prophylaxis of VTE, the risk of major bleeding is <1%. Antiplatelet medications or other drugs that potentiate warfarin activity are important contributors to bleeding (Table 55.10).
FIGURE 55.8. Relationship between a patient’s prothrombin time (PT) ratio on warfarin therapy and the corresponding international normalized ratio (INR) value. The slope of the line represents the international sensitivity index (ISI) value of the particular thromboplastin preparation used in the laboratory’s PT assay. In this example, for low-intensity warfarin therapy (INR 2.0 to 3.0), a PT ratio between 1.50 and 1.75 would be required. Thromboplastins with higher ISI values would have slopes greater than that shown and would be less sensitive reagents for the PT assay, whereas thromboplastins with lower ISI values would have slopes less than that shown (more sensitive reagents). From Greenberg PL, Negrin R, Rodgers GM. Hematologic disorders. In: Melmon KL, Morrelli HF, Hoffman BB, et al., eds. Clinical pharmacology: basic principles in therapeutics, 3rd ed. McGraw-Hill, 1992:524-599, with permission.

Treatment strategy of bleeding in patients receiving warfarin depends on several factors: The duration of expected warfarin therapy, the severity of bleeding, and the extent of INR elevation. Patients with minor bleeding (bruising, microscopic hematuria) and an INR of <6.0 can have warfarin withheld until the INR approaches the desired INR target. Warfarin can then be resumed at a lower maintenance dosage. If patients have visceral bleeding that is not immediately life threatening, their coagulopathy can be reversed with vitamin K, 2.5 to 10 mg, IV or PO. Patients with significant emergent bleeding should be reversed with freshfrozen plasma (4 to 5 U) or prothrombin complex concentrates in addition to parenterally administered vitamin K. If the INR < 10 and no clinical bleeding exists, several warfarin doses should be held and the INR reassessed; the routine administration of vitamin K in these patients does not lead to improved outcomes and is not recommended. For an INR > 10 in patients without bleeding, oral vitamin K can be given (2 to 10 mg) and repeated at 12- to 24-hour intervals, depending on posttreatment INR values and the patient’s clinical condition. Failure of vitamin K to correct the coagulopathy suggests that another process is present, such as liver disease or DIC. The management of warfarin overdosage and reversal has been reviewed.

Patients who ingest rodenticides that contain long-acting vitamin K antagonists (“superwarfarins”) may require massive daily doses (≥100 mg) of vitamin K to correct the coagulopathy, for periods of weeks to months (see Chapter 54).

For patients on long-term warfarin therapy who require temporary interruption for procedures or elective surgery, an individualized risk-benefit assessment should be performed to determine the need for bridging therapy with a parenteral anticoagulant during the period of interruption (i.e., when warfarin is discontinued 4 to 5 days before surgery; Table 55.11). Postoperatively, heparin or LMWH can be used to achieve anticoagulation overlap until re-initiation of therapeutic warfarin has been achieved; however, in most cases after a major surgical procedure, the use of therapeutic-dosed
Parenteral anticoagulants should be avoided in the first 48 to 72 hours postoperatively due to a high risk of bleeding. A warfarin embryopathy can occur when pregnant mothers receive warfarin during the first trimester. A bone matrix protein, osteocalcin, is vitamin-K-dependent, and in the presence of vitamin K deficiency induced by warfarin, osteocalcin is synthesized in a nonfunctional manner, resulting in fetal bone malformations. Additional fetal abnormalities have been noted when warfarin is used during pregnancy. Because of these fetal risks, most practitioners avoid warfarin during pregnancy.

$^a$ CHADS2 stroke score is calculated by adding one point for each of: congestive heart failure, hypertension, Age > 75 years old, diabetes and 2 points for prior stroke. Adapted from Douketis JD, Spyropoulos AC, Spencer FA, et al. Perioperative management of antithrombotic therapy: antithrombotic therapy and prevention of thrombosis, 9th ed: American college of chest physicians evidence-based clinical practice guidelines. Chest 2012;141(2):e326S-e350S.

Warfarin-induced Skin Necrosis. Skin necrosis is an unusual but devastating complication of warfarin therapy, occurring within the first week of initiating therapy. Affected patients have usually received large loading doses of warfarin, perhaps in the absence of therapeutic heparin anticoagulation. The basis for this complication is thought to be a warfarin-induced rapid reduction in protein C levels in patients with a pre-existing inherited protein C deficiency that results in a hypercoagulable state and thrombosis. Not all heterozygous protein-C-deficient patients receiving warfarin experience this complication, and not all patients with this complication have protein C deficiency.

Clinically, the skin lesions begin on certain subcutaneous areas of the body (breasts, abdomen, thighs) as erythematous patches. Lesions progress to blebs followed by demarcated skin necrosis. Skin biopsy reveals generalized thrombosis of skin vessels. This complication may require amputation, plastic reconstructive surgery, or both. The use of standard maintenance doses of warfarin (5 to 10 mg/day) beginning after patients are therapeutically anticoagulated with heparin may avoid this complication. Patients who experience warfarin-induced skin necrosis should be heparinized, warfarin should be discontinued, and vitamin K should be administered promptly. Patients experiencing this complication should be screened for protein C deficiency. A few cases of warfarin-induced skin necrosis have been reported in protein-S-deficient patients. A literature review of warfarin-induced skin necrosis found that warfarin therapy could be re instituted in affected patients; smaller initial doses of warfarin were recommended.
The “purple toe syndrome” is an uncommon disorder that has been described in patients with underlying atherosclerotic vascular disease who are receiving anticoagulants including warfarin therapy. These patients present with atheroembolic symptoms including ischemic toes (purple toes), livedo reticularis, gangrene, abdominal pain, or symptoms of renal infarction. Involved visceral organs include the kidneys, pancreas, spleen, and liver. This complication may be difficult to distinguish from warfarin-induced skin necrosis, except that on biopsy, cholesterol emboli are present in the purple toe syndrome, and widespread vascular thromboses are seen in skin necrosis. Treatment involves prompt recognition of the syndrome and discontinuation of warfarin therapy.

Novel Oral Anticoagulants. Warfarin has substantial limitations including inter- and intrapatient dosing variability, drug-drug and drug-diet interactions, and a narrow therapeutic index. These limitations necessitate routine laboratory monitoring and dose adjustment that can be cumbersome for some patients. An oral anticoagulant that is safe and effective, has predictable pharmacology, has few drug-drug and drug-diabetic interactions, and does not require laboratory monitoring has the potential to revolutionize the chronic management of patients with atrial fibrillation, prosthetic heart valves, and recurrent venous thrombosis as well as facilitate better compliance with out-of-hospital thromboprophylaxis regimens. Over the past 5 years, there has been a rapid emergence of such novel oral anticoagulants (NOACs) into the clinical landscape. At the forefront are the oral DTI dabigatran etexilate and the oral factor Xa inhibitors (e.g., rivaroxaban, apixaban, and edoxaban). Tables 55.12 and 55.13 summarize the properties of the NOACs that are currently available for clinical use and the comparative results of large-scale studies in patients with atrial fibrillation, respectively. It is important to note that numerous additional agents are also currently under investigation.

Dabigatran Etxetiate

Dabigatran etexilate is an oral prodrug that is rapidly converted by serum esterases to dabigatran, a potent univalent DTI. Oral bioavailability is ~6% to 7%, and uptake is reduced by proton pump inhibitors and delayed with food; however, these kinetic alterations are not thought to be clinically significant and do not require dose adjustments. Peak dabigatran serum levels occur ~2 hours after an oral dose; dabigatran is primarily eliminated by renal clearance, and has a half-life of ~14 to 17 hours. Although a reduced dose has been approved for use in the United States by the FDA for patients with a creatinine clearance of less than 30 ml/minute, this recommendation is solely based upon drug kinetic modeling, and the drug is contraindicated in patients with a clearance <15 ml/minute. A reduced dose should also be considered for frail elderly patients with a reduced creatinine clearance; however, no dose reduction is needed at any age for patients with normal renal function. Strong p-glycoprotein inhibitors (e.g., quinidine, ketoconazole) and inducers (e.g., rifampin, St John’s Wort) affect serum levels. Because of the predictability in dose-response, laboratory monitoring is unnecessary. If, however, laboratory assessment is required (e.g., need for urgent surgery or management of bleeding) a normal aPTT, thrombin time, or ecarin clotting time suggest little drug activity is present. Conversely, the INR is insensitive to the presence of dabigatran and is not a useful test for drug presence. Table 55.14 suggests a management approach to patients requiring temporary interruption of anticoagulation for an invasive procedure. As with all anticoagulants, the primary adverse effect of dabigatran is an increase in bleeding risk. In addition, dabigatran is associated with an increased risk of dyspepsia, and in some clinical trials has been associated with higher gastrointestinal bleeding rates and myocardial ischemia events as compared to warfarin. In cases of overdose, the rapid administration of charcoal may decrease absorption, and hemodialysis can remove 60% of plasma drug levels. Management of bleeding is problematic as there is no known reversal agent. Patients who have bleeding on dabigatran should be managed with aggressive conservative measures including active control of bleeding site. In cases of life-threatening bleeding, the administration of recombinant factor VIIa or activated prothrombin complex concentrates can be tried, although their utility is unproven.

To date, dabigatran etexilate has undergone extensive clinical investigation in the REVOLUTION program, a large clinical trials program assessing the efficacy and safety of dabigatran across a variety of indications. For a recent and thorough survey of clinical trial results, we refer the reader to a recent review.\textsuperscript{473} Based upon the results of the RE-LY trial, dabigatran etexilate is currently approved in the United States for the prevention of stroke and systemic embolism in patients with atrial fibrillation.\textsuperscript{475} In RE-LY, 18,113 patients with nonvalvular atrial fibrillation and at least one additional stroke risk factor were randomized to receive warfarin or dabigatran dosed either 110 mg or 150 mg twice daily. Dabigatran dosed at 110 mg twice daily was demonstrated to be noninferior to warfarin (RR, 0.91; 95% [CI], 0.74 to 1.11; \(p < 0.001\)), and dabigatran dosed at 150 mg twice daily was demonstrated to be superior to warfarin (RR, 0.66; 95% [CI], 0.53 to 0.82; \(p < 0.001\)) in preventing the primary outcome of stroke or systemic embolism. As compared to warfarin, major bleeding, the primary safety outcome, was less common in the 110-mg twice-daily dabigatran group (RR, 0.80; 95% [CI], 0.69 to 0.93; \(p = 0.003\)), but was similar when compared to the 150-mg twice-daily dose (RR, 0.93; 95% [CI], 0.81 to 1.07; \(p = 0.31\)), but hemorrhagic stroke was lower for both dabigatran doses.\textsuperscript{475} Using a composite of adverse clinical events (stroke, systemic embolism, MI, death, PE, and major bleeding), dabigatran was clearly superior for those patients on warfarin who have a time in TTR of less than 57.1% whereas benefit was less certain in those with a TTR of >72.6% with hazard ratios of 0.67 (95% CI, 0.56 to 0.80) and 1.11 (95% CI, 0.91 to 1.35), respectively.\textsuperscript{476}

Oral Factor Xa Inhibitors

Because of the demonstrated efficacy and safety of factor Xa inhibition with fondaparinux, oral factor Xa inhibitors have entered the clinical landscape. Oral factor Xa inhibitors that are available for clinical use or are in development include rivaroxaban (Bayer Healthcare), apixaban (Bristol Myers Squibb/Pfizer), edoxaban (Daiichi), betrixaban (Portola), and TAK-442 (Takeda).\textsuperscript{471} Currently, rivaroxaban and apixaban are the most advanced in their clinical trials programs and are approved for use in the European Union, Canada, or the United States.

Rivaroxaban is a reversible small molecule direct factor Xa inhibitor that binds to and inactivates both fluid-phase factor Xa as well as factor Xa associated with the prothrombinase complex. Rivaroxaban has an oral bioavailability of ~60% to 80%, with peak levels achieved 2 to 3 hours after an oral dose. The drug is metabolized in part by both CYP3A4-dependent and CYP3A4-independent pathways, and has an elimination half-life of ~7 to 11 hours. The kidneys eliminate approximately 35% of active drug as well as inactive metabolites. Potent combined P-gp and CYP3A4 inhibitors (e.g., ketoconazole, itraconazole, lopinavir/ritonavir, ritonavir, indinavir/ritonavir, and conivaptan) and inducers (e.g., carbamezapine, phenytoin, rifampin, St John’s Wort) should be avoided in patients on rivaroxaban because they can significantly increase or decrease plasma drug concentrations, respectively.

Rivaroxaban is currently approved for the prevention of VTE in patients undergoing elective joint replacement surgery, the prevention of stroke and systemic embolism in patients with nonvalvular atrial fibrillation, and the treatment of VTE.

In the RECORD trials, rivaroxaban (10 mg daily) was compared to enoxaparin for thromboprophylaxis in patients undergoing elective joint replacement surgery. In a pooled analysis, the combined endpoint of symptomatic VTE and mortality occurred less often in patients receiving rivaroxaban (1.3% vs. 0.6%, p < 0.001), whereas clinically relevant bleeding was more frequent (2.6% vs. 3.3%, p = 0.026). The ROCKET-AF trial was a large (n = 14,000) double-blind, noninferiority, randomized trial comparing rivaroxaban (20 mg daily in patients with normal renal function and 15 mg daily in patients with a creatinine clearance of 30 to 49 ml/min) to adjusted-dose warfarin (target INR 2 to 3) in patients with atrial fibrillation who were at an increased risk of stroke or systemic embolism. Rivaroxaban met the prespecified endpoint of stroke/systemic embolism occurrence with a HR of 0.88 (95% CI 0.74 to 1.03, p < 0.001 for noninferiority), had similar rates of major bleeding (HR 1.04, 95% CI 0.9 to 1.2, p = 0.58), and less intracranial hemorrhage (HR 0.67, 95% CI 0.47 to 0.93, p = 0.02).

**Thrombolytic Drugs**

The major reaction of the fibrinolytic (plasminogen) system involves the conversion by PAs of the inactive proenzyme, plasminogen, into the active enzyme, plasmin. Plasmin can degrade fibrinogen, fibrin monomers, and cross-linked fibrin (as found in thrombi) into FDPs. These plasmin-mediated reactions generate many species of FDPs including unique species of FDP such as fragment X from fibrinogenolysis and cross-linked FDPs such as (DD)E- and D-dimer from cross-linked fibrin. Knowledge of these reactions is necessary to appreciate the mechanisms of action and limitations of commercial PAs.

A common feature of the management of all thromboembolic diseases is the desire to restore vascular patency in a timely fashion to prevent loss of tissue, organ, and limb function, as well as life. Acute arterial thrombosis warrants an attempt at immediate thrombolysis, whereas venous thrombosis only warrants such intervention in extreme cases. Recognition of the importance of the endogenous fibrinolytic system in limiting the size of hemostatic thrombi, clearing hemostatic thrombi after vascular repair, and preventing pathologic thrombosis has resulted in the development of pharmacologic fibrinolytic (thrombolytic) agents to facilitate rapid restoration of vascular patency. Most thrombolytic agents are recombinant forms of physiologic PAs. The commercially available PAs differ with regard to plasma half-life, fibrin selectivity, primary clinical usage, primary infusion strategy, and immunogenicity. Currently available and investigational PAs and their key characteristics are summarized in Table 55.15.

Most thrombolytic agents are fashioned after endogenous t-PA or urokinase. Traditional thrombolytic drugs include bacteriaderived streptokinase (SK), anisoylated plasminogen 5K activator complex, urokinase (two-chain u-PA), and recombinant t-PA (rt-PA). Newer molecules have been and are being developed in an attempt to improve on the
traditional agents. Major goals of new thrombolytic agent development include increasing fibrin specificity, theoretically to reduce bleeding complications, prolonging initial plasma half-life to facilitate single- or double-bolus administration, reducing sensitivity to inactivation by PAI-1, and improving production efficiency. New thrombolytic agents include mutants of PAs, chimeric PAs, conjugates of PAs with monoclonal antibodies, and novel PAs from animal or bacterial origin. Non-PA thrombolytic agents that can degrade fibrin and/or fibrinogen directly (e.g., microplasmin, alfimeprase, and ancrod) are also under investigation.

**Streptokinase**

SK is obtained from cultures of β-hemolytic streptococci. By itself, SK has no PA activity, but after combining with plasminogen, a complex is formed that is capable of activating other plasminogen molecules to plasmin. Purified SK has a molecular weight of 47,000 D. SK was the first clinically used thrombolytic agent. It is not fibrin-selective in that its therapeutic use results in systemic fibrin(ogen)olysis and what is termed the lytic state from proteolysis of fibrinogen, factors V and VIII, and other plasma proteins. Platelet function may also be perturbed, because plasmin can proteolyze key platelet membrane receptors. Generation of FDPs also contributes to the significant hemostatic defect of thrombolytic therapy. Although the lytic state predisposes patients to bleeding, the benefit of decreased blood viscosity that results from the lytic state may be clinically important. The half-life of SK is ~20 minutes. Because SK is a bacterial protein, it is antigenic, and allergic reactions occur in ~6% of patients. Anaphylaxis during SK use occurs in ~0.1% of patients. Patients previously exposed to SK or those with previous streptococcal infections may acquire ...
antistreptococcal antibody levels sufficient to neutralize the activity of SK. Therefore, all patients receiving SK should be monitored to ensure attainment of the lytic state. This can be done with the thrombin time assay. SK has been used primarily to treat VTE and MI, as well as to treat central venous access-device-associated thrombosis.

**Urokinase-type Plasminogen Activator**

In the past, u-PA was obtained from human fetal kidney cell cultures. It is currently produced using nonhuman mammalian tissue cultures. Its molecular weight is 34,000 D. u-PA is not fibrin-selective, and this drug also produces a lytic state. The half-life of u-PA is ~15 minutes. u-PA is used to treat VTE, MI, and thrombolysis of clotted catheters.

**Tissue-type Plasminogen Activator**

Currently, t-PA is produced by recombinant technology as a two-chain species, with a molecular weight of ~65,000 D. In vitro, t-PA is fibrin-specific, because of its high affinity for fibrin with which it forms a ternary complex with plasminogen. However, with t-PA dosage regimens currently being used, the lytic state is produced in vivo. Consequently, bleeding complications with t-PA are similar to those with SK or u-PA. The half-life of t-PA is much shorter than that of SK or u-PA, ~5 minutes. t-PA is used to treat VTE and acute MI, and has also been approved for use in acute ischemic stroke (within 3 hours of stroke onset) and venous catheter withdrawal occlusion. Laboratory monitoring of t-PA therapy is usually not recommended.

**Tissue-type Plasminogen Activator Variants**

Recombinant PA (r-PA; reteplase) is a nonglycosylated deletion mutant of wild-type human t-PA comprised of only the kringle 2 and the protease domains of the parent molecule. Lack of the finger domain imparts lower fibrin-binding affinity. Lack of glycosylation, a finger domain, and an epidermal growth factor domain impart an extended half-life (15 minutes vs. 5 minutes). The longer half-life allows for double-bolus administration. The longer half-lives of r-PA and TNKrt-PA compared with t-PA facilitate bolus administration primarily for acute coronary thrombosis.

**Other Plasminogen Activators**

Recombinant glycosylated prourokinase (single-chain u-PA) has a greater stability than recombinant nonglycosylated prourokinase and has been evaluated for catheter-directed, intra-arterial treatment of stroke. Staphylokinase is produced by Staphylococcus aureus. It appears to have substantial thrombolytic activity, but it may also be immunogenic. Vampire bat (Desmodus rotundus) salivary PA (rDSPAα1, desmoteplase) possesses >72% primary structure homology to human t-PA but lacks a kringle 2 domain which may impart greater fibrin specificity. Finally, although not a PA, plasmid therapy has been investigated in arterial vascular disease.

**Thrombolytic Therapy-Associated Bleeding**

Bleeding is the most common complication associated with thrombolytic therapy, regardless of the agent. The bleeding stems from plasmin's inability to distinguish between hemostatic and pathologic thrombi. This complication can range from minor bleeding at an intravenous infusion site to life-threatening hemorrhage. Intracranial hemorrhage is a relatively uncommon but serious complication of thrombolysis in patients being treated for acute MI.

The factors that increase the risk for bleeding during thrombolytic therapy are not fully understood. However, Gurwitz and associates used the National Registry for MI to determine risk factors for this adverse event in individuals treated with t-PA. Their analysis of 673 patients with intracranial hemorrhage indicated that older age, female sex, black ethnicity, systolic blood pressure ≥140 mm Hg, diastolic blood pressure ≥100 mm Hg, history of stroke, t-PA dose ≥1.5 mg/kg, and lower body weight were all significantly associated with an increased risk for intracranial hemorrhage. It is also possible that the properties of the agent used for thrombolysis may contribute to the risk for bleeding complications.

**Thrombolytic Fibrin Specificity and Hemorrhagic Risk**

Thrombolytic agents can be characterized along a variety of dimensions, but one that is often mentioned is fibrin specificity. The ability of a thrombolytic agent (PA) to distinguish between plasminogen in the general circulation and plasminogen bound to fibrin surfaces dictates its fibrin specificity. Activation of fibrin-bound plasminogen results in the generation of fibrin-bound plasmin that is protected from inactivation by α2-antiplasmin. Bound plasmin generates soluble fibrin degradation products; circulating plasmin degrades fibrinogen into FDPs. Fibrin specificity differs from fibrin affinity, which is a measure of how avidly a given agent binds to fibrin, but not its specificity for this molecule. At present, there is little evidence to support the view that differences in fibrin affinity among PAs are significantly correlated with either the efficacy or safety of these preparations. High fibrin specificity is thought to be associated with lower risk for hemorrhagic complications in patients undergoing thrombolytic therapy because of the belief that plasmin generated on
the fibrin surface of a thrombus restricts its activity only to that surface. This view is not universally supported by available data from large-scale clinical trials.

A relationship between high fibrin specificity and reduced bleeding risk has been demonstrated. The results of the Assessment of the Safety and Efficacy of a New Thrombolytic (ASSENT)-2 trial, which included 16,949 patients with acute MI, showed that the use of the highly fibrin-specific thrombolytic agent TNK-tPA, compared with rt-PA, was associated with a significantly lower risk for major noncerebral bleeding. This lower rate of bleeding complications was correlated with a significant reduction in the need for blood transfusions. The ASSENT-2 investigators also reported that TNK-tPA was associated with a significantly lower risk for noncerebral bleeding than the lessspecific agent alteplase. Intracranial bleeding rates were comparable with the two agents.

Results from other large-scale studies support the opposing view that high fibrin specificity may actually be associated with increased risk for intracranial bleeding in patients undergoing thrombolytic therapy for acute MI. For example, the Global Utilization of Streptokinase and Tissue Plasminogen Activator for Oculuded Coronary Arteries (GUSTO) trial showed that the risk of intracranial bleeding was slightly higher in 41,021 patients with MIs who received treatment with rt-PA as compared with SK. These findings are consistent with those from another very large-scale comparison of SK with rt-PA in 20,768 patients with MI (Gruppo Italiano per lo Studio della Streptochinas nell'Infarto Miocardico 2 [GISSI-2]), which showed a significantly higher risk of stroke in patients who received the latter, more fibrin-specific agent. Similarly, the Third International Study of Infarct Survival (ISIS-3) showed that treatment of patients with anisoylated plasminogen SK activator complex was associated with increased risk for intracranial bleeding compared with SK in a large cohort of 41,299 patients who received thrombolytic therapy for suspected MI.

There are a number of potential explanations for the association between high fibrin specificity and increased intracranial bleeding observed in the patients treated in the GUSTO, GISSI-2, and ISIS-3 trials. These include the inability of fibrin-specific agents to distinguish between pathologic thrombi and hemostatic thrombi, and the possibility that treatment with fibrin-specific agents resulted in greater degradation of hemostatic fibrinogen and other circulating coagulation factors than SK. Finally, it may be that fibrin-specific therapy resulted in increased production and accumulation of fragment X, and that this enhanced the bleeding risk.

VENOUS THROMBOEMBOLIC DISEASE

VTE, encompassing both DVT and PE is a common disease that carries a substantial risk of morbidity and mortality, is associated with high healthcare costs, and for many patients can be prevented. It has been estimated that between 500,000 and 2 million VTE cases, including calf vein thrombosis, proximal DVT, and PE, occur annually in the United States alone. It is estimated that up to 50% of DVT and PE are asymptomatic or undetected.

The major clinical consequences of extremity DVT include the PTS (chronic swelling, stasis dermatitis, stasis ulceration, and venous claudication: All secondary to venous insufficiency) and PE. The major clinical consequences of PE include acute lung infarction, chronic dyspnea, chronic pulmonary hypertension, and death. DVT restricted to the calf veins uncommonly results in clinically important PE and is rarely associated with a fatal outcome. In contrast, inadequately treated DVT involving the popliteal or more proximal leg veins is associated with a 20% to 50% risk of clinically relevant recurrence and is strongly associated with both symptomatic and fatal PE. In untreated patients, death from PE occurs most frequently within 24 to 48 hours of initial presentation. All-cause mortality rates in treated patients with PE is as high as 11% at 2 weeks and 17% at 3 months. Even small PE in patients with emphysema, cardiac disease, or lung involvement with malignancy may result in death. Any VTE in a patient with a contraindication to anticoagulation presents a therapeutic challenge and greater likelihood of adverse outcome.

Management of Venous Thromboembolism

For a majority of patients with VTE, treatment is traditionally straightforward and includes an initial treatment phase (first 5 to 7 days) wherein there is an immediate initiation of a therapeutically dosed parenteral anticoagulant (e.g., heparin or low-molecular-weight heparin) and simultaneous initiation of long-term therapy (e.g., vitamin K antagonist), followed by a long-term treatment phase (from 5 to 7 days to 3 months) where the parenteral anticoagulant is discontinued, and VKA therapy is continued, and then an extended treatment phase (3 months to indefinite) where there is a decision to continue treatment or not. The emergence of the NOACs will greatly simplify this approach for a majority of patients.
Initial Treatment of Venous Thromboembolism

The mainstay of pharmacologic therapy for VTE is anticoagulation. A delay in achieving therapeutic anticoagulant intensity may have a negative effect on a patient's long-term VTE recurrence rate. V18 V19 VKA have a delayed onset of action and the necessity of instituting a rapid-onset parenteral anticoagulant (e.g., heparin) in patients with acute VTE during VKA initiation has been highlighted. V20 As long as warfarin is dosed to a therapeutic level, overlap therapy with heparins can be minimized to 5 days. V17, V21, V22

UFH remains the preferred initial parenteral anticoagulant for certain patients with acute VTE such as those with end-stage renal disease. When heparin is used, weight-based dosing (80-U/kg bolus followed by 18 U/kg/hour) with subsequent dose adjustments based on a standardized nomogram (Table 55.7) facilitates achieving a target aPTT. V23 Use of any published nomogram helps facilitate the rapid achievement of target intensity anticoagulation. Adjusted-dose subcutaneous UFH, intermittent intravenous UFH boluses, and fixed dose subcutaneous heparin have also been used effectively in the treatment of VTE. V12, V14, V25 The therapeutic intensity of UFH is monitored using the aPTT. An aPTT therapeutic range that correlates with an anti-FXa activity level of 0.3 to 0.7 U/ml is preferred. V37 The aPTT should be checked every 4 to 6 hours until the aPTT surpasses the minimum of the therapeutic range.

As compared to heparin, weight-based subcutaneous LMWH is a preferred treatment option for most patients with acute VTE. V11 In 1992 two separate groups of investigators demonstrated that fixed-dose LMWH therapy was at least as safe and effective as adjusted-dose intravenous heparin in patients with proximal vein thrombosis. V26, V27 Subsequently, numerous other comparative trials have been performed, and in a meta-analysis of 13 comparative trials Dolovich et al. V28 demonstrated the LMWHs to be comparable to heparin for the initial treatment of VTE with regard to recurrence, major bleeding, and total mortality. V28 Similarly, in a meta-analysis of 2,110 patients who presented with acute symptomatic PE, LMWH were found to be at least as effective (OR for recurrence, 0.68, 95% CI, 0.42 to 1.09) and safe (OR for major bleeding, 0.67, 95% CI, 0.36 to 1.27) as heparin. V29 Enoxaparin sodium is dosed at 1.0 mg/kg body weight every 12 hours or 1.5 mg/kg once daily. V50 Tinzaparin is dosed at 175 U/kg once daily. V17 Dalteparin is dosed at 200 U/kg (up to 18,000 U) once daily. The Matisse trials also support the use of fondaparinux in patients with VTE with efficacy and safety at least as good as LMWH. V17, V31

Efficient initial dosing of VKA therapy in patients with VTE minimizes excessive duration (i.e., beyond 5 to 7 days) of potentially costly parenteral anticoagulants and may allow for shorter hospitalization. The use of standardized warfarin initiation dosing nomograms has been shown to be efficient and safe. V45, V52, V53 In two separate studies of predominantly inpatients, dosing nomograms using a 5-mg initial dose was compared to 10 mg and shown to be effective in achieving a therapeutic INR within 5 days with less risk of excessive anticoagulation. V45, V52 More recently a 10-mg initial VKA dose nomogram in outpatients being treated for VTE had a greater percentage of patients achieving a therapeutic INR by day 5 of therapy with no difference in excessive anticoagulation or adverse events as compared to a lower initial dose. V53 Lower initial doses (e.g., 5 mg or less) may be most appropriate for those patients who are elderly, have low body weight, are on interacting medications, or have poor nutrition, whereas a higher dose (e.g., 10 mg) may be acceptable for others.

The initial treatment of VTE used to be confined to the inpatient setting; however, two clinical trials demonstrated that outpatient LMWH treatment for carefully selected patients with acute DVT is safe and effective and can lead to substantial cost savings. V54, V55, V56 Assuming an appropriate care-delivery system is in place, outpatient DVT treatment has become appropriate for a majority of DVT patients except perhaps, those with massive iliofemoral DVT, a high bleeding risk, or substantial co-morbid illness that otherwise necessitates hospitalization. V57 Appropriate initial site-of-care for patients who present with acute PE is more controversial. Unlike patients with acute DVT, patients with acute PE represent a very heterogeneous risk-group with 3-month mortality rates ranging from 1.4% to 17.4%. V52, V58 Standardized clinical assessments, biomarkers, and right ventricular size on imaging can all help to identify patients with a favorable prognosis. For carefully selected, low-risk patients with acute PE, a predominantly outpatient management approach has been shown to be safe and effective. V59

Anticoagulation Considerations in Special Populations with Venous Thromboembolism

In occasional patients with thrombosis, the aPTT assay may not be reliable in monitoring UFH therapy, for example, patients with the lupus anticoagulant and a prolonged baseline aPTT. For these patients, one option would be to use UFH levels that can be obtained by an automated assay using an anti-factor Xa method. In this instance, the targeted therapeutic range would be 0.35 to 0.7 U/ml. Alternatively, these patients could be given LMWH or fondaparinux, with
the dosage determined solely by body weight and no necessity for laboratory monitoring. Patients with marked elevation in factor VIII levels may also be more reliably anticoagulated using LMWH.400

Obese patients are underrepresented in VTE treatment trials, and that has led to uncertainty about optimal LMWH dosing in these patients.540, 541 Studies evaluating drug (e.g., dalteparin, enoxaparin, tinzaparin) activity with the use of anti-Xa activity levels, suggest the pharmacodynamics of LMWHs in obese patients (weighing up to 190 kg) are similar to nonobese patients.542, 543, 544 Consequently, weight-based dosing (using total body weight) in obese patients without dose-capping and without anti-Xa monitoring appears appropriate.540, 542 However, due to limited published experience, anti-Xa monitoring with subsequent dose adjustment should be considered in patients at extreme weights, i.e., those patients weighing over 190 kg in whom LMWH are used.540

The concomitant presence of renal insufficiency (creatinine clearance [CrCl] <30 ml/minute) is associated with worse outcomes, including fatal bleeding, in patients with VTE.545 Although inconsistent, the LMWHs have a significant degree of renal clearance with anti-Xa activity levels strongly correlating with CrCl and drug accumulation occurring in those patients with a CrCl less than 30 ml/minute.397 Clinically, unadjusted LMWH therapy is associated with greater bleeding complications (OR 2.25, 95% CI 1.19 to 4.27) in patients with CrCl <30 ml/min compared to those without renal impairment.546 Because of potentially worse outcomes with LMWHs in patients with significant renal impairment, weight-based adjusted-dose UFH is recommended over LMWH for VTE treatment.397, 540, 541

Extended Treatment of Venous Thromboembolism

The optimal duration of anticoagulation should be determined for each individual patient. Patients with DVT secondary to a time-limited (transient) risk factor such as recent surgery, immobilization, trauma, or pregnancy may be anticoagulated for a short duration of 3 months, as long as the risk factor has resolved. Patients with recurrent unprovoked VTE (two or more events) or ongoing major risk factors, such as malignancy or antiphospholipid antibody syndrome, require indefinite therapy. Patients with a first unprovoked VTE should be anticoagulated for a minimum of 3 months and consideration should be given to longer duration of therapy.517 In general, patients with an unprovoked VTE have a risk of recurrence of ~5% to 7%/year after 3 months of therapy if anticoagulation is discontinued.517 Continuation of anticoagulation beyond 3 months (e.g., 6 or 12 months) reduces this risk as long as the patient remains on anticoagulation, but the heightened long-term recurrence risk remains unchanged once anticoagulation is discontinued. Unfortunately, residual thrombus on repeat imaging and the presence of the most common thrombophilias (e.g., heterozygote factor V Leiden mutation, prothrombin gene mutation, etc.) are only weak predictors of recurrence risk and so their utility in helping to decide whether to continue or stop anticoagulation after the initial 3 months in patients with unprovoked VTE is controversial.547, 548, 550 For these reasons, current guidelines suggest extended duration of therapy for patients with unprovoked VTE as long as the predicted long-term bleeding risk is estimated to be low.517 The use of posttreatment D-dimer to guide the decision to continue or stop anticoagulation after 3 months has potential utility.553 It is probable that with additional data, D-dimer testing will continue to have an emerging role in helping with duration of therapy decisions in some patients with unprovoked VTE. Guidelines for the duration of anticoagulant therapy are suggested in Table 55.16.

For those patients assigned to extended (e.g., beyond initial 3 months) duration therapy, the intensity of oral anticoagulation has been a subject of controversy. A consensus group concluded that low-intensity oral anticoagulation (INR 1.5 to 2.0) was less effective and no safer than standard-intensity therapy (INR 2.0 to 3.0).552

All patients anticoagulated with warfarin should be educated regarding maintaining a stable diet. Patients should be encouraged to consume a constant intake of dietary vitamin K and avoid large variations or fluctuations in their diet. Because of the number of pharmacologic interactions that exist between warfarin and other drugs (Table 55.10), patients should be instructed to inform their physician of the addition or withdrawal of any medication during warfarin therapy. In addition, patients should be encouraged to avoid over-the-counter multivitamin supplements or herbal preparations that contain vitamin K or vitamin K analogs and those known to have an effect on warfarin anticoagulation (e.g., ginkgo biloba). The risk of bleeding during therapy should be explained to all patients. It is strongly recommended that patients avoid high-risk activities, including contact sports. Patients should be instructed to seek medical attention for severe bleeding or bleeding that is not controlled after 10 to 15 minutes of continuous compression. The appropriate use of protective gear, such as bicycle helmets, should be emphasized. Patients should be instructed to carry a wallet card that identifies their use of an anticoagulant. In addition, they should be encouraged to wear a medical identification bracelet or necklace.

P.1250

Patient instruction is best provided by anticoagulation clinics that focus specifically on anticoagulation monitoring and education. Studies suggest that anticoagulation services offer better control of anticoagulation (time in therapeutic range,

<sup>a</sup> For example, malignancy, antiphospholipid antibody syndrome, or natural anticoagulant deficiency.

In select cases, LMWH may be used in lieu of oral warfarin for chronic-phase anticoagulation. Because of its teratogenic effects, warfarin therapy is contraindicated in pregnancy, so long-term heparin or LMWH is prudent for pregnant patients; LMWH may be preferred in pregnancy, because osteopenia occurs less often with LMWH than with UFH.<sup>558</sup>

In addition, patients with variable oral intake, episodic vomiting, malabsorption, and difficult to regulate INR values on warfarin may be better served by chronic subcutaneous LMWH administration.

The management, efficacy, and safety of VKA are particularly problematic in cancer patients with VTE.<sup>559</sup> Both recurrent VTE and major bleeding events are significantly more common in patients with cancer compared to those without the first month of therapy and are not explained by anticoagulant intensity outside the target range.<sup>560</sup> Due to the limitations of VKA in this population, long-term LMWH therapy has been evaluated as an alternative to LMWH followed by VKA in cancer patients with VTE. In the pivotal 2003 CLOT trial, Lee et al. randomized 672 patients with acute proximal DVT, PE, or both to either 6 months of dalteparin (200 IU per kilogram of body weight once daily for 1 month followed by 150 IU per kilogram once daily for 5 to 7 days of dalteparin followed by 6 months of VKA with a target INR of 2.5). During the 6-month study period, recurrent VTE was significantly less common in the long-term LMWH group (hazard ratio 0.48, 95% CI 0.30 to 0.77) without a difference in bleeding events or mortality.<sup>561</sup> In a separate randomized open-label clinical trial comparing usual care to longterm tinzaparin in patients with a proximal DVT in the setting of cancer (n = 200), Hull et al.<sup>562</sup> demonstrated long-term tinzaparin to be associated with fewer recurrent VTE events, 16% versus 7% (absolute risk difference -9%, 95% CI -21.7% to -0.7%).<sup>562</sup> Most recently, a Cochrane meta-analysis of six randomized trials showed that long-term LMWH, compared to usual therapy provided a reduction in VTE (HR 0.47, 95% CI 0.32 to 0.71) with no statistically significant survival benefit (HR 0.96, 95% CI 0.81 to 1.14) or difference in bleeding outcomes (RR 0.91, 95% CI 0.64 to 1.31).<sup>563</sup> From a patient perspective, long-term LMWH therapy is deemed acceptable and is preferable to VKA. Based upon favorable outcomes, long-term LMWH therapy in cancer patients is currently endorsed by numerous practice guidelines as the preferred therapeutic approach in these patients.<sup>517, 565, 566, 567</sup>

Novel Oral Anticoagulants for the Treatment of Venous Thromboembolism

Rivaroxaban has recently been approved for VTE treatment, and the continued emergence of the NOACs will likely change the treatment approach for many patients with VTE. Noninferiority trials have compared a single drug treatment approach (e.g., rivaroxaban) or treatment after an initial course of LMWH (e.g., dabigatran etexilate) to standard therapy in patients with acute VTE. Other similar trials evaluating apixaban and edoxaban are near completion. In the EINSTEIN-DVT trial (n = 3449), oral rivaroxaban, 15 mg twice daily for 3 weeks and then 20 mg once daily, was compared to standard therapy in patients with acute DVT.<sup>568</sup> Rivaroxaban was demonstrated to have both similar efficacy (hazard ratio for the primary endpoint of symptomatic recurrence was 0.68, 95% CI 0.44 to 1.04) and safety.<sup>568</sup> In a companion study of patients with acute PE, the EINSTEIN-PE trial (n = 4,832), as compared to usual therapy, rivaroxaban was similarly effective and safe, HR 1.12 (95% CI 0.75 to 1.68) and 0.49 (95% CI 0.31 to 0.79), respectively.<sup>569</sup> In the RE-COVER trial (n = 2,539), patients with acute VTE received either VKA or dabigatran, 150 mg twice daily, after an initial period of parenteral
anticoagulation with LMWH. After 6 months of therapy recurrence, HR 1.10, 95% CI 0.65 to 1.84, and major bleeding, HR 0.82, 95% CI 0.45 to 1.48, were similar. 570

Calf Deep Venous Thrombosis

Many perceive that calf DVT is of limited clinical significance. This misunderstanding and underappreciation of the potential morbidity and mortality associated with calf DVT have resulted in a lack of clear consensus on the optimal management strategy for this condition. Isolated calf DVT may account for as few as 6.2% of all symptomatic acute DVT and as many as 43.0% of all acute VTE. 572 Studies have also demonstrated that although calf DVT and proximal DVT may be considered separate diseases at their outset, 15% to 25% of calf DVT propagate into the proximal veins within 2 to 3 weeks wherein a risk of embolism ensues. 573, 574, 575 Such “proximal conversion” renders what was initially a calf DVT just as dangerous as any proximal DVT.

Whereas the primary goals of proximal DVT treatment include the prevention of DVT recurrence and PE, the most essential goals of calf DVT treatment should be to treat severe symptoms and to prevent early proximal conversion. Current treatment approaches for isolated calf DVT are either to implement the same intensity and duration of anticoagulant therapy as is used for proximal DVT or to implement serial duplex ultrasound surveillance, with therapy begun only in the event of proximal conversion or significant extension. Surveillance consists of serial imaging (e.g., twice weekly) for 2 weeks, the usual period for proximal conversion. The limitations of serial surveillance include cost, compliance, and convenience whereas anticoagulant therapy has limitations of cost, inconvenience, and risk of bleeding. Anticoagulation is preferable for those patients with a low bleeding risk who have severe symptoms or risk factors for extension (thrombus >5 cm, involves multiple calf veins, proximal extent near the calf trifurcation, ongoing underlying risk factors such as immobility or cancer, prior history of VTE, or occurrence without provocation). 517

Whereas 6 months of anticoagulation has been shown to be superior to 6 weeks’ duration of therapy in patients with proximal DVT, the shorter course of therapy has not been shown to be inferior in patients with initial distal thrombosis. 571 In general, calf vein DVT should be treated for 3 months. 517 However, patients with situational calf DVT (DVT with a clear precipitant such as major surgery or hospitalization) can be considered for only 6 weeks of treatment, assuming the precipitating illness or event has resolved. Inferior vena cava (IVC) filter placement is not recommended for calf DVT in most circumstances.

Advanced Therapies for Venous Thromboembolism

Vena Caval Filter

Patients with acute VTE and active bleeding require placement of an IVC filter, as do patients with acute VTE who have failed therapeutic anticoagulation. Relative contraindications to anticoagulation are listed in Table 55.17. It is important to note that active bleeding may be a treatable and transient contraindication to anticoagulation. An IVC filter should not be viewed as an equivalent substitute to anticoagulation in the setting of acute VTE and is certainly not an “insurance policy” against subsequent PE. The use of IVC filters has been associated with an increased risk of recurrent DVT, reduced PE, and no difference in overall mortality. 576, 577 In patients with filters placed because of bleeding, appropriate anticoagulation should begin as soon as the bleeding source has been properly and completely treated. Because of the significant risk of rebleeding, such a patient should have his or her anticoagulation begun in the hospital. Placement and subsequent removal of a temporary (or retrievable) IVC filter once the contraindication to anticoagulation has passed seems ideal. Placement of an IVC filter because of a “free-floating” DVT may not be necessary in all patients. 578 Guidelines on using IVC filters have been published. 517, 579

Catheter-directed Thrombolysis of Deep Venous Thrombosis

Catheter-directed thrombolytic therapy is usually reserved for patients with extensive DVT involving the IVC or iliac veins and for patients who have signs and symptoms of actual or impending phlegmasia cerulea dolens. An initial venogram is performed via a distal vessel, usually a popliteal or foot vein, to delineate fully the extent of the DVT. Access for the vascular access sheath is best accomplished via the popliteal vein, typically using ultrasound guidance to assure nontraumatic, single-puncture catheter placement. A multiple-side-hole catheter is advanced and embedded within the thrombus. Thrombolytic agent is infused through this catheter. At a minimum, low-dose heparin (500 U/hour) should be infused through the sheath to prevent sheath thrombosis. Periodic surveillance with venography should be performed to assess resolution of the DVT. As lysis is achieved, the infusion catheter may require repositioning to maintain infusion within the thrombus.

Lytic therapy for DVT carries the same contraindications as for lysis of PE. Active bleeding is an absolute contraindication to the procedure; relative contraindications include those for any anticoagulant. In addition, a history of contrast allergy or renal insufficiency is a relative contraindication to the procedure. Complications are similar to the complications for PE lysis. The major complication associated with the use of lytic agents is bleeding. Access-site bleeding is the most common complication. Bleeding in the popliteal space may be particularly significant because the popliteal vein is poorly compressible. Additional complications such as intracranial bleeding are also seen with lytic infusion for DVT lysis. PE, potentially fatal, has been reported in patients undergoing DVT lytic therapy.

Only SK has an approved indication for use in lytic treatment of DVT. Urokinase, rt-PA, t-PA, and TNK-t-PA are not approved for DVT lysis. After the completion of thrombolytic therapy, patients should be anticoagulated with an appropriate parenteral agent (UFH, LMWH, or DTI) and converted to warfarin in the usual fashion. Patients who have a contraindication to lysis may be able to derive some benefit from mechanical thrombectomy performed at the time of venography/intervention. However, mechanical thrombectomy should not be attempted in patients with a contraindication to anticoagulation because any benefit from suction thrombectomy would likely be lost without maintenance of therapeutic anticoagulation.

Benefits of DVT thrombolysis include the ability subsequently to diagnose and treat any underlying venous stenosis, venous compression (as in May-Thurner syndrome), or venous webs that may be discovered after thrombolysis. The use of angioplasty, stent placement, or both may improve outcomes in these patients. Most recently, the combined use of localized pharmacomechanical intervention has been demonstrated to reduce subsequent PTS occurrence but increase overall bleeding. These more recent findings are important as the primary goal of catheter-based interventions for the management of DVT is to reduce the subsequent occurrence of PTS. PTS develops in up to 50% of patients with symptomatic DVT. Pain, swelling, edema, pigmentation changes, and skin ulcers may occur. PTS results from damage to venous valves by clot, leading to valvular incompetence and venous reflux. Management of PTS involves use of graduated elastic compression stockings, and, as discussed, consideration of use of invasive catheter-directed approaches to treat DVT (and prevent PTS); however, consensus opinion currently recommends against the routine use of thrombolytic therapy, and large randomized trials are in progress. Thrombolysis for Pulmonary Embolism

Most patients with symptomatic PE should be treated solely with anticoagulation. Some patients with PE may derive benefit from thrombolytic therapy to actively degrade the thrombus obstructing the pulmonary vasculature. Clear indications for PE thrombolysis are debatable. Thrombolysis has been demonstrated to improve survival in patients with massive PE plus shock and is probably indicated in these patients. When compared to anticoagulation alone, thrombolytic therapy results in more rapid thrombus lysis, an early improvement in pulmonary blood flow, and improvement of right ventricular function. However, these improvements in cardiopulmonary function alone have not resulted in decreased mortality in stable patients without significant hemodynamic compromise. Even in patients with submassive PE, initial thrombolysis with intravenous alteplase did not reduce mortality. It remains unclear whether patients with PE and evidence of right ventricular dysfunction or elevated cardiac troponin levels (or both) benefit from thrombolysis.

Currently approved drug regimens for PE lysis include the following: SK, 250,000-U intravenous bolus over 30 minutes followed by 100,000-U/hour intravenous infusion for 24 hours; rt-PA, 100-mg intravenous infusion over 2 hours; and urokinase, 4,400-U/kg bolus over 10 minutes followed by intravenous infusion of 4,400 U/kg/hour for 12 hours. Reteplase
is not FDA-approved for PE management, but when administered as two 10-U boluses separated by 30 minutes, it has been shown to improve pulmonary vascular resistance and blood flow more rapidly than standard-dose rt-PA.\textsuperscript{594} Lytic therapy is contraindicated in patients with an increased risk of bleeding. Active bleeding is an absolute contraindication to therapy. In addition, recent organ biopsy or arterial puncture in a noncompressible site and recent cardiopulmonary resuscitation, uncontrolled hypertension, and pregnancy or recent delivery are relative contraindications. For all patients, the potential benefits of lysis must be weighed heavily against the potential risks of bleeding.\textsuperscript{595}

Major hemorrhage rates have varied between 4% and 22% in studies at the currently recommended doses. Extrapolation from acute MI thrombolysis trials supports intracranial hemorrhage rates between 1% and 3%, approximately one half of which are fatal. There is no benefit to lytic infusion via a centrally placed catheter when compared to peripheral infusion in patients with PE. Many believe that heparin should not be administered concomitantly with the lytic agent. An aPTT should be determined at the completion of the lysis; if the aPTT is ≤2.5 times the control, then heparin infusion should be started/resumed. If the aPTT is >2.5 times the control, the aPTT should be repeated every 4 hours; once it decreases into an acceptable range, the heparin infusion may be initiated. If a complication of therapy occurs, the lytic agent and any other anticoagulants should be held. Freshfrozen plasma and cryoprecipitate may be used to replete fibrinogen and clotting factors. Consideration should be given to the use of antifibrinolytic agents to reverse excessive fibrinolysis.\textsuperscript{590, 591}

PREVENTION OF VENOUS THROMBOEMBOLIC DISEASE

If physicians focused more on VTE prophylaxis, much less time would be needed to emphasize methods for VTE diagnosis and treatment. Fatal PE is considered to be the most common preventable cause of hospital death.\textsuperscript{596} Because the clinical diagnosis of VTE is unreliable and serial surveillance of all high-risk patients is expensive, widespread use of anticoagulants (or other prophylactic measures) has been recommended and is the subject of recent comprehensive practice guidelines by the American College of Chest Physicians.\textsuperscript{359, 597, 598, 599}

Optimal delivery of thromboprophylaxis requires an assessment of risk versus benefit, and this is particularly relevant to medically-ill patients wherein the absolute risk of clinically relevant VTE may be less than in patients undergoing major surgical procedures. There is an abundance of literature supporting the benefits of thromboprophylaxis in surgical patients, but the absolute clinical impact in nonsurgical patients is less certain. In a recent meta-analysis by Lederle and colleagues, medically-ill patients who received pharmacologic prophylaxis had reduced incidence of symptomatic PE (number needed to treat 306), but increased bleeding events (number needed to harm 296 for major bleeding), and no reduction in total mortality.\textsuperscript{600} Risk assessment, however, is imperfect and can be viewed as group risk (e.g., all orthopedic patients) or individualized risk (e.g., based upon individual patient characteristics). Figure 55.9 illustrates several VTE risk assessment models that have been validated.\textsuperscript{601, 602, 603} It is important to note that not all patients at risk develop a thrombosis, and not all thromboses result in symptoms, morbidity, or death. The benefit of pharmacologic thromboprophylaxis must always be weighed against the bleeding risk. Patients at high risk for bleeding should still receive prophylaxis in the form of an intermittent pneumatic compression device, thromboembolism-deterrence stockings, or both. Furthermore, prophylaxis strategies must take into account whether a patient has a history of HIT. Figure 55.10 illustrates a general approach to thromboprophylaxis, and Table 55.17 lists relative contraindications to anticoagulant therapy.

\textsuperscript{590}

Duration of thromboprophylaxis has also received attention. In general, extended prophylaxis (i.e., up to 4 weeks) has been suggested for patients undergoing elective hip arthroplasty, hip fracture repair, and high-risk abdominal-pelvic cancer surgery. Extending prophylaxis in medical patients, however, has not been shown to be effective and is associated with increased bleeding.

HEPARIN-INDUCED THROMBOCYTOPENIA

Although bleeding is the most common adverse event associated with heparin and LMWH therapy, HIT, also known as the white clot syndrome, is increasingly recognized as a potentially severe, albeit paradoxical, immune-mediated complication of heparin therapy. HIT is a “clinical-pathologic” syndrome, meaning that the diagnosis is optimally based on compatible clinical features as well as laboratory assay results positive for heparin-dependent antibodies. Platelet activation occurs in vivo in normal people. This results in release of PF4, a tetrameric platelet α-granule constituent into blood where it may also bind to the external platelet surface. Heparin is a polyanion, i.e., a chain of negatively charged oligosaccharides, that can bind to positively charged PF4 tetramers, resulting in heparin-PF4 complex formation that is immunogenic under certain circumstances. Binding of IgG to the heparin-PF4 complex forms an immune complex that triggers cross-linking of the platelet Fcγ IIa receptor, an event that leads to platelet activation and formation of thrombogenic microparticles. The end result is development of thrombocytopenia in the setting of a profound hypercoagulable state.
FIGURE 55.10. General approach to venous thromboembolism (VTE) prophylaxis in hospitalized patients. Some form of venous thromboembolism risk assessment should be performed in patients admitted to the hospital to identify those patients who are most likely to benefit from thromboprophylaxis. Risk assessment can be either individualized or considering at-risk patient groups (e.g., orthopedic surgery patients). Once risk has been identified, the choice of prophylactic strategy should be based upon the patient’s bleeding risk, history of heparin-induced thrombocytopenia, renal function, duration of therapy, and cost. CrCl, creatinine clearance; DTI, direct thrombin inhibitor; HIT, heparin-induced thrombocytopenia; LMWH, low-molecular-weight heparin; ml/min, milliliters per minute; NOACs, novel oral anticoagulants; VKA, vitamin-K-antagonists.

HIT typically develops between 5 and 14 days after the commencement of heparin therapy and produces a variable but often moderate degree of thrombocytopenia wherein nadir platelet counts are typically in the range of 60,000/µl and the development of severe thrombocytopenia (<20,000/µl) is unusual. A platelet count fall that begins before day 5 of heparin is unlikely to represent HIT except in patients with a recent (within 3 months) heparin exposure. These patients may experience an abrupt onset of thrombocytopenia on re-exposure to heparin as a result of acute platelet activation due to preformed, circulating HIT-associated antibodies. In contrast, delayed-onset HIT represents a clinical challenge as patients may develop thrombocytopenia with or without thrombosis days to weeks after heparin cessation.

Although the exact incidence of HIT has not been well established, HIT has been noted to develop in up to 3% to 5% of patients exposed to unfractionated porcine-intestine-derived heparin. Patients exposed to bovine-lung-derived UFH have been reported to have a greater likelihood of developing HIT than those exposed to porcine-intestine-derived UFH, and UFH induces pathogenic HIT antibodies to a greater extent than LMWH (~5% vs. ~1%, respectively, in orthopedic patients). Warkentin et al. evaluated the incidence of HIT in 665 patients randomized to receive subcutaneous UFH or LMWH for venous thromboprophylaxis after elective hip surgery. HIT was diagnosed in 2.7% (9/332) of patients given UFH versus 0% (0/333) of those given LMWH. HIT with thrombosis developed in 88.9% (8/9) of the patients who developed HIT, compared with a thrombosis rate of 17.8% (117/656) in patients without HIT. The clinical setting also influences the frequency of HIT; patients undergoing cardiac surgery who receive UFH have a higher incidence of pathogenic HIT antibodies (2.5%) compared to medical (<1%) or obstetric (<0.1%) patients, and HIT may develop more commonly in women.
The most feared complication of HIT is thrombosis. Thirty-six to fifty percent of patients with HIT have been noted to develop life- or limb-threatening thromboembolic phenomena. The thrombotic tendency associated with HIT can last for at least 30 days, and HIT with thrombosis can develop well after the discontinuation of heparin and platelet-count recovery. Venous thrombosis is more common than arterial thrombosis in HIT patients, especially in those who receive UFH for postoperative DVT prevention. Extremity DVT is the most frequently encountered venous thrombotic complication in HIT patients, followed in frequency by PE and cerebral sinus thrombosis. Most HIT-associated arterial thromboses involve the extremities, but stroke, MI, and renal artery thrombosis related to heparin infusions have been described. HIT with thrombosis after coronary artery bypass grafting may present as bypass-graft occlusion, left atrial thrombus formation, valvular thrombosis, or PE. Acute graft occlusion secondary to HIT has been described in vascular surgery patients even after platelet-count normalization. It is reasonable to assume that patients with pre-existing vascular lesions, intravascular catheters, sepsis, or postoperative venous stasis are particularly susceptible to the thrombotic complications of HIT.

Other clinical presentations of HIT include heparin-induced skin lesions, heparin “resistance,” and adrenal vein thrombosis leading to hemorrhagic infarction. Heparin-induced skin lesions have been observed in 10% to 20% of patients who generate HIT-IgG in response to subcutaneous UFH injections. The skin lesions develop at heparin injection sites and can range from painful red plaques to overt skin necrosis reminiscent of warfarin-induced skin necrosis. Thrombocytopenia may not develop in the majority of patients with heparin-induced skin lesions, but those who develop skin lesions and thrombocytopenia appear to be at extremely high risk for arterial thrombosis. The thrombocytopenia that develops in HIT is not normally associated with hemorrhagic events, and platelet transfusion may exacerbate the HIT-induced prothrombotic tendency.

HIT is primarily a clinical diagnosis. HIT should be strongly suspected in any patient who develops thrombocytopenia while receiving heparin in any dose or by any route of administration. Whereas HIT is usually associated with a platelet count below the lower limits of normal (150,000/µl in most laboratories), the extent of thrombocytopenia is quite variable, and the diagnosis should be strongly considered in any patient in whom the platelet count falls below 50% of the baseline value (even if still within the normal range) after the fifth day of heparin treatment. Similarly, a 30% fall in baseline platelet count combined with any form of thrombosis in a patient receiving heparin should be considered due to HIT until proven otherwise. Thrombotic events occurring or progressing during therapeutic-intensity heparin therapy, even if the platelet count is normal, may also constitute a HIT variant.

Limitations of laboratory assays for HIT (discussed below) have led to development of a clinical scoring system to determine the pretest probability of HIT, in an attempt to identify patients with the likely diagnosis more rapidly. The “4T's” scoring system (Table 55.18) uses easily available clinical information (nadir platelet count, timing of thrombocytopenia, presence or absence of thrombosis, and alternative explanations for thrombocytopenia) to classify patients into high (score of 6 to 8), intermediate (score of 4 to 5), or low (score of ≤3) probability of HIT. Study results indicate that this scoring system has a high negative predictive value. Consequently, a low pretest score may be useful in ruling out an HIT diagnosis. A meta-analysis of clinical trials using the 4T's scoring system found that the negative predictive value of a low probability score was 99.8%. The currently available in vitro diagnostic assays for HIT are either immunoassays or functional assays. Immunoassays detect the presence of heparin-PF4 antibodies using ELISA methodology. HIT ELISAs have high sensitivity, but poor specificity for the diagnosis. Most will detect IgG, IgM, and IgA antibodies, but only IgG antibodies are thought to be pathogenic in the disorder. In addition, not all antibodies to the heparin-PF4 complex will induce platelet activation. Recent data indicate that the optimal immunoassay uses ELISA methodology to detect only IgG antibodies. The reliability of an IgG ELISA in diagnosing HIT can be further improved by considering the “positivity” of the result. ELISA optical density results near the upper limit of the normal range (usually ~0.4 O.D. units) are less likely to be associated with clinical HIT than a much higher positive result (≥1.0 O.D. units).

- **Possible**
- **Probable/definite (DIC, sepsis, drug-induced, etc.)**

Each 4T's parameter is evaluated and scored; patients with scores ≤3 points are at low risk for HIT. Those with scores of 4-5 points are at intermediate risk, and patients with scores of 6-8 points are at high risk of HIT.

DIC, disseminated intravascular coagulation; UFH, unfractionated heparin; VTE, venous thromboembolism.

Data from references 422, 624.
alternative anticoagulation, and for any positive immunoassay result, no further testing is indicated. Patients with a high pretest probability, but who have negative immunoassay results should be tested with the SRA to confirm or refute a diagnosis of HIT. Patients with an intermediate likelihood of HIT should receive an alternative anticoagulant while awaiting immunoassay results. If the result is strongly positive (e.g., >1 O.D. units), no further testing may be necessary. If the result is negative or only weakly positive, the SRA should be performed to diagnose or exclude HIT definitively. Alternative anticoagulation should be continued while awaiting the SRA results. Figure 55.11 suggests an initial diagnostic and management approach to HIT.

FIGURE 55.11. Initial management of patients with suspected heparin-induced thrombocytopenia (HIT). Patients with suspected HIT should be approached in a rapid and evidence-based fashion, wherein a pretest probability assessment is completed (e.g., using the 4T’s scoring system, Table 55.18) and application of an immunoassay test, in particular to those patients at intermediate to high pretest probability. While awaiting immunoassay test results, implementation of an
alternative anticoagulant (e.g., direct thrombin inhibitor) is recommended. Patients with discordant clinical probability assessment and immunoassay results or those with intermediate findings should undergo additional testing with a functional platelet activation assay, such as the serotonin release assay (SRA). HIT, heparin-induced thrombocytopenia; O.D., optical density.

The initial treatment of HIT with or without thrombosis is to discontinue all exposure to heparin or LMWHs (including heparin-coated catheters) and immediately begin an alternative anticoagulant, usually a DTI, such as argatroban, lepirudin, or bivalirudin). DTI therapy is continued as monotherapy until normalization of the platelet count, at which time bridging therapy with warfarin is started. Warfarin anticoagulation may be desired for long-term therapy, but should never be used as the sole alternative anticoagulant in patients with HIT. Warfarin treatment is the major factor contributing to limb amputation caused by progression of otherwise unremarkable deep vein thromboses to phlegmasia cerulea dolens in patients with HIT. The combination of HIT-associated hypercoagulability and warfarin-induced protein C deficiency most likely produces a profound procoagulant state that causes venous limb gangrene. After both platelet count normalization and subsequent initiation of warfarin, both warfarin and DTI are continued for at least 5 days, or until a therapeutic INR (2.0 to 3.0) is achieved on warfarin alone. For isolated HIT without and with thrombosis, respectively, warfarin therapy duration of 4 weeks and 12 weeks is recommended. Fondaparinux has also been used to treat HIT in small case series, but is not approved to treat HIT. Patients should be informed that they should never be exposed to heparin again, although protocols are available in which short-term exposure to heparin can be safely done in patients who require heparin therapy.

Considering the complexity of HIT diagnosis and treatment, HIT prevention must be emphasized. Patients receiving UFH should have platelet-count monitoring at baseline and at least every third day between day 5 and day 14 of heparin exposure. Platelet count monitoring recommendations in patients receiving heparin have been published in the recent ACCP guidelines. Appropriate medical record documentation and patient education should help avert heparin re-exposure in patients with a history of HIT. Re-exposure to heparin in patients with past HIT should be delayed at least 3 months, kept to a minimum duration to provide succinct anamnesis, and avoided whenever possible. LMWH and fondaparinux may be preferable to UFH for both the treatment and prevention of thromboembolic disease because of the greatly reduced likelihood of initiating HIT. For those patients with acute or subacute HIT who require urgent cardiac surgery or PCI, the use of bivalirudin is recommended.

**Part VI - Benign Disorders of Leukocytes, The Spleen, and/or Immunoglobins**

Chapter 56 Diagnostic Approach to Malignant and Nonmalignant Disorders of the Phagocytic and Immune Systems

Cost-effective, efficient evaluation of patients with hematologic diseases is often based on the quality of collaboration between clinicians and pathologists. This has become even more important as the number and complexity of diagnostic tests has exploded. Flow cytometry, cytogenetic, fluorescence in situ hybridization (FISH), and molecular genetic testing present opportunities for improving diagnostic precision but are expensive, and each has its limitations and shortcomings. The goal of this chapter is to guide selection of testing to minimize the cost and time involved in making diagnoses in common clinical problems in hematology.

This chapter introduces an approach to disorders that produce abnormalities of circulating blood cells, constitutional symptoms, or enlargement of lymph nodes or the spleen. The emphasis is on distinguishing benign from malignant disease. The disorders may take the form of (a) immune reactions, particularly infection resulting in changes in blood leukocytes, lymphadenopathy, and/or organomegaly; (b) neoplastic diseases (leukemias, lymphomas, and plasmacytic neoplasms and related diseases); and (c) inherited or acquired diseases that result in immunodeficiency.

**APPROACH TO DIAGNOSIS**

Patients with disorders of the immune system (innate and adaptive) usually come to medical attention with symptoms and signs suggestive of infection. Many patients with hematopoietic lymphoid neoplasms may also present with fever or other nonlocalizing constitutional signs and symptoms such as fatigue, generalized lymphadenopathy, abnormal bleeding, weight loss, bone pain, arthralgias, and pruritus. Suspicion of an underlying immune disorder, benign or malignant, may be raised during the course of a routine examination or during the evaluation of unrelated disorders by the detection of
skin lesions, lymphadenopathy, splenomegaly, or hilar or mediastinal masses. In other instances, routine blood examination may disclose abnormalities in the numbers or morphology of circulating red cells, white cells, or platelets.

A detailed history should be obtained, and a thorough physical examination should be performed. Age of the patient, immunocompetence (focusing on types and number of infections), family history, travel history, animal exposure, history of prior therapy, and drug ingestion are particularly important areas to address. Complete blood cell count (CBC) and blood examination (including morphologic assessment of red cells, white cells, and platelets) may be diagnostic or help determine the next step in diagnosis. Chest x-ray and computed tomography (CT) may assist in identifying possible biopsy sites. Electrophoresis to characterize serum or urine immunoglobulins, marrow examination, lymph node aspiration or biopsy, liver biopsy, and splenectomy with flow cytometry immunophenotyping of blood, marrow, or tissue, may be necessary. In addition, evaluation of delayed type hypersensitivity and tests of neutrophil and/or lymphocyte function may be required. Finally, cytogentic and molecular genetic testing may be necessary for a complete assessment. Clearly, not all or even most of these tests and surgical procedures are indicated for each patient who has the symptoms or signs described. Rather, a logical sequence is undertaken for each patient, tailored to the particular findings. A diagrammatic summary of a sequential approach is shown in Figure 56.1.

The examination of stained tissues by light microscopy remains the principal means of establishing a diagnosis in most of the benign and malignant conditions considered in Parts VI (Nonmalignant Disorders of Leukocytes, the Spleen, and/or Immunoglobulins) and VII (Hematologic Malignancies). Other studies, however, including immunophenotypic studies, cytogentic, and molecular genetics, are increasingly valuable in making, confirming, and “fine-tuning” diagnoses as well as in defining clinically important subcategories of disease. Flow cytometry has become a primary immunophenotyping method in the diagnosis, classification, and detection of residual disease in patients with hematologic malignancies, and is covered in more detail in Chapter 2. For example, flow cytometry is helpful in the differential diagnosis of reactive and neoplastic lymphoid proliferations, but requires specimens that are submitted fresh or in saline. Figure 56.2 demonstrates the difference between immunoglobulin light chain distribution in a patient with follicular hyperplasia (with polytypic light chain expression) versus a patient with a diffuse large B-cell lymphoma (with monotypic light chain expression). In T-cell neoplasms, the detection of a population of lymphocytes with aberrant phenotypes (e.g., lost or diminished expression of pan T-cell markers) as illustrated in Figure 56.3, is very helpful in detecting abnormal T-cell populations. Flow cytometry is essential for classification of acute leukemia, in part because most diagnostic studies can be completed in less than 2 hours. Additionally, flow cytometry immunophenotyping detects myeloid antigen expression in cases that are myeloperoxidase or Sudan black B negative by cytochemical studies. Finally, flow cytometry can detect aberrant blast cell immunophenotypes, which are useful for the detection of minimal residual disease in post-therapy specimens. The level of detection of minimal residual disease by flow cytometry is well below what can be identified by morphologic assessment of aspirate smears. However, flow cytometry does have limitations. It requires fresh or viable tissue and is of less value in the diagnosis of Hodgkin lymphoma (HL), T-cell-rich B-cell lymphomas, and subclassification of reactive processes (see Table 56.1), and may miss some T-cell neoplasms that do not demonstrate aberrant immunophenotypes. Most laboratories do not use methods that are effective in detecting the rare tumor cells of HL, but some studies have used this method effectively and this application of flow cytometry may emerge in the future. Additional applications in morphologically difficult areas such as myelodysplastic syndromes are evolving.
FIGURE 56.1. Diagnostic steps in diseases of the hematopoietic lymphoid system. CBC, complete blood cell count; HIV, human immunodeficiency virus.

P.1261
FIGURE 56.2. Flow cytometry of reactive B cells and monotypic B cells. A: Histogram (picture) of pan B-cell anti-CD19 antibody expression versus this log side scatter signal (related to cellular complexity), which is used to define and identify the B-cell lymphocytes. B: Histogram shows lymphocytes based on forward scatter signal (size) versus log side scatter signal. The red population shows that the CD19^+ B cells and predominantly T-cell CD19^− population (black dots) are of similar small size. (1) C: A two-parameter histogram gating on CD19^+ B cells with anti-Kappa fluorescein isothiocyanate (FITC) versus anti-lambda phycoerythrin. This pattern, which shows a mix of kappa and lambda, is consistent with a reactive polyclonal B-cell population. D: Histogram (picture) of anti-CD19 antibody expression versus log side scatter in a second patient. E: Histogram shows lymphocytes based on forward scatter signal versus log side scatter signal. The red population which represents the CD19^+ B cells is larger in size than the smaller CD19^− population (black dots). F: A two-parameter histogram of anti-kappa fluorescein isothiocyanate (FITC) versus anti-lambda phycoerythrin. Red dots are the CD19^+ B cells from histogram and show a dominant kappa expressing B-cell population consistent with a large B-cell lymphoma. (Diagrams courtesy of Bruce Grieg, MT, Vanderbilt University.)

Cytogenetic studies have made enormous contributions to our understanding of the genetic pathogenesis of hematologic malignancies, and the field has established itself as a primary player in the diagnosis of prognostically important subsets of leukemia and lymphoma (e.g., Burkitt lymphoma, mantle cell lymphoma, and acute promyelocytic leukemia) (see Chapter 3). FISH has an expanding role in diagnosis (Table 56.2), and has several key advantages over routine cytogenetics: (1) it can be performed on interphase nuclei in fixed tissues (including paraffin-embedded), (2) results are available in 24 to 48 hours, and (3) it shows enhanced sensitivity over routine cytogenetics for critical translocations. Figure 56.4 illustrates FISH studies showing a MYC break apart probe in a patient with an 8;14 translocation in Burkitt lymphoma.

Molecular genetic studies, primarily polymerase chain reaction (PCR) techniques, are the most sensitive for detecting small critical genetic mutations or translocations in samples which may contain very few (less than one in a million) tumor cells (see Chapter 4). PCR has also replaced Southern blot analysis as the standard for the demonstration of T-cell and B-cell clonality and is ideal for detecting minimal residual disease in patients with lymphoma as well as in patients with chronic myelogenous leukemia (CML) (Table 56.3). Many of these applications work in fixed tissues. These studies are of limited or no value in patients with HL, myelodysplasia (MDS), or translocations that have widely spaced, variable breakpoints, as in mantle cell lymphoma.
Hematologic neoplasms are clonal tumors, and methods that can prove clonality of a cell population are extremely useful when the differential diagnosis is between a benign and neoplastic proliferation. The demonstration that an expanded B-cell population is clonal by immunoglobulin light chain restriction, karyotype analysis, or gene rearrangement studies facilitates the distinction between benign and malignant proliferations. However, clonality does not always indicate malignancy, and small clonal populations and pseudoclones may exist in non-neoplastic conditions. Clinicians have recognized for years that the vast majority of patients with monoclonal gammapathies do not have an underlying B-cell neoplasm. Similarly, sensitive molecular genetic techniques frequently identify oligoclonal and monoclonal T- and B-cell populations in “benign” disorders, including lymphomatoid papulosis, autoimmune disorders (e.g., Sjögren syndrome and Hashimoto thyroiditis) in association with viral infections, celiac disease, and other lymphoid hyperplasias (particularly those in extranodal sites) (Table 56.4). Although these disorders may evolve into frank malignancy, they can remain clinically benign, remit spontaneously, or regress in the setting of antibiotics and removal of an antigen (Helicobacter pylori in gastric marginal zone lymphoma). Thus, although new techniques to identify clonality have astonishing sensitivity, the clinical, laboratory, and histopathologic data must be correlated to distinguish benign from malignant disorders. A major pitfall in diagnosis is failure to recognize that very sensitive studies for clonality by flow cytometry, protein electrophoresis, or molecular techniques are accompanied by a corresponding loss of specificity for the diagnosis of frank neoplasia.

**FIGURE 56.3.** Histograms demonstrating a phenotypically aberrant T-cell population in a patient with peripheral blood involvement by a T-cell lymphoproliferative disorder. In A, a side scatter versus forward histogram, the lymphocytes (low forward scatter, low side scatter) are painted red. The granulocytes with high side scatter and high forward scatter are painted yellow and the monocytes with forward scatter similar to granulocytes but with intermediate side scatter are painted blue. B displays the granulocytes and monocytes stained with anti-CD3 and anti-CD4, both of which do not stain with the pan T-cell marker anti-CD3 but the monocytes express intermediate levels of CD4. In C which displays CD3 and CD4 expression on the lymphocytes (painted red), normal T helper cells express CD4 and CD3 while the neoplastic T-cell population (upper left) expresses bright CD4 but have lost CD3. (Histograms courtesy Bruce Grieg, MT, Vanderbilt University.)

In the next sections, the examination of the blood, marrow, nodes, and spleen are reviewed in the context of making a diagnosis, introducing the subsequent chapters, and outlining overviews on the evaluation of fever of unknown origin (FUO) and patients with recurrent infection.

Major disadvantage of this technique: Requires viable cells. False negatives occur with necrotic or sclerotic tissues, partial tissue involvement and in tumors where neoplastic cells are in a minority (e.g., T-cell-rich B-cell lymphoma).

Major advantages of this technique: Can be applied to any tissue or body fluid. Rapid turnaround times.

Flow cytometry should be performed on all fine-needle aspirations and tissue biopsies in which a hematopoietic lymphoid process is suggested by clinical history or touch preps/frozen sections.

Flow cytometry using cytoplasmic immunoglobulin light chain markers is effective in establishing clonality of plasma cells in multiple myeloma, but not useful in accurately enumerating plasma cells.

FIGURE 56.4. FISH studies demonstrating a MYC translocation in Burkitt lymphoma using a dual color MYC break apart probe with the red labeled probe binding the 5 prime end of MYC and the green labeled probe binding the 3 prime end of MYC. In the chromosomes with unarranged MYC, the green and red signals are together but the colors separate when MYC is part of a translocation with the IGH@ gene on chromosome 14.

EXAMINATION OF THE BLOOD

Physicians are too busy to examine peripheral blood smears in all of their patients. They usually do so in one of these circumstances: (a) patients with constitutional symptoms, particularly fever (see section on “Fever of Unknown Origin”) or weight loss, without an obvious underlying cause; (b) an abnormality in blood counts, either cytosis or cytopenia; or (c) as a part of the evaluation of a patient with clinical features of immunodeficiency.

The blood counts and peripheral smear are frequently abnormal in patients with constitutional symptoms, immunodeficiency, hematologic neoplasms, or a variety of other syndromes associated with lymphadenopathy or splenomegaly. Anemia, when present, usually is normochromic and normocytic. Many patients with chronic disease, MDS,
plasma cell myeloma, and, rarely, acute leukemias have anemia but no other abnormalities. In patients with anemia of unknown origin, the evaluation begins with examination of the blood smear, red cell indices, and reticulocyte count. The evaluation proceeds based on the results of these simple tests as outlined in Chapter 22.

**TABLE 56.4 EXAMPLES OF CLONAL PROCESSES WHICH MAY BE CLINICALLY IRRELEVANT**

**B-Cell Clonality**

Monoclonal gammapathies on protein electrophoresis with immunofixation

Small circulating monotypic B-cell populations in healthy adults by flow cytometry

Transient clonal **IGH@ rearrangements** by PCR in (1) salivary glands in Sjögren syndrome, (2) in thyroid tissues in Hashimoto thyroiditis, (3) in bone marrow following solid organ or bone marrow transplantation, (4) small biopsies (i.e., skin, gastric)

Clonal **IGH@-BCL2 rearrangements** detected in low quantity in normal children and adults in blood and tonsil by ultrasensitive PCR methods

**T-Cell Clonality**

Transient clonal T-cell receptor rearrangements by PCR in blood of healthy elderly patient

Clonal T-cell receptor rearrangement by PCR in skin of patients with reactive dermatitis
Clonal T-cell receptor rearrangement by PCR in celiac disease

PCR, polymerase chain reaction.

Abnormal Platelet Counts

Thrombocytopenia

The major differential diagnosis of patients with thrombocytopenia includes (a) thrombocytopenia secondary to autoantibody-mediated platelet destruction (idiopathic thrombocytopenic purpura [ITP], systemic lupus erythematosus [SLE], drug-related thrombocytopenia, and perhaps human immunodeficiency virus [HIV]); (b) primary marrow disease, particularly MDS or acute leukemia; and (c) peripheral consumption secondary to intravascular activation of clotting (e.g., disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, or hemolytic uremic syndrome). Although thrombocytopenia can be secondary to a nutritional deficiency (e.g., folate, vitamin B₁₂), usually the macrocytic anemia is the dominant clinical feature.

In ITP and drug-related thrombocytopenias, the peripheral smear red cell and white cell morphology should be normal and rare giant platelets (megathrombocytes) are present. Thrombocytopenic patients with SLE may also be neutropenic and lymphopenic. Thrombocytopenia is present in up to 50% of patients with antiphospholipid antibody syndrome. Thrombocytopenia is the first sign of HIV infection in 10% of patients who may also be lymphopenic. Thrombocytopenia occurs in up to 45% of patients with hepatitis C viral infection. MDS and leukemia rarely present with isolated thrombocytopenia. Most MDS patients are anemic and have white blood cell (WBC) abnormalities (e.g., blasts or hyposegmented or hypogranulated polymorphonuclear neutrophils [PMNs]) that indicate primary marrow disease. Schistocytes and polychromatophilic red cells in patients with disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, and hemolytic uremic syndrome are helpful in pointing away from marrow disease or an autoimmune thrombocytopenia. In rare patients, platelets will satellite around PMNs or clump in blood collected in ethylenediaminetetraacetic acid. This artifact, readily apparent on examination of stained blood smears, disappears when blood is anticoagulated in heparin. Similarly, when blood is collected for platelet counts on heel sticks, clumping (also seen on smears) may produce spurious thrombocytopenia.

Congenital thrombocytopenias are rare, but can be misdiagnosed as ITP, and size of platelets may guide further evaluation. Small platelets in a male suggest X-linked Wiskott Aldrich syndrome (WAS). Large platelets are found in von Willebrand 2B, May-Hegglin anomaly, Bernard-Soulier syndrome, and the gray platelet syndrome. Normal-sized platelets are found in amegakaryocytic thrombocytopenia, thrombocytopenia with absent radii, and familial platelet disorders with a predisposition to acute myeloid leukemia (AML).

Drug-induced thrombocytopenia (DITP) may be misdiagnosed as ITP and overlooked if patients are not asked about over-the-counter medicines, food, beverages, and/or herbal supplements. DITP can be due to immune-mediated or non-immune processes. In a large series of patients initially diagnosed as ITP, 8% were found to have DITP with quinine (including tonic water) as the most common cause. Hematologists are frequently consulted about heparin-induced thrombocytopenia (HIT) which is due to antibodies against platelet factor 4 heparin complexes and leads to an increased risk of thrombosis.

Bone marrow examination with cytogenetic studies is essential only in the cases of thrombocytopenia in patients with suspected MDS or acute leukemia or in those for whom the diagnosis of autoimmune or consumptive thrombocytopenia is in doubt. In most children or young adults with otherwise normal counts and a normal blood smear, a bone marrow is probably not needed. Amegakaryocytic thrombocytopenias secondary to genetic or autoimmune disease are exceedingly rare.

Thrombocytosis

Thrombocytosis with platelet counts of greater than 600 × 10⁹/L are commonly seen transiently during a variety of infections, after splenectomy, after acute blood loss, or during recovery from marrow injury or nutritional deficiency. The concern in persistent thrombocytosis is the presence of an underlying myeloproliferative neoplasm or occult malignancy. The presence of a myeloproliferative neoplasm is almost always suggested by the peripheral blood counts and smear (e.g., polycythemia vera [PV], leukoerythroblastic changes in primary myelofibrosis [PMF or agnogenic myeloid metaplasia], and leukocytosis with immature myeloid precursors in CML). The one myeloproliferative neoplasm in which thrombocytosis is often an isolated finding is essential thrombocythemia (ET), a diagnosis that is supported by the
demonstration of megakaryocytic dysplasia on bone marrow examination or the demonstration of JAK2 mutations on molecular genetic studies of peripheral blood.\textsuperscript{15, 16} The JAK2 V617F mutation is estimated to occur in 60% of ET and myelofibrosis and 95% of PV.\textsuperscript{17} Congenital thrombocytosis is rare and results from mutations in either thrombopoietin (THPO) or its receptor (MPL).\textsuperscript{18}

Morphologic Changes in Leukocytes

Morphologic changes in WBC are often diagnostic of certain rare diseases such as Alder-Reilly or Pelger-Huët anomaly, some of which are associated with infection (Chediak-Higashi syndrome) (Chapter 58).

Changes in the blood of patients with acute leukemia strongly suggest the diagnosis in virtually all patients.\textsuperscript{7} In approximately 60% of these individuals, the smear confirms the diagnosis by the presence of a large proportion of immature cells, whether or not the leukocyte count is increased. Blasts are easily demonstrable in blood smears of more than 90% of patients, and, even in patients whose blood smears have few blasts, anemia, thrombocytopenia, neutropenia, or combinations of these changes are suggestive of acute leukemia. For almost all such patients, bone marrow aspiration proves diagnostic and should be supplemented by flow cytometry immunophenotyping and karyotype analysis.

Lymphocytosis of Small Mature Lymphocytes

More than 5.0 \( \times \) 10^9 small lymphocytes/L of blood in adults over 50 years of age is usually indicative of chronic lymphocytic leukemia (CLL). Many patients are asymptomatic and one-fourth are diagnosed while undergoing blood work for another problem. Flow cytometry demonstrating small B lymphocytes with weak CD20 and weak, monotypic light chain expression and coexpression of CD5 and CD23 is characteristic. Proceeding with other examinations in such patients, such as lymph node biopsy or bone marrow examination, is usually unnecessary, but immunophenotyping is required to exclude other B-cell lymphomas in the blood, such as mantle cell lymphoma, that may mimic CLL. In children, pertussis is associated with lymphocytosis of small CD4 T cells\textsuperscript{19} that may be worrisome for a lymphoid leukemia on review of the blood smear. Chronic polyclonal B-cell lymphocytosis is well described in young to middle-aged asymptomatic women who usually smoke.\textsuperscript{20} These women typically present with a lymphocyte count that is less than 5 \( \times \) 10^9/L, the number required for a diagnosis of CLL, and the B cells are polytypic by immunoglobulin light chain studies and by PCR studies of the immunoglobulin heavy chain. Monotypic B-cell proliferations that present with less than 5 \( \times \) 10^9/L B cells are now classified as monoclonal B lymphocytosis rather than as overt CLL.\textsuperscript{21}

Lymphocytosis of “Atypical Lymphocytes”

Atypical or abnormal lymphocytes are a classic feature of Epstein-Barr virus (EBV) infectious mononucleosis but also occur in other acute viral infections including cytomegalovirus (CMV), hantavirus, hepatitis, HIV, and less commonly in lymphomas with a leukemic phase (e.g., human T-lymphotropic virus -1, hepatosplenic T-cell lymphoma, etc.). Thrombocytopenia, an elevated hematocrit, neutrophilia, and circulating lymphoblasts in a patient from the desert Southwest strongly suggest hantavirus infection.\textsuperscript{22} Usually the clinical features and other routine laboratory tests such as serologic studies for viral infection make the diagnosis straightforward. When distinguishing reactive lymphocytes from leukemic blasts or the leukemic phase of a lymphoma is difficult, flow cytometry can provide invaluable help in defining the phenotype and clonality of circulating cells.

Neutrophilic Leukocytosis

The presence of CML is strongly considered in a patient with neutrophilic leukocytosis, particularly when the WBC count is greater than 50.0 \( \times \) 10^9/L and is accompanied by an increase in circulating immature myeloid cells and basophilia. Additional findings suggesting the diagnosis of CML include (a) symptoms of fatigue, bone pain, left upper quadrant pain, or fullness; (b) sternal tenderness and splenomegaly on physical examination; and (c) thrombocytosis. A leukemic reaction must also be considered and can be caused by either benign, particularly infectious, or malignant conditions. Interphase FISH studies on peripheral blood for the BCR/ABL1 translocation can establish the diagnosis of CML, obviating the need for bone marrow examination; but many recommend an initial bone marrow to screen for other cytogenetic abnormalities that could affect prognosis.

Chronic idiopathic neutrophilia is defined by leukocytosis of 11.0 to 40.0 \( \times \) 10^9/L and is associated with smoking and obesity.\textsuperscript{23} Familial neutrophilia (WBC > 20.0 \( \times \) 10^9/L) is a rare autosomal dominant disorder which is caused by a mutation in the granulocyte colony-stimulating factor (G-CSF) receptor.\textsuperscript{24} A transient myeloproliferative disorder is seen in up to 10% of children

P.1265
with Down syndrome. \textsuperscript{25} Neonates with persistent leukocytosis, delayed separation of the umbilical stump, and recurrent infections should be screened for leukocyte adhesion deficiency (LAD) (see section "Recurrent Infections").

Monocytosis

Monocytosis (> 1.0 × 10\(^9\)/L) is commonly caused by infections, including granulomatous disease (tuberculosis [TB], fungal disease), brucellosis, infectious mononucleosis, syphilis, protozoal infections (kala-azar, malaria) and rickettsial infections. Monocytosis may be prominent in chronic myelomonocytic leukemia (CMML), juvenile myelomonocytic leukemia, or AMLs with a monocytic component.\textsuperscript{26} These neoplastic monocytic proliferations cannot be distinguished on peripheral blood evaluation alone and a bone marrow examination is necessary to separate CMML from AML. Autoimmune disease, inflammatory bowel disease, and sarcoidosis may be associated with monocytosis. Monocytosis has been associated with carcinomas (lung, colorectal, renal) and has been caused by secretion of interleukin (IL)-6 by the neoplastic cells.\textsuperscript{27}

Eosinophilia

Unexpected eosinophilia is most commonly seen in patients with atopy or reactions to drugs or environmental allergens.\textsuperscript{28} Autochthonous parasitic disease as a cause of eosinophilia is rare in the United States, but visceral larva migrans caused by Toxocara canis or cati can be seen. In international travelers and immigrants, evaluations for tissue invasive parasites is warranted. In patients who are immunosuppressed (particularly organ transplant recipients and patients on high-dose steroids for autoimmune diseases) strongyloides should be excluded.

Persistently high eosinophilia (> 1.5 × 10\(^9\)/L for > 6 months) carries significant risk for end organ damage and requires thorough investigation. A minority of these patients have elevated IL-5 levels with circulating clonal T-cell populations with aberrant phenotypes by flow cytometry.\textsuperscript{29} Several neoplastic eosinophil proliferations are now recognized (see Chapter 84), including a group with a cryptic translocation involving FIP1L1-PDGFR\(\alpha\).\textsuperscript{30, 31} The latter patients can respond to imatinib therapy, while other genetic subtypes do not.

Increased Circulating Plasma Cells

Patients with plasma cell (multiple) myeloma usually have a few plasma cells in the blood, although occasionally large numbers are noted (plasma cell leukemia). Such patients almost invariably have other symptoms and signs of myeloma. A few plasma cells may also be observed in blood smears of patients with infectious mononucleosis or other viral infections. Plasma cells also are seen in the blood of persons recovering from bacterial infections or having allergic reactions, especially serum sickness. The first step when the diagnosis of myeloma is considered is to perform studies of serum and urine immunoglobulins. The technique of immunoelectrophoresis has been replaced by electrophoresis with immunofixation. This sensitive and specific technique identifies a monoclonal serum Ig and/or light chain in urine in more than 5% of patients with myeloma. The diagnosis is confirmed on bone marrow examination.

Neutropenia

Neutropenia may be mild (ANC < 1.5 but > 1.0 × 10\(^9\)/L), moderate (ANC < 1.0 but > 0.5 × 10\(^9\)/L), or severe (ANC < 0.5 × 10\(^9\)/L).\textsuperscript{32} There can be ethnic variation, as exemplified by a prevalence of neutropenia of 4.5% among African-Americans in the United States compared to 0.79% and 0.38% in whites and Mexican-Americans, respectively.\textsuperscript{33} While infections and drugs are the leading causes of neutropenia, nutritional deficiencies (B\textsubscript{12}, folate, copper) should be ruled out early because of their responsiveness to replacement therapy. Alcohol abuse may present with isolated neutropenia, but is usually accompanied by other features of alcohol or nutritional marrow injury (macrocytosis, ringed sideroblasts). Immune-mediated neutropenia can be primary without an etiology or secondary to drugs, particularly β-lactam antibiotics and antithyroid medications; and autoimmune disease, including SLE, rheumatoid arthritis, and Graves' disease.\textsuperscript{34, 35, 36} Late-onset neutropenia following rituximab therapy has been reported in 5% to 27% of lymphoma patients.\textsuperscript{37}

Chronic idiopathic neutropenia (CIN) is a diagnosis of exclusion, rarely has increased infections, and is due to increased inflammatory changes within the bone marrow microenvironment. CIN is associated with activated T cells and increased levels of interferon γ (IFN-γ), tumor necrosis factor α, Fas-ligand, and transforming growth factor β1, which suppresses IL-10, an antiinflammatory cytokine, and promotes apoptosis of neutrophil progenitor cells.\textsuperscript{38}

Hematologists should be familiar with congenital neutropenias, particularly cyclic neutropenia and severe congenital neutropenia (Kostmann syndrome), because the former can be mild and not be recognized until adulthood and the latter, which is supported by G-CSF, can evolve into leukemia in one-fifth of patients.\textsuperscript{39} Mutations in the neutrophil elastase gene (ELA2) account for 60% of cases of severe congenital neutropenia, either in autosomal dominant or sporadic forms, while mutations in the HS-1-associated protein X (HAX1) gene are found in 30% of cases and are autosomal recessive.\textsuperscript{40}
Bone marrow aspiration and biopsy are usually reserved for neutropenia patients where there is an index of suspicion of malignancy usually due to immature cells in the differential; physical clues, such as adenopathy or splenomegaly; and/or other hematologic and laboratory abnormalities. MDS rarely presents as an isolated neutropenia and usually will have accompanying dysplastic abnormalities in more than one cell line. Patients with two indolent leukemias, hairy cell leukemia and large granular lymphocyte (LGL) leukemia, often present with bacterial infections secondary to neutropenia. Circulating hairy cell cases may be few in number, but a bone marrow examination with flow cytometry is usually diagnostic. LGL leukemia can be either T-cell (85% to 90%) or NK-cell (10% to 15%) in origin, is suspected when there are LGLs in the peripheral blood smear, and can be diagnosed by flow cytometry. Molecular genetic studies of the T-cell receptor gene can be confirmatory of clonality in T-LGL.

**Lymphopenia**

Lymphopenia is defined as an absolute lymphocyte count $< 1.5 \times 10^9$/L in adults and $< 2.0 \times 10^9$/L in children. Since 70% to 80% of circulating lymphocytes are T cells (most of which are CD4 T cells), severe lymphopenia implies T-cell deficiency and warrants serologic investigation for HIV infection. In infants with infection, the possibility of severe combined immunodeficiency (SCID) or DiGeorge syndrome is suggested. Lymphopenia is common in systemic autoimmune diseases like lupus and sarcoidosis and in serious illness/infections associated with hypercortisolism.

A variety of viral infections including influenza and measles may produce transient lymphopenia in association with loss of skin test reactivity and transient susceptibility to reactivation of TB. One rare but noteworthy population with persistent lymphopenia is HIV-negative patients with CD4 T-cell counts less than $0.3 \times 10^9$/L. These patients fall into two categories, those susceptible to infection (who usually have low CD4/CD8 ratios) and those who have no increased susceptibility for infection with normal CD4/CD8 ratios.

Peripheral Blood Findings in Infection

Blood leukocyte changes that are secondary to a variety of diseases usually consist of neutrophilia, eosinophilia, monocytosis, or abnormal-appearing lymphocytes. Changes in the distribution or appearance of circulating WBCs may provide important clues to the presence and type of an underlying infection. Eosinophilia is common in atopic individuals but can be seen in many parasitic infections. Atypical lymphocytosis is a helpful diagnostic clue in viral infections, particularly EBV infection. In many parasitic diseases, such as malaria, acute Chagas disease, and filariasis, the infectious agent may be demonstrated on peripheral blood smears. However, these three parasitic diseases are rarely autochthonous in North America, and the diagnosis is suggested by the nationality as well as the recent travel history of the patient.
FIGURE 56.5. Wright-stained peripheral blood smears demonstrating (A) Mycobacteria avium-intracellulare as negative staining rods in a monocyte from patient with human immunodeficiency virus infection, (B) Histoplasma capsulatum with three intracellular yeast forms in a monocyte at the feather edge of smear in patient with acquired immunodeficiency syndrome, (C) Ehrlichia chaffeensis as a single basophilic cytoplasmic inclusion (photomicrograph courtesy of Dr. Charles Coleman, University of Missouri), (D) Babesia as single intracellular ring forms in two erythrocytes, (E) Malassezia furfur as extracellular budding yeasts (one of which is overlying an erythrocyte) in an infant on total parenteral alimentation, and (F) intracellular bacteria in a neutrophil with an adjacent vacuolated neutrophil in a patient with septicemia.

Although in most infections the causative agents are not demonstrable in peripheral blood, there are certain notable exceptions. In acquired immunodeficiency syndrome (AIDS) patients or in other severely immunocompromised patients, mycobacteria (Fig. 56.5A), fungi, such as histoplasmosis (Fig. 56.5B), or Candida may occasionally be identified on the peripheral blood smear. Residents of the central United States (particularly Arkansas and Missouri) and the Southeast may acquire ehrlichiosis through tick vectors. Anaplasmosis, formerly called human granulocytic ehrlichiosis, is a closely related tickborne disease found more often in the Northeast and upper Midwest. The typical inclusions in mononuclear cells (Ehrlichia chaffeensis) (Fig. 56.5C) or in neutrophils (Anaplasma phagocytophilum) are present in up to one-third of these patients, who often present with unexplained fever with accompanying leukopenia and elevated transaminases. The diagnosis of ehrlichiosis/anaplasmosis may be confirmed either serologically or by PCR methods. Babesiosis, first recognized in the 1890s as the cause of Texas cattle fever, has now been identified in febrile
patients in the Northeast (Nantucket, Martha’s Vineyard, Connecticut), Wisconsin, and on the West Coast. Infections can be life threatening in splenectomized patients. The diagnosis is suggested by finding single ring forms (1.0 to 3.5 μm in diameter) in red blood cells (Fig. 56.5D) (characteristic tetrads are usually seen only in infected animals). In nonimmunocompromised patients with indwelling venous catheters, Malassezia furfur (Fig. 56.5E), Candida, and Torulopsis (C. glabrata) may be identified in the peripheral blood. In bacterial sepsis, visible circulating bacteria are rare, but the presence of cytoplasmic neutrophilic vacuoles in a fresh finger stick blood smear is a specific clue to the diagnosis of septicemia (Fig. 56.5F). Toxic granulation (also seen in patients with sepsis) is often quite prominent in uninfected patients receiving granulocyte or granulocyte/macrophage colony-stimulating factor.

EXAMINATION OF THE BONE MARROW

If a diagnosis is not established by examining the blood, bone marrow examination may be helpful (Table 56.5). Needle biopsy is usually performed in addition to aspiration, particularly if lymphoma, carcinoma, granulomatous conditions, or myelofibrosis are under consideration. To adequately triage marrow, the stained aspirate smear is reviewed along with the clinical information and any previous studies shortly after the procedure. This allows rapid decisions about cytogentics (including FISH), molecular genetics, and flow cytometry to be made when viable cells are still available and also limits inappropriate studies (Table 56.6). In the case of inaspirable marrows, touch preparations should be made for morphologic assessment, and sufficient cells for flow cytometry may be obtained by maintaining negative pressure on withdrawal of the biopsy or aspirate needle and then rinsing the needle in nutrient media or buffered saline. In some cases, a second, fresh core biopsy can be minced and processed for flow cytometry and cytogenetic studies.

In cases of acute leukemia, the first question is whether it is lymphoid or nonlymphoid. Identification of Auer rods on Wright-stained aspirate smears is specific for a myeloid leukemia; however, Auer rods are found only in a minority of cases. Morphology is very important in the early identification of myeloid leukemias with promyelocytic differentiation, which can be sent for confirmatory FISH studies for the 15;17 translocation and can be completed in less than 24 hours. Flow cytometry is now a standard part of the diagnosis of many hematologic diseases, including all acute leukemias (Table 56.1), and for detecting minimal residual disease post therapy. Most cases (> 95%) can be classified as to lineage in less than 2 hours during the normal working hours of the laboratory. Flow cytometry is helpful in suggesting possible promyelocytic differentiation (DR−, CD2+, bright myeloperoxidase), megakaryoblastic differentiation (CD61+, CD41+, myeloperoxidase−), or the t(8;21)(q22;q22) (CD19+, CD34+, myeloid antigen+), but is not as useful in identifying other subsets in the French-American-British Cooperative Group (FAB) or World Health Organization classification. Cytochemical stains which were essential for FAB classification are now being performed infrequently and are now used most commonly when flow cytometry findings are ambiguous, especially in the case of possible mixed phenotype acute leukemia. Immunohistochemistry on the bone marrow core biopsy is helpful for lesions that may not be present in aspirated material, such as fibrosed areas of lymphoma or metastatic tumors. In some cases, both flow cytometry immunophenotyping and immunohistochemistry are required due to sampling differences between the aspirate and biopsy. Some cytoplasmic markers, such as BCL2 and cyclin D1, are only available by immunohistochemistry in most laboratories.

### TABLE 56.5 INDICATIONS FOR BONE MARROW EXAMINATION

| Unexplained cytopenia |
| Evaluation of leukemia |
| Confirmation of myeloproliferative neoplasm |
| Unexplained lymphadenopathy |
| Splenomegaly without a diagnosis |
| Diagnosis or staging of lymphoid neoplasms |
| Constitutional symptoms (fever, weight loss) without a diagnosis |
| Bone pain with abnormal laboratory work (e.g., complete blood cell count, ↑ protein, ↑ lactate dehydrogenase, and ↑ uric acid) |

### TABLE 56.6 SUSPECTED DIAGNOSIS ON MARROW SMEAR

| Suspected Diagnosis | Flow Cytometry/Cytogenetics/FISH |
Acute leukemia + +
Suspected myelodysplasia $^a$ +
Myeloproliferative neoplasm (particularly chronic myelogenous leukemia) $^b$ +
Lymphocytosis (predominantly small cells)

$^c$ If flow cytometry shows an aberrant T-cell or monotypic B-cell population

$^d$ Flow cytometry underestimates the percentage of plasma cells in bone marrow which is better assessed by immunohistochemistry on tissue sections

FISH and cytogenetics are playing an expanded role in the classification of hematologic neoplasia and the identification of prognostically favorable and unfavorable subsets of disease. $^{54, 58, 59, 60, 61}$ Favorable cytogenetics in AML include t(15;17)[q24.1;21.1] (PML/RARA) of APL, t(8;21)[q22;q22] (RUNX1-RUNX1T1), and inv(16) (p13.1q22) or t(16;16)[p13.1;q22] (CBFB/MYH11); these identify patients who are predominantly treated with either all-transretinoic acid plus chemotherapy (APL) or chemotherapy alone without early transplantation. Hyperdiploidy (more than 50 chromosomes per leukemia cell) and t(12;21)[q22;q22] (ETV6-RUNX1) are found in approximately 50% of childhood acute lymphoblastic leukemia (ALL) and confer a favorable prognosis. $^{62}$ Hypodiploidy (less than 45 chromosomes per leukemia cell), t(4;11)[q21.3;q23] (AFF4-MLL), and t(9;22)[q34;q11.2] (BCR-ABL1) are associated with a poor prognosis in ALL.

In suspected MDS, FISH and cytogenetic studies are helpful when morphologic abnormalities in hematopoietic cells are relatively subtle. $^{63, 64}$ Identifying 5q31 deletion in MDS is important because the patients may respond to lenalidomide. $^{65}$ Patients with abnormalities of chromosome 7 and/or complex cytogenetics are more likely to evolve to AML and should be considered for early allogeneic transplantation. Flow cytometric evaluation of MDS is an evolving application which holds great promise, although it is not well standardized in this application and thus not available at many institutions. $^{66}$ Flow cytometry is of no help in the evaluation of myeloproliferative neoplasms except when the presence of increased blasts on marrow smear point to an evolving acute leukemia/blast transformation. $^{53}$

Molecular genetics can identify clonality in lymphoid neoplasms, confirm diagnoses in CML and subtypes of acute leukemia, and monitor minimal residual disease when a molecular marker is present (Table 56.3). NPM1 and CEBPA mutations, when present alone, are favorable mutations in AML while FLT3 and DNMT3 mutations are usually unfavorable. In the core binding factor leukemias (AML with t[8;21][q22;q22][RUNX1-RUNX1T1] and AML with inv[16][p13.1q22] or t[16;16][p13.1;q22][CBFB/MYH11]), mutations of KIT are usually unfavorable. JAK2 mutations are present in most patients with PV and over one-half of patients with PMF and ET. $^{15, 17}$ Genomic profiles are being evaluated in hematopoietic neoplasms and can discriminate prognostic subgroups. Restriction fragment length polymorphisms and chimerism studies identifying percentage of donor myeloid and lymphoid cells are employed to monitor engraftments in allogeneic transplantation.

Lymphocytosis on a marrow smear is common in very young children. Phenotypically, the lymphocytes are usually B cells in all stages of differentiation (so-called hematogones). In such cases, the numbers and morphology of the myeloid, megakaryocytic, and erythroid cell lines are usually normal, which is helpful in differentiating these non-neoplastic
precursor B cells from the blasts of the pre-B ALL. Lymphocytosis on marrow smear in an older adult should always have phenotypic studies by flow cytometry. Further cyogenetic/FISH studies are helpful in small B-cell lymphomas with ambiguous phenotypes or in confirmation of the diagnosis of mantle cell lymphoma (by FISH). In unusual proliferations, cells from the bone marrow aspiration should be frozen for possible future studies.

Bone marrow examination should also be considered in patients who complain of bone pain whether or not bone lesions have been demonstrated radiographically and particularly if there is an abnormal CBC or abnormal chemistries, such as an elevated lactate dehydrogenase (LDH), total protein, or uric acid. Some processes, including myeloma, lymphoma, carcinoma, neuroblastoma, and granulomatous infections, may be quite focal and missed on marrow examination. Occasionally, radionuclide scans with gallium-67 or indium, CT, magnetic resonance imaging (MRI), and/or positron emission tomography (PET) scans may be helpful in localizing various types of tumors and identifying specific marrow sites for biopsy. Again, serum and urine electrophoresis, with immunofixation (which allows detection of monoclonal immunoglobulins hiding in the beta region) should be performed on adults with bone pain. Screening tests for neuroblastoma, including urine catecholamines, should be performed in children with bone pain and a nondiagnostic marrow examination.

EXAMINATION OF LYMPH NODES AND TISSUES

This section is concerned with the evaluation of the patient with palpable or visible enlargement of cervical, supraclavicular, axillary, inguinal, mediastinal, or hilar lymph nodes or tonsils. If the blood and marrow (when indicated, as discussed in the previous sections) fail to provide a diagnosis, the clinician should consider a fine-needle aspiration (FNA) or biopsy of enlarged lymphoid tissue. The presence of a variety of signs and symptoms may modify and shorten the diagnostic evaluation. For example, if the patient is ill with B symptoms or the clinical picture is fairly typical of a lymphoma, lymph node biopsy or aspiration should be performed immediately.

The causes of enlargement of lymph nodes are extremely varied. Table 56.7 outlines the major categories of disease leading to lymphadenopathy. This table is in no sense exhaustive. The approach to lymphadenopathy is similar to that of FUO, with the most common broad diagnoses being infection, cancer, and immune disorders. The first step is determining whether adenopathy is localized or generalized, and this differentiation points to a local disease versus systemic illness.

The most common cause of lymphoid enlargement is lymphocyte proliferation in response to antigenic stimulation.

The frequency of trichophyton infection of toes and trauma to feet and legs is reflected in the frequency of palpable inguinal nodes (usually smaller than 1 cm in diameter). If the patient’s occupation or hobby leads to frequent trauma of hands and arms, small palpable epitrochlear and axillary nodes are expected. Thus, the assessment of the lymphoid system in a laborer differs somewhat from that of an educator (unless the latter’s hobby is gardening or hunting).

---

**TABLE 56.7 CONDITIONS LEADING TO LYMPH NODE ENLARGEMENT**

**Lymphadenopathy Primarily Related to Immune Response from Infections**

Viral infections

Local or generalized lymphadenopathy with systemic infections (e.g., infectious mononucleosis (cervical), rubella (occipital), infectious hepatitis, and acquired immunodeficiency syndrome)

Pyogenic infections

Local enlargement of nodes draining areas of local infection (e.g., furuncles caused by staphylococci and oral infection)

Local enlargement of nodes draining the portal of entry of infections such as cat scratch fever, cryptococcosis, lymphogranuloma venereum, primary chancre of syphilis, and tularemia

Generalized lymphadenopathy from (e.g., Salmonella septicemia bacterial endocarditis, secondary syphilis, and toxoplasmosis)

Lymphadenopathy primarily from infection of the node by organisms

Pyogenic infection: the classic example is the bubo of Pasteurella pestis; more commonly, abscess

---

2913
formation by staphylococcal invasion

Granuloma formation: the entrance of tubercle bacilli or fungi, such as *Histoplasma capsulatum*, into nodes often results in granuloma formation as well as hypertrophy; identifiable organisms can be present within the granuloma.

**Neoplasia**

Primary neoplastic diseases of nodes: non-Hodgkin and Hodgkin lymphomas

Metastatic neoplastic processes occurring in nodes

Lymphoid leukemias: acute lymphoblastic leukemia and chronic lymphocytic leukemia

Myeloid leukemias: acute myeloid leukemia (granulocytic sarcoma) and chronic myelogenous leukemia

Primary myelofibrosis with extramedullary hematopoiesis, producing lymph node enlargement

Metastases from carcinoma, producing lymph node enlargement

**Autoimmune Diseases** (e.g., systemic lupus erythematosus, rheumatoid arthritis, Sjögren syndrome, and Hashimoto thyroiditis)

**Reaction to Drugs, such as the Hydantoins**

**Dermatopathic Related to Skin Diseases**

**Miscellaneous Diseases**

Granuloma formation as seen with sarcoid or in patients exposed to beryllium

Reactive hyperplasia, as seen in hyperthyroidism

Progressive transformation of germinal centers

Kikuchi-Fujimoto disease (histiocytic necrotizing lymphadenitis)

Kawasaki disease

Castleman disease

Histiocytic disorders

Langerhans cell histocytosis

Erdheim Chester disease

Rosai Dorfman disease

Children and adolescents commonly have more palpable nodes than do adults. This difference is presumed to reflect their more frequent exposure to new antigens and a larger total lymphoid mass in relation to body weight as compared to adults. Thus, significant generalized adenopathy has a more liberal definition in the young than in adults. Prominently visible tonsils, protruding into the oropharynx, are expected in preschool children but are uncommon in adults.

Retroperitoneal lymphadenopathy must be extreme before an abdominal mass becomes palpable. CT scan and lymphangiography (LG) provide complementary information concerning the status of retroperitoneal lymph nodes, although LG is no longer used. Abdominal CT scan provides images of nodal areas that usually are not visualized with LG, such as pararectal, omental, and superior retroperitoneal areas, and the hilus of the spleen and liver. Other imaging techniques, such as PET scan, gallium scan, and radiolabeled monoclonal antibody scans, may further delineate worrisome lymph nodes.

Improvements in imaging and clinical dependence upon imaging has led to its increased use and contributed to the rising cost of health care. Additionally, imaging techniques are so sensitive that incidental findings of uncertain clinical significance such as chest, adrenal, or renal masses may require additional evaluation, which further contributes to the expense. In conjunction with CT scans, PET scans are used to assess extent of disease and response to therapy in HL and many types of non-Hodgkin lymphoma (NHL).
Experience with many patients is the best guide in the selection and timing of lymph node biopsies or FNA. If doubt exists as to whether enlargement is significant, the choice between immediate biopsy or periodic observation to discover whether the nodes will enlarge or shrink should be made on the basis of ancillary findings. If other signs and/or symptoms are suggestive of lymphoma, biopsy of small, questionably enlarged nodes may yield a diagnosis. Biopsy should be performed after no more than 1 or 2 months of observation if the physician is still suspicious that the nodes are abnormal. Again, however, the physician's suspicion must be tempered by experience. Persistently enlarged lymph nodes considered abnormal in an adult may be well within the limits of normal in a child or adolescent patient.

There is no absolute size which can be used to determine the presence of pathology. Age of the patient, history, location, and physical evaluation assist in making a decision about biopsy. A size of 1.5 cm was used as a discrimination measurement in a study of 220 lymph node biopsies. Others have suggested that a persistent lymph node of 10 mm or more except in the inguinal region is a reasonable guideline. A multifactorial, retrospective analysis involving 22 clinical findings was made of 123 patients, ages 9 to 25 years, in whom results of lymph node biopsies were known. Only three variables proved to have significant discriminatory function; nodes larger than 2 cm in diameter on physical examination and abnormal findings on chest radiographs favored the diagnosis of a disorder necessitating treatment, whereas a history of recent symptoms related to otolaryngologic disease in the presence of enlarged cervical nodes was strong evidence against the presence of a disease requiring therapy.

Certain physical characteristics of nodes aid in the diagnosis of the cause of lymphadenopathy. Infected nodes usually are tender, and the overlying skin often is inflamed. Such nodes may be matted together. In certain types of infection, such as TB, aspergillosis, or actinomycosis, sinus tract formation is common. Infected nodes may be fluctuant. Nodes undergoing an immune response to infection also may be tender, but other signs of inflammation usually are absent. Tenderness may be related to other conditions, but this is uncommon. Carcinomatous nodes usually are hard and may be bound to one another and to surrounding tissue. Lymphomatous nodes are more often firm, rubbery, discrete, and freely movable; occasionally, anaplastic large cell lymphoma has a significant inflammatory component.

The location of the nodes may be helpful in diagnosis, and, again, the age and immunocompetence of the patient are critical factors in determining the approach. Axillary and inguinal adenopathy are often enlarged because of trauma or infection distally. Cervical lymphadenopathy is often due to localized infection but also can represent metastatic disease from the head and neck. Posterior occipital lymphadenopathy is classically seen in rubella (also toxoplasmosis) usually in conjunction with a maculopapular rash. Supraclavicular lymphadenopathy more often represents distant metastases or contiguous spread from the mediastinum. Isolated mediastinal adenopathy in a young person is usually HL. Large, bilateral hilar nodes without other detectable adenopathy are unusual in lymphomas and are more suggestive of sarcoidosis.

Infections may be either localized or generalized as the cause of lymphadenopathy. The most common forms of localized infections with cervical lymphadenopathy are pharyngitis and tonsillitis due to viral, mycoplasmal, and pyogenic infections (Streptococcus, Staphylococcus aureus, and S. epidermidis). Although the above usually cause bilateral adenopathy, unilateral adenopathy occurs with tonsillar abscesses, salivary adenitis, and dental abscesses. Systemic infections that may present with localized adenopathy include cat scratch disease, Lyme disease, tularemia, toxoplasmosis, and bubonic plague, but these patients usually have constitutional symptoms and may give a history of animal or tick exposure, or have a characteristic rash (e.g., Lyme disease). TB involving the cervical lymph nodes (scrofula) is one of the more common presentations of extrapulmonary TB. Adenopathy in HIV patients tends to be generalized and painless and can be due to HIV alone or other infections (e.g., atypical mycobacteria, toxoplasmosis, syphilis) or lymphoma.

Immunologic disorders may present with adenopathy as a prominent clinical feature. Kikuchi-Fujimoto disease (histiocytic necrotizing lymphadenitis) is a self-limiting illness characterized by cervical adenopathy and systemic symptoms; excisional biopsy is often performed to rule out neoplasia. Kawasaki disease is a multisystem vasculitis of infants and children usually with mucocutaneous lesions and cervical adenopathy; therapy with intravenous gammaglobulin and aspirin can prevent or ameliorate coronary artery abnormalities. Patients with SLE and rheumatoid arthritis may develop adenopathy but usually have characteristic clinical features and serology. Early lymph node biopsy should be considered in patients at increased risk for developing lymphoma such as those with an underlying autoimmune disorder (e.g., Sjögren syndrome and rheumatoid arthritis treated with methotrexate) or immunodeficiency (e.g., HIV infection and posttransplant). Drugs, such as phenytoin, allopurinol, and cephalosporins, can be associated with diffuse adenopathy that may regress with discontinuation of the drug.

In the event of a strong presumption of malignancy (particularly metastatic carcinoma or in patients with a previous diagnosis of lymphoma), or in lymphadenopathy in areas difficult to biopsy (retroperitoneum), needle biopsy or aspiration is becoming the primary procedure for diagnosis. The procedure for lymph node aspiration is simple and can produce diagnostic information in the time it takes to stain and examine the smears. In addition the use of cultures,
flow cytometry, and cytogenetic studies on aspirated material greatly amplifies the quality of diagnostic information and its availability. This approach requires a two-step triage: 1) rapid examination of the smear to determine

P.1270

if flow cytometry is warranted; 2) if flow shows evidence for a neoplasm, deciding whether or which cytogenetic/FISH/molecular genetic studies are indicated. However, the frequency of indeterminate or incorrect diagnosis is higher with needle biopsy aspiration than with excisional biopsy, as the histologic diagnosis often depends on changes in the overall architecture of the lymph node in addition to the cytology of individual cells. Excisional biopsy yields more tissue for diagnostic studies, facilitating preparation of multiple histologic sections for routine and special stains as well as providing more adequate material for cultures and immunophenotypic and genetic studies. Therefore, when appropriate, excisional lymph node biopsy is preferred over FNA or core biopsy for complete diagnostic evaluation.

*Most of these require flow cytometry as an adjunct. In processes which are focally neoplastic or tumor cells are in minority (Hodgkin and T-cell-rich B-cell lymphoma), a missed diagnosis is possible.

For excisional biopsy or FNA, the largest palpable node available is given preference. More than one node should be removed, if possible, avoiding irradiated areas. When other considerations are equal, biopsy of cervical or supraclavicular nodes is preferable to biopsy of axillary nodes, and biopsy of nodes from any of these regions is preferable to that of inguinal nodes. As previously mentioned, inguinal nodes frequently are enlarged from chronic foot infection, in which case the architecture often is distorted. Axillary nodes, unless enlarged, may be difficult to find during surgical procedures because of the complex and changed anatomy during exposure of this area.

FISH, fluorescence in situ hybridization.

a If clinical features are highly suggestive of non-Hodgkin lymphoma or tissue is from a site difficult to sample (e.g., mediastinum or retroperitoneum) a limited panel for B-cell clonality and T-cell
distribution may be helpful.

If clinical features and gross appearance are typical for Hodgkin lymphoma, flow cytometry and genetic studies are unlikely to be helpful.

If flow cytometry suggests a neoplastic process.

Usually not helpful except if screening flow cytometric studies demonstrate an abnormal B- or T-cell population.

In the “good old days” when most diagnoses of disease involving marrow or lymph nodes were made (or not made) based solely on the morphology of smears and tissue sections, coordination of the efforts of the clinician, surgeon, and pathologist was less important and much less complex. Today, with a bewildering array of morphologic, cytochemical, immunologic, molecular genetic, and cytogenetic techniques available (and essential for many diagnoses), the clinician, surgeon, and pathologist must work closely together to optimize the diagnostic information of any biopsy while, at the same time, limiting expense. The major pitfall in these efforts is improper specimen handling, precluding the use of important techniques available only in fresh tissue (i.e., cultures for pathogens, cytogenetics, and flow cytometry for surface markers).

The process of evaluation begins before the procedure. The studies that are done are guided by clinical information and a review of previous biopsy material. At the time of biopsy or needle aspiration, the studies available within minutes of the procedure (i.e., the Wright-stained marrow aspirate smear of bone marrow or the hematoxylin- and eosin-stained smear of a lymph node biopsy touch prep) are used to decide which diagnostic techniques will be applied to any given case. If the suspicion of infection is high, material for cultures is best obtained in the sterile environment of the operating room before sending it to pathology.

Table 56.9 includes guidelines for the diagnostic evaluation of tissue biopsies and aspirations based on clinical information and the aspirate smear/touch prep appearance. The most important clinical information is the likelihood that a process is (a) NHL, (b) HL, (c) a carcinoma, or (d) a reactive process. The clinical information, including the age of the patient along with the touch prep or smear appearance, often helps in determining whether flow cytometry or cytogenetics is needed (as in many cases of NHL or leukemia).

NHL would be uncommon in a child or young adult with a predominance of small lymphocytes on touch preps (Fig. 56.6A), but would more likely occur in an elderly patient. In a child or teenager, the major differential diagnosis would be between a reactive node or lymphocyte-predominant HL. In neither diagnosis would flow cytometry or cytogenetics be of much benefit. On the other hand, in an older patient in whom a small B-cell NHL is more likely, immunophenotyping is of great help in proving clonality and in identifying immunophenotypic patterns characteristic of subsets of NHL of therapeutic and prognostic significance (e.g., hairy cell leukemia and mantle cell lymphoma). The role of FISH and cytogenetic studies is assuming increasing importance in the diagnosis of small B-cell lymphomas, particularly follicular (t[14;18]) and mantle cell (t[11;14]) lymphoma, and is prognostically important in subsets of extranodal marginal zone lymphoma (e.g., t[11;18]).

P.1271
FIGURE 56.6. High power of hematoxylin eosin-stained touch preps of lymph node biopsies demonstrating (A) predominance of small lymphocytes in an adult with small lymphocytic lymphoma/chronic lymphocytic leukemia; (B) mixed pattern of small and large lymphocytes, macrophages, plasma cells, and neutrophils in a child with reactive adenitis; (C) mixed population of small and large lymphocytes with occasional large atypical cells in a patient with classical Hodgkin lymphoma; and (D) predominance of large lymphocytes (many with polylobate nuclei) in a patient with large B-cell lymphoma of the mediastinum.

In children and young adults with a touch prep showing a polymorphous mix of small and large lymphocytes and inflammatory cells (Fig. 56.6B), flow cytometry is not routinely performed. Most patients with this mixed pattern on touch preps will have a reactive process or HL (Fig. 56.6C); however, a few B-cell NHL and peripheral T-cell lymphomas may show such patterns. If the clinical likelihood of NHL is high, or in those patients with occasional large atypical cells who do not have clinical features of HL, a limited and inexpensive panel for B-cell clonality and T-cell antigen loss can be performed. If these studies demonstrate an abnormality either in the small or large cell population, then more expanded panels can be run. If the case is not typed and on permanent tissue sections appears to be NHL, immunophenotyping can be performed on paraffin sections and information about clonality (T and B) can be retrieved from frozen tissue or the paraffin-embedded tissue as needed.96,97

In patients with numerous large cells or blasts on a touch prep (Fig. 56.6D) typing studies (and in many, cytogenetics) are essential in identifying prognostically significant patient subgroups. For example, in patients with blast cells on touch prep, the differential diagnosis would be lymphoblastic lymphoma (both B and T), blastic transformation of mantle cell lymphoma, and extramedullary acute leukemia. Flow cytometry is quite useful in the differential diagnosis and can provide an answer in hours (well in advance of other cytogenetic or immunohistologic techniques) (Figs. 56.2 and 56.3). Tissue should also be placed in glutaraldehyde for electron microscopy in these cases, because poorly differentiated tumors, such as neuroblastoma or rhabdomyosarcoma, may mimic hematopoietic neoplasms on touch prep.

A histologic appearance of reactive hyperplasia or of nonspecific granulomatous changes does not rule out the possibility of HL or NHL at another site. For example, not all enlarged nodes from patients known to have HL show evidence of the disease;98 it is not surprising that the first biopsy may give negative findings in a patient in whom a second biopsy is diagnostic.99,100 Similarly, analysis of surface antigens on cells from an initial biopsy that may not contain the tumor may indicate that the B-cell population is polyclonal when later specimens containing the tumor show a monoclonal
proliferation. Molecular studies may identify monoclonal lymphoid populations earlier than flow cytometry or routine immunoperoxidase stains in selected cases. In equivocal or difficult cases, particularly those in which there are discrepancies between the histologic diagnosis, the clinical picture, and the results of ancillary studies, consideration should be given to obtaining consultation in hematopathology. If more than one node is removed initially, the likelihood of positive findings is enhanced. In nondiagnostic biopsies, the decision to obtain more tissue for further study must be individualized. If no other nodes are enlarged and the patient has few or no symptoms, observation may be advisable. Prompt diagnosis and proper therapy are important in bacterial and fungal infections, HL, aggressive NHL, and acute leukemias, but are less important for the eventual outcome of the other conditions listed in Table 56.7.

EXAMINATION OF THE SPLEEN

Many of the conditions that lead to lymphadenopathy also produce a palpably enlarged spleen. Consequently, the preceding discussion regarding evaluation of the patient with lymphadenopathy is equally applicable to the patient with splenomegaly. When splenomegaly is associated with systemic infection (acute splenic tumor), the spleen usually is barely palpable, soft to firm, but not hard, and splenomegaly disappears shortly after recovery from the infection. A palpable spleen usually indicates disease, but a soft spleen tip can be palpated by an experienced physician in approximately 1% to 2% of apparently healthy persons.

Splenic puncture may be helpful in the evaluation of patients with certain conditions (e.g., leishmaniasis and kala-azar), but is rarely used in North America. Diagnostic splenectomy is required in some patients, especially those in whom the only palpably enlarged tissue is the spleen. Before this procedure is considered, however, numerous other studies should be considered and may include CT scan, liver/spleen scan, and other imaging studies to outline splenic vein patency, as well as hepatic blood flow and any associated adenopathy. In many cases, results of these studies indicate the diagnosis. For instance, splenic hypertrophy owing to increased red cell destruction, such as occurs in hereditary spherocytosis and thalassemia, should be detected by means of appropriate blood and other examinations. Biopsy of enlarged nodes should always be carried out before splenectomy is undertaken. Examination of the marrow should also be considered. Liver function tests (LFTs) and needle biopsy of the liver also are warranted to exclude, among other considerations, the possibility that the splenomegaly results from hepatic disease, producing increased portal pressure.

Indications for splenectomy are discussed in Chapter 65 and elsewhere in relation to the various diseases associated with splenomegaly. If no explanation is found for splenomegaly, splenectomy should be considered to make or to exclude a diagnosis of lymphoma.

FEVER OF UNKNOWN ORIGIN

The classic definition of FUO proposed by Petersdorf and Beeson in 1961 is a temperature elevation of 38.3°C (101°F) or higher persisting over 3 weeks in duration and without a diagnosis after 1 week of intensive in-hospital investigation. The definition of FUO has been modified due to the changing medical environment which required a shift to an initial outpatient evaluation. Durack and Street proposed the duration of evaluation for FUO be changed to only 3 days of hospitalization or at least 3 outpatient visits or 1 week of ambulatory investigation. Because of changing medical practices and different types of patients with prolonged fever, FUO is currently subdivided according to four categories: (a) classic FUO, (b) nosocomial FUO, (c) immune-deficient FUO, and (d) HIV-related FUO. Host factors (e.g., age of the patient and immunocompetence) and environment (e.g., socioeconomic status and geographic location) are factors in the evaluation of FUO. Arnow and Flaherty have proposed a minimum number of tests to be performed prior to labeling a patient with FUO.

The “big three” categories of FUO remain infections, autoimmune or non-infectious inflammatory disease (NIID), and malignancies (Table 56.10), although the incidence of cancer has declined due to improved diagnostic techniques. Miscellaneous diseases and undiagnosed conditions round out the main five categories of FUO. There are over 200 different causes of FUO, but most patients have common illnesses presenting with unusual manifestations. In a systematic review of the literature for 1995 to 2004 which identified 1,488 cases of FUO, 74% of the patients were accurately diagnosed, with 37% due to infections, 16% due to NIID, 11% due to neoplasms and 10% due to miscellaneous diseases. In developing countries, infections, particularly TB, often represent
more than one-half the cases of FUO, whereas developed countries have a higher incidence of NIID and neoplasms. Undiagnosed conditions and infections are more common in younger patients, whereas NIID, including temporal arteritis and polymyalgia rheumatica, and malignancies are more common in the elderly. Despite improved imaging and better culture techniques, the percentage of undiagnosed conditions has increased to the 25% to 50% range in recent series and is higher in children. 

### TABLE 56.10 DISEASES CAUSING FEVER OF UNKNOWN ORIGIN

#### Malignancy
- **Common**
  - Hodgkin lymphoma
  - Non-Hodgkin lymphoma
  - Hypernephroma
  - Metastatic carcinoma: liver, central nervous system
- **Uncommon/rare**
  - Hepatomas
  - Pancreatic carcinoma
  - Acute leukemia/myelodysplastic syndrome
  - Atrial myxoma
  - Neuroblastoma
  - Central nervous system tumor

#### Infection
- **Common**
  - Tuberculosis: extrapulmonary—renal, meningitis, miliary
  - Abscesses
  - Intraabdominal
  - Subdiaphragmatic (periappendiceal, pericolonic, hepatic)
  - Pelvic
- **Uncommon**
  - Abscesses: splenic, perinephric, dental, brain
  - Subacute bacterial endocarditis (if culture-negative, suspect rightsided endocarditis, intravenous drug abuse)
  - Cytomegalovirus
  - Toxoplasmosis
  - *Salmonella* enteric fevers
- **Rare**
  - Localized, culture-negative infections: sinusitis, osteomyelitis, chronic meningitis, cholecystitis, urinary tract infection, mastoiditis
  - Viruses: Epstein-Barr, hepatitis (all types), human immunodeficiency virus, parvovirus, other
  - Cat scratch disease
Brucellosis
Listeriosis
Spirochetal infections
Relapsing fever
Lyme disease
Leptospirosis
Rat bite fever
Rickettsial infections: Rocky Mountain spotted fever, endemic typhus, Q fever, ehrlichiosis, trench fever, bacillary angiomatosis
Parasitic disease: malaria, babesiosis, toxoplasmosis, trypanosomiasis, leishmaniasis, trichinosis, amebic liver abscess
Fungal infections: blastomycosis, histoplasmosis, coccidioidomycosis, cryptococcosis, candidiasis
*Yersinia* infections
Chlamydial infections: psittacosis, lymphogranuloma venereum
Foreign object-related infections: vascular grafts, indwelling catheters, prosthetic devices
Vascular infections: aortic aneurysm, jugular phlebitis

**Autoimmune Disease**

Common
Still disease
Giant cell (temporal) arteritis
Uncommon
Periarteritis nodosa
Rheumatoid arthritis
Wegener granulomatosis
Rare
Systemic lupus erythematosus
Vasculitis (Takayasu arteritis, hypersensitivity vasculitis)
Felty syndrome
Acute rheumatic fever
Pseudogout
Sjögren syndrome
Behçet disease
Familial Mediterranean fever
Polymyositis
Tumor necrosis factor receptor-associated periodic syndrome

**Miscellaneous**

Undiagnosed Conditions

Nosocomial FUO is a particular problem for the patient in an intensive care unit and is related to the type of instrumentation (indwelling vascular lines, Foley catheters, and endotracheal tubes), the specific spectrum of microorganisms and their antimicrobial sensitivity, and the degree of immunodeficiency. Common conditions causing nosocomial FUO include septic thrombophlebitis, pulmonary embolism, Clostridium difficile enterocolitis, and drug fever. More than 60% of FUO in the immunodeficient host is due to infections; the type and severity of infection correlate with the severity and length of neutropenia. Occult fungal infections, including hepatosplenic candidiasis, aspergillosis, and mucormycosis should be considered in the immunodeficient host with prolonged neutropenia.

The initial exposure to HIV may cause FUO, and the HIV may go undetected due to lack of seroconversion. FUO in HIV patients is due to an opportunistic infection in over 70% of patients. Atypical and typical mycobacteria are the most common infections in HIV patients; other infections causing FUO in AIDS include CMV, Pneumocystis jiroveci, toxoplasmosis, histoplasmosis, leishmaniasis, and cryptococcosis. In Asia, Penicillium marneffei is a common cause of FUO in HIV patients; papular skin lesions with central necrosis are seen in 70% of HIV patients. Lymphoma, both aggressive B-cell NHL and HL, multicentric Castleman, and drug reactions may also be a cause of FUO in HIV patients. Long-lasting fever in HIV without a diagnosis is seen in patients with advanced HIV and low CD4 T lymphocytes. The use of highly active antiretroviral therapy (HAART) in AIDS has led to a decline in FUO. After the start of HAART, an immune reconstitution inflammatory syndrome is seen in 25% to 35% of HIV-positive patients and usually occurs within 2 months. The patient can deteriorate due to worsening of an opportunistic infection, particularly Mycobacterium tuberculosis, M. avium complex, or Cryptococcus neoformans.

The pattern of fever has been extensively evaluated, but rarely is so specific as to be diagnostic of a disease. Possible exceptions include a Pel-Ebstein pattern of recurrent high fever with intermittent afebrile, asymptomatic periods in HL; the tertian and quartan patterns of malaria; the pulse-temperature dissociation of typhoid fever; the reversal of the normal diurnal pattern observed in disseminated TB; and a cyclical pattern (every 3 to 4 weeks) with cyclic neutropenia.
A continuous fever is more likely to be diagnosed than a periodic fever.\textsuperscript{124, 125} The prognosis of a patient with undiagnosed FUO is favorable, with mortality less than 5%\textsuperscript{126}.

In the evaluation of a patient with FUO, history and physical examinations often need to be repeated.\textsuperscript{119, 127, 128} Host factors (e.g., HIV, sickle cell disease, prior malignancy, organ transplant, cardiac valve disease, diabetes, and prior surgery) and external factors (e.g., occupation; travel; and exposures to infections, animals, and drugs) may point to the types of studies warranted to diagnose the etiology of FUO. The goal of the history and physical examination is to identify potentially diagnostic clues. The physical examination should pay particular attention to the skin (e.g., rashes, subcutaneous nodules, aphthous ulcers, and nail beds), eyes (e.g., uveitis and Roth spots and infections on funduscopic examination), sinuses, lymph nodes, heart (e.g., rubs and murmurs), lungs, organomegaly, and perirectal area. Bone, joint, and musculoskeletal examinations are important when symptoms of pain, limping, or weakness are associated with FUO.

The laboratory evaluation of FUO involves a minimal set of tests which may further direct the investigation: CBC, sedimentation rate, C-reactive protein; comprehensive metabolic profile, including lactose dehydrogenase; urinalysis, antinuclear antibodies, rheumatoid factor; viral screens, particularly CMV, EBV, and HIV; tuberculin skin test, and chest x-ray and/or CT scans of specific areas as determined by history and/or physical exam. Three sets of routine blood cultures have been added to the initial battery of tests.\textsuperscript{108} If a patient has two of the three laboratory abnormalities: elevated C-reactive protein, elevated ferritin but < 500 µg/L, or eosinopenia, infection is more likely than non-infection.\textsuperscript{129} Table 56.11 outlines possible etiologies as suggested by the findings on CBC and sedimentation rate or C-reactive protein. Anemia, an abnormal white cell count, elevated LFTs, and elevated LDH were independent predictors of having a serious illness, commonly neoplasia, and a poor prognosis for patients with FUO.\textsuperscript{130} Examination of the blood smear for abnormal cells or pathogens may be warranted according to history, such as travel or tick exposure; or physical exam, particularly petechia, adenopathy, or organomegaly. Flow cytometry can be confirmatory in specifying the type of malignant cell. Ehrlichiosis, malaria, leishmaniasis, histoplasmosis, TB, and babesiosis are among the diseases in which organisms may be seen in the peripheral blood.

NIID that have remained a cause of FUO are those that are not readily diagnosed by serologic testing, such as temporal arteritis and Still disease.\textsuperscript{131} Giant cell, or temporal, arteritis (GCA) represented 17% of cases of FUO in the elderly and is suggested by jaw or tongue claudication, localized headaches, visual disturbances, and temporal artery abnormalities (e.g., decreased pulse, tenderness, or nodularity). The diagnosis is suggested by an elevated sedimentation rate (> 50 mm/hour) and formerly was confirmed by an abnormal temporal artery biopsy. Color Doppler ultrasonography and high resolution MRI can diagnose GCA in most patients so that biopsy may be reserved for patients with negative imaging.\textsuperscript{132} Adult onset Still disease can present as an FUO in a younger patient with or without a characteristic rash. Four variables associated with Still disease are arthritis, pharyngitis, splenomegaly, and neutrophilia.\textsuperscript{133} The highest elevations in serum ferritin are seen in Still disease and hemophagocytic lymphohistiocytosis (HLH).

2923
HLH may be familial, with 70% to 80% occurring in children under the age of 1 year, or sporadic secondary to infections, malignancies, particularly peripheral T/NK lymphomas, or autoimmune diseases. The most common features of HLH are FUO, hepatosplenomegaly, and cytopenias; and a diagnosis can be made by confirmation of an underlying genetic defect (in 80% of familial cases), or by having five of eight clinical criteria, including ferritin ≥ 500 µg/L, soluble CD25 (IL-2 receptor) ≥ 2,400 U/ml, and decreased natural killer cell activity. Early diagnosis of HLH is critical because of a high early mortality, varying from 20% to 70%, and the availability of effective therapy. After the syndrome is controlled by immunotherapy with a combination of dexamethasone, etoposide, and cyclosporine, familial forms of HLH which have mutations in genes regulating the granule-dependent exocytosis pathway, and genetic immune deficiencies, such as X-linked lymphoproliferative (XLP), Chediak-Higashi, and Hermansky-Pudlak, should undergo allogeneic stem cell transplant.
Rare, hereditary disorders characterized by recurrent episodes of fever and autoimmune features include familial Mediterranean fever, tumor necrosis factor receptor-associated periodic syndrome, and the hyperimmunoglobulinemia D syndrome. Familial Mediterranean fever is an autosomal recessive disorder and is caused by mutations in the pyrin-marenostrin gene MEFV, which provides inhibitory signals to inflammatory cells. Tumor necrosis factor receptor-associated periodic syndrome is an autosomal dominant condition caused by missense mutations in the gene encoding type I tumor necrosis factor receptor (TNFRSF1A), which results in an exaggerated response to tumor necrosis factor. Hyperimmunoglobulin D syndrome is due to mutations in the gene mevalonate kinase (MVK), but the mechanism producing fever and autoimmune features is unknown.

Two diseases that can be overlooked are factitious fever and Whipple disease. Patients presenting with factitious fever tend to be young adults who are often in the medical field and have a relative bradycardia. Intravenous injections of organisms or a febrile child with a Munchausen by proxy parent are other indications of factitious fever. Whipple disease should be suspected in patients with FUO, arthritis, mental status changes, and malabsorption. Diagnosis is made by demonstration of PAS-positive macrophages on small bowel biopsy and can be confirmed by detecting Tropheryma whippelii by PCR.

Imaging tests (e.g., CT, MRI, PET/CT, transesophageal echocardiography, and radioisotope scans) have altered the distribution but not the type of illnesses causing FUO. Endocarditis and abscesses, as well as neoplasia, have decreased with improved imaging and cultures. The ability to diagnose an etiology of FUO has paradoxically decreased and led to a higher incidence of unclassifiable causes in some recent series. [18F]-fluorodeoxyglucose (FDG-PET) in conjunction with fusion CT is emerging as an effective modality in the diagnostic work-up of FUO. Advantages of PET/CT over gallium scintigraphy include completion of the exam within a short period of time and improved resolution, while disadvantages include a relatively high cost and limited availability in most of the world. A meta-analysis of FUO studies indicated that 32% of FDG-PET scans and 62% of FDG-PET/CT scans contributed to a final diagnosis. Indium 111 granulocyte scintigraphy may be more helpful than PET scans in diagnosing infections.

Invasive tests have a variable yield and depend upon the type of host, the initial evaluation of FUO, physical exam findings, and laboratory abnormalities. Bone marrow aspiration with biopsy was diagnostic in nearly a fifth of patients with FUO and was particularly helpful in the presence of anemia or thrombocytopenia. Bone marrow exam with cultures is more rewarding in immunocompromised than in immunocompetent hosts. Percutaneous liver biopsy is similarly helpful in HIV-infected patients with FUO, organomegaly, and increased LFTs. Lymph node biopsy is useful in diagnosing lymphomas for which an excisional or core needle biopsy is preferable over a FNA for the initial diagnosis. Necrotizing lymphadenopathy may be present in lymphomas or in reactive processes, including infections (toxoplasmosis, lymphogranuloma venereum, Yersinia pseudotuberculosis, cut scratch, tularemia), rheumatologic disorders, Kawasaki, and Kikuchi-Fujimoto disease. The latter is usually seen in middle-aged women of Asian descent who present with fever, cervical adenopathy, and leukopenia and have a self-limited course over 1 to 4 months. Granulomas in lymph node biopsies are nonspecific and may be seen in sarcoidosis, infections, both HL and NHL, and carcinoma. Laparotomy is rarely performed unless there is adenopathy that is not easily approached by less invasive procedures, including FNA, mediastinoscopy, thoracoscopy, and laparoscopy. The goal is to identify treatable disease as expeditiously as possible.

Empirical antibiotic trials are rarely warranted except in the immunocompromised patient with neutropenia and fever. Empirical antifungal therapy was established as an effective strategy in the 1980s for acute leukemia patients with prolonged neutropenia following chemotherapy and for patients undergoing stem cell transplantation (SCT). Prophylaxis against infections and pre-emptive antiviral strategies are routinely used in SCT. Occasionally, antibiotics are given in culture-negative endocarditis; and antituberculosis therapy is used in the elderly with suspected miliary TB. High-dose steroids with or without alkylating agents can be considered in cases of vasculitis which have diagnostic images or proven biopsies. Naprosyn has been advocated as a means to distinguish fever of malignancy from infection but should not prevent the search for infection. Treatment for malignancy should almost never be instituted without a tissue diagnosis.

RECURRENT INFECTIONS

The most common clinical presentation of immunodeficiency (either congenital or acquired) is infection (Table 56.12). More than one infection requiring hospitalization, infection with unusual pathogens, or an inappropriately delayed response to optimal therapy should all be tip-offs to possible underlying immunodeficiency. Chronic sinusitis, recurrent otitis, persistent thrush, chronic diarrhea, or skin rashes may be an early manifestation of immunodeficiency. Delayed
umbilical cord stump separation is indicative of neutrophil defects, including LAD and interleukin-1 receptor (ILR-1)-
associated complex deficiency. Eczema or pustular rash, skin abscesses, and sinupulmonary infections within the
first few weeks of life suggest hyper-IgE (HIES or Job) syndrome. Patients may present with sequelae of
immunodeficiency (e.g., delayed growth or failure to thrive in children or unexplained chronic obstructive pulmonary
disease). Cytopenias, including lymphopenia or thrombocytopenia, or splenomegaly, may be an early finding. In some
patients, particularly those with HIV infection, lymphoma or a nonhematologic malignancy may be the presenting
manifestation. In congenital immunodeficiency diseases, such as IgA deficiency, or deficiency of classic pathway
complement components, features of autoimmunity may dominate the clinical picture.

TABLE 56.12 CLINICAL APPROACH TO IMMUNODEFICIENCY

**Red Flags for Immunodeficiency**

More than one hospitalization for infection
Infection with organisms not usually pathogenic
Recurrent otitis, sinusitis or pneumonia
Persistent thrush
Deep skin or organ abscesses
Growth failure in children
Delayed or absent response of infection on appropriate therapy

**Initial Evaluation**

History
Family history of primary immunodeficiency
Age of onset of infection
Type of infection
Physical examination

**Initial Investigation for:**

Bacterial infection (implies B-cell, phagocyte, or complement deficiency)
Infection with intracellular organisms (implies deficient T-cell/cellular immunity)
CBC and differential for neutrophil count and morphology, quantitative immunoglobulins, CH50
Human immunodeficiency virus serology, CBC and differential for lymphocyte count, T-subset
analysis, skin testing in adults
CBC, complete blood count.

Age of onset of infection, family history, including parental consanguinity, and clinical findings provide clues to diagnosis,
but laboratory tests identifying abnormal component(s) of the immune system are essential. Testing is directed at
different parts of the immune system: T cells and cell-mediated immunity, B cells and humoral immunity, phagocytes, and
complement. Congenital defects in T-cell-mediated immunity may appear in the neonatal period and usually effect
antibody production which is dependent on intact T-cell function, whereas antibody deficiencies appear at the 6 to 9
months stage after the waning of maternal antibodies. Immunoglobulin levels, flow cytometry, and complement levels
detect deficiencies of the immune system, but immune function studies, such as lymphocyte response to mitogens,
specific antibody response to vaccine antigens, skin testing, and assays of neutrophil function may be more important in
diagnosis. Skin testing is of little value in children younger than 1 year because they are unlikely to have previously been
exposed to antigen used in testing. In older children and adults, the presence of reactive skin tests to recall antigens
virtually excludes a significant defect in cell-mediated immune response. In utero or neonatal screening.
for immune deficiencies can be critical in identifying congenital disorders, many of which are optimally treated with early SCT. T-cell receptor excision circles and kappa-deleting recombination circles can detect T- and B-cell lymphopenia and suggest a diagnosis of SCID and X-linked agammaglobulinemia, respectively. Detecting a molecular mutation in a gene and/or protein controlling part of the immune system is the ideal diagnosis.

Primary immunodeficiency disorders (PIDs) refer to a heterogeneous group of diseases characterized by defects in one of more parts of the immune system (Chapter 63). PIDs are usually inherited and are rare, with an estimated prevalence of 1 in 1,200 live births. IgA deficiency is the most common; it occurs in 1 in 300 to 500 births, but only one-third have significant infections. Although PID may present as life-threatening infections in childhood, more than 40% may not be diagnosed until adulthood. Time until diagnosis of any PID has decreased with better awareness and improved diagnostic tests. Antibody deficiency syndromes comprise approximately 50% to 65% of PID, followed by 30% to 40% combined immune deficiencies, 10% to 18% phagocyte dysfunctions, and 1% to 2% complement deficiencies.

An early test in any patient of any age with suspected immunodeficiency is HIV serology. In the HIV-negative patient, the age of the patient, geographic location, and type of infection or problem should dictate the tests ordered. Congenital immunodeficiencies predisposing to sepsis can be subdivided into those affecting innate immunity and those affecting the adaptive immune system. The subdivision is somewhat arbitrary and there can be clinical overlap, as some molecular lesions will affect both types of immunity. The former involves the immediate response of the immune system to a pathogen and includes defects in complement proteins and mannose-binding lectin (MBL) activation, phagocyte quantity and quality, and the type-1 cytokine axis. Neisseria bacteremia and meningitis are seen in complement deficiencies. Neutrophil defects result in periodontal disease, oral ulceration, or cutaneous and visceral abscesses; and they have a narrow spectrum of infections: Staphylococcus aureus, Burkholderia cepacia, Serratia marcescens spp., or Aspergillus spp. In the absence of immune suppression, invasive aspergillosis is seen only in chronic granulomatous disease (CGD), and disseminated nontuberculous mycobacterial infection is seen in patients with defects of the IFN-γ/IL-12 axis. An overwhelming EBV infection may be the initial presentation of XLP syndrome. XLP1 results from defects in signaling lymphocytic activation molecule -associated protein, which is required for the activation of NK and cytotoxic lymphocytes. The adaptive immune system requires time after the initial exposure and representative defects include the different types of SCID, ataxia telangiectasia, and WAS.

In a patient with recurrent bacterial infection, the three major screening tests are a CBC with differential and peripheral blood smear, quantitative immunoglobulins, and a CH50. Giant granules in neutrophils in a patient with oculocutaneous albinism indicates Chédiak-Higashi syndrome. Thrombocytopenia with small platelets in a patient with eczema and abnormal gamma globulin levels is consistent with WAS. Interpretation of quantitative immunoglobulins depends on an awareness of the variation in the normal ranges with age. IgG, IgA, and IgM are markedly decreased in children with physiologic hypogammaglobulinemia of infancy, common variable immunodeficiency (CVID), and X-linked agammaglobulinemia. In the first two conditions, patients have circulating B cells by flow cytometry, whereas in X-linked agammaglobulinemia B cells are absent. Thymoma is another circumstance with decreased immunoglobulins and decreased or absent B cells. In hyper-IgM syndrome, the presence of markedly elevated IgM with depressed IgG and IgA is virtually diagnostic. Patients with WAS who respond poorly to encapsulated bacteria often have an isolated decrease in IgM or may also have increases in IgE and IgA. Marked elevations of IgE (HIES or Job syndrome) are seen in patients with chemotactic defects, recurrent staphylococcal skin disease, cyst-forming pneumonia, and musculoskeletal abnormalities. Autosomal dominant form involving a mutation in signal transducer and activator of transcription 3 (STAT3) and an autosomal recessive form resulting from mutation of the inhibitor of cytokinesis 8 protein (DOCK8) have been described. In occasional patients with recurrent bacterial infection, measurement of IgG subclasses or responses to individual antigens (e.g., tetanus and diphtheria) may be helpful in making a diagnosis.

In adults with low IgG, the three major considerations are CVID, CLL, and multiple myeloma. Patients with CVID not only have recurrent infections but also may develop ITP, autoimmune hemolytic anemia, sarcoid-like granulomatous disease, inflammatory bowel disease, hepatitis, and NHL. Patients with CLL have hypogammaglobulinemia, lymphocytosis, and immunophenotypic studies demonstrating a monotypic CD5+, CD23+ B-cell population. In myeloma patients with a decreased IgA, IgM, or IgG, electrophoresis of serum identifies a paraprotein in more than 80% of patients, although immunofixation may be required to uncover IgA monoclonal protein hiding in the beta region. Some myeloma patients have a negative serum electrophoresis with immunofixation. Most of these patients have a monoclonal light chain on urine electrophoresis. Serum light chain assays can identify and quantify the kappa and lambda light chains.
The complement system is a part of innate immunity and can be activated by three pathways.¹⁸⁵ The classical pathway (C1, C4, C2) is activated by binding C1q to immunoglobulins on microbes or by direct binding to cells undergoing apoptosis. Patients with deficiency in the early classic complement pathway often have autoimmune disease (e.g., SLE and rheumatoid arthritis), which in part may be related to the physiologic role of the classic pathway in clearing immune complexes from the circulation.¹⁸⁶ The alternative pathway can be directly activated by microbes; and the lectin pathway is activated by carbohydrate moieties present on microbes. Hemolytic assays to assess the classical and alternative pathways have been available for years, but a complement kit can now assess all three pathways.¹⁸⁷

Congenital complement deficiencies are rare autosomal recessive diseases except for properdin deficiency which is X-linked. All patients with deficiency of C1, C2, C3, C4, C5, C6, C7, or C8 have a zero CH50 (also seen with improperly handled specimens and occasionally in patients with severe immune complex disease).¹⁸⁶ Deficiency of C3, the central component of all three pathways is associated with SLE, glomerulonephritis, and bacterial infections. Deficiencies of properdin and factor D, components of the alternative pathway, and deficiencies of the late components C5, 6, 7, 8, and 9 often present with fulminant infection due to Neisseria species. Deficiency of MBL, an initiator of the lectin pathway, is due to point mutations of the MBL2 gene and is associated with an increased risk to a variety of infections.¹⁸⁶ ¹⁸⁷

If quantitative immunoglobulins, CH50, the absolute neutrophil count, and neutrophil morphology are normal in a patient with recurrent bacterial infections, WBC functional studies for CGD or other enzyme deficiencies are indicated (Chapter 58). The nitroblue tetrazolium test is abnormal in many, but not all, of these defects.¹⁷³ CGD is due to deficient function of the reduced nicotinamide adenine dinucleotide phosphate oxidase, which is responsible for the respiratory burst in phagocytes.¹⁷¹ The diagnosis of CGD is now made by assays that rely on superoxide production. There are four genetic subtypes of CGD, with two-thirds X-linked due to mutations of the cytochrome b-245, beta polypeptide (CYBB) gene, and one-third autosomal recessive with the most common due to mutation of the neutrophil cytosolic factor 1 (NCF1) gene on chromosome 7q11.23.¹⁷¹

Flow cytometry for the CD11b/CD18 complex is diagnostic of patients with LAD type 1.¹⁸⁸ ¹⁸⁹ LAD1 is an autosomal recessive disorder due to mutations in the gene ITGB2, which encodes the common beta 2 subunit of the integrin (CD18) on chromosome 21q22.³ ¹⁸² ¹⁸⁸ There is diminished CD18 on leukocytes, which affects the third phase of the adhesion cascade, the firm adhesion of leukocytes to the endothelium. The severe type of LAD1 is caused by less than 1% expression of CD18 and presents early in life with delayed umbilical stamp separation; while moderate types have 1% to 30% expression, have fewer severe infections, and are diagnosed later in life.¹⁹⁰ LAD2 is due to mutations in the guanosine diphosphate fucose transporter which lead to a lack of sialyl Lewis X (CD153) and a defect in the first phase, the rolling phase. LAD3 is caused by mutations in ITGB2, encoding the ITGB2/KINDLIN-3 complex from the circulation.

Defects affecting phagocyte signaling via the Toll-like receptor canonical pathway include mutations of the myeloid differentiation primary response gene 88 (MYD88) and ILR-1-associated kinase 4 (IRAK4) which lead to invasive bacterial infections, primarily caused by Streptococcus pneumoniae, Staphylococcus aureus, and Pseudomonas aeruginosa.¹⁶³ Mutations in IKBKGA, encoding the NF-κB essential modulator (NEMO), result in a susceptibility to a wider variety of infections and frequently have ectodermal dysplasia.¹⁶³ ¹⁹¹ Mutations in the alternative pathway lead primarily to herpes simplex encephalitis.

WHIM (warts, hypogammaglobulinemia, infections, and myelokathexis) syndrome is due to heterozygous mutations of the intracellular c-terminus of the chemokine receptor 4 (CXCR4).¹⁹² Hyperfunction of CXCR4 delays egress of neutrophils leading to neutropenia, and reduces circulating CD27⁺ memory B cells resulting in B-cell lymphopenia and hypogammaglobulinemia.

In HIV-negative children with infections suggesting defective cell-mediated immunity (viral, fungal, or mycobacterial), the evaluation begins with the absolute lymphocyte count (Chapter 63). Because 75% of circulating lymphocytes are T cells, moderate lymphopenia implies T-cell lymphopenia. Distinct forms of SCID are characterized by different combinations of T/B/NK counts: T⁺ B⁻ NK⁺, T⁺ B⁻ NK⁻, T⁻ B⁻ NK⁺, T⁻ B⁻ NK⁻. There are over 20 different gene mutations associated with SCID.¹⁹³ Most newborns with SCID appear normal at birth, and the median age at diagnosis is 4 to 7 months.¹⁹¹ X-linked SCID, the most common type, has absent T and NK cells with normal or elevated B cells, which can mask T-cell lymphopenia and is due to mutation of the IL2RG gene, localized at Xg13.1 and encoding the γ chain of the ILR-2. In adenosine deaminase
deficiency, the second most common type of SCID, purine nucleoside phosphorylase deficiency, and reticular dysgenesis, all lymphocytes are absent (T B N K ).

T B NK SCID can be due to mutations in recombination activating genes RAG1 and RAG2, which lead to defects of the first step of antigen receptor V(D)J recombination for both T and B lymphocytes. Defects of the second step of recombination affect nonhomologous end-joining proteins and result not only in immunodeficiency, but also in defects in DNA repair, which predispose to neoplasia and toxicity to conditioning regimens. In DiGeorge syndrome (suggested by hypocalcemia and congenital heart disease), T-cell numbers are decreased, whereas B cells are normal or elevated (sometimes masking T-cell lymphopenia). In the bare lymphocyte syndrome in which either class I or class II HLA antigens are observed, the CD8 T-cell subset is decreased in defects involving class I HLA, and CD4 T cells are decreased in defects involving class II. TSCID can be due to engraftment of transplacentally derived maternal T lymphocytes or to Omenn syndrome, characterized by erythroderma, hepatosplenomegaly, and eosinophilia, and caused by hypomorphic mutations (“leaky SCID”) of RAG 1/2 and other genes whose null mutations cause typical SCID.

In HIV-negative adults, acquired defects in cell-mediated immunity with unusual susceptibility to viral, fungal, or mycobacterial infection are most commonly secondary to immunosuppressive therapy, chemotherapy (particularly nucleoside analogs), or malnutrition. Patients with sarcoidosis and neoplasms, such as HL, may be anergic on skin testing but usually do not develop infection before immunosuppressive therapy. In 1992, idiopathic CD4 lymphocytopenia (ICL) was defined in HIV-negative patients who had low CD4 T lymphocytes (0.3 × 10^9/L or < 20% of total T cells) on a minimum of two separate points at least 6 weeks apart. Patients with a profound decrease in CD4 T-cell numbers and low CD4/CD8 ratios present with opportunistic infections similar to those seen in AIDS. Hypomorphic gene mutations, which control T-cell receptor recombination or signaling, have been identified in a few patients with ICL. Rarely, ICL patients have normal CD4/CD8 ratios and do not have increased susceptibility to infection.

SUMMARY

This chapter is a brief overview and introduction to the subsequent chapters in Part VI on nonmalignant disorders of the phagocytic and immune system. A primary objective is to separate benign from malignant disorders. Identifying a specific defect in the immune system begins with a history and physical examination followed by tests to identify the defect. A single gene mutation may account for a congenital immune deficiency, and prenatal diagnosis may be possible by sex determination in utero if X-linked or by fetal blood sampling if the defective gene is known or if characteristic abnormalities in the peripheral blood can be identified. Some of the congenital immune deficiencies, such as SCID and its variants, represent medical emergencies. Acquired immune abnormalities, particularly functional asplenia, severe hypogammaglobulinemia, and iatrogenic neutropenia or T-cell deficiency, can also be life threatening. Knowledge of the site of the defect in a host’s immune system—whether in the neutrophils, humoral, cell-mediated, or complement arms or a combination thereof—is critical in predicting types of infections that can occur and instituting appropriate therapy.

INTRODUCTION

The normal range for the peripheral white blood count (WBC) is between $4.5 \times 10^9/L$ and $10.0 \times 10^9/L$, with a mean of $7.5 \times 10^9/L$. The total WBC includes neutrophils and lymphocytes, as well as smaller numbers of monocytes, basophils, and eosinophils. Leukopenia, a depressed WBC, may reflect either neutropenia or lymphopenia. Neutrophils constitute about 60% of the peripheral WBC, and therefore, reduction of WBC number most commonly reflects a decreased absolute neutrophil count (ANC). Neutropenia can occur as a secondary manifestation of an underlying disease or exposure or may reflect primary hematologic disease. This chapter focuses on the primary and secondary causes of neutropenia.

NORMAL NEUTROPHIL KINETICS

The circulating neutrophil pool represents only approximately 5% of the body's total neutrophil number. It is therefore a fairly distant reflection of the dynamics of neutrophil maturation within the bone marrow. Neutrophils arise in the bone marrow from a multipotent progenitor cell that also gives rise to all other formed elements of the blood. Maturation of neutrophil precursors occurs over 6 to 10 days. The majority of mature neutrophils constitute a storage pool that remains in the bone marrow poised for release as needed. The proliferating pool and storage pool together make up about 95% of the total granulocyte mass. Of the remaining 5% of neutrophils that enter the peripheral circulation, about 60% are a "marginating pool" that adheres to the vascular endothelium. These marginated neutrophils are easily mobilized into the circulation in response to stress. Circulating neutrophils survive for only 6 to 12 hours; when mobilized to sites of infection or inflammation, they can migrate into tissues where they survive for 1 to 4 days. Neutropenia can occur upon disruption of any of these processes: it may reflect decreased marrow production, increased margination (especially in the setting of splenomegaly and sequestration by the spleen), or peripheral immune destruction of mature cells.

DEFINITION AND CLASSIFICATION OF NEUTROPENIA

Neutropenia is defined by a decreased ANC, calculated by multiplying the total WBC by the percentage of neutrophils and bands noted on the differential cell count. What constitutes a low ANC differs by age, sex, race, and other factors; the normal range for the ANC for a given population, then, is defined as the mean ANC for that population +/- two standard deviations. In general, however, an ANC less than $1.5 \times 10^9/L$ is considered neutropenic in most patient populations. Neutropenia can be further classified as mild, moderate, or severe based on the degree of ANC depression: an ANC of 1.0 to $1.5 \times 10^9/L$ is considered mild, 0.5 to $1.0 \times 10^9/L$ is considered moderate, and less than $0.5 \times 10^9/L$ is considered severe. Although this classification is useful in predicting the risk of severe bacterial infection, other features may modify the risk. The risk of infection may be modified by the neutrophil storage pool. Risk may also be modified by the cause of neutropenia. For instance, chemotherapy-induced neutropenia is associated with a much greater risk of serious infection than chronic immune or nonimmune neutropenia. The risk of infection is also a function of both the degree and duration of neutropenia.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of neutropenia includes pseudoneutropenia, primary or congenital neutropenias (Table 57.1), and acquired neutropenias (Table 57.2). Global marrow defects such as aplastic anemia, leukemia, myelodysplasia, or myeloproliferative disorders can also cause neutropenia and are discussed in other chapters. Here we outline and discuss the causes of isolated neutropenia.
Pseudoneutropenia
Neutropenia may be the result of laboratory or clerical error, an artifact due to prolonged processing time of a peripheral blood specimen, the consequence of neutrophil clumping due to the presence of a paraprotein or certain anticoagulants, or as a result of marginalization of the circulating neutrophil pool. In each of these situations, the ANC is not actually low and these patients are not at increased risk of infection. Manual examination of the peripheral blood smear and repeated measurements can help to differentiate these causes of pseudoneutropenia from true neutropenia.

Primary Causes of Neutropenia

Ethnic and Benign Familial Neutropenia
A number of racial and ethnic groups have neutrophil counts that fall below the published normal range, which is largely based on Caucasian populations. These include African Americans, Yemenite Jews, Falasha Jews, and African Bedouins. The occurrence of ethnic neutropenia has been linked to single nucleotide polymorphisms in the gene encoding the Duffy antigen receptor for chemokine (DARC), which is also the receptor for the malarial parasite. Loss of expression of the Duffy blood group is prevalent in the areas where malaria is endemic, which are also areas where ethnic neutropenia has been described. There is also an autosomal dominantly inherited condition called benign familial neutropenia characterized by neutrophil counts in the 800 to 1,400/µl range, for which the responsible gene is not known.

Ethnic and benign familial neutropenias are not associated with an increased risk of infection. Bone marrow biopsies have normal cellularity but a reduction in mature granulocytes and neutrophil kinetic studies reveal a reduced myeloid precursor pool in the marrow, reduced mitotic pool size, and reduced concentration of colony-forming unit culture (CFU-C) consistent with the faulty release of mature neutrophils from the bone marrow.

Nonfamilial Chronic Benign and Idiopathic Chronic Severe Neutropenia
Nonfamilial chronic benign neutropenia is a condition defined by neutropenia in the absence of a familial pattern and without an increased risk of infection. There is often a compensatory monocytosis and eosinophilia and bone marrow biopsies show hypercellularity and myeloid hyperplasia with maturation arrest at the band stage of myeloid ontogeny. Neutrophil counts do rise, however, under conditions of stress such as infection or exogenous epinephrine or corticosteroid administration, perhaps explaining the absence of risk for infection. Some cases are associated with the presence of autoantibodies pointing toward an immune mechanism in the pathophysiology of this condition. Other cases seem to be the result of abnormal phagocytosis of normal marrow neutrophils by macrophages or the result of T-cell and cytokine-mediated suppression of granulopoiesis in the bone marrow. Included in this diagnosis is chronic benign granulocytopenia of infancy and childhood which typically resolves spontaneously around age 4 years. Although neutrophil counts do rise in response to G-CSF administration, G-CSF therapy is not recommended given the relatively benign clinical course associated with this condition.

° Indicates the most commonly mutated complementation group in Fanconi anemia.

Idiopathic chronic severe neutropenia is distinguished from this benign condition in that it typically affects patients in their late childhood or as adults and has a more severe clinical course with increased risk and number of infections. °°° There is evidence of myeloid hypoplasia, maturation arrest, or abnormal myeloid morphology on bone marrow biopsy; the form
associated with severe myeloid hypoplasia is called chronic hypoplastic neutropenia. To diagnose patients with idiopathic chronic severe neutropenia, other causes of neutropenia must be ruled out, including autoimmune etiologies. The pathogenesis of this form of severe neutropenia is completely unknown. Despite ANCs that may be in the 100 to 250 cells/µL range, these patients have a remarkably benign course, although some have recurrent infections requiring chronic cytokine support with G-CSF.

A large body of literature has focused on chronic neutropenia in Greece. The incidence of neutropenia on the island of Crete is quite high. This should be distinguished from chronic severe neutropenia, in that nearly all these patients have an ANC in the 0.8 to 1.4 × 10⁹/L range, and an ANC of <0.5 × 10⁹/L rarely if ever occurs. There is evidence that these patients may have a cytokine-mediated, inflammatory component to their illness. It is unknown whether these patients have an increased prevalence of the DARC polymorphism associated with neutropenia.

Severe Congenital Neutropenia

Severe congenital neutropenia (SCN) is a disorder of severe neutropenia first described in 1956 by Rolf Kostmann. He postulated that this was the first described congenital disorder of neutrophil number, presenting as an autosomal recessive disorder in neonates and infants with neutrophil counts <500 cells/µL associated with recurrent bacterial infections, most commonly due to Staphylococcus aureus, Escherichia coli, and Pseudomonas aeruginosa. His original report described this syndrome in nine families from a remote region in northern Sweden where consanguinity was common, explaining the increased incidence of this rare autosomal recessive syndrome. The syndrome was named infantile genetic agranulocytosis, which later was renamed SCN or Kostmann syndrome. Afflicted children suffer from infections that can occur as early as the first months of life and often include omphalitis and perirectal abscesses; otitis media, pneumonia, gingivitis, and urinary tract infections are also common. The diagnosis is usually apparent within the first 3 months of life. Death may occur as a result of sepsis, peritonitis, and enteritis, with fatal infections common in infancy and early childhood. All patients have severe neutropenia with an ANC <0.5 × 10⁹/L, but often <0.2 × 10⁹/L, and there is often an increase in other myeloid cell lines including monocytes and eosinophils. SCN was previously hypothesized to be a result of a deficiency in G-CSF or its receptor but further studies have demonstrated that G-CSF production is not impaired in patients with SCN, G-CSF receptor number and function are normal in patients with SCN, and the administration of G-CSF results in correction of neutropenia and improved clinical outcomes.

Kostmann’s early studies suggested that intramedullary apoptosis of myeloid precursors was a prominent feature of SCN, and more recent studies have confirmed that accelerated apoptosis is a central defect of this disorder, suggesting that G-CSF functions to correct the phenotype in part through its activity as an antiapoptotic agent.

Valproic acid, Carbamazepine, β-lactams

**fixation or the formation of circulating immune complexes**

**Dose-dependent inhibition of CFU-GM resulting in marrow suppression**

### Immune-mediated

**Systemic/autoimmune disease**

Pan-reactive antibodies against neutrophils and neutrophil precursors

Supportive care; treatment of the underlying condition; G-CSF as needed

**LGL/Felty's syndrome**

Antineutrophil antibodies and immune complex mediated neutrophil destruction; increased neutrophil adhesion to the endothelium; FAS mediated apoptosis of neutrophils; impaired myelopoiesis; splenic destruction

Supportive care; immunosuppression with methotrexate, cyclosporine, cyclophosphamide, and/or rituximab; G-CSF as needed

**Neonatal alloimmune neutropenia**

Maternal IgG antibodies to paternally inherited neutrophil antigens

Self-limited; supportive care with antibiotics as needed; plasma exchange, IVIg, maternal neutrophils for life-threatening infections

**Autoimmune neutropenia of infancy and childhood;**

Antibody mediated neutrophil destruction, usually against a specific neutrophil antigen

Supportive care; G-CSF therapy to prevent recurrent or severe infection

**Primary autoimmune neutropenia of adults**

Cellular and humoral immune mediated; associated with thymoma

Thymectomy; adjuvant cyclophosphamide, steroids, cyclosporine, IVIg, and/or SCT

**Neutrophil margination/hypersplenism**

C5a and complement activation leading to increased adhesion and aggregation within pulmonary vessels; splenic sequestration

**Nutritional deficiency (B12, folate, copper)**

Ineffective myelopoiesis and maturation arrest

Vitamin and mineral replacement

**Abbreviations:** G-CSF - granulocyte colony stimulating factor; WBC - white blood cell; IVIg - intravenous immunoglobulin; PTU - propylthiouracil; CFU-GM - colony forming unit granulocyte macrophages; LGL - large granular lymphocytosis; IgG - immunoglobulin class G; SCT - stem cell transplantation.

Since the initial description in 1956, SCN has come to be recognized as a syndrome resulting from a heterogeneous mix of genetic mutations with different patterns of inheritance. SCN can follow autosomal dominant, autosomal recessive, and X-linked patterns of inheritance and has been shown to be associated with mutations in a variety of genes including those for neutrophil elastase, HAX-1, WAS (WASP), GF11, SBDS, and G6PC3. Neutrophil elastase (ELANE) is a serine protease that is synthesized predominantly at the promyelocyte stage of neutrophil maturation and stored in primary granules. It has been hypothesized that ELANE mutations lead to cytoplasmic accumulation of defective protein, subsequently triggering apoptosis. Evidence supports activation of the unfolded protein response as the driver of...
apoptosis in ELANE-associated SCN.\textsuperscript{43, 44} SCN due to ELANE mutations is inherited in an autosomal dominant fashion. It was the first SCN gene to be identified and is responsible for the majority of cases of SCN. It is not the mutation found in the original Swedish cohort described by Kostmann, however, which is an autosomal recessive disorder that results from mutations in HAX-1.\textsuperscript{45} “Kostmann’s syndrome” now refers only to SCN with mutant HAX-1.\textsuperscript{41} HAX-1 is a mitochondrial protein with weak homology to BCL-2 and its absence results in mitochondrial-independent apoptosis. WASP regulates actin polymerization in hematopoietic cells. Absolute deficiency in this protein resulting from gene-inactivating mutations results in the Wiskott-Aldrich syndrome, characterized by thrombocytopenia, small platelets, sinopulmonary infections, and eczema. WASP mutations resulting in hypomorphic alleles, however, may lead to X-linked thrombocytopenia and neutropenia.\textsuperscript{40, 42} GF11 encodes a transcription factor, growth factor independent-1, that regulates the expression of genes involved in granulopoiesis, Shwachman-Bodian-Diamond syndrome gene (SBDS) encodes a gene involved in ribosomal RNA regulation and is responsible for Shwachman-Diamond syndrome (SDS) (which is discussed in a later section), and G6PC3 encodes the catalytic subunit 3 of glucose-6-phosphatase. Mutations in each of these three genes have been associated with SCN.\textsuperscript{46, 47, 48}

The gene(s) responsible for approximately 40% of SCN, however, remains unknown.\textsuperscript{40} Although G-CSF receptor signaling is intact in the vast majority of patients with SCN, rare patients have been described in which SCN arises from a congenital abnormality in the G-CSF receptor. Not surprisingly, these patients are marked by resistance to therapy with G-CSF.\textsuperscript{49, 50, 51, 52} The most important observation to emerge from the studies of the G-CSF receptor in SCN, however, is the finding of frequent somatic mutations in the G-CSF receptor arising in patients with SCN on cytokine therapy. When searching for potential constitutional mutations in the G-CSF receptor that might cause SCN, investigators identified a somatic missense mutation that appeared to be associated with transformation to myelodysplastic syndrome (MDS) and acute myelogenous leukemia (AML).\textsuperscript{49} This mutation introduces a stop codon leading to truncation of the distal intracellular domain of the receptor. The distal portion of the receptor is known to be the site of JAK-STAT activation and maturation signaling.\textsuperscript{49} Some investigators have postulated that the mutation causes proliferation at the expense of maturation, explaining why patients with this mutation have a higher risk of MDS/AML.\textsuperscript{53} It has clearly been demonstrated that the mutation shifts the doseresponse curve for G-CSF, rendering the cells hyperproliferative, and permitting clonal dominance of the mutant clone in the setting of G-CSF therapy. Whether the mutation actually blocks differentiation or merely predisposes to further genetic events by virtue of increasing cell proliferation remains controversial. Regardless, these G-CSF receptor mutations have been found to confer resistance to apoptosis and enhance cell survival in patients with SCN.\textsuperscript{54}

In general, patients with SCN have an increased risk of developing MDS and AML at a rate of approximately 2% to 8% per year.\textsuperscript{55, 56, 57} In patients who do develop MDS and/or AML, there appears to be a sequential gain of mutations that were not present in the subpopulation of progenitor cells in the early SCN phase such that over two thirds of patients with SCN that develop MDS or leukemia have a G-CSF receptor mutation (CSF3R).\textsuperscript{58} Increasing mutations in the G-CSF receptor gene point toward a role for aberrant G-CSF receptor signaling in leukemogenesis.\textsuperscript{59, 60} The role of G-CSF in causing or promoting these mutations remains unknown and a subject of considerable controversy.

G-CSF has revolutionized the treatment and management of SCN. Prior to the development of G-CSF as a clinical agent, SCN was almost uniformly fatal, with death from infection occurring in infancy or early childhood. Patients were treated with corticosteroids, testosterone, splenectomy, vitamin B6, and lithium, all of which were largely ineffective.\textsuperscript{50, 61, 62, 63} The use of G-CSF for this disease began in the 1980s, and has prevented infection in the vast majority of patients (80% to 90%), although some patients require higher doses.\textsuperscript{57, 64} The resultant increased life expectancy of these patients has coincided with an increased incidence of MDS and AML. This has led some to posit that G-CSF therapy facilitates the transformation to these malignant diseases, whereas others contend that prolonged survival allows for the emergence of a predisposition to MDS/AML as part of the natural history of this disease. The potential role of G-CSF in the development of MDS/AML in SCN is discussed later in this chapter. Chronic G-CSF therapy in this disease has led to other complications, including osteoporosis, vasculitis, splenomegaly, hepatomegaly, and glomerulonephritis.\textsuperscript{57, 64}

Cyclic Neutropenia

Cyclic neutropenia (CN) is a periodic disorder characterized by neutropenia (ANC ≤ 0.2 × 10\(^9\)/L) occurring at approximately 21-day intervals, although one quarter of patients may have cycles as short as 12 days or as long as 36 days.\textsuperscript{65, 66, 67} Nadirs of the ANC last 3 to 5 days and may be associated with recurrent fevers, aphthous ulcers, and infections of the skin, upper respiratory tract, and ears. The severity of infection reflects the severity and duration of neutropenia.\textsuperscript{68} Fatal infections
are uncommon, however, owing to the relatively brief period of neutropenia that is the hallmark of this disease, and as a result patients enjoy favorable overall survivals. With time, the cyclic nature of the disorder becomes less prominent, however, and patients can look more like patients with chronic neutropenia.69 It was first described in 1910 in an infant with recurrent episodes of fever, stomatitis, skin infections, and neutropenia.70 Diagnosis of CN can be demonstrated by documenting intermittent neutropenia via blood counts every 2 to 3 weeks over a course of 6 weeks, but can now be confirmed by the detection of a pathogenetic mutation in the setting of a suggestive pattern of WBC fluctuation. CN is inherited as an autosomal dominant disorder, although it may arise sporadically. CN can also be acquired in association with systemic diseases such as large granular lymphocytosis.71,72 Virtually 100% of patients with congenital CN also have point mutations in the gene for neutrophil elastase (ELANE).73 These mutations are largely distinct from those that are associated with SCN, although both syndromes have been seen arising from the same mutation within the same pedigree.74,75 Serial measurements of other hematopoietic cells in patients with CN reveal a periodicity to the numbers of platelets, reticulocytes, monocytes, and eosinophils as well, and the condition is sometimes referred to as cyclic hematopoiesis.76 As opposed to the depression seen in the neutrophil count, these other cells are often increased in number on or around periods of neutropenia.77 Bone marrow biopsies done during times of neutropenia and times of normal neutrophil counts reveal an absence of neutrophils and neutrophil precursors immediately preceding the period of neutropenia, whereas neutrophil precursors increase in number before recovery of peripheral neutrophil counts.78 The periodicity of the cell counts is thought to be the result of variations in the rate of release of mature cells from the marrow. Although knock-in mice fail to reproduce the phenotype of either SCN or CN, a dog model of CN has provided insight into its pathogenesis.79 In grey collie dogs, the disease can be transmitted to unaffected animals following bone marrow transplantation from an affected animal and can be cured following transplantation from an unaffected animal.80 In humans, a patient with acute lymphoblastic leukemia treated with a donor stem cell transplantation from a sibling with this disorder developed the disease.81 These observations and experiments support the notion that this disease is the result of an intrinsic stem cell regulatory defect, possibly related to accelerated apoptosis.82 A comparison of bone marrow biopsies from patients with CN and SCN, and normal subjects revealed that there were no differences in the frequency of CD34+, KIT, and G-CSF expression on marrow precursor cells between CN patients and normal subjects.83 Differences emerged, however, in response to hematopoietic growth factors with impaired granulopoiesis in both CD34+/KIT-/G-CSF⁺ and CD34+/KIT+/G-CSFR-cells in patients with CN; in SCN impaired granulopoiesis was only observed in the former.

Despite the impairment of granulopoiesis observed in response to hematopoietic growth factors, this disease is successfully treated with G-CSF and is not associated with an increased risk of leukemic transformation.57,69,84 G-CSF therapy does not prevent the cyclical depressions in neutrophil counts but does decrease the duration of neutropenia. GM-CSF therapy, on the other hand, has been noted to prevent the cycles but not to increase the neutrophil numbers to the same extent as seen with G-CSF.85 G-CSF remains the treatment of choice for this disease when therapy is required. Lower doses of G-CSF are needed for the treatment of CN than SCN, with a median dose of 2.5 µg/kg/day in one cohort.65 G-CSF is safe and well tolerated, although patients may develop a gradual asymptomatic splenic enlargement.69 The acquired, adult-onset forms of CN that are associated with systemic diseases are treated differently and are often successfully managed with immunosuppression including daily or alternatedaily corticosteroids or cyclosporine.86,87 These therapies are not successful in the congenital forms of this disease.65,68

P.1283

Congenital Immune Defects with Associated Neutropenia

Patients with inherited immunodeficiencies of humoral and/or cellular immunity are at risk of developing neutropenia. The infectious consequences in such patients are magnified due to the co-existing immune defects. Diseases involving immunoglobulin production, including X-linked agammaglobulinemia, hyper-IgM syndrome, dysgammaglobulinemia type I, isolated IgA deficiency, and familial forms of hypogammaglobulinemia have all been associated with periodic neutropenia and in some are thought to be related to the production of autoantibodies.88,89,90,91,92 These patients should be treated with intravenous immunoglobulin, which may correct both immune defects, with growth factors reserved for patients who do not respond to immunoglobulin replacement.93 Likewise, neutropenia has been associated with defects in cellular immunity; one familial syndrome was described in 1976 in which patients manifested severe neutropenia coincident with decreased antibody production in response to tetanus and poliomyelitis vaccines with resultant infectious complications.94 Finally, reticular dysgenesis is a rare immunodeficiency marked by severe neutropenia, lymphopenia, agammaglobulinemia and absent cellular immunity believed to be due to an inherent defect in
hematopoietic stem cells committed to myeloid and lymphoid development. It is not responsive to G-CSF but can be cured with stem cell transplantation.

Other Congenital Syndromes with Associated Neutropenia

Neutropenia is an important feature of several other congenital disorders. (see also Chapter 37.) These include SDS, Fanconi anemia (FA), dyskeratosis congenita (DKC), glycogen storage disease Ia, myelokathexis, Chediak-Higashi syndrome (CHS), Griscelli syndrome type II (GS2), Hermansky-Pudlak syndrome II (HPSII), and cartilage-hair hypoplasia.

SDS usually presents with neutropenia in infancy and subsequently progresses to marrow failure. It is also associated with pancreatic dysfunction and skeletal abnormalities. It was initially described in 1964 and is also associated with anemia, thrombocytopenia, developmental and mental retardation, diarrhea, weight loss, failure to thrive, eczema, recurrent otitis media and pneumonia, and neutrophil motility defects. SDS is an autosomal recessive disease caused by mutations in the **SDSB** on chromosome 7q, which is involved in the regulation of ribosomal RNA processing. Neutropenia, in the range of 0.2 to 0.8 × 10⁹/L, appears to be the result of myeloid hypoplasia. The mechanism of neutropenia is unknown, but neutrophils from affected patients appear to have increased ubiquitin-proteasome-rich cytoplasmic structures. SDS patients are predisposed to the development of MDS/AML, with myelodysplasia or clonal cytogenetic abnormalities (usually monosomy 7) present in up to one third of patients. The risk of severe hematologic complications is greatest in patients with cytopenias and symptoms before 3 months of age. Before the use of G-CSF for this disease mortality reached 25% and was the result of infection, marrow failure, and/or malignancy. The use of G-CSF, at an average dose of 4.3 µg/kg/day, corrects the neutropenia and decreases the risk and mortality from infection. As seen in SCN, however, the use of G-CSF and improvements in survival have also been associated with increased risk of MDS and AML and it is unclear if this is due to G-CSF or the natural history of the disease; the risk of MDS/AML is similar to that seen in SCN in the International Registry but was slightly lower than this in the French Registry. Stem cell transplantation can be curative but is associated with increased transplant-related morbidity and mortality and thus requires careful consideration and consultation with experienced transplant centers. The successful use of reduced intensity conditioning transplantation for this disease may make transplant a more widely available option for these patients.

FA is the most common cause of congenital aplastic anemia. It can be inherited in an autosomal recessive or X-linked manner and is due to mutations in genes involved in DNA repair. Marrow failure develops somewhat later than in other congenital marrow syndromes (median age 7 years), presumably because marrow failure occurs secondary to acquired mutations in the setting of defective DNA repair. Multiple genes have been found to be mutated in FA and 15 complementation groups have been identified (FANCA-SLX4 I [FA-P]), with FANCA being the most common. In addition to marrow dysfunction, up to two thirds of patients with FA have a constellation of other abnormalities, including short stature with upper limb anomalies, and hyperpigmented, café-au-lait spots. FA patients are at increased risk for malignancies, especially MDS/AML and squamous cell carcinomas. The diagnosis of FA is established by demonstrating chromosomal fragility following exposure to diepoxybutane or mitomycin C; subsequent gene analysis can then identify mutations in one of the genes involved in the DNA repair complex. Stem cell transplantation can treat the hematologic manifestations of the disease but carries a high risk of morbidity and mortality due to the effects of conditioning on these patients with impaired DNA repair; consequently, reduced intensity conditioning regimens are necessary.

Other therapies for the hematologic manifestations of this disease include androgens, which may be effective in half of FA patients, and growth factors such as G-CSF, at an average dose of 4.3 µg/kg/d, corrects the neutropenia and decreases the risk and mortality from infection. Other therapies for the hematologic manifestations of this disease include androgens, which may be effective in half of FA patients, and growth factors such as G-CSF at doses starting at 5 µg/kg/d.

DKC is a rare multiorgan syndrome associated with neutropenia and/or aplastic anemia; patients may also have other abnormalities, including nail dystrophy, leukoplakia, and abnormal skin pigmentation. Additional clinical manifestations include premature graying of the hair, idiopathic pulmonary fibrosis, cancer predisposition (including AML and solid tumors including squamous cell carcinomas), osteoporosis, and cirrhosis. The majority of cases involve mutations in the **DKC1** gene on chromosome Xq28 but DKC can also be due to genetic mutations that are inherited in an autosomal dominant or recessive manner such as mutations in TERT and TERC. The DKC1 gene encodes dyskerin, a protein that is involved in RNA function and telomere maintenance. TERT and TERC are the genes for the reverse transcriptase portion of telomerase and the telomerase RNA component, respectively, and as is DKC1, are crucial for maintenance of telomere length. Clinical manifestations reflect progressive telomere shortening, and are therefore not present at birth; clinical symptoms typically do not present until the second decade of life. The severity and penetrance of some variants of DKC is unpredictable. However, inasmuch as offspring of affected individuals will inherit shortened telomeres, this is a syndrome that can manifest anticipation, with earlier and more severe symptoms occurring in consecutive generations. Telomere length in three different lymphocyte subsets can be measured to screen for this disease; patients with DKC have telomere lengths less than the first percentile for age in all three cell lines. Genetic
testing for known mutations can be helpful but does not rule out the disease as a subset of patients lack identifiable mutations. G-CSF or GM-CSF is effective in improving neutrophil counts in patients with DKC, and allogeneic stem cell transplantation, with reduced intensity conditioning given the sensitivity to genotoxic agents, is effective in treating the hematologic manifestations of this disease.\textsuperscript{139, 140, 162, 166} DKC affects other organ systems, however, which will not improve following stem cell transplantation, and pulmonary disease and solid tumors remain a major source of morbidity and mortality following stem cell transplantation.

Glycogen storage disease Ia is an autosomal recessive disorder caused by mutations in the gene for glucose-6-phosphatase translocase. This leads to hepatomegaly and a metabolic disorder related to intracellular accumulation of polysaccharide. It is also

P.1284

associated with defects in the neutrophil respiratory burst that increase apoptosis of circulating neutrophils and lead to neutropenia.\textsuperscript{139, 140} Patients typically present at 6 months of age with hepatomegaly, hypoglycemia, and lactic acidosis.\textsuperscript{141} Neutropenia presents within the first year of life in the majority of patients and although it is usually intermittent, it has no faithful periodicity or cycle.\textsuperscript{142} Diagnosis is made by looking for the most common genetic mutations but if none are identified, liver biopsy to confirm excess glycogen stores and steatosis without prominent fibrosis is recommended. A strict carbohydrate-restricted diet is necessary to control the disease and G-CSF can be used to treat the neutropenia.\textsuperscript{143, 144} Liver transplantation has been used to correct many complications of this disease but neutropenia persists.\textsuperscript{145} Neutropenia has also been reported in other metabolic disorders, including propionic academia, methylmalonic academia, and isovaleric academia.\textsuperscript{146, 147, 148}

Myelokathexis is a rare syndrome in which mature neutrophils are retained in the bone marrow, leading to a decreased peripheral ANC.\textsuperscript{149} Retained neutrophils display an abnormal morphology with cytoplasmic vacuolization, pyknotic nuclei, nuclear hypersegmentation, and thin nuclear strands connecting nuclear lobes.\textsuperscript{150} There is also evidence that neutrophils undergo accelerated apoptosis in affected patients, resulting in a shortened peripheral lifespan. Evidence suggests that this is a cell-intrinsic defect, as neutrophil survival is also reduced following injection into unaffected volunteers.\textsuperscript{150, 151} Accelerated apoptosis may be due to decreased expression of Bcl-x, an inhibitor of apoptosis. The storage pool of mature neutrophils is not reduced, and neutrophil counts rise in response to infection in patients with myelokathexis, making the risk of overwhelming infectious complications low. There is a female predominance in this disease and most patients are diagnosed in infancy.\textsuperscript{152} The combination of myelokathexis with hypogammaglobulinemia and warts is termed WHIM syndrome (warts, hypogammaglobulinemia, immunodeficiency, myelokathexis),\textsuperscript{153} which is caused by heterozygous mutations in the gene for the chemokine receptor CXCR4.\textsuperscript{154} These mutations cause hyperreactivity of CXCR4, leading to retention of neutrophils in the marrow. These patients respond to growth factor therapy with G-CSF or GM-CSF, which down-regulate the expression of CXCR4.\textsuperscript{155, 156} The CXCR4 antagonist, plerixafor, has been given to nine patients with the WHIM syndrome with resultant transient normalization of WBC counts.\textsuperscript{157, 158}

Congenital disorders of vesicular trafficking are also associated with neutropenia. These include CHS, GS2, and HPSII.\textsuperscript{159} These diseases are also associated with disorders of other granulated cells, leading to oculocutaneous albinism (from disrupted melanin granules), bleeding (from abnormal platelet secretory granules), and neurologic disease (from abnormal trafficking and release of neuronal granules). All of these diseases can enter a terminal phase of hemophagocytic syndrome, often in the setting of Epstein-Barr virus (EBV) infection. In all cases, this is postulated to occur because of abnormal secretion of perforin-containing granules into the immunologic synapse, impairing natural killer-cell-mediated killing. CHS is an autosomal recessive disorder caused by mutations in the LYST gene (lysosomal trafficking regulatory gene) and is associated with characteristic neutrophils containing giant granules.\textsuperscript{159, 160, 161} Three quarters of patients with CHS develop moderate to severe neutropenia, thought to be the result of increased destruction of peripheral neutrophils and decreased marrow release of neutrophils.\textsuperscript{160, 162} Infectious risk is increased above that expected for the ANC due to concomitant humoral and cellular immune defects in this disease.\textsuperscript{163, 164} GS2 is also an autosomal recessive disorder, due to mutations in a small GTPase RAB27A, which is part of the protein complex necessary for granule release.\textsuperscript{165, 166} HPSII is due to defects in AP3B1 which encodes a part of a protein transport complex that mediates sorting of lysosomal proteins.\textsuperscript{167} Defects in AP3B1 lead to widespread functional impairment of cells carrying secretory granules. As for many of the syndromes and diseases noted above, stem cell transplantation can cure the hematologic manifestations of these diseases and may be necessary to control the hemophagocytosis associated with CHS and GS2, but does not treat the other systemic findings.\textsuperscript{168, 169} Otherwise, growth factor support and antibiotics provide supportive care and steroids, splenectomy, intravenous immunoglobulin, and chemotherapy have been used to manage the accelerated phase of CHS.\textsuperscript{170, 171}
Lastly, cartilage-hair hypoplasia is a rare syndrome associated with moderate to severe neutropenia, as well as short-limb dwarfism, fine hair, and defects in cellular immunity.\textsuperscript{172} It is inherited in an autosomal recessive manner and has increased prevalence in the Amish and Finnish populations.\textsuperscript{173, 174} It is caused by mutations in the RMRP gene on chromosome 9 which has an unknown function but is a noncoding RNA essential for early murine development.\textsuperscript{175, 176} As in other syndromes with combined neutropenia and cellular immune defects, infectious risk is additive. G-CSF is effective and stem cell transplantation can cure the hematologic and immunologic manifestations of this disease.\textsuperscript{177, 178}

Secondary Causes of Neutropenia

Post-infectious Neutropenia

Several viral infections have been shown to cause a transient neutropenia, including varicella, measles, rubella, hepatitis A and B, Epstein-Barr, influenza, parvovirus, and cytomegalovirus. Neutropenia typically corresponds to the period of peak viremia during the first 1 to 2 days of clinical symptoms. Neutropenia usually resolves within 3 to 7 days. Neutropenia results from a combination of decreased production and immune destruction of neutrophils; in addition, some viral infections increase neutrophil adherence to the vasculature, causing increased margination.\textsuperscript{179, 180} Because neutropenia is short lived, it rarely results in bacterial superinfection regardless of its severity. However, the neutropenia associated with hepatitis B and EBV infections can be more prolonged and thus more dangerous. Human immunodeficiency virus (HIV) infection is commonly associated with neutropenia that arises from a combination of decreased marrow production of neutrophils and peripheral immune destruction.\textsuperscript{181} As with EBV and hepatitis B infection, this neutropenia may be protracted as a result of direct viral infection of hematopoietic precursor cells or as a result of antineutrophil antibodies. Moderate neutropenia can also be seen in association with atypical bacterial infections, including those caused by Mycobacterium tuberculosis, ehrlichiosis, rickettsia, tularemia, and brucellosis. This may be related to direct bone marrow suppression of myelopoiesis by toxins released by the pathogenic organisms, decreased neutrophil production as a result of infection-mediated decrease in growth factor production, and complement mediated peripheral neutrophil destruction. Neutropenia is fairly common in the setting of overwhelming sepsis, and reflects consumption of marrow reserves of neutrophils. This is usually seen at the extremes of life, in infants and elderly patients, in which patients typically have decreased marrow reserves.\textsuperscript{182} Management of patients with infection-related neutropenia requires good supportive care with treatment of the underlying infection. G-CSF or white blood cell transfusions are reserved for protracted and severe cases.\textsuperscript{183, 184} Intravenous immunoglobulin may be effective for neutropenia that results from autoimmune or complement-mediated destruction as a result of the underlying infection.\textsuperscript{185}

Drug-induced Neutropenia and Neutropenia due to Marrow Injury

Although accurate estimates of the incidence of drug-induced neutropenia are not readily available, a 10-year Swedish experience, a 5-year Dutch experience, a 22-year Spanish experience, and the International Aplastic Anemia and Agranulocytosis Study demonstrate an annual incidence of severe drug-induced neutropenia of 1.0 to 3.4 cases per million population per year.\textsuperscript{186, 187, 188} Multiple drugs have been implicated in neutropenia and agranulocytosis, both in predictable and idiosyncratic patterns. Antineoplastic, antiviral, and immunosuppressive agents all cause an expected dose-dependent decrease in neutrophils, often accompanied by general marrow suppression. Common drugs known to cause neutropenia that is more idiosyncratic include clozapine, the thionamides, and sulfasalazine. Most drugs cause direct dose-dependent marrow suppression and others incite immune-mediated destruction; these mechanisms may not be mutually exclusive.\textsuperscript{189, 190, 191, 192} Immune-mediated destruction may occur by one of two mechanisms: the drug may act as a hapten and induce antibody formation and complement fixation, or the drug can cause the formation of circulating immune complexes that bind to neutrophils. The former is the mechanism associated with penicillin, propylthiouracil, and gold and the latter is associated with quinine administration. Marrow suppression, on the other hand, is the result of dose-dependent inhibition of colony-forming unit granulocyte macrophages and can be seen with valproic acid, carbamazepine, and β-lactam antibiotics. Finally, drugs can cause damage to the marrow microenvironment and myeloid precursors; certain patients with specific genetic polymorphisms or other medical problems may be at increased risk for drug-induced neutropenia by this mechanism.\textsuperscript{193, 194, 195}

Drug-induced neutropenia typically occurs after 1 to 2 weeks of exposure to the drug, although it may occur after a longer period of exposure. Recovery usually begins within days of stopping the drug, but this pattern is highly variable depending on the mechanism of neutropenia. For example, immune-mediated neutropenia may be immediate, occurring within hours of administration of the drug especially if there has been a previous exposure and prior antibody production, whereas drugs that cause direct marrow suppression or toxicity follow the paradigm above.\textsuperscript{196} Some patients may present
with agranulocytosis, fever, and possible sepsis; in these patients mortality may be significant. Neutrophil recovery is often preceded by the appearance of monocytes and immature neutrophil forms. Although marrow examination is rarely necessary, one can roughly predict the duration of neutropenia from the cellularity of the marrow, as patients with hypercellular marrows or marrows with abundant metamyelocytes and later forms tend to have more rapid reconstitution following discontinuation of the offending medication. Management is similar to that for post-infectious neutropenia with supportive care and removal of the offending agent, although growth factor support is recommended for patients presenting with agranulocytosis.197

Radiation can also result in acute or chronic marrow failure. Exposure to radiation is also a risk factor for AML/MDS. These diseases are discussed in greater detail in Chapters 75 and 79, respectively. Likewise, metastatic carcinoma to the bone can also cause marrow failure as the marrow becomes increasingly occupied by the metastatic cells.

Immune Neutropenia

As previously discussed, infection and drugs can cause immune-mediated neutrophil destruction. However, primary immune neutropenia can occur in the absence of other inciting events, or can also arise in association with an underlying systemic autoimmune disease. Antineutrophil antibodies are implicated in mediating neutrophil destruction either by destruction in the spleen or by intravascular complement mediated neutrophil lysis. A number of neutrophil-specific antigens have been identified in patients with a history of autoimmune neutropenia, including human neutrophil antigen (HNA)-1, an isoform of the Fcy illB receptor, and HNA-4 and HNA-5, which are CD11b and CD11a, respectively.198 199 The clinical presentation is variable, and depends on whether the antineutrophil antibodies react primarily with mature neutrophils or with myeloid progenitor cells, whether the antibodies are primary or secondary to an underlying condition, and whether the antibody is of restricted or nonrestricted clonality.200 201 Some patients may have an absence of only mature neutrophils, whereas others may be missing all or some myeloid forms. In primary immune neutropenia, antibodies are more likely to be directed against a specific neutrophil-specific antigen whereas secondary conditions are commonly associated with pan-reactive antibodies. Similarly, antibodies that are produced as a result of an exposure to a foreign antigen are more likely to be polyclonal and short lived, whereas those due to the loss of suppression of a clone of cells producing an autoantibody are associated with a more protracted and severe course of neutropenia. Bone marrow biopsy findings will depend on the stage in neutrophil maturation against which the antibodies are directed, but in most cases, the marrow is hyper- or normocellular with a “maturation arrest” that reflects destruction of later stage cells.

Hyperthyroidism, Wegener granulomatosis, rheumatoid arthritis, systemic lupus erythematosus (SLE), chronic hepatitis and other systemic infections, and malignancy are autoimmune and systemic disorders associated with antineutrophil antibodies. In many of these diseases, especially SLE, neutropenia is often mild and reflects the activity of the underlying disease. It rarely requires treatment outside of treatment of the underlying disease.202

Felty syndrome and large granular lymphocytic (LGL) leukemia can also cause immune-mediated neutrophil destruction, and may be associated with profound neutropenia and increased infections. LGL is a syndrome of autoimmune neutropenia in association with marrow infiltration by clonal large granular lymphocytes.203 These lymphocytes are cytotoxic T-cells with the following immunophenotype: CD3+, CD8+, CD16+, and CD57+. LGL can occur sporadically or in association with systemic autoimmune diseases, especially rheumatoid arthritis.204 LGL is closely related to Felty syndrome, a syndrome associated with splenomegaly and neutropenia in the setting of rheumatoid arthritis.205 Ninety percent of patients with Felty syndrome and LGL associated with RA are HLA-DR4+, leading many investigators to postulate that the two syndromes are in a spectrum of the same disease.206 The pathophysiology of neutropenia is complex, including both antibodemediated and cell-mediated destruction, immune complexes, and increased FAS mediated apoptosis.207 208 209 210 211 The neutropenia is responsive to G-CSF, which is usually utilized until the primary disease can be treated.212 Treatment options for LGL and Felty syndrome include immunosuppressive therapies including methotrexate, cyclosporine, cyclophosphamide, and, most recently, rituximab for Felty syndrome.213 214 215 216 217

Neonatal neutropenia, or neonatal alloimmune neutropenia, is caused by transplacental passage of maternal IgG antibodies against paternal neutrophil antigens, resulting in neutropenia in a similar manner to anemia in Rh hemolytic disease. During gestation, the mother is sensitized to unique fetal neutrophil antigens and produces IgG antibodies against these antigens that can cross the placenta. These antigens will be shared with the father and so will be reactive against the father’s neutrophils, thus facilitating the diagnosis. Neutropenia typically resolves within 2 months, and appropriate antibiotics will usually be sufficient to support the patient. In the event of severe or life-threatening infection, plasma exchange, intravenous immunoglobulin, and transfusion of maternal neutrophils have all been used.218

Autoimmune neutropenia of infancy and childhood, termed “primary immune neutropenia,” occurs in children ages 6 months to 10 years and is the most frequent primary immune neutropenia.219 Infections tend to be mild and include otitis
media, gastroenteritis, and/or cellulitis. Resolution of neutropenia occurs in over 95% of patients by age 2. Primary autoimmune neutropenia in adults is rare, and tends to be more chronic. However, even adults tend to have a mild clinical course.

P.1286

Lastly, pure white cell aplasia is a rare disease associated with severe pyogenic infections, and associated with a thymoma in over two thirds of cases. It has also occurred following ibuprofen therapy. There is a complete absence of myeloid precursors on bone marrow examination. It is immune-mediated but removal of the thymoma in thymoma-associated cases may not be sufficient for remission. Adjuvant therapy with cytoxan, steroids, cyclosporine, IVIg, and even stem cell transplantation may be needed.

Neutropenia Due to Increased Margination and Hypersplenism

Complement activation increases margination of neutrophils and can suppress the peripheral ANC. This has been seen in patients suffering from burns and transfusion reactions as well as a result of exposure to artificial membranes used in dialysis, cardiopulmonary bypass, apheresis, and extracorporeal membrane oxygenation. Neutropenia in the setting of transfusion is due to an anamnestic response to foreign antigens on neutrophils in a prior transfused blood product. Complement activation may also lead to direct neutrophil destruction, as in the case of paroxysmal nocturnal hemoglobinuria. Splenomegaly with hypersplenism can also reduce the neutrophil count.

Neutropenia Due to Nutritional Deficiency

Neutropenia is part of the clinical spectrum of megaloblastic anemia arising from deficiency of vitamin B12, folate, and copper. These diseases typically cause pancytopenia because of disordered maturation of all cell lines.

CLINICAL PRESENTATION AND DIAGNOSTIC APPROACH TO NEUTROPENIA

One of the first definitions of the syndrome of neutropenia and infection was in 1922 by Werner Schultz who described the findings of sore throat, prostration, and neutropenia in a cohort of middle-aged women and called this entity agranulocytosis. This fulminant form of neutropenia has sometimes been referred to as Schultz disease. The description highlights that the first evidence of neutropenia is often the development of infection, and that severe neutropenia is associated with a risk for spontaneous infection. Although the lower level of the normal ANC is 1,500 cells/µl, patients rarely develop infectious complications of neutropenia until their ANC falls below 500 cells/µl, and in fact, patients with chronic neutropenia rarely develop fever unless their ANC is below 200 cells/µl. Common sites of infection include the oral cavity and mucous membranes including mouth ulcers, pharyngeal inflammation, and periodontitis, the skin with rashes, cellulitis, abscesses, and poor wound healing, the perirectal and anal areas, and the respiratory tract. Endogenous flora are the primary pathogens. It should be remembered that most of the signs and symptoms of infection are generated by neutrophils. Consequently, patients with neutropenia may have minimal signs and symptoms of infection, with minimal inflammatory infiltrates. Fever is the most informative sign in neutropenia patients, and should be evaluated emergently, because in the setting of profound neutropenia, patients may rapidly develop fatal sepsis. A presentation of neutropenia should prompt a careful evaluation for signs and symptoms of infection with cultures and antibiotic administration when indicated.
FIGURE 57.1. Diagnostic approach to neutropenia in the infant. ANC, absolute neutrophil count; a/w, associated with; G-CSF, granulocyte colony stimulating factor; IV, intravenous.

In children presenting for the first time with neutropenia, growth and development should be documented (Fig. 57.1). Attention should be paid to the skin, bones/appendages, and nails as abnormalities in these may point toward one of the congenital neutropenia syndromes. Family history of recurrent infections and sudden death may be helpful in this regard. If congenital neutropenia is suspected, appropriate genetic testing should be obtained. In adults previously known to have a normal ANC who present with profound neutropenia (agranulocytosis) and an otherwise normal CBC, the diagnosis is almost invariably drug-induced neutropenia. These patients usually present with an acute febrile episode. A thorough history of drug and toxin exposure should be obtained and all potential offending agents discontinued. For patients of all ages, the perineum and perirectal area should be examined, in addition to a complete physical exam. The peripheral blood smear should be examined and tests for vitamin B12 and folate levels obtained. Older tests included hydrocortisone stimulation tests (for marrow myeloid reserve), the epinephrine challenge test (for estimation of the size of the marginated neutrophil pool), and the Reubuck skin window (which evaluates neutrophil margination into tissues) but these are rarely used today. Bone marrow examination is not required unless there are other features to suggest an alternative diagnosis.

In patients presenting with unexplained neutropenia in the absence of a well-documented normal ANC in the past, evaluation depends on the severity of the neutropenia (Fig. 57.2). There is little information to be gained from an extensive evaluation of healthy patients with no history of infections and ANC of 1,200 to 1,500 cells/µl that has been present for many years. In appropriate ethnic groups the diagnosis of constitutional neutropenia obviates the need for further evaluation. Even in patients who do not have clear ethnic or familial neutropenia, studies to rule out marrow pathology in the absence of clinical sequelae or evidence of continued decrease in the blood counts are unlikely to be informative.
In patients with severe neutropenia of indeterminate duration, the pace and extent of diagnosis should be determined by the clinical presentation. In patients in whom cycling is suspected, genetic testing for ELANE mutations and peripheral blood flow cytometry and T-cell receptor rearrangement studies to assess for LGL should be obtained. In the cases of a selective severe chronic neutropenia, even in the absence of a history of infection or drug/toxin exposure or an evident B12 or folate deficiency, a single bone marrow examination is recommended to assess for myelodysplasia. If marrow morphology is unremarkable and cytogenetics are normal, repeated bone marrow examination is not recommended unless there is a significant change in the peripheral blood counts that suggests a new intervening diagnosis. Bone marrow biopsy should be performed in all patients with bi- or tricytopenias to evaluate the adequacy of hematopoietic marrow pools, the relative maturation of these pools, and the morphology of these pools for clues as to the etiology of the cytopenias.

MANAGEMENT OF NEUTROPENIA

Decisions regarding the treatment of neutropenia depend primarily on the presence or absence of fever. Neutropenia with fever should be treated as a medical emergency, with the goal of evaluating patients and initiating antibiotics within 30 to 60 minutes. The administration of empiric broad-spectrum antibiotics to patients with febrile neutropenia has been demonstrated to improve survival. Third- or fourth-generation cephalosporins as single agents have become the standard initial empiric therapy, replacing previous combinations that emphasized double coverage for pseudomonal species. In patients with indwelling lines, the addition of vancomycin may be considered, and patients at increased risk for fungal infection or who remain febrile despite 3 to 5 days of antibiotics should receive antifungal agents.

FIGURE 57.2. Diagnostic approach to neutropenia in the adult. ANC, absolute neutrophil count; G-CSF, granulocyte colony stimulating factor; IV, intravenous; LGL, large granular lymphocytosis; MDS, myelodysplastic syndrome.

For patients with mild neutropenia and infections, outpatient antibiotic therapy may be warranted and is based on the clinical judgment of the treating physician. The cause of neutropenia is important in determining further therapies: transient neutropenia due to a drug, infection, or chemotherapy administration may require no further therapy, although G-CSF can be used for high-risk patients with pneumonia, hypotension, and/or fungemia whereas neutropenia due to autoantibodies, an underlying systemic disease, or a congenital syndrome may require preventative approaches including immunologic therapies such as corticosteroids, intravenous immunoglobulin, and/or plasmapheresis, treatment of the
underlying disease, G-CSF therapy, or possibly a hematopoietic stem cell transplant. For cases of severe life-threatening infection that is unresponsive to antibiotics, granulocyte transfusion may be warranted. In patients with neutropenia who have not had a history of infection, treatment is rarely necessary. Patients should be educated to simple approaches to preventing infection, including skin and mouth care, good oral and dental hygiene, avoidance of rectal trauma by rectal thermometers and prevention of constipation with stool softeners, proper cleaning and topical antibiotic application to all skin abrasions. For patients with profound neutropenia not on G-CSF, they should be instructed to notify a physician as soon as they develop a fever. It is advisable that they also be supplied with prophylactic antibiotics such as trimethoprim-sulfamethoxazole or ciprofloxacin to take in the event there is a delay in seeking medical attention; it should be emphasized, however, that use of these agents is for emergencies only and should not be used in place of seeking appropriate medical evaluation and care.

Patients with SCN require lifelong G-CSF therapy. The use of G-CSF has extended the life expectancy for these patients from 2 to 3 years to adulthood. Some patients with CN also require G-CSF, but can often restrict treatment to low daily doses of G-CSF or cyclical administration during the period around the nadir of the ANC. Dose requirements vary depending on G-CSF response. As previously mentioned, with improved survival of patients with SCN, a significant risk of MDS/AML has emerged. The risk of MDS/AML appears to be associated with higher doses of G-CSF, but whether this is a reflection of the underlying disease phenotype or whether transformation is enhanced or accelerated by G-CSF itself is unknown.

Other congenital syndromes associated with neutropenia, such as SDS, FA, and DKC, respond to doses of G-CSF similar to those used in SCN and these patients are also at increased risk of MDS and/or AML, but again it is not clear if this is due to the G-CSF or the underlying disease. Patients with idiopathic and CN, as well as neutropenia associated with glycogen storage Ib, and myelokathexis, however, do not develop MDS or AML, despite therapy with G-CSF. One could argue, though, that this may be a dose-dependent phenomenon as patients with SCN, SDS, FA, and DKC require higher doses of G-CSF than do those with idiopathic and CN. Long-term use of G-CSF or GM-CSF has been associated with osteoporosis and organomegaly.

Severe drug-induced neutropenia/agranulocytosis requires the permanent discontinuation of the causative agent. However, agents that cause dose-related marrow suppression and mild neutropenia can be continued if necessary, provided the neutropenia is not progressive or severe. Patients with agranulocytosis frequently present with life-threatening infections. They should be admitted to the hospital for broad-spectrum antibiotics. G-CSF speeds the recovery of the ANC and, given the morbidity and mortality associated with this syndrome, is recommended.

Immune neutropenia related to SLE or other systemic autoimmune disease rarely needs direct treatment, and ANC usually responds to decreased disease activity with therapy directed at the underlying rheumatologic disorder. Patients with LGL respond well to low-dose immunosuppression with cyclophosphamide or methotrexate.

Finally, stem cell transplantation can be useful to reverse the hematologic effects and neutropenia associated with a number of the congenital neutropenias and bone marrow failure syndromes such as SDS, FA, DKC, and cartilage-hair hypoplasia. The risk of transplant in many of these patients is greater than that seen in transplantation for hematologic malignancies due to the nature of the underlying genetic disorder. Furthermore, many of these disorders are associated with disease of other organs, including pulmonary fibrosis, or a risk of solid tumors. Transplantation does nothing to prevent these manifestations of the underlying disease and should be considered before undertaking the procedure.

DISORDERS OF PHAGOCYTIC LEUKOCYTES CHARACTERIZED BY MORPHOLOGIC CHANGES

For the most part, the disorders considered here are rare, are usually familial, and often reflect a general metabolic defect, the major manifestation of which may be more serious in tissues than in leukocytes. Nevertheless, the leukocytic morphologic abnormalities may come to the attention of the hematologist, and familiarity with them and the associated diseases may facilitate diagnosis.

Pelger-Huët Anomaly

Pelger-Huët anomaly is a benign anomaly of leukocytes and is inherited as a non-sex-linked, dominant trait. It is characterized by distinctive shapes of the nuclei of leukocytes, a reduced number of nuclear segments (best seen in the neutrophils), and coarseness of the chromatin of the nuclei of neutrophils, lymphocytes, and monocytes. The nuclei appear rod-like, dumbbell-shaped, peanut-shaped, and spectacle-like (“pince-nez”) with smooth, round, or oval individual lobes, contrasted with the irregular lobes seen in normal neutrophils. The incidence of this disorder in different studies has ranged from as high as 1 in 1,000 persons to 1 in 4,000 or even 10,000. Originally observed mainly in Holland, Germany, and Switzerland, the anomaly has now been described in other parts of the world, including individuals of Asian and African descent and whites. The practical importance of identifying the Pelger-Huët anomaly lies in distinguishing this defect from the shift to the left that occurs in association with infection.

The discovery of this anomaly in rabbits led to breeding experiments and the production of homozygotes. These studies demonstrated that in the heterozygote, bilobed, rod-shaped, and spectacle forms predominate, whereas in the homozygote, round nuclei with no evidence of segmentation are predominant. In rabbits, the homozygous form was often lethal, with most animals dying in utero; some survivors suffered skeletal malformations.

\(^a\) Mean and variance.

Two human homozygotes have been reported.\(^2,9\) In them, the cytoplasm of the neutrophils appeared mature, but the nuclei were round or oval in all the neutrophils, in contrast to the fewer than 40% single-lobed neutrophils present in heterozygotes (Table 58.1).\(^2,6,9\) In the homozygotes, the eosinophils, basophils, and megakaryocytes also were characterized by dense nuclear chromatin and rounded nuclear lobes; these individuals had fewer nuclear lobes than normal subjects.\(^2\) Examination of the bone marrow revealed normal morphologic features in myeloid precursors through the myelocyte stage, and electron microscopy revealed persistence of nucleoli in the otherwise mature neutrophils that contained single oval nuclei.\(^9\) This finding was interpreted as indicating some retardation of nuclear maturation, because no cytochemical defects were noted in the cytoplasm. This syndrome is now known to be due to mutations in the lamin B receptor (LBR) gene, a gene important in maintaining nuclear structure.\(^10,11,12\)

Pelger-Huët cells appear to be normal functionally,\(^9,13,14\) are able to phagocytize and kill microorganisms,\(^5\) and survive normally in the circulation in both humans\(^15\) and dogs.\(^16,17\)

The Pelger-Huët heterozygote is recognized by finding (a) 69% to 93% of the neutrophils to be of the bilobed, pince-nez type; (b) few cells with three lobes (usually <10%); and (c) rare or no cells with four lobes (Table 58.1).\(^4,5,6\) In normal blood smears, no more than 27% of the cells are bilobed, and significant numbers of cells have three or more lobes.\(^5\) The presence of similar abnormalities in the blood smear in other family members also is helpful in establishing the diagnosis. In heterozygotes, mature neutrophils with round or oval nuclei of the type that is characteristic of the homozygous state may increase after stress, such as the injection of colchicine.\(^18,3\) A shift toward increased numbers of neutrophil lobes was described in a patient with the anomaly who developed pernicious anemia.\(^19\)

Pseudo- or Acquired Pelger-Huët Anomaly

Cells with morphologic changes, such as those just described, have been observed occasionally in association with myxedema, acute enteritis, agranulocytosis, multiple myeloma, malaria, leukemoid reactions secondary to metastases to the bone marrow,\(^20\) drug sensitivity,\(^21\) or chronic lymphocytic leukemia.\(^3\)

More commonly, pseudo-Pelger-Huët cells (Fig. 58.1)\(^22\) are seen in patients with myeloid leukemia of either the acute or chronic type or in those with myeloid metaplasia.\(^23,24\) In these subjects, the pseudo-Pelger-Huët cells tend to appear late in the disease, often after considerable chemotherapy has been administered. In addition, most of the nuclei are of the single oval type characteristic of the homozygous state.\(^23\)
Alder-Reilly anomaly, inherited as a recessive trait, apparently does not interfere with leukocyte function. It is characterized by the presence of larger-than-normal azurophil and basophil granules (Alder-Reilly bodies), which may be easily confused with granulations due to toxic states (Fig. 58.2). These granules stain dark lilac with Wright-Giemsa stains and are seen in patients with various types of bone and cartilage abnormalities. They are most common, however, in association with Hurler syndrome, Hunter syndrome, and Maroteaux-Lamy polydystrophic dwarfism.
Similar inclusions may be seen in blood lymphocytes (Gasser cells) and monocytes.\textsuperscript{30,31} The lymphocyte inclusions stain dark red or purple with May-Grünwald-Giemsa stain and metachromatically with toluidine blue; normal azurophilic granules do not stain at all.\textsuperscript{31,32} Such lymphocyte granules are found in all types of mucopolysaccharidoses except Morquio syndrome, but they are most common in the Hurler, Hunter, Sanfilippo, and Maroteaux-Lamy syndromes.\textsuperscript{29,31,32} They tend to occur in clusters rather than diffusely throughout the cytoplasm, are surrounded by vacuoles, and are shaped like a dot or comma. In one series of 19 patients, 8\% to 50\% of the lymphocytes contained the inclusions, and their presence was thought to be of diagnostic significance.\textsuperscript{32}

These inclusions are seen inconsistently in the blood but are more common in the bone marrow. For example, in a series of 18 patients with Hurler form of mucopolysaccharidosis, Alder-Reilly bodies were present in the blood of <10\% of them. Careful examination of the bone marrow, however, revealed mucopolysaccharide granules in large mononuclear cells (Buhot cells) in 17 of 18 patients.\textsuperscript{33,34,35}

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{image}
\caption{FIGURE 58.2. Neutrophils with Alder-Reilly bodies (A) compared with neutrophils exhibiting toxic granulation (B,C).}
\end{figure}

The type of inclusion seen is not diagnostic of a particular type of mucopolysaccharidosis, and the frequency of the inclusions is not correlated with clinical severity.\textsuperscript{36} The basic defect in this group of diseases lies in the incomplete degradation of the protein-carbohydrate complexes known as mucopolysaccharides, and the different forms of mucopolysaccharidosis involve different enzymatic deficiencies.\textsuperscript{29} The accumulation of partially degraded mucopolysaccharides within lysosomes has been demonstrated by electron microscopy\textsuperscript{29}; the degradation of the protein core of the mucopolysaccharide appears to proceed normally, but catabolism of the carbohydrate side chains is impaired.

May-Hegglin Anomaly
The May-Hegglin anomaly is a rare, dominantly inherited disorder characterized by large (2 to 5 µm), well-defined, basophilic, and pyroninophilic inclusions in granulocytes (neutrophils, eosinophils, basophils, monocytes), and accompanied by variable thrombocytopenia and giant platelets containing few granules. For the most part, affected family members have not been ill, but occasionally abnormal bleeding has occurred. Clot retraction time is prolonged, and the reaction to the tourniquet test may be positive. Platelet survival was short (half-life = 3 days, as compared with the normal, which is 6.9 ± 1.5 [1 standard deviation] days). Platelet aggregation and retraction were normal, but spreading and serotonin uptake were increased. Enzyme and substrate content per platelet were increased, but this value was decreased as related to platelet volume. The granulocyte inclusions are similar to Döhle bodies in appearance, but they often are larger, are more round and discrete, and may be present in a large percentage of the cells. It is claimed that these inclusions differ from the Döhle bodies of infection in morphologic appearance in that they are present in granulocytes other than neutrophils. Like Döhle bodies, the inclusions were felt to consist mainly of RNA and may exhibit differing ultrastructure. More recently, mutations in MYH9, the gene encoding NMMHC-A, have been found in this syndrome. NMMHC-A is a nonmuscle myosin heavy chain that is part of a family of genes coding for proteins that form part of the actin-myosin force-generating complexes. In the bone marrow, clumping of the megakaryocyte cytoplasm has also been reported. Mutations in MYH9 are inherited in an autosomal dominant fashion, but depending on the mutation generate a spectrum of clinical findings manifest as several syndromes due to variable expressivity of the clinical features. These clinical syndromes include May-Hegglin anomaly, Sebastian syndrome, Fechtner syndrome, and Epstein syndrome and are characterized by giant platelets, leukocyte inclusions, and variable thrombocytopenia, in addition to problems with hearing, vision, or renal function. Chédiak-Stevenbrinck-Higashi Anomaly (Congenital Gigantism of Peroxidase Granules) Chédiak-Stevenbrinck-Higashi anomaly, an autosomal recessive disorder, has been reported in humans, mice, mink, cattle, cats, rats, and a killer whale. It is characterized by partial ocular and cutaneous albinism, increased susceptibility to pyogenic infections, the presence of large lysosome-like organelles in most granule-containing cells, and a bleeding tendency. The abnormal granules are most readily seen in blood and marrow leukocytes, especially granulocytes (Fig. 58.3), and in melanocytes. In the first families that were reported with this anomaly, the mothers noted that some of their children exhibited pale hair (Fig. 58.4) and photophobia. Because these children often had infections and adenopathy and died at an early age, the children born subsequently who were similarly affected were brought to medical attention in the hope of avoiding a fatal outcome. It was then that the large, peroxidase-positive granules were noted in their blood and marrow granulocytes. Nevertheless, without definitive treatment (bone marrow transplantation, described later) most patients die in infancy or early childhood; only a few survive into early adult life.
During the 30 years after the first description of Chédiak-Higashi syndrome (CHS)\(^9\) 59 cases were reported.\(^6\) The similar disorder in animals is of use in investigations of the pathogenic defect and is of significant economic impact in mink, in that affected animals, inbred for their unusual color, seldom survive more than a year and exhibit increased susceptibility to a slow viral infection that produces hepatitis and a myeloma-like illness (Aleutian mink disease).\(^6\)

Etiology and Pathogenesis

The manifestations of this disorder appear to result from abnormal intracellular protein transport, resulting in abnormal granule fusion with larger, fewer-than-normal, and perhaps defective granules being formed in most granule-containing cells throughout the body.\(^7\) \(^4\) \(^5\) \(^6\) \(^7\) The resulting abnormalities can be found in the hematopoietic tissues, hair, ocular pigment, skin, adrenal glands, pituitary gland, gastrointestinal organs, peripheral nerves, and elsewhere.\(^4\)

In neutrophils, the anomalously large, peroxidase-positive granules seen by light microscopy\(^5\) \(^6\) \(^9\) \(^5\) \(^6\) have been shown by electron microscopy to be abnormal primary (azurophilic) granules, the contents of which remain pleomorphic, the normal granule crystalloid structure not being formed.\(^3\) \(^4\) \(^5\) Characterization of the abnormal granules by means of immunofluorescence microscopy demonstrated that they were formed by the progressive aggregation and fusion of azurophilic granules.\(^7\) \(^8\) \(^5\)

In a subsequent electron microscopic study, investigators demonstrated the presence of two types of giant, peroxidase-positive granules in CHS neutrophils: large, round, or oval granules with homogeneous internal structure similar to normal azurophilic granules; and irregular granules much larger than those of the first type. Because basophils and eosinophils from CHS patients do not contain type 2 granules, and because type 2 granules are less common in promyelocytes, myelocytes, and young neutrophils in the bone marrow than in blood neutrophils, the authors suggested that normal primary (azurophil) granules are formed, but progressive granule fusion occurs during maturation, especially in the blood. In this process, granules and bits of cytoplasm are trapped within the fused granules.\(^3\) An abnormal calcium uptake pump in CHS lysosomes may be part of the underlying defect.\(^3\) \(^8\) \(^5\) Also noted is an increased tendency to autophagic vacuole formation in Chédiak-Higashi neutrophils, perhaps because of increased permeability and leakage of injurious materials from the massive granules.\(^8\) A secretory defect appears to prevent granule release in CHS T cells.\(^8\) Abnormal granules have been observed less often in erythroid cells, whereas in megakaryocytes and platelets, the granules appear normal by light microscopy.\(^3\) By electron microscopy, however, a decrease in dense bodies was seen,\(^3\) and decreased serotonin, adenosine triphosphate, and adenosine diphosphate levels were noted.\(^5\)
Similar large granules containing a glycolipid have been observed in the Schwann cells of peripheral nerves, in neurons in the central nervous system,\(^84\), \(^86\) in renal tubular cells,\(^86\) and in the vascular endothelium and fibroblasts.\(^86\), \(^87\) In addition, giant pigment granules have been demonstrated in melanosomes\(^86\) and in hair strands.\(^86\), \(^88\) In the several different tissues affected, the consistent feature is that the histochemical reactions of the large abnormal granules are those usually seen in normal granules of that cell line\(^86\); no qualitative alteration in granule enzyme content is noted, but some decrease in granule enzymes and an increase in cytoplasmic enzyme content have been described.\(^88\) The effects of the abnormality in different tissues depend on granule function in that tissue. Thus, the large but fewer melanin granules produce pigment dilution, which explains the peculiar hair color, partial albinism, photophobia, and nystagmus.\(^86\)

The abnormal large granules in neutrophils lead to increased susceptibility to infection. Infection occurs despite an above-normal rate of phagocytosis and a normal postphagocytic metabolic burst (H\(_2\)O\(_2\) production).\(^90\) Apparently, the intracellular destruction of some bacteria by Chédiak-Higashi leukocytes is delayed because the postphagocytic delivery of lysosomal enzymes into phagosomes is inefficient and incomplete.\(^90\) A similar defect in granule extrusion has been noted in the renal tubule.\(^91\)

Chédiak-Higashi neutrophils from humans lack cathepsin G and elastase\(^92\) and have reduced C3bi receptor expression.\(^93\) Because measurements of elastase and cathepsin G were normal in the bone marrow of beige mice, the primary lesion is thought not to be a gene defect but rather is likely a disorder of protein processing, protein synthesis, or granule assembly.\(^92\) In addition, a defect in cellular response to chemotactic stimuli both in vitro and in vivo skin windows has been demonstrated in humans, mice, and mink,\(^94\), \(^95\) and a neutrophil membrane abnormality consisting of spontaneous cap formation has been described.\(^96\) Recent studies show that lysosomes function as calcium-regulated secretory compartments and may play an important role in membrane resealing. Lysosomal exocytosis triggered by membrane wounding is defective in human CHS and beige mouse fibroblasts, and this defect may be central to the CHS phenotype.\(^82\)

**Inheritance**

In 1972, in families with 127 children, 59 were reported to be affected.\(^69\) This statistic and animal studies\(^64\) indicate that this disorder is inherited as an autosomal recessive trait. Male and female subjects are affected at a ratio of 0.87:1.00. A high proportion of marriages producing affected children have been consanguineous. Some heterozygotes may be identifiable by the presence of granulation in some of their lymphocytes.\(^97\), \(^98\)

**Clinical Features and Course**

The partial albinism (more properly, pigment dilutional defect),\(^86\) silvery hair (Fig. 58.4), and photophobia are usually noted early in infancy. The poor resistance to respiratory and cutaneous infection, especially by Staphylococcus and other Gram-positive organisms, soon becomes evident. Four patients studied for more than 1 year experienced 29 episodes of fever and pyogenic infection.\(^71\) Increased bleeding with abnormal platelet function has also been recognized.\(^99\) Many of the afflicted children develop potentially fatal infections during infancy or early childhood. In others, the disease remains quiescent. Eventually, in more than 85% of patients, it changes to an accelerated phase that is characterized by lymphadenopathy, hepatosplenomegaly, neuropathy, anemia, neutropenia, and, less often, thrombocytopenia.\(^100\) During this phase, infiltration of the tissues by mononuclear cells is widespread and the accelerated phase is now considered akin to the disorder hemophagocytic lymphohistiocytosis.\(^101\) During the accelerated phase, neurologic manifestations (peripheral neuropathy) may become prominent, and hemorrhage may occur.

**Laboratory Findings**

The characteristic microscopic findings are the large, often multiple, peroxidase-positive lysosomal granules in the granulocytes of the blood and bone marrow, and the large melanosomes in the hair. Less common are granules in the lymphocytes. Abnormal platelet aggregation can be demonstrated regularly.\(^96\) During the early phases of the disease, blood counts yield normal values, but as the disease progresses, anemia, neutropenia, and thrombocytopenia often develop. Immunoglobulin (Ig) and complement levels are normal, as are cellular immune reactions. In the accelerated phase, erythrocyte and granulocyte survival may be shortened.\(^69\)

**Gene Defect**
The origin of CHS in mice has been found to be a mutation in the CHS/LYST gene on chromosome 1 in humans, which codes for a lysosomal trafficking regulatory protein.\textsuperscript{102, 103} The human homologue CHS1 has since been cloned, and mutations of this gene have been found in patients with CHS.\textsuperscript{104, 105, 106, 107, 108, 109, 110}

Management

Some believe that the prophylactic administration of antibiotics may be beneficial.\textsuperscript{71} The administration of ascorbic acid corrected the defective leukocyte function in vitro and in vivo in several patients,\textsuperscript{111, 112} and the administration of cholinergic agonists was effective in mice.\textsuperscript{126, 113} The increased susceptibility to infection has been corrected in mice by the transplantation of normal bone marrow, and the hematopoietic defects can be transmitted to normal mice by transplanting marrow from an animal with CHS.\textsuperscript{114} In the accelerated phase, splenectomy has been only temporarily helpful\textsuperscript{69}; a few patients have been treated with a combination of vincristine and prednisone. Bone marrow transplantation appears to be a logical treatment, if possible,\textsuperscript{115, 116, 117} but does not alter the neurologic deterioration.\textsuperscript{109, 117}

Familial Vacuolization of Leukocytes (Jordan Anomaly)

Jordan anomaly is characterized by the presence of vacuoles in the cytoplasm of granulocytes, monocytes, and occasionally lymphocytes and plasma cells. In members of one family, all of the blood neutrophils and more than 70% of the monocytes contained three to ten vacuoles ranging in size from 2 to 5 µm; fewer and smaller vacuoles were seen in eosinophils, basophils, and lymphocytes.\textsuperscript{118} By means of histochemical and fluorescence microscopic analysis, the vacuoles were shown to contain lipids. These lipids were seen in promyelocytes, myelocytes, metamyelocytes, and occasionally plasma cells in the bone marrow, but they were not present in myeloblasts, erythroblasts, or megakaryocytes.\textsuperscript{118} This type of vacuolization must be distinguished from that characterized by fat-staining vacuoles occurring in people with serious infections, toxic hepatitis, or diabetic ketoacidosis.\textsuperscript{119}

The disorder appears to be familial. Two members were affected in each of two unrelated families.\textsuperscript{118, 119} None of the four patients had acute disease, but in members of one family, progressive muscular dystrophy was present,\textsuperscript{118} whereas in members of the other, ichthyosis was associated.\textsuperscript{119}

Other Inclusions in Leukocytes

In an infant with congenital bile duct atresia, amorphous, roundto-oval bodies stained green or gray-green with Romanovsky stains in 3% to 13% of the blood neutrophils and in 1% to 5% of the monocytes.\textsuperscript{120} Similar inclusions were present in all stages of myeloid cells in the bone marrow but not in lymphocytes or plasma cells. Electron microscopic analysis showed that the inclusions were not enclosed in a phagocytic vesicle.

P.1294

In the blood monocytes of patients with the Hermansky-Pudlak syndrome,\textsuperscript{121} a rare familial disorder characterized by albinism, mild bleeding related to platelet dysfunction, accumulation of ceroidlike pigment in marrow macrophages, and deficiency of the tetraspan protein CD63 in platelets,\textsuperscript{122} lipopigment bodies as well as another type of inclusion were demonstrated.

Abnormal Specific (Secondary) Granule Formation

A syndrome of recurrent staphylococcal skin and sinus infections associated with abnormal chemotaxis, impaired staphylococcal killing, and morphologic abnormalities in the neutrophils was described in a 14-year-old boy.\textsuperscript{122} No other family members were affected. The patient’s polymorphonuclear neutrophils exhibited bilobed nuclei with unevenly distributed chromatin, drumsticklike nuclear projections, and nearly absent cytoplasmic granules that stained with peroxidase but not with alkaline phosphatase. Electron microscopy revealed primary granules, but specific granules were small and reduced in number. These neutrophils were capable of phagocytosis, generated H₂O₂, reduced nitroblue tetrazolium (NBT) dye, and killed Candida, but staphylococcal killing was impaired.

Since the original report, at least five cases of specific granule deficiency (SGD) have been identified with both sexes affected, leading to the assumption that the disorder is an autosomal recessive disease.\textsuperscript{124, 125} SGD neutrophils exhibit decreased chemotaxis and bacterial killing in vitro and decreased migration into skin windows in vivo, and they fail to upregulate CD11/CD18, laminin, or f-met-leu-phe (FMLP) receptors after activation,\textsuperscript{124} although oxygen radical generation is apparently normal. Myeloperoxidase (MPO)-positive primary granules are present, but the specific secondary granules appeared to be absent in Wright-stained blood smears and were decreased in number and small when viewed with
electron microscopy. These structures do not stain with alkaline phosphatase. The specific granule constituents lactoferrin and B$_{12}$ binding protein are reduced or absent.

Lactoferrin deficiency in patients with SGD is tissue specific (i.e., confined to myeloid cells, whereas lactoferrin is secreted normally in nasal secretions) and is secondary to a deficiency of RNA transcripts. Because morphologic changes have been described in the primary granule and because other granule proteins, such as primary granule defensin and “tertiary” granule gelatinase, are also deficient in SGD neutrophils, it was suggested that the basic defect in SGD is one of regulation of production of these proteins. Thus, this disorder may be one of incomplete granule synthesis rather than a true SGD.

C/EBPE is an important regulator of neutrophil secondary granule genes and mutations in the C/EBPE gene have been found in two patients with SGD. Neutrophils from Cebpe deficient mice have functional defects very similar to those of patients with SGD, and these mice have defects in eosi inophil and macrophage function as well. Monocyte/macrophage abnormalities have also been noted in an SGD patient. One case of SGD has been reported with no mutation in the C/EBPE gene.

Hereditary Giant Neutrophilia

Neutrophils with a diameter of approximately 17 µm (as compared with a normal diameter of about 13 µm) are rare in blood smears from normal people (1 in 20,000 neutrophils or less). They may be seen with greater frequency in patients who are ill, but even then the number rarely exceeds 0.2% unless a disease involving leukocyte production is present or a reaction to a cytotoxic drug occurs. A family with giant neutrophils in healthy members of three generations has been reported. Over several years, the propositus had an average of 1.6% giant neutrophils in the blood. The large neutrophils appeared to be nearly double the normal cell volume and contained from six to ten nuclear lobes. Therefore, it was suggested that the cells may have been tetraploid. This anomaly appeared to be transmitted as an autosomal dominant trait.

Hereditary Hypersegmentation of Neutrophil Nuclei

Several families have been described whose members had a hereditary (autosomal dominant) increase in the number of neutrophil nuclear segments (Fig. 58.5). The proportion of neutrophils containing five lobes or more exceeded 10% in most heterozygotes and was >14% in several suspected homozygotes, as compared with no more than 10% in normal controls. The bone marrow findings suggested a tendency toward nuclear indentation in early myeloid forms (eosinophils and basophils as well as neutrophils). The normal size of these neutrophils was thought to provide evidence against tetraploidy, but in one study of five female family members, the mean number of nuclear drumsticks appeared to be increased above normal. The chief significance of this anomaly is in its differentiation from other causes of hypersegmentation such as folate or vitamin B$_{12}$ deficiency.

Hypersegmentation of Eosinophils and Negative Staining for Peroxidase and Phospholipids

Hypersegmentation of eosinophils can be inherited as an autosomal recessive trait, and the abnormality is characterized by a lack of sudanophilia and peroxidase activity in all of the eosinophils, whereas these histochemical reactions remain positive in the neutrophils and monocytes. In addition, the number of eosinophilic granules per cell appears to be reduced, and some hypersegmentation of the eosinophil nucleus may occur. No disease accompanies the disorder. This has been most commonly reported in people of Jewish (predominantly Yemenite) extraction, although members of other races have not been studied adequately.

FUNCTIONAL DISORDERS OF LEUKOCYTES NOT CHARACTERIZED BY MORPHOLOGIC CHANGES

The topic of neutrophil dysfunction is under active study. Several reviews summarize this topic; the reader is also referred to the current literature.

Chronic Granulomatous Disease of Childhood

Chronic granulomatous disease (CGD) is a rare clinical syndrome that results from genetically heterogeneous inherited defects of leukocyte function, that result from mutations in one of four genes coding for subunits of the neutrophil NAPDH oxidase.
FIGURE 58.5. Hypersegmented neutrophil.

Activation of the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase requires protein kinases, lipid-mobilizing enzymes, and factors that activate the Rac GTPase, and thus the CGD phenotype could be due to a variety of other mutations as well. Recent reviews have been published.\textsuperscript{145, 150, 151, 154, 155, 156, 157, 158, 159, 160, 161, 162, 163}

CGD neutrophils are characterized by a defective respiratory burst during phagocytosis and an inability to generate superoxide. The impaired superoxide production usually occurs transiently in each phagosome with phagocytosis and leads to recurrent bacterial and fungal infections, most commonly at epithelial surfaces. CGD is characterized by recurrent infections with catalase-positive bacteria. CGD neutrophils can use H\textsubscript{2}O\textsubscript{2} produced by ingested bacteria to generate hypochlorous acid (HOCl) via MPO and aid in killing the bacteria. Catalase-positive bacteria generate H\textsubscript{2}O\textsubscript{2} levels in the phagocytic vacuole that are too low for generation of sufficient HOCl to contribute to significant bacterial killing via this mechanism.\textsuperscript{155} This syndrome can be the result of different genetic defects in the superoxide generating system. Variable inheritance patterns have been observed with approximately two-thirds of the pedigrees being X-linked and one-third autosomal recessive. Multiple molecular defects have been identified that result in the CGD phenotype.\textsuperscript{144, 145, 155, 157, 158, 161, 164, 165} Potential treatments include prophylactic antibiotics, interferon-\textgamma, and bone marrow transplantation. Knowledge in this field is changing rapidly.\textsuperscript{151}

CGD neutrophils, eosinophils, monocytes, and macrophages fail to generate superoxide, hydrogen peroxide, and other oxygen radicals after particle phagocytosis (or other stimulation), and thus have decreased microbicidal activity. CGD is associated with no leukocyte morphologic abnormalities and was first noted in male children with a history, beginning in early childhood, of recurrent suppurative infections caused by organisms of low-grade pathogenicity, including fungi, or by staphylococci. The eczematoid, granulomatous, and sometimes purulent skin infections recur repeatedly and clear slowly. Associated adenopathy develops and may persist. Pulmonary and other infections (e.g., osteomyelitis) also are common, and progressive granulomatous disease of the lungs, liver, and other sites develops. Hepatosplenomegaly is common, and biopsy reveals necrotizing granulomas, often with associated purulent inflammation. The disorder often progresses to death in early childhood,\textsuperscript{166, 167} but some patients survive longer.\textsuperscript{152, 168} Although rare, CGD has assumed great importance as a prototype of defects in leukocyte bactericidal capacity.

History and Mode of Inheritance

CGD was first described from 1954 to 1957\textsuperscript{166, 167} as affecting only males. By 1970, more than 90 cases were reported.\textsuperscript{148, 168} X-linked inheritance was established, and female heterozygotes were identifiable by the presence of defective leukocyte bactericidal capacity intermediate in degree between that of affected patients and that of normal individuals.\textsuperscript{169}
Measurements of postphagocytic release of $^{14}$CO$_2$ from glucose-1-$^{14}$C or reduction of NBT dye were used to detect the defect. By means of the NBT dye test, female carriers were found to have a mixed population of neutrophils, approximately one-half being NBT negative and one-half being NBT positive. The defect is transmitted on an X chromosome, and the degree of deficit in female subjects varies according to random X chromosome inactivation. Consequently, one may expect to find an occasional female carrier with clinical disease as severe as that in male patients.

Because of the clinical and pathologic picture of chronic recurrent infection caused by low-grade pathogens and the resultant granuloma formation, it was suggested that a defect in inflammatory response results in lesions comparable to those that normal people develop after infection with tubercle bacilli or brucella. No abnormality in antibody response to diphtheria, tetanus, or poliovirus was demonstrated in these patients, and their delayed hypersensitivity response also was normal. In addition, leukocyte migration and surface phagocytosis were normal. Nevertheless, when leukocytes of CGD patients were incubated with bacteria, such as staphylococci, serratia, or other organisms causing infection in these patients, decreased bacterial killing and prolonged bacterial survival in the phagocytic vacuoles were observed. Decreased killing of fungi and incomplete inactivation of vaccinia and herpes virus also was reported, but streptococci were killed normally by CGD leukocytes.

Although the mechanisms of bacterial killing by normal leukocytes are still incompletely understood, it is clear that phagocytosis is followed by fusion of lysosomes with the phagocytic vacuole, discharge of lysosomal enzymes into the phagosome, and a burst of postphagocytic metabolic activity. These events are usually accompanied by bacterial death and digestion (see Chapters 7 and 10). Early studies of CGD reported that a deficiency of NADPH oxidase or an abnormality in its activation is the underlying cause of this syndrome. The finding that iodination of bacteria in the phagosome appears to be one mode of bacterial killing, and that this process is defective in CGD leukocytes and can be partially repaired by the insertion of an oxidase into the phagosome, either carried on oxidase-coated polystyrene particles or as part of the ingested bacteria, provided strong evidence incriminating defective generation of H$_2$O$_2$, superoxide, or related ions as the pathogenic defect in this disorder. Although most studies have focused on neutrophils, it was recognized in the earliest reports that lipid-laden macrophages were present in the granulomatous lesions, and a defect in the mononuclear phagocytes and in eosinophils also has since been demonstrated. The platelets appear normal.

In the late 1960s and 1970s, an autosomal recessive form of CGD was described. It is clinically identical to the X-linked forms, with the exception that the parents of affected children usually have normal neutrophil function, and the clinical course may be milder.

Molecular Pathology

In 1978, a unique cytochrome β, termed β$_{558}$ (named for its absorption spectrum) or β$_{245}$ (named for its midpoint potential), present only in phagocytic cells, was described and suggested to be a primary component of the oxidase that normally generates superoxide but, when defective, results in CGD. This cytochrome was absent from X-linked CGD phagocytes (thus termed X’) but was present in phagocytes from patients with autosomal recessive inheritance patterns (A’). In 1985, a family with CGD and an autosomal recessive inheritance pattern but with absence of cytochrome β was reported, thus identifying a third type of CGD (A°). In these studies, a somatic cell hybridization technique was used to demonstrate that fusing monocytes from any two of these three types of CGD (X’, A’, or A°) restored their ability to oxidize NBT, thus defining three distinct molecular defects. Also in 1985, several groups demonstrated that both membrane and cytosolic components are necessary for superoxide generation, and deficiencies in either can result in CGD.

In 1987, cytochrome β was purified and shown to be a heterodimer composed of two polypeptides, a heavily glycosylated, 91,000-dalton heavy chain (approximately 50,000 of the molecular weight is peptide) and a 22,000-dalton light chain. Antibodies to these two polypeptides showed them both to be absent from the phagocytes of two types of CGD (X’ and A’). The defective gene in X-linked, cytochrome-negative CGD has since been cloned and shown to encode for the polypeptide portion of the 91,000-dalton subunit of cytochrome β now known as gp91phox. Because postphagocytic activation of the respiratory burst with generation of superoxide and peroxide, as well as bacterial killing, involves complex reactions and multiple enzymes (e.g., phospholipases, protein kinases, NADPH oxidase, glucose-6-phosphate dehydrogenase [G6PD],
glutathione peroxidase), one might expect that defects other than those described in NADPH oxidase would result in a disorder phenotypically like that described in the section Variants.

Clinical and Laboratory Features

The clinical picture of CGD includes the development of recurrent infections, especially of the skin and lungs, with septic lymphadenitis, development of hepatosplenomegaly and granulomas, and ultimately death from infection. Because chronic infection is common, the Ig levels often are elevated, and plasma cells may be present in increased numbers in the bone marrow. Ig deficiencies have not been encountered, and antibody titers (both IgM and IgG) increase normally after antigenic stimulation. Reticuloendothelial clearance of colloidal gold also is normal. Peroxidase staining of blood cells demonstrates more intense dye uptake in CGD neutrophils than in normal cells. The classical method for detecting the defect is the postphagocytic, intraphagosomal reduction of almost colorless NBT dye to blue-black formazan. When tests are properly standardized with respect to time of incubation of leukocytes with the dye-tagged zymosan particles, affected patients and most carriers are readily recognized. When the reaction to this test is negative in suspected carriers, the reaction to the quantitative dye reduction test usually is positive. Nowadays, the preferred diagnostic test is flow cytometry-based detection of the conversion of the nonfluorescent dye dihydrorhodamine to its oxidized form that emits green fluorescence. The sensitivity and quantitative nature of this method make it more reliable and also allow for detection of residual oxidase activity that can be important in prognosis.

An alteration in the B-cell compartment in patients with CGD has been reported. It appears that CGD is associated with a reduction in the peripheral blood memory B-cell compartment, suggesting a role for NADPH in memory B-cell formation.

Course and Prognosis

There is considerable heterogeneity in the severity of the clinical course of patients with CGD. Without treatment, this disease usually runs a progressive downhill course because of repeated infections and granuloma formation. The average life expectancy was reported to be 5 to 7 years in 1968. One-half of patients are projected to survive into the fourth decade in 2008. Recent studies suggest that the clinical course may be predictable by the specific mutation and those individuals with higher residual ability to produce reactive oxygen intermediates might fare better.

Treatment

Treatment of infections with appropriate antibiotics and surgical procedures remains the cornerstone of management. Prophylactic use of antibiotics, including trimethoprim-sulfamethoxazole and itraconazole with interferon-γ, is generally recommended. Trimethoprim-sulfamethoxazole alone or in combination with dicloxacillin can prolong the infection-free interval in many CGD patients.

In some patients with CGD, the administration of interferony has induced partial correction of cytochrome β content and restored phagocyte bactericidal capacity toward normal, and reports have suggested that interferon-γ increases the ability of CGD neutrophils to kill Aspergillus and decreases the number of serious infections in patients with CGD. The exact mechanism by which interferon-γ exerts its beneficial effect in CGD is unclear and may include other effects in addition to augmentation of the respiratory burst. Bone marrow transplantation and gene therapy are potential experimental approaches.

Variants

Because the clinical picture of CGD results from delayed killing of catalase-positive bacteria, enzymatic defects in the bactericidal system other than decreased NADPH oxidase may produce an almost identical picture. Results of several studies demonstrate clearly that such biochemical variants exist. For example, in a brother and sister with the clinical picture of CGD, after phagocytosis of latex particles by their neutrophils, all oxidative metabolic reactions were absent. If the latex particles were opsonized with Ig, however, postphagocytic oxidative changes were stimulated dramatically. Another patient was reported in whom no oxidative changes (measured by chemiluminescence) occurred after phagocytosis of a variety of opsonized particles (latex, bacteria, or zymosan), but normal chemiluminescent responses occurred when the neutrophils were stimulated with soluble agents (concanavalin A and phorbol myristate acetate). These patients appear to have a defect in signal transduction and activation of the oxidase system rather than in the oxidase enzyme(s). Another patient with clinically mild, X-linked CGD exhibited normal membrane depolarization (and therefore presumably normal activation), but NADPH oxidase apparently had a low affinity for NADPH and thus produced low but measurable amounts of superoxide.
Neutrophil dysfunction also occurs in a variety of immunodeficiency states. Deficiency in any of the steps of oxidase assembly and activation could result in decreased superoxide production. In the primary immunodeficiency state interleukin-1 receptor-associated kinase 4 deficiency, there was decreased phosphorylation of p47phox, and decreased translocation to the membrane of p47phox, p67phox, and other oxidase components with associated decreased oxidase activity. In NF-kappaB essential modulator (NEMO) deficiency, NEMO-deficient cells had similar but less prominent changes, although p47phox translocation was normal. With Bruton tyrosine kinase (Btk) deficiency (also known as X-linked agammaglobulinemia), the picture is less clear. In patients with X-linked agammaglobulinemia there is both a deficiency of the kinase Btk and neutropenia. Studies suggest that in humans Btk-deficient neutrophils produce excessive NADPH oxidase activity after various stimuli, and that this was associated with increased apoptosis. It appears that the NADPH oxidase complex is partially assembled in resting Btk-deficient human neutrophils, making them ready for activation; that is, human Btk-deficient neutrophils are in a primed state. This is in contrast to studies of BTK-deficient mouse neutrophils where impaired NADPH oxidase activity was found. The model is that in humans BTK functions as a cytosolic component that inhibits translocation of NADPH oxidase components to the membrane and subsequent interactions with other NADPH components.

Lipochrome Histiocytosis

A clinical variant lipochrome histiocytosis was described in three sisters with rheumatoid arthritis, hyperglobulinemia, splenomegaly, pulmonary infiltrates, and increased susceptibility to infection. No granulomas were found in tissue biopsies, but lipochrome pigmentation in large macrophages was present throughout the tissues. Studies of blood leukocyte function in two of the sisters revealed impaired postphagocytic respiration, NBT reduction, and hexose monophosphate shunt activity identical to that seen in patients with CGD.

Glucose-6-Phosphate Dehydrogenase Deficiency

NADPH is the major substrate for the respiratory burst oxidase. A bactericidal defect similar to CGD has been described in a patient with a complete deficiency of G6PD, an enzyme important in the generation of NADPH. Apparently, almost complete absence of G6PD activity is necessary to interfere with bacterial killing, because no difference from normal could be detected in cells with 25% activity or greater.

Glutathione Peroxidase Deficiency

Two unrelated 9- and 13-year-old girls presented a clinical picture similar to that of CGD and with decreased bactericidal capacity. The findings in these girls differed from those in males with CGD only in that no heterozygotes were detected in their families and their clinical course was somewhat milder. These patients were reported before the nature of the NADPH oxidase was known, and it was suggested that the CGD phenotype was due to glutathione peroxidase deficiency, resulting in inhibition of the oxidase by accumulated peroxides. A subsequent study, however, suggested that glutathione peroxidase activity was normal in these patients and that both had mutations in the NADPH oxidase. Thus, there is no firm evidence that glutathione peroxidase deficiency is a cause of the CGD phenotype.

Glutathione Synthetase or Reductase Deficiency

Reduced glutathione plays an important role in protecting neutrophils (including the NADPH oxidase system) from reactive metabolites, including H$_2$O$_2$. Because glutathione levels are generated by both direct synthesis via glutathione synthetase and the reduction of oxidized glutathione by glutathione reductase, deficiencies of these enzymes might be expected to result in defective neutrophil function. The neutrophils of a normally growing infant with a relatively benign history of recurrent otitis and repeated episodes of neutropenia were found to have 5% of normal glutathione synthetase activity and 10% to 20% of normal glutathione content. The cells ingested particles and metabolized $^{14}$C glucose normally, but after phagocytosis, excess peroxide accumulated and impaired iodination and killing of bacteria were demonstrable. Electron microscopic examination showed damage to the microtubules and membranes of the neutrophils. Neutrophil dysfunction resulting from a deficiency of glutathione reductase has also been reported. Patients with glutathione reductase deficiency or glutathione synthetase deficiency generally pursue a fairly benign clinical course. Vitamin E may be useful in patients with severe glutathione synthetase deficiency.

Catalase Deficiency
The neutrophil is protected from products of the NADPH oxidase not only by glutathione but also by superoxide dismutase, which generates H$_2$O$_2$ from superoxide, and by catalase, which converts H$_2$O$_2$ to H$_2$O and O$_2$. A deficiency in neutrophil catalase has been reported in which the surface of the neutrophil was more susceptible to damage by H$_2$O$_2$ than normal.\textsuperscript{215} These patients do not appear to have severe complications with infections.\textsuperscript{215}

Job Syndrome

Job syndrome (also known as hyperimmunoglobulinemia E syndrome) was reported as occurring in two unrelated girls with red hair and fair skin who suffered from repeated staphylococcal cold abscesses, sinusitis, eczema, and pulmonary disease, a syndrome not unlike the affliction of Job.\textsuperscript{216} The leukocytes of these patients were capable of normal phagocytosis, bacterial killing, NBT reduction, and iodine fixation,\textsuperscript{216, 217} unlike those of patients with CGD. Subsequently, hyperimmunoglobulinemia E and defective chemotaxis were demonstrated.\textsuperscript{218, 219} It is now clear that this disorder is not limited to red-haired women, in that it is seen in both sexes and in patients of varied racial backgrounds and hair colors.\textsuperscript{220}

The common features are increased susceptibility to infection (usually evident in the first 6 weeks of life), chronic dermatitis, and hyperimmunoglobulinemia E.

Job syndrome is now recognized as a multisystem disease, characterized by not only recurrent infections, elevated IgE, and dermatitis, but also retained primary dentition, unusual facial phenotype, bone fragility, and hyperextensible joints.\textsuperscript{221, 222} While typically sporadic, autosomal dominant transmission in kindreds has been reported.\textsuperscript{220} Most cases of Job syndrome have been associated with mutations of STAT3, though others with the syndrome do not have this finding and mutations in other genes have been reported.\textsuperscript{223, 224, 225} Less frequent autosomal recessive transmission is now also recognized, with the gene defect being localized to Dock8.\textsuperscript{226}

Job syndrome is rare but with the advent of genetic diagnosis, more patients are being identified and the complete clinical repertoire of the disease is now being realized.\textsuperscript{227} Fungal, viral, and bacterial infections are common. Survivors with Dock8 mutations have developed T-cell lymphomas and squamous cell carcinoma of the skin in early adulthood.\textsuperscript{228} Blood eosinophilia and elevated IgE levels are the most common laboratory findings. Prophylactic treatment with dicloxacillin or trimethoprim-sulfamethoxazole may be helpful in managing afflicted patients. The role of interferon-\gamma is unclear.\textsuperscript{229}

Myeloperoxidase Deficiency

An inherited deficiency of MPO was described in 1969.\textsuperscript{230} The 49-year-old male propositus, one of his two sisters, and all four sons exhibited decreased MPO activity; no increased frequency of infections accompanied this defect. In two other families, apparently similarly affected, infection was also not a problem.\textsuperscript{230}

Until the late 1970s, this disorder was described in only rare cases (some familial, others apparently sporadic and acquired).\textsuperscript{231, 232, 233} This frequency seemed consistent with the apparently pivotal role of MPO in the oxygen-dependent killing of microorganisms.\textsuperscript{220, 232} With the development of flow cytometry and automated differential cell-counting techniques, however, MPO deficiency was often detected (approximately 1 in 2,000 subjects) during routine hematologic evaluation of patients admitted to the hospital.\textsuperscript{231, 233} From these studies, MPO deficiency clearly is the most common disorder of neutrophil function.\textsuperscript{233} This disorder is now known to be autosomal recessive with mutations localized in the MPO gene on chromosome 17q23.\textsuperscript{235}

Most studies of MPO-deficient neutrophils reveal that bacteria and fungi are phagocytized normally, and ingestion is followed by a vigorous respiratory burst. Bactericidal killing, however, is somewhat delayed, reaching normal levels only after 1 to 3 hours.\textsuperscript{232} The findings of these studies and the rarity of clinical infections in MPO-deficient individuals support the concept of MPO-independent microbicidal mechanisms.\textsuperscript{230, 232} In contrast, although ingested normally, several Candida species and Aspergillus are killed poorly, if at all; and several MPO-deficient patients, including one of the first reported cases, suffered from disseminated fungal infection.\textsuperscript{230, 232} MPO-deficient mice also have impaired defense against Candida,\textsuperscript{233, 237} and have also been noted to have increased atherogenesis.\textsuperscript{236, 237}

The respiratory burst in MPO-deficient cells is actually prolonged and supernormal, and evidence exists that MPO normally acts to modulate and terminate the inflammatory response; for example, MPO oxidizes the methionine group in FMLP, thus modulating chemotaxis, and it also modulates NADPH oxidase activity.\textsuperscript{232}

Results of studies of the structure of MPO have shown it to be a tetramer (150,000 D) composed of two heavy and two light chains ($\alpha_2\beta_2$) of 55,000 to 60,000 and 10,000 to 15,000 daltons, respectively.\textsuperscript{238, 239} MPO is encoded by a single gene
generating an 80-kD product that is modified and glycosylated generating a 90-kD enzymatically inactive apoprotein. In one study, completely MPO-deficient neutrophils lacked all of these subunits but contained the precursor protein, whereas partially MPO-deficient neutrophils contained decreased amounts of the precursor protein and the subunits derived from it. In some cases, specific mutations in the MPO gene in MPO deficiency have been described. In spite of these abnormalities, a majority of the patients are asymptomatic and a small percentage suffer from Candida infections.

MPO deficiency also occurs as an acquired defect in a variety of situations (e.g., pregnancy, lead intoxication, Hodgkin lymphoma, and activated coagulation), but it is encountered most commonly in association with acute myeloblastic leukemia (up to 48% of patients), myeloproliferative states (20% to 60% in chronic myelogenous leukemia, 32% in myelofibrosis), and myelodysplastic syndromes (25%). In many of these conditions, only some of the circulating myeloid cells are deficient, presumably those produced by the abnormal clone.

Other Enzymatic Defects

Two siblings with negative peroxidase, oxidase, and lipid reactions in the neutrophils and monocytes also have been reported.

Cystic Fibrosis

As described above, an important mechanism of bacterial killing by neutrophils involves the production of HOCl from H$_2$O$_2$ and chloride. Cystic fibrosis (CF) is caused by mutations in the gene encoding the CF transmembrane conductance regulator (CFTR), a cyclic adenosine monophosphate-regulated chloride channel. CFTR is present in neutrophil secretory vesicles and phagolysosomes. Although CF neutrophils produce extracellular HOCl normally, they have impaired chlorination and killing of phagocytosed bacteria due to defective HOCl production in phagolysosomes.

Leukocyte Adhesion Defects

As described in Chapter 7, cell-cell adhesion plays an important role in neutrophil function. Three types of leukocyte adhesion deficiency (LAD) have been described.

Leukocyte Adhesion Deficiency-1 (CD11/CD18 Deficiency)

CD11/CD18 deficiency is a rare, inherited disorder of leukocyte function first reported in 1974. It usually is detected in infancy or early childhood as a result of frequent bacterial (and sometimes viral) infections or delayed umbilical cord separation, and high neutrophil counts. The infections are recurrent, often life threatening or fatal, and usually involve the skin and subcutaneous tissues, middle ear, and oropharynx. Neutrophils are present in the blood in increased numbers (even between infections) and appear normal, but fail to migrate into Reubuck skin windows or sites of infection in normal numbers. When studied in vitro, they exhibit defects in motility, phagocytosis, granule secretion, and particle-stimulated respiratory burst activity. Humoral (immunoglobulins and complement) and cellular immunity (skin tests and lymphocyte stimulation tests) otherwise appeared normal, and no specific enzyme deficiencies were detectable.

The pathogenesis of this disorder was first suggested in 1980 when a patient’s neutrophils were found to lack a high-molecular-weight glycoprotein. Subsequent work revealed the absence of CD11/CD18. As described in Chapter 7, the CD11/CD18 family consists of three heterodimeric proteins each composed of a noncovalently associated $\alpha$ ($\alpha_c$, $\alpha_m$, or $\alpha_y$) and $\beta$ ($\beta_2$) chain (Table 58.2). Translocation of $\alpha$- and $\beta$-chains to the cell surface requires assembly of the $\alpha\beta$ heterodimer. Mutations in the $\beta_2$-chain (ITGB2) prevent normal assembly of the $\alpha\beta$ heterodimer and subsequent translocation to the surface. CD11/CD18-deficient neutrophils roll normally on endothelial cells but do not adhere or migrate with chemotactic stimulation (Table 58.2). Studies involving eight patients revealed two distinct phenotypes: patients with severe deficiency (<0.3%) and patients with moderate deficiency (2.5% to 31.0%) of CD11a/CD18 glycoproteins on the neutrophil surface. The severity of clinical manifestations correlated directly with the degree of glycoprotein deficiency. Results of other studies further expand the heterogeneity of defects causing this disorder in which mutations in CD18 have been identified. The disease has also been reported in cattle.

Hematopoietic cell transplantation is curative for this disease and recommended.

Leukocyte Adhesion Deficiency-2

A second form of LAD has also been described in which the patients have severe mental retardation, short stature, a distinctive facial appearance, the Bombay (hh) blood phenotype, and recurrent bacterial infections, including pneumonia, otitis media, periodontitis, and localized cellulitis without the accumulation of pus, in association with an elevated white cell count. Phagocytosis was normal, but motility and homotypic aggregation were defective. Surface
CD18 expression was normal. As described in Chapter 7, cell surface selectins, including CD62E (E-selectin), CD62P (P-selectin), and CD62L (L-selectin), and their ligands (carbohydrates whose structures appear to be related to sialyl-Lea [CD15s]), play an important role in neutrophil adhesion. The critical structure of CD15s is (NeuAc α2 → 3 Gal β1 → 4, [Fuc α1 → 3] GlcNAc) and the Bombay phenotype is a deficiency of Fuc α1 → 2 Gal linkages, which serve as the core of the A, B, and O blood groups. Therefore, neutrophils do not polymerize well and have lower levels of F-actin. Patients with this syndrome and

Leukocyte Adhesion Deficiency-3

A third form of LAD was described in four patients, which appeared to be due to a defect in integrin activation following stimulation of G-protein-coupled chemokine receptors. This syndrome has since been termed congenital disorder of glycosylation, type IIC, and is a member of a group of disorders characterized by defects in processing protein-bound glycans. In some of these patients mutations in SLC35C1, a GDP-fucose transporter, have been described. Oral fucose supplementation may be useful in some patients. Bone marrow transplantation might be considered in some cases.

TABLE 58.2 LEUKOCYTE β2 INTEGRINS

Rac2 GTPase Mutation

A defect of neutrophil adhesion, oxidase activation, degranulation, and chemotaxis in response to chemoattractants has been reported in one patient who had a double negative mutation in Rac2 GTPase. This patient had leukocytosis with a deficiency of pus at sites of infection, exhibiting a similar phenotype as that of Rac2 knockout mice.

FcyRII Deficiency

Several patients who lack the IgG receptor FcγRIIb (CD16) have been reported. Two homologues of FcγRII (FcγRIIA and FcγRIIB) have been identified. FcγRIIB is glycosyl-phosphatidylinositol-linked and expressed on neutrophils. Because FcγRIII bears the NA1 and NA2 polymorphic neutrophil-specific antigens, these cells are NA1 and NA2 negative. The clinical expression of this deficiency ranges from a normal state to one characterized by multiple infections.

Actin Dysfunction

A genetic disorder of neutrophil actin function, characterized by recurrent bacterial infections and defects in chemotaxis, adhesion, and phagocytosis, due to neutrophil actin dysfunction (NAD) also has been described. These cells appeared to have actin that does not polymerize well and had lower levels of F-actin in both the resting state and after stimulation. Subsequent studies after the death of the index case found that one, but not both, parent was heterozygous for LAD-1. Most patients with LAD-1 do not have abnormal actin polymerization. Patients with this syndrome and

static conditions, LAD-2 neutrophils can adhere and migrate. Few patients have been described, and these cases may represent different biochemical defects. Oral fucose supplementation may be useful in some patients. Bone marrow transplantation might be considered in some cases.
overexpression of 47- and 89-kD proteins (NAD 47/89) were also described.\textsuperscript{294} A more recent patient was described with overexpression of leufactin—an F-actin-binding protein that regulates microfilaments—and NAD with serious infections.\textsuperscript{297, 298} Leufactin was shown to be the 47-kD protein overexpressed in NAD 47/89. Overexpression of leufactin, also known as lymphocyte-specific protein 1, can create the morphologic and motility abnormalities seen in leufactin-overexpressing neutrophils.\textsuperscript{299}

Localized Juvenile Periodontitis

Localized juvenile periodontitis is an adolescent disease characterized by alveolar bone loss, most prominently of the incisors and first molars.\textsuperscript{300, 301} Interestingly, these patients do not have demonstrable problems with extra-oral infections. Abnormal neutrophil chemotaxis to FMLP and C5a in these patients has been reported,\textsuperscript{300, 301} and a similar chemotactic defect was also observed in siblings of patients before developing clinical disease. Neutrophils from patients with localized juvenile periodontitis have been reported to express CR2 (the C3d receptor) on the cell surface, in contrast to control cells, which do not.\textsuperscript{302} CR2 is present on normal immature neutrophils but is lost during maturation before release from the marrow. The mechanism of this abnormality has not been defined.

Desensitization

After previous exposure to a stimulus, neutrophils react less to subsequent stimulation by the same stimulus.\textsuperscript{303, 304, 305} This phenomenon has been termed desensitization. In some cases, the desensitization appears specific to the original stimulus, but in other cases desensitization to different stimuli is also observed (cross-desensitization).\textsuperscript{303, 304, 305} Such desensitization has been observed in patients undergoing hemodialysis, in which exposure of blood to a cuprophane dialyzer membrane results in the generation of C5a, which causes a transient neutropenia due to pulmonary leukostasis, as described in Chapter 7.\textsuperscript{306, 307} Although C5a generation persists throughout dialysis, the neutropenia is transient.\textsuperscript{308} In contrast to neutrophils obtained at the start of dialysis, neutrophils obtained after 2 hours of dialysis (after the leukostasis has resolved) do not aggregate in response to plasma leaving the dialyzer membrane, demonstrating desensitization in vivo.\textsuperscript{309} A patient with cytomegalovirus infection and serum-induced granulocyte aggregation (presumably due to C5a) did not experience neutropenia during dialysis; and his neutrophils did not aggregate in response to serum leaving the dialyzer, in contrast to control cells, also demonstrating in vivo desensitization.\textsuperscript{309} Similar desensitization was demonstrated in rabbits using the chemotactic peptide FMLP, wherein continuous intravenous infusion of FMLP reproduced a transient neutropenia due to pulmonary sequestration.\textsuperscript{309} It is likely that neutrophil desensitization may also occur in other pathologic states, including infection, trauma, and multiorgan failure syndrome, and may contribute to neutrophil dysfunction, although the clinical significance of this phenomenon is unclear.

The phenomenon of desensitization has also been implicated as part of the mechanism by which glucocorticoids inhibit neutrophil function. It appears that the glucocorticoid-regulated protein annexin 1 (lipocortin 1) can bind a formyl-peptide receptor, induce calcium transients, and desensitize neutrophils to subsequent stimulation by other agents.\textsuperscript{310} Two formyl-peptide receptors are expressed in neutrophils, the classic FPR and the related receptor FPRL-1/AXL. Annexin 1 appears to bind to FRPL-1/AXL, while some peptides derived from annexin 1 may bind both receptors.\textsuperscript{311} Viral Infection

Neutrophil dysfunction has been reported to occur in response to influenza A exposure. Both influenza A virus and its purified hemagglutinin activate neutrophils, and neutrophil responses to other stimuli are depressed after preexposure to influenza A and parainfluenza.\textsuperscript{312, 313, 314, 315, 316, 317, 318, 319} Neutrophils from patients with human immunodeficiency virus (HIV) infection also may exhibit abnormal function. In one study, neutrophils from patients with early HIV infection had enhanced superoxide production in response to bacterial products.\textsuperscript{320} Another study found evidence for neutrophil activation in patients with HIV infection as manifested by increased CD11b expression, decreased CD62L expression, increased $\text{H}_2\text{O}_2$ production, and increased actin polymerization.\textsuperscript{321} Interestingly, $\text{H}_2\text{O}_2$ production, in response to FMLP after tumor necrosis factor and interleukin-8 priming, was decreased, and CD62L downregulation in response to FMLP was less complete; these abnormalities correlated with the clinical stage of disease. Whether these abnormalities are a direct effect of the HIV virus, a manifestation of desensitization as described in the previous section, or the result of another mechanism is unclear. These observations suggest that neutrophil dysfunction may occur in response to other viral infections as well, although the clinical significance of such a phenomenon is unclear.

Hyperalimentation Hypophosphatemia

P.1300
In the past, the use of hyperalimentation without adequate phosphate occasionally resulted in hypophosphatemia that was associated with neutrophil dysfunction, including impaired chemotaxis. The exact mechanism of this defect is unclear, and this syndrome is now rarely encountered, although evidence suggests that the impairment of phagocytosis seen in phosphate depletion may result from an increase in intracellular calcium.

Hyperglycemia

Abnormalities have been observed in several neutrophil functions in patients with poorly controlled diabetes, including phagocytosis, chemotaxis, adhesion, and the oxidative burst. Improvement in glucose control is associated with an improvement in neutrophil function. Improvement in neutrophil function can occur after incubation with insulin for as little as 15 minutes. In patients with non-insulin-dependent diabetes, neutrophil dysfunction is associated with an increased intracellular calcium that returns to normal in association with normalization of phagocytic function when glucose control is improved.

Miscellaneous

Other apparently unique neutrophil disorders have been reported. One patient with leukocytosis, severe bacterial infections, and impaired wound healing had neutrophils that appeared to have a defect in signal transduction. These cells had a severe defect in chemotaxis, activation of the respiratory burst, and azurophil granule release in response to a variety of chemotaxis. In contrast, FMLP induced a normal increase in intracellular free calcium and specific granule release. Actin polymerization was defective in response to FMLP but normal in response to some other stimuli. Phagocytosis of opsonized bacteria was normal. Presumably, these cells have a defect in the intracellular signal transduction pathway.

Neutrophil Dysregulation in the Systemic Inflammatory Response Syndrome

Although this chapter has primarily addressed disorders resulting in decreased neutrophil function, neutrophil activity may also be increased. For example, one study reported increased neutrophil functional activity in patients with severe acute pancreatitis. The clinical significance of this phenomenon is unclear.

FREQUENCY OF IDENTIFIABLE QUALITATIVE NEUTROPHIL DISORDERS

Most patients suspected of having a defect in neutrophil function do not have a well-defined abnormality. In one study of 100 patients referred for evaluation of a suspected neutrophil abnormality, only four were identified as a described syndrome. Some degree of impaired chemotaxis or superoxide production was found in 53 of 100 patients, but no abnormality was found in 41 of 100.

Chapter 59 Lysosomal Abnormalities of the Monocyte-Macrophage System: Gaucher and Niemann-Pick Diseases

Abnormalities of the monocyte-macrophage system include certain of the inherited lysosomal storage diseases that result from specific defects in lysosomal function. Most of these disorders are caused by the deficiency of a particular hydrolytic enzyme, but others are due to impaired receptors, transporters, or deficiencies of crucial cofactors or protective proteins. Prevalent among these disorders are the sphingolipidoses, which are a unique family of diverse diseases related by their molecular pathology. Here, the clinical, biochemical, and genetic features of two of these disorders are presented: Niemann-Pick types A and B disease, caused by defects in the acid sphingomyelinase (SMPD1) gene, and Gaucher disease, caused by defects in the acid α-glucosidase (GBA) gene. In each of these autosomal recessive disorders, mutations in the gene that encodes the lysosomal enzyme result in a defective gene product (i.e., a noncatalytic enzyme) that is unable to perform its normal function as a hydrolase. The deficiency of these lysosomal hydrolases results in abnormal metabolism of the enzyme’s specific sphingolipid substrate, and the substrate accumulates in the cells of the monocyte-macrophage system, causing the clinical manifestations. For example, in Gaucher disease and Niemann-Pick types A and B diseases, anemia, thrombocytopenia, leukopenia, and/or hepatosplenomegaly can be the presenting symptoms. Thus, these disorders are frequently diagnosed by the hematologist and must be included in the differential diagnosis for patients with monocyte-macrophage involvement.

PATHOPHYSIOLOGY OF THE LYSOSOMAL STORAGE DISEASES

The underlying defect in the inherited lipidoses is the accumulation of metabolites, including glycolipids and sphingomyelin. The glycosphingolipids, which are present in the membranes of many cell types, are formed by the addition of various carbohydrates to a ceramide backbone (Fig. 59.1). The fatty acid portion of ceramide consists primarily of stearic acid (C18) in the brain, whereas in non-neural tissues it is somewhat longer (C16 to C24). Each sphingolipid is characterized by the nature of the compound that is esterified to the first carbon of the ceramide molecule. For example, the addition of hexoses and N-acetyleneuraminic acid to ceramide forms the gangliosides, which are found in brain, whereas the neutral glycolipids are found more ubiquitously in cell membranes. The blood group antigens are also glycosphingolipids. In the lysosomal storage diseases, these lipid compounds vary in amount in different cell types, so their rate and amount of accumulation because of a specific lysosomal enzyme defect will vary, leading to their cell-related manifestations (Fig. 59.2). Tables 59.1 and 59.2 outline the biochemical and phenotypic characteristics and the molecular basis of the lysosomal storage diseases, respectively.
GAUCHER DISEASE

Definition and History

Gaucher disease is a lipid storage disease characterized by the deposition of glucocerebrosid in cells of the macrophage-monocyte system. It was first described by Gaucher in 1882, and the storage of glucocerebrosid was first recognized by Epstein in 1924. The metabolic defect, which is the deficiency of the lysosomal hydrolase acid β-glucosidase, or β-glucocerebrosidase, was identified by Brady et al. There are three clinical subtypes, which are delineated by the absence or presence and progression of neurologic involvement: type 1 or the non-neuronopathic form; type 2, the infantile-onset, acute neuronopathic form; and type 3, the juvenile-onset neuronopathic form. All three subtypes are inherited as autosomal recessive traits. Type 1 disease is the most common lysosomal storage disease and one of the most prevalent genetic disorders among Ashkenazi Jewish individuals, with an incidence of about 1 in 1,000 and a carrier frequency of about 1 in 15.
FIGURE 59.2. Schematic structure of globoside (A) and ganglioside (B) to show site of action of the several catabolic enzymes, which result in one of the storage diseases when defective.

Etiology and Pathogenesis

All three subtypes of Gaucher disease result from the deficient activity of the lysosomal hydrolase, acid β-glucosidase (Table 59.1). The major acid β-glucosidase gene mutations that cause Gaucher disease among Ashkenazi Jewish patients have been identified (Table 59.2). Genotype/phenotype correlations have been made for the different subtypes and provide insight into the molecular basis for the remarkable clinical variation in Gaucher disease. Presumably, the amount of residual enzymatic activity determines disease subtype and severity. For example, the mutations that cause the severe type 2 (infantile) disease express little, if any, enzymatic activity in vitro, whereas type 1 patients who are homozygous for the milder N370S mutation tend to have a later onset and a milder course than patients with one N370S allele and another mutant allele. However, the wide variability in clinical presentation among Gaucher disease patients cannot be fully explained by the underlying acid β-glucosidase mutations, and presumably other “modifier” genes can influence disease severity.

Pathology

The pathologic hallmark in Gaucher disease is the presence of Gaucher cells in the macrophage-monocyte system, particularly in the bone marrow. These cells, which are 20 to 100 µm in diameter, have a characteristic wrinkled-paper appearance resulting from intracytoplasmic substrate deposition. These cells stain strongly positive with periodic acid-Schiff reagent, and their presence in bone marrow and/or other tissues suggests the diagnosis (Fig. 59.3). The accumulated glycosphingolipid, glucosylceramide, is derived primarily from the phagocytosis and degradation of senescent leukocytes and, to a lesser extent, erythrocyte membranes. Glucosylceramide storage results in organomegaly and pulmonary infiltration. Neuronal cell loss in patients with types 2 and 3 disease presumably results from the neural accumulation of the cytotoxic glycosphingolipid, glucosphingosine, due to the severe deficiency of acid β-glucosidase activity. Glucosylceramide accumulation in the bone marrow, liver, spleen, lungs, and kidney leads to pancytopenia, massive hepatosplenomegaly, diffuse infiltrative pulmonary disease, and nephropathy or glomerulonephritis. The progressive infiltration of Gaucher cells in the bone marrow causes thinning of the cortex, pathologic fractures, bone pain,
bony infarcts, and osteopenia, particularly in type 1 disease. Central nervous system (CNS) involvement occurs only in patients with types 2 and 3 disease.

**FIGURE 59.3.** Splenic histopathology in Gaucher disease. There are sheets of histiocytes with bland nuclei and abundant pink cytoplasm with a fine “tissue paper” appearance.

**Clinical Manifestations**

**Type 1 Disease**

There is a broad spectrum of clinical expression among type 1 disease patients, in part because of the combination of different mutant alleles. Onset of clinical manifestations occurs from early childhood to late adulthood, with more symptomatic patients presenting in childhood or adolescence. At presentation, patients may have easy bruisability resulting from thrombocytopenia, chronic fatigue secondary to anemia, hepatomegaly with or without elevated liver function tests, splenomegaly, and bone pain or pathologic fractures. Occasional patients present with pulmonary involvement. Patients who are diagnosed in the first 5 years of life are frequently non-Jewish and typically have a more malignant disease course. Milder patients are discovered later in life during evaluations for hematologic or skeletal problems, or are found to have splenomegaly on routine examinations. In symptomatic patients, splenomegaly is progressive and can become massive. Clinically apparent bony involvement can present as bone pain or pathologic fractures. Most patients have radiologic evidence of skeletal involvement, including an “Erlenmeyer flask” deformity of the distal femur, which is an early skeletal change. In patients with symptomatic bone disease, lytic lesions can develop in the long bones, ribs, and pelvis, and osteosclerosis may be evident at an early age. Bone crises with severe pain and swelling can occur. Bleeding secondary to thrombocytopenia may manifest as epistaxis and bruising and is frequently overlooked until other symptoms become apparent. Children with massive splenomegaly are short of stature because of the energy expenditure required by the enlarged organ.

**Type 2 Disease**

Infants with the rare and panethnic type 2 subtype have a rapid neurodegenerative course with extensive visceral involvement and death within the first 2 years of life. The disease presents in infants with increased tone, strabismus, and
organomegaly. Failure to thrive and stridor resulting from laryngospasm are typical. The progressive psychomotor degeneration leads to death, usually due to respiratory compromise.

Type 3 Disease

Patients with type 3 Gaucher disease typically present in infancy or childhood. In addition to the organomegaly and bony involvement, neurologic involvement is present. There is a high frequency of type 3 disease in Sweden (1 in 50,000), which has been traced to a common founder in the 17th century. Type 3 has been further classified as type 3a or 3b based on the extent of neurologic involvement and whether there is progressive myotonia and dementia (type 3a) or isolated supranuclear gaze palsy (type 3b).

Diagnosis

Gaucher disease should be considered in the differential diagnosis of patients who present with unexplained organomegaly, easy bruisability, and/or bone pain. In the past, bone marrow examination revealing the presence of Gaucher cells was used for diagnosis. Today, all suspect diagnoses should be confirmed by demonstrating deficient acid β-glucosidase activity in isolated leukocytes or cultured fibroblasts. For genotype/phenotype correlations, the specific acid β-glucosidase gene mutation should be determined, particularly in Ashkenazi Jewish patients. Carrier identification can be achieved by enzymatic assay, although in the Ashkenazi this can be achieved by detection of the common mutations. Testing should be offered to all family members, keeping in mind that heterogeneity even among members of the same kindred can be significant and that asymptomatic affected individuals may be diagnosed during such testing. Prenatal diagnosis is available by determining the enzymatic activity and/or the parent’s specific mutations in chorionic villi or cultured amniotic fluid cells.

Treatment

Enzyme replacement with recombinant acid β-glucosidase (imiglucerase [Cerezyme, Genzyme Corporation, Cambridge, MA] or velaglucerase alfa [VPRIV, Shire HGT, Lexington, MA]) is the standard of care for the treatment of patients with type 1 disease. Clinical trials have demonstrated that most extra-skeletal symptoms are reversed within 12 to 36 months by an initial debulking dose of enzyme (60 units/kg) administered by intravenous infusion every other week. Initial higher doses may be indicated in patients with severe disease (type 3) at the time of diagnosis and in those with rapid progression or significant comorbidities. Early treatment may be efficacious in normalizing linear growth and bone morphology in affected children. Experience during the last 20 years has proven enzyme replacement therapy to be safe and effective in preventing the complications of type 1 disease. However, enzyme replacement does not alter the neurologic progression of patients with Gaucher disease types 2 and 3. It has been used in these patients as a palliative measure, particularly in type 3 patients with severe visceral involvement. Alternative treatments being evaluated include therapies targeted to reducing the synthesis of glucosylceramide by chemical inhibition of glucosylceramide synthase, as well as pharmacologic chaperone monotherapy to increase the residual activity of missense mutations, and pharmacologic chaperone coadministration with the recombinant enzyme to stabilize it in the circulation and to increase its delivery to other tissues.

NIEMANN-PICK DISEASE

Definition

Niemann-Pick disease (NPD) types A and B are lipid storage disorders that result from the deficiency of the lysosomal enzyme, acid sphingomyelinase, and the subsequent accumulation of its substrate, sphingomyelin. The original description of NPD referred to what is now known as type A NPD, which is a fatal neurodegenerative disorder of infancy characterized by failure to thrive, hepatosplenomegaly, and a rapidly progressive neurodegenerative course that leads to death by the age of 2 or 3 years. Type B NPD has a wide phenotypic spectrum that can include neurologic manifestations, but typically does not. Type C NPD is a neurodegenerative disorder that results from defective intracellular cholesterol transport and accumulation of unesterified cholesterol in lysosomes. Previously, a type D disease was identified in patients from Nova Scotia; however, these patients actually have type C disease. All the subtypes are inherited as autosomal recessive traits and display variable clinical features.

Etiology and Pathogenesis
Types A and B NPD result from the deficient activity of the lysosomal hydrolase, acid sphingomyelinase (Table 59.1). In type C NPD, the genetic defect involves the defective transport of cholesterol from the lysosome to the cytosol. Two different genes causing the altered cholesterol transport in type C disease have been identified (NPC1 and NPC2), permitting more precise diagnosis, carrier detection, and prenatal diagnosis in affected families. Only types A and B are discussed here; for type C, see Refs. 7 and 8.

Pathology

Types A and B Niemann-Pick Disease

The pathologic hallmark in types A and B NPD is the histochemically characteristic lipid-laden foam cell, often referred to as the “Niemann-Pick cell.” These cells, which can be readily distinguished from Gaucher cells by their histologic and histochemical characteristics, are not pathognomonic for NPD, because histologically similar cells are found in patients with Wolman disease, cholesterol ester storage disease, lipoprotein lipase deficiency, and in some patients with GM1 gangliosidosis, type 2 (Fig. 59.4). Sphingomyelin is the major lipid that accumulates in the cells and tissues of patients with types A and B NPD. In most normal tissues, sphingomyelin constitutes from 5% to 20% of the total cellular phospholipid content; however, in patients with types A and B NPD, the sphingomyelin levels may be elevated up to 50-fold, constituting ≈70% of the total phospholipid fraction. Lysosomal sphingomyelin accumulation in liver, kidney, and lungs has been documented with organs from types A and B NPD patients containing about the same amount of sphingomyelin, with the notable finding of significant sphingomyelin and psychosphingosine in the CNS of type A NPD patients. In general, patients with type A disease have <5% of normal acid sphingomyelinase activity when assayed in cultured fibroblasts and/or lymphocytes, whereas cells from type B patients typically have >5% of normal activity, which presumably prevents the development of the neurologic symptoms.

vacuoles. Although some large vacuoles are seen, most are small. (Image provided by Professor Attilio Orazi, Department of Pathology, Indiana University.)

Clinical Manifestations

Types A and B Niemann-Pick Disease

The clinical presentation and course of type A NPD is relatively uniform and is characterized by a normal appearance at birth. Hepatosplenomegaly and psychomotor retardation are evident by 6 months of life, followed by rapid neurodegeneration and death by 3 years. The loss of motor function and the deterioration of intellectual capabilities are progressive. In later stages, spasticity and rigidity are evident, with affected infants experiencing complete loss of contact with their environment.

In contrast to the stereotyped type A phenotype, the clinical presentation and course of patients with type B disease are more variable. Most patients are diagnosed in infancy or childhood, when enlargement of the liver and/or spleen is detected during a routine physical examination. At diagnosis, type B patients also have evidence of mild pulmonary involvement, usually detected as a diffuse reticular or finely nodular infiltration on chest roentgenogram. In most patients, hepatosplenomegaly is particularly prominent in childhood, but with increasing linear growth the abdominal protuberance decreases and becomes less conspicuous. In mildly affected patients, the splenomegaly may not be noted until adulthood, and there may be minimal disease manifestations. In most type B patients, decreased pulmonary diffusion resulting from alveolar infiltration becomes evident in childhood and progresses with age. Severely affected individuals may experience significant pulmonary compromise by age 15 to 20 years. Such patients have low Po2 values and dyspnea on exertion. Life-threatening bronchopneumonias may occur, and cor pulmonale has been described. Severely affected patients also may have liver involvement leading to life-threatening cirrhosis, portal hypertension, and ascites. Clinically significant pancytopenia resulting from secondary hypersplenism may necessitate partial or total splenectomy, although removal of the spleen can exacerbate the pulmonary disease.

Cholesterol abnormalities characterized by low high-density lipoprotein cholesterol and increased total cholesterol are found in most patients and can be associated with early atherosclerotic changes. Some type B patients have neurologic involvement, which can include cerebellar signs and nystagmus, extrapyramidal involvement, mental retardation, and psychiatric disorders. As in other lysosomal storage diseases, it is evident that neurologic manifestations in acid sphingomyelinase deficiency may occur along a continuum among patients. Nevertheless, there is a distinctive, fatal neurodegenerative form (NPD-A), characterized by a brief period of normal development followed by a severe neurodegenerative course and death in early childhood.

Patients with NPD type C disease often have prolonged neonatal jaundice, appear normal for 1 to 2 years, and then experience a slowly progressive and variable neurodegenerative course. Their hepatosplenomegaly is less severe than that in patients with type A or B disease, and they may survive into adulthood.

Diagnosis

Type A NPD patients are diagnosed in the first year of life with failure to thrive, organomegaly, and severe psychomotor retardation. In type B NPD patients, splenomegaly is usually noted early in childhood; however, in very mildly affected patients, the enlargement may be subtle and detection may be delayed until adolescence or adulthood. The presence of the characteristic Niemann-Pick cells in the bone marrow supports the diagnosis. However, patients with type C disease also have extensive infiltration of these cells in the bone marrow. Thus, all suspect cases should be evaluated enzymatically to confirm the clinical diagnosis by measuring the acid sphingomyelinase activity in peripheral leukocytes, or cultured fibroblasts and/or lymphoblasts. Patients with type A or B disease will have markedly decreased levels of enzymatic activity (1% to 10% of normal), whereas patients with type C disease may have slightly decreased sphingomyelinase activities (50% to 75% of normal), and patients with Gaucher disease and other storage disorders presenting with hepatosplenomegaly and/or neurologic involvement will have normal or near-normal acid sphingomyelinase levels. Type C NPD can be documented biochemically by demonstrating the cholesterol transport defect in cultured fibroblasts or by determining the specific mutations in the NPC1 or NPC2 genes.

The enzymatic identification of type A and B carriers is problematic. However, in families in which the specific molecular lesion has been identified, family members can be accurately tested for heterozygote status by DNA analysis. Prenatal diagnosis of types A and B disease may be made reliably by measuring the acid sphingomyelinase activity in cultured amniocytes or chorionic villi. In families in which the specific gene mutations are known, the prenatal diagnosis can be made by DNA analysis of fetal cells. In type C disease, the cholesterol defect can be demonstrated by filipin staining, but DNA diagnosis using fetal cells is most accurate.
Treatment

Orthotopic liver transplantation in an infant with type A disease and amniotic cell transplantation in several type B patients have been attempted, with little or no success. Bone marrow transplantation of type B patients has reduced the spleen and liver volumes, the sphingomyelin content of the liver, the number of Niemann-Pick cells in the marrow, and the radiologic infiltration of the lungs. However, no long-term information is available, as these patients often lose their engraftment or have significant morbidity and mortality in the post-transplant period. To date, lung transplantation has not been reported in any severely compromised type B patient. Clinical trials of enzyme replacement therapy have begun for NPD type B. Treatment of types A and C disease is limited by the severe neurologic involvement.

Chapter 60 Langerhans Cell Histiocytosis

Chapter 60 Langerhans Cell Histiocytosis

Suman Malempati
H. Stacy Nicholson

Langerhans cell histiocytosis (LCH) is a disorder characterized by clonal proliferation of cells in the mononuclear phagocyte system. Since the first case was described more than a century ago, LCH has often been a source of confusion, perhaps best demonstrated by the several labels given to the disorder during the past 100 years. Since 1985, Langerhans cell histiocytosis has been the preferred term, replacing histiocytosis X, coined in 1953. The X demonstrated the lack of knowledge about the etiology and pathophysiology of LCH, and about how the different clinical syndromes were related. The term histiocytosis X did serve to bind the syndromes, which included Hand-Schuller-Christian syndrome, Letterer-Siwe disease, eosinophilic granuloma, Hashimoto-Pritzker syndrome, self-healing histiocytosis, and pure cutaneous
histiocytosis,\textsuperscript{7} into one clinical entity. The term Langerhans cell histiocytosis reflects the central role of the Langerhans cell in these diseases. LCH also distinguishes these disorders from other histiocytic syndromes, which include primary and secondary hemophagocytic lymphohistiocytosis, Rosai-Dorfman disease, and neoplastic disorders such as acute monocytic leukemia, malignant histiocytosis, and true histiocytic lymphoma.\textsuperscript{3} This chapter focuses on LCH.

**HISTORY**

The clinical triad of defects in membranous bone, exophthalmos, and polyuria in children, which became known as Hand-Schuller-Christian disease,\textsuperscript{9} was described in 1921 in a review by Hand.\textsuperscript{9} Hand described the first six reported cases, including those of Christian, Schuller, and his own first case reported in 1893.\textsuperscript{7} All six patients had hepatosplenomegaly, lymphadenopathy, and bone lesions. However, not all had exophthalmos and polyuria. Attempts to link the disorder to xanthoma tuberosum, lipid storage disease, and the xanthomatoses proved unsuccessful, and to this day, no evidence exists that a specific biochemical defect is responsible for the condition. However, the foamy or xanthoma cell came to be regarded as a pathognomonic feature of the syndrome.\textsuperscript{10}

A different syndrome, consisting of fever, bilateral otitis media, hepatosplenomegaly, and adenopathy in a young infant who died, was described by Letterer in 1924.\textsuperscript{11} In 1933, Siwe described a 16-month-old girl who died after a 3-month illness characterized by fever, hepatosplenomegaly, lymphadenopathy, neutrophilia, and a destructive lesion in her fibula.\textsuperscript{12} At autopsy, massive infiltrates of large cells resembling histiocytes were found. Siwe reviewed five other cases from the literature (including that of Letterer) and concluded that they constituted a single clinical entity.\textsuperscript{12}

![FIGURE 60.1. Historical timeline demonstrating the major discoveries regarding the pathogenesis and treatment of Langerhans cell histiocytosis (LCH).](image)

In 1940, two groups of investigators described a syndrome in which a characteristic feature was infiltration of bone by eosinophilic granulomas.\textsuperscript{13, 14} In 1942, Green and Farber described a series of patients with eosinophilic granulomas of bone, which usually healed promptly after irradiation or curettage.\textsuperscript{15} They noted that these cases shared pathologic features similar to those of the Letterer-Siwe and Hand-Schuller-Christian syndromes. In 1953, because of the similarity of the histiocytes observed in these three disorders, Lichtenstein combined them into a single entity called histiocytosis X to indicate their unknown cause.\textsuperscript{4} The recognition that these three disorders were related was an important contribution. The term Langerhans cell histiocytosis, proposed in 1985, reflects an improved understanding of these disorders.\textsuperscript{3}

Despite our understanding of the central role played by the Langerhans cells in LCH, little is known about the etiology of LCH. Although clinical features of LCH were first recognized over a century ago, the pathogenesis remains uncertain. In 1994, two separate groups detected clonality of the involved histiocytes from LCH lesions.\textsuperscript{16, 17} Clonality was demonstrated in LCH cells from unifocal lesions as well as disseminated disease. However, debate continues as to whether LCH represents a neoplastic disorder or a reactive proliferation of histiocytes (Fig. 60.1).

**EPIDEMIOLOGY**

Although estimates vary by region and time period, the annual childhood incidence of LCH has been estimated to be approximately 4 to 9 cases per million.\textsuperscript{18, 19, 25} The discrepancy between epidemiologic studies is likely due to variation in reporting and data collection. Across studies, there is consistently a slight
LCH occurs less frequently in adults with an incidence of 1 to 2 cases per million per year. In a case-control study comparing 177 children with LCH to children with cancer and community controls, LCH was associated with a family history of benign tumors and less strongly with feeding problems during infancy. Other factors associated with LCH in this study were maternal urinary tract infections during pregnancy and blood transfusions during infancy. Factors not associated with LCH were the typical childhood viral infections and medication use. In a case-control study of 459 children with LCH, which compared risk factors in children with LCH to those in both community and cancer controls, LCH was associated with neonatal infections, solvent exposure, and thyroid disease in the proband or the family. Childhood immunizations appeared to be protective. Reports of seasonal variation in incidence are conflicting. Familial clustering of LCH has been observed, suggesting that a genetic predisposition may exist. The concordance rates between dizygotic and monozygotic twins are 33% and 80%, respectively. In addition, patients with LCH may have a predisposition to cancer and vice versa. Links with both solid tumors and leukemia have been documented. Several cases of LCH developing in patients with acute lymphoblastic and acute myelogenous leukemia have been reported. Patients with LCH have genetic instability and increased chromosomal breakage, which also suggests a genetic predisposition to malignancy.

**PATHOLOGY AND PATHOPHYSIOLOGY**

The basic histologic lesion in LCH is granulomatous, with lesions containing histiocytes, mature eosinophils, and lymphocytes. Other cells present may include giant cells, neutrophils, and plasma cells. Initially, lesions are proliferative and dominated by histiocytes, some of which are Langerhans cells. Although mitotic figures may occasionally be identified, the histiocytes are not neoplastic by histologic criteria. As lesions progress, necrosis may develop, and the number of eosinophils and phagocytic cells containing cellular debris increases. Ultimately, xanthomatous changes and fibrosis may occur, and late in the course of disease, Langerhans cells may no longer be demonstrable. Multinucleated giant cells occasionally are prominent, especially in bone and lymph nodes. The histologic findings do not correlate with the extent or aggressiveness of disease.

The Langerhans cell is the sine qua non of the diagnostic lesion. Langerhans cells are dendritic antigen-presenting cells that are normally found in skin and other organs. Langerhans cells are classified as dendritic cells because of their capacity to form long cytoplasmic extensions through which they establish intimate contact with other cells. The presence of fascin, a highly selective marker of dendritic cells, on the surface of Langerhans cells confirms their derivation from dendritic cells. Langerhans cells are found primarily in normal epidermis, but also are evident in lymph nodes and spleen. A hematopoietic progenitor of Langerhans cells has been identified in normal bone marrow. In the skin, Langerhans cells form a trap for external contact antigens and are involved in delayed hypersensitivity. Despite low phagocytic activity, they fix antigens for presentation to other cells, especially T lymphocytes.

Although its demonstration is essential for diagnosis, the Langerhans cell may constitute no more than a small proportion of histiocytes within lesions. Viewed by light microscopy, these cells appear as large mononuclear cells with few cytoplasmic vacuoles and little or no phagocytic material. The nuclei are irregularly shaped and contain a fine chromatin pattern. Electron microscopic or immunohistochemical studies may be required to identify Langerhans cells with confidence. The former demonstrate structures known as Birbeck granules (Langerhans bodies, X granules), rood-shaped organelles with a central striation and occasional terminal vesicular dilation, giving them a tennis racket appearance (Fig. 60.2). Birbeck granules are thought to be produced by invagination of the cell membrane, and their function is not known. The other feature that conclusively establishes the diagnosis of LCH is the demonstration of either CD1a antigen or CD207 (Langerin) on the surface of LCH cells by immunohistochemical staining. Langerin is a cell-surface receptor that induces the formation of Birbeck granules. Langerin expression has recently been recognized as a sensitive and relatively specific marker in establishing the diagnosis of LCH. Other distinctive features of Langerhans cells that can be demonstrated with immunohistochemical techniques include the expression of S-100 protein, la-like antigen, and CD101.
FIGURE 60.2. Electron micrograph of Langerhans cells from a bone lesion demonstrating characteristic Birbeck granules with a trilaminar structure. (Magnification ×45,000; courtesy of Roma Chandra.)

The intralesional histiocytes of LCH were previously thought to be similar to normal Langerhans cells found in skin. However, it is now recognized that pathologic Langerhans cells or LCH cells are a less differentiated and more activated type of dendritic cell. CD1a-positive LCH cells from bone lesions express CD14 and CD68, monocyte antigens that are not expressed or are expressed at low levels in normal skin Langerhans cells. A recent study demonstrated a gene expression profile of intralesional LCH cells that was distinct from that of normal skin Langerhans cells. LCH cells also express the immature dendritic cell marker CCR6 in the absence of CCR7, which is expressed on mature dendritic cells. LCH cells exhibit a degree of migration capability, which is absent in mature dendritic cells. LCH cells can be induced to differentiate in the presence of CD40 ligand in vitro. However, as CD40 ligand is abundant in LCH lesions, the reason for maturational arrest is unclear. Abnormal cellular adhesion molecules in LCH cells, suggested by the presence of CD2, CD11a, CD11b, and CD11d, may contribute to the migration of Langerhans cells into LCH lesions, as well as their abnormal persistence and proliferation. Compared to normal Langerhans cells, LCH cells are defective in their alloantigen-presenting activity. The focal accumulation of Langerhans cells, macrophages, lymphocytes, and eosinophils suggests that LCH is immunologically mediated. This reasoning is supported by both histologic abnormalities of the thymus and disturbances of immunoregulation in patients with active disease. Thymic abnormalities were noted by Letterer in his initial description of the disorder, later known as Letterer-Siwe disease. Abnormalities noted on pre-therapy biopsy samples and postmortem materials include dysmorphic changes, dysplasia, and nonspecific involution. In patients with LCH, the number of normal thymocytes (expressing CD6) and late differentiating suppressor lymphocytes (expressing CD8) is decreased. These abnormalities are noted even when the disease is limited in its distribution.

Recognition of the possible pathogenic significance of thymic abnormalities prompted several studies of T lymphocytes in blood. The demonstration of decreased numbers of H2 receptors on blood lymphocytes suggested loss of T-suppressor cells. This loss was confirmed by quantitation of T-cell subsets in patients with active disease. Both the relative and absolute numbers of suppressor T lymphocytes (CD8+ cells) are decreased, resulting in an increase in the T4-to-T8 ratio.
Suppressor cell activity as measured by the concanavalin A and indomethacin stimulation assays also is poor. That T-suppressor cell deficiency may be causally related to a functionally abnormal thymus is suggested by the normalization of T4-to-T8 ratios with thymic extract. Moreover, the apparent ability of crude thymic extract to reverse disease activity in some patients suggests that the T-cell abnormalities may be of primary pathogenic significance.

Although less consistent, other abnormalities in immune regulation also have been described, including hypergammaglobulinemia, deficiency in antibody-dependent monocyte-mediated cytotoxicity, and abnormal in vitro response to mitogens and antigens. However, most investigators note normal mitogen-induced responses and normal delayed hypersensitivity. Also, several cytokines are increased in LCH. Cytokines serve as mediators of inflammation, regulators of lymphocyte growth and differentiation, and activators of specialized effector cells. In tissue culture, Langerhans cells purified from bony LCH lesions secrete interleukin-1 (IL-1) and prostaglandin E2, both of which induce bone resorption in vitro. These lesions also secrete angiotensinconverting enzyme, transforming growth factor-β1 and IL-2. These mediators are probably responsible for the osteolytic lesions that are a prominent clinical feature of LCH. Other cytokines that have been demonstrated to be increased in the serum of LCH patients include granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-3, IL-8, IL-10, and tumor necrosis factor-α. These cytokines are related to local activation of T lymphocytes and other inflammatory leukocytes. In addition, GM-CSF receptors are expressed by Langerhans cells. GM-CSF induces Langerhans cell proliferation and activation in vitro, and serum levels of GM-CSF have been correlated with the extent of disease.

The link between proliferation of Langerhans cells and immune dysfunction has not been worked out entirely. One suggestion is that the disorder results from a physiologically appropriate response of the Langerhans cell to an external antigen or neoantigen, possibly infectious in origin. However, the lack of seasonal variation or geographic clustering argues against an infectious basis. In addition, no direct evidence for a viral etiology (viral particles or nuclear material) in LCH lesions has been demonstrated. Alternatively, LCH may result from an appropriate response of the Langerhans cell to abnormal signals from other cells in the immune system, perhaps from T lymphocytes. In either event, deficiency of T-suppressor cells may disrupt the mechanism for termination of immune responses. Failure of this homeostatic mechanism could result in unrestrained macrophage proliferation. Patients with interferon-γ deficiency present with findings that mimic LCH.

suggesting a reactive process. Therefore, although the clonality of LCH cells has fueled the argument that LCH may be a neoplastic disorder, the debate continues.

**CLINICAL FEATURES**

LCH can present along a continuum of illness, ranging from indolent to explosive disease. In some patients, pathologic lesions are solitary, whereas in others they are widely disseminated. Moreover, the distribution of lesions in a given patient may vary considerably over time. Although LCH can occur at any age, it occurs with greatest frequency in infants and children. The median age at diagnosis for all disease variants is 3 to 6 years. The acute disseminated form of the disease characteristically occurs in younger children and almost all cases occur before the age of 5 years. Children younger than 1 year old, in particular, often present with multiple organ involvement. The more indolent forms of LCH occur primarily in older children and young adults. Approximately 70% of cases of LCH in children involve a single organ system, with bone being the most common site. Table 60.1 shows the distribution of involved sites by age at diagnosis of LCH. The most commonly involved organ in adults is bone, often accompanied by an adjacent soft tissue mass. Other organs that are involved less often in adults include the lungs and pituitary gland. In adults, multisystem disease, including liver, lymph node, and bone marrow involvement, is extremely rare.

The traditional classification of clinical variants was based on patterns of organ involvement. Eosinophilic granuloma was used to describe a syndrome characterized by single or multiple bone lesions in the absence of visceral involvement. When granulomas involved the liver, spleen, lymph nodes, skin, central nervous system (CNS), or bone marrow as well as bones, the disorder was called Letterer-Siwe disease. The triad of multiple bone lesions, exophthalmos (resulting from retro-orbital granulomas), and diabetes insipidus (DI; the result of hypothalamic or pituitary involvement) constituted Hand-Schuller-Christian disease (Figs. 60.3 and 60.4). The separation of eosinophilic granuloma of bone from syndromes characterized by visceral dissemination proved to be useful prognostically. However, the distinction between Letterer-Siwe disease and Hand-Schuller-Christian disease was often subtle and clinically irrelevant. The current classification is based on the number of organ systems involved and the number of sites involved within an organ system. The main classifications of disease are unifocal eosinophilic granuloma (i.e., single-system, single-site disease, usually in bone), multifocal eosinophilic granuloma (i.e., single-system, multisite disease, usually in bone), and acute disseminated histiocytosis (i.e., multisystem disease). The presence and degree of organ dysfunction are important distinctions in those with multisystem disease.
FIGURE 60.3. A: Axial magnetic resonance image of the orbits in a 4-year-old boy with recurrent disseminated Langerhans cell histiocytosis and marked proptosis. There are large orbital soft tissue masses bilaterally. B: Computed tomography scan of the same patient showing marked bony erosion of skull and orbit.
Bone is the most commonly involved organ, with the skull being the most commonly involved site in both children and adults. Unifocal eosinophilic granuloma of bone is the most common form of the disease. Multifocal bone involvement may or may not be associated with visceral disease. Characteristically, patients note mild discomfort at the site of bone involvement. However, skull lesions are often painless and are found only because of a soft tissue mass over the bony defect. In young children, multifocal lesions of the skull are often associated with other head and neck manifestations. Gingival swelling and inflammation, usually associated with cervical adenopathy, may be the first manifestations of disease. Premature eruption or loss of teeth and breakdown of the lower alveolar ridge result from involvement of the mandible. Mandibular lesions may be palpable and painful, giving rise to facial swelling. The maxilla and upper gingival ridge are involved less often. Involvement of the Petrous ridge of the temporal bone and mastoid is common, predisposing to chronic otitis media. Vertebral lesions pose special problems because of the risk of injury to the spinal cord. Vertebral collapse gives rise to vertebral plana (Fig. 60.5). Extension of granulomas into the spinal space may compress the cord, causing permanent neurologic damage. Recurrent bony lesions in children, particularly those involving the craniofacial region, are often associated with DI.

Radiographically, skeletal lesions are characterized by sharply demarcated rarefactions of the medullary portions of bone, producing a “punched out” appearance (Fig. 60.6). Reactive sclerosis in surrounding uninvolved bone is unusual at diagnosis, but when present, signifies that healing has begun. As healing occurs, the sharp endosteal margins become less distinct, and sclerosis is often seen. Both tables of the skull characteristically are involved, the outer more so than the inner. Erosion of mandibular bone around unerupted teeth gives them the appearance of floating in space. Skeletal lesions are well delineated with conventional radiography, computed tomography, and magnetic resonance imaging. The relative benefit of radionuclide bone scintigraphy, on the other hand, is controversial. Radionuclide bone scans...
often are falsely negative for skull lesions, but may be more sensitive in identifying lesions in the ribs, spine, and pelvis.\textsuperscript{90, 91}

P.1311

Positron emission tomography (PET) may have greater specificity in identifying active osseous lesions, but its clinical utility in LCH requires further study.\textsuperscript{92, 93}
FIGURE 60.5. Sagittal magnetic resonance image of the thoracic spine showing collapse of the T8 vertebral body, more prominent in the anterior aspect, in a patient with reactivation of Langerhans cell histiocytosis.

Skin involvement occurs in about one third of patients overall. \(^{22,25}\) Although skin manifestations are seen in only 10% of patients with single-system disease, it is a much more common feature of acute disseminated histiocytosis. \(^{81,94}\) Even in
those with skin-only disease, the rate of progression to multisystem disease is 30% to 40%. The skin lesions are typically vesiculopustular and may have a hemorrhagic crust. They are similar in appearance to those of seborrheic dermatitis. LCH is often suspected after a seborrheic rash fails to respond to treatment. The rash has a predilection for the scalp, postauricular areas, and diaper area (Fig. 60.7). The back, axillae, and intertriginous areas also may be involved. With advanced stages of the disease, the entire integument may be affected. Breakdown of severely affected areas is common, and concurrent thrombocytopenia imparts a hemorrhagic component to the rash.

FIGURE 60.6. Skull radiograph showing active osteolytic lesions in a patient with disseminated Langerhans cell histiocytosis. Note absence of reactive sclerosis.

A rash indistinguishable from that seen in acute disseminated histiocytosis may occur as a congenital, self-limited phenomenon not associated with skeletal or visceral disease. This form of histiocytosis has been called congenital self-healing histiocytosis or Hashimoto-Pritzker syndrome. The lesions are present at birth or appear within the first 2 or 3 weeks of life. They are most numerous over the scalp and face, but also may extend over the trunk and proximal extremities. Mucous membranes are spared. Langerhans cells present in biopsy material have the same immunophenotypic characteristics as those in the other variants of histiocytosis, although they contain fewer Birbeck granules. The lesions typically undergo spontaneous regression, with complete healing by the time the patient is 3 to 4 months of age. The prognosis is generally excellent without therapy, although occasionally isolated cutaneous LCH in infants can progress to multisystem disease.

Increasingly appreciated as a problem in LCH, CNS involvement occurs by contiguous spread of skull lesions into brain substance or by granulomatous infiltration of deep structures. The disease demonstrates a predilection for the hypothalamic nuclei and cerebellum, although focal lesions may occur in the temporal lobe, occipital lobe, and spinal cord. Rarely, CNS
lesions are found in patients who have no other evidence of histiocytosis. Neurologic signs and symptoms include ataxia, nystagmus, dysmetria, seizures, dysphagia, cranial nerve deficits, and spastic paraparesis. DI resulting from infiltration of the hypothalamus or pituitary stalk is common. Whereas mass lesions are satisfactorily visualized by computed tomography or magnetic resonance imaging, infiltrative lesions within the hypothalamus and elsewhere often are of similar density to adjacent brain tissue and produce little or no mass effect. Some of these lesions may be seen with magnetic resonance imaging. CNS involvement may leave survivors with permanent sequelae.
Of the endocrinopathies associated with LCH, DI is the most common. LCH is a common cause of DI in both adults and children. DI is caused by infiltration of the hypothalamus, pituitary stalk, or posterior pituitary by Langerhans cells. The
prevalence of DI in large series of patients ranges from 10% to 50%. In a study of 1,741 children with LCH, the cumulative risk of DI was 20% at 15 years from diagnosis. DI is more common in patients with multisystem disease and in those with proptosis. Patients with multiple craniofacial bone lesions are also at increased risk. DI is not typically a complication of unifocal bone disease not involving the skull. Characteristically, the onset of DI is after the diagnosis of LCH is made. Symptoms of DI occur at or preceding the diagnosis of LCH in only about one third of patients. However, LCH should be considered in the differential diagnosis in patients who present with central DI. In such cases a thickened pituitary stalk seen on MRI may be the only radiographic manifestation (Fig. 60.4). For most children, symptoms occur within 2 years of diagnosis and rarely, if ever, after 4 to 5 years. Although most affected patients have complete absence of antidiuretic hormone, partial deficiency may occur. Progression from partial to complete DI may occur, and once complete DI has developed, it cannot be reversed. Whether systemic chemotherapy for LCH may prevent the development of DI is unclear. However, more rapid response to therapy and shorter disease duration corresponds to a decreased incidence of DI. Reactivation of disease after complete resolution is associated with an increased risk of DI.

Neurodegenerative disease is the next most common CNS consequence of LCH after DI. The typical MRI findings are diffuse, symmetrical signal changes of variable intensity in the basal ganglia or cerebellum (Fig. 60.8). Patients with LCH-associated neurodegenerative disease demonstrate variable manifestations of disease. Some patients have no neurologic signs or symptoms, whereas others may have significant neurologic effects. Clinical signs may include tremor, ataxia, spasticity, dysarthria, and behavioral or psychiatric problems. The time course of disease progression is also variable, but neurologic deterioration may be severe and devastating. Histologic evaluation of neurodegenerative lesions show a T-cell mediated inflammatory process with tissue degeneration, and most importantly, absence of CD1a-positive cells.

Growth retardation resulting from growth hormone (GH) deficiency is another complication of LCH. GH deficiency occurs in approximately 10% of patients with LCH overall and up to 60% of patients with LCH-associated DI. Loss of GH, along with deficiency of other anterior pituitary hormones, is usually due to involvement of the hypothalamus or anterior pituitary by Langerhans cells. GH replacement has been shown to be safe and effective in children with LCH and GH deficiency.

Thyroid involvement by histiocytosis gives rise to goiter and may lead to hypothyroidism. Obstruction of the upper airway by diffuse enlargement of the thyroid gland has been described. Most children with thyroid involvement have DI and other evidence of disseminated disease.

Enlargement of the liver, often associated with abnormal liver function, is observed in many children with the disseminated form of LCH. In some patients, liver involvement leads to portal cirrhosis or intrahepatic cholestasis. Tissue from liver biopsies obtained from children with hepatomegaly infrequently shows the infiltrates of Langerhans cells, eosinophils, and lymphocytes that are hallmarks of the disease in other organs. Instead, subtle changes in the portal triads are observed, including triaditis, bile duct proliferation, and fibrosis. Patients with triaditis alone at diagnosis are less likely to have abnormal liver function or progressive liver disease than those with fibrohistiocytic or cirrhotic changes. Persistent abnormality of liver function is a wellrecognized adverse prognostic indicator.
FIGURE 60.8. Axial magnetic resonance imaging scan showing diffuse bilateral signal abnormality in the cerebellum in a patient with neurodegenerative Langerhans cell histiocytosis.
Involvement of lymph nodes and spleen is often a feature of disseminated disease.\(^{23}\) Lymph nodes may be involved because of contiguous bone or skin disease or as a result of widespread histiocytic dissemination. Splenomegaly is caused by portal hypertension or involvement of the spleen by large numbers of histiocytes. Curiously, Birbeck granules are rarely seen in otherwise characteristic Langerhans cells in the spleen and liver.\(^{41,42}\)

Although not common, the lungs may be involved with disseminated histiocytosis.\(^{124}\) As with other forms of disseminated disease, lung involvement occurs primarily in infants and young children. In contrast, primary pulmonary histiocytosis is principally a disease of young and middle-aged adults,\(^{125-129}\) although it does occur in children.\(^{126,127}\) Smoking is often associated with pulmonary LCH.\(^{132,133}\) Affected patients are without apparent multisystem disease at diagnosis; with further evaluation, however, some patients have asymptomatic bone lesions,\(^{130}\) and as many as 10% subsequently develop DI.\(^{134}\) Signs and symptoms of pulmonary involvement may be subtle or may include growth failure or weight loss, dyspnea, tachypnea, and hemoptysis. Recurrent pneumothoraces occur in as many as 20 to 25% of cases.\(^{135}\) Lung involvement is characterized radiographically by diffuse micronodular densities with cyst formation, sometimes giving rise to a picture of “honeycomb lung.” Lesions are usually prominent in the perihilar regions and the upper lung fields. Costophrenic angles are usually spared, and enlargement of hilar nodes is unusual. Permanent pulmonary sequelae often occur,\(^{136}\) and reactivation in the lungs may be associated with smoking.\(^{133}\)

Bone marrow involvement by Langerhans cells has been described most often in infants with disseminated disease.\(^{23,24,131}\) It is characterized by anemia, neutropenia, and thrombocytopenia, occurring singly or together. Erythrophagocytosis may rarely be a factor in the pathogenesis of anemia.\(^{138}\) Because bone marrow and splenic involvement often occur together, splenic sequestration of blood cells may further exaggerate the cytopenias of bone marrow involvement.

### Diagnosis

The clinical and radiographic features of LCH are distinctive enough to suggest the diagnosis in most patients. However, the diagnosis must be made pathologically, and for a definitive diagnosis, the presence of Birbeck granules or the presence of Langerin and/or CD1a on the surface of LCH cells must be demonstrated.\(^{139}\)

Assessment of the extent of disease is critical. To help standardize the workup and management of LCH patients, the Histiocyte Society has published guidelines on how to evaluate and follow patients.\(^{140}\) A thorough physical examination is necessary to evaluate for hepatomegaly or splenomegaly, lymphadenopathy, and any bone or soft tissue masses. Bony lesions may be diagnosed by either bone scan or skeletal survey. Each modality has been shown to discover lesions missed by the other. However, radionuclide bone scan may miss osteolytic lesions that do not have any osteoblastic characteristics. This is particularly true for skull lesions.\(^{95,96}\) Other studies required include a chest radiograph, complete blood count, assessment of liver function, and determination of renal concentrating ability. A bone marrow examination is required if cytopenias exist, and a high-resolution chest CT scan may be necessary if signs and symptoms suggest pulmonary involvement.\(^{131}\) Although not required to evaluate disease, some authors have recommended studies of T- and B-cell numbers, T-cell subsets, and lymphocyte function. New imaging modalities, including PET and octreotide scans, may be useful in LCH, but they require additional study.\(^{93,141,142}\)

Several staging or scoring systems have been proposed as having prognostic and therapeutic relevance. Most cite age (age younger than 2 years being a liability), extent of disease, and the function of involved organs as the important prognostic variables. An important distinction made by the Histiocyte Society and proven to be highly prognostic is whether “risk” organs are involved. “Risk” organs are the hematopoietic system defined as at least two cytopenias (with or without documented bone marrow involvement), spleen, liver, and lungs. The presence of “CNS-risk lesions” results in a higher risk of developing DI. CNS-risk lesions are those involving the craniofacial bones, particularly those around the eyes, ears, and oral cavity. The Histiocyte Society also recognizes “Special Sites” as being bone lesions that are located in critical anatomic sites in which lesions may cause immediate morbidity. Examples include the odontoid peg and vertebral lesions with intraspinol soft tissue extension. Stratification for treatment is defined based on these parameters. Patients are divided into those with single-system LCH or multisystem disease. Patients with multisystem disease with or without risk organ involvement and those with single-system disease and either CNS-risk, multifocal bone lesion, or special site lesions are candidates for systemic therapy.

**PROGNOSIS**

For most patients with LCH, the prognosis is excellent. Although LCH may wax and wane over many years, most patients improve over time. However, patients with multisystem disease may experience organ failure, which can be fatal. Outcome by single bone, multiple bone, and multiple organ involvement are shown in Table 60.2.

Most patients with unifocal bone disease experience complete resolution of lesions with or without treatment. Progression of bone erosion and recurrences at new sites are the exception rather than the rule. In a study of 48 patients with single bone involvement, the recurrence rate was 8% and no deaths were reported. In contrast, disease that is multifocal at the time of diagnosis is often characterized by one or more recurrences after disease control. Patients with multiple bone lesions, particularly those with skull involvement, have a much higher incidence of disease reactivation than those with single bone lesions. In addition, most patients with multiple organ involvement will experience disease recurrence. In one large series, 72% of patients with multisystem disease who initially responded to treatment experienced recurrent LCH from 2 months to more than 5 years after cessation of therapy, and most recurrences were in previously uninvolved sites. Young children, especially those younger than 2 years of age at diagnosis, are at particular risk for multiple relapses. However, in most patients the disease appears to eventually burn out.

Despite the favorable prognosis for most patients, mortality from disease progression can occur. Approximately one third of adults with pulmonary LCH die from the disease. The highest incidence of mortality, however, is seen in children with involvement of the liver, lungs, hematopoietic system, or spleen at diagnosis (“risk” organs as defined by the Histiocyte Society). A 5-year survival rate of only 25% has been reported in children with liver or spleen involvement at diagnosis. In a series of 18 patients with “risk” organ involvement, 7 died after either disease progression or recurrence. In contrast, in two separate studies, all patients 2 years of age or older without “risk” organ involvement survived. After disease resolution, LCH survivors may be left with permanent complications, including DI, pulmonary difficulties, neurologic complications, orthopedic abnormalities, neuropsychological impairment, dental problems, chronic otitis, or hearing impairment. Patients with one or more reactivations after initial therapy are more likely to have long-term sequelae from LCH.

**MANAGEMENT AND TREATMENT**

Management is dictated by the likely natural history of the disease based on the location and extent of lesions and by the presence of specific organ involvement and/or dysfunction. Given that LCH tends to improve with time, most patients do not require treatment aimed at ablating the disease. In most patients, disease manifestations are reversed with therapy that is far less intensive than that used for neoplastic disease. As noted previously, multiple courses of treatment may be required for recurrences. DI is not ameliorated by chemotherapy. Although some authors describe reversal of DI with radiotherapy directed to the hypothalamus-pituitary region soon after the onset of symptoms, the consensus is that radiotherapy, like chemotherapy, is without benefit in this situation.
Treatment decisions should be based on the number of systems involved and on whether a particular lesion is likely to result in disability. Children with single-system disease, particularly if they have a solitary lesion of bone (e.g., eosinophilic granuloma of bone), may require no therapy other than curettage.\textsuperscript{144} However, some patients have aggressive disease, warranting treatment with multiagent chemotherapy.\textsuperscript{123} In addition, multiple courses of treatment may be required for recurrences. However, in contrast to neoplastic disease, patients with LCH recurrence can often be successfully re-treated with a previously received regimen. Sometimes, recurrence can be ameliorated with less intensive therapy than originally received. Rarely are aggressive approaches, such as bone marrow or liver transplantation, justified.

Because unifocal bone disease is associated with a uniformly excellent prognosis, therapy with potential late effects should be avoided. The surgical procedure required for diagnostic purposes often is definitively therapeutic as well. Lesions other than those for which curettage is performed for diagnostic purposes often heal spontaneously.\textsuperscript{150} Lesions that progress or recur; those that threaten an important function, such as sight or hearing; and those that pose a risk of pathologic fracture or future disability may be treated effectively with low-dose radiotherapy. Doses of 600 to 1,000 cGy in three to five fractions effect local control in most patients.\textsuperscript{148, 149, 151} Lesions in weight-bearing sites, such as the neck of the femur, may require curettage and autologous bone grafting. Direct steroid injection into the lesion has been used\textsuperscript{152}; however, the benefit of this treatment has never been proven in a randomized fashion. Isolated histiocytosis of the skin in infants usually regresses spontaneously and does not require systemic therapy.\textsuperscript{5, 96, 153} Skin lesions in older children or adults may respond at least temporarily to radiation with ultraviolet light.\textsuperscript{154}

Systemic therapy is required for multisystem disease and for single-system disease in which multiple bones or CNS-risk bones are involved. Approximately 50% of patients requiring systemic therapy respond to corticosteroids alone.\textsuperscript{155} Because of the toxicity of corticosteroids when used for more than brief periods, however, other chemotherapeutic agents are now the mainstay of management. Vinblastine, vincristine, 6-mercaptopurine, methotrexate, alkylating agents, anthracyclines, and etoposide, singly or in combinations, are effective in controlling LCH.\textsuperscript{143} Patients with liver, lung, or bone marrow dysfunction as well as those at high risk for adverse CNS outcome are best treated with combination chemotherapy. In a clinical trial in which patients were stratified by risk, treatment included induction chemotherapy with vinblastine, etoposide, and prednisone, followed by maintenance chemotherapy with etoposide, vinblastine, prednisone, 6-mercaptopurine, and methotrexate.\textsuperscript{113} Two thirds of those patients with organ dysfunction achieved a complete remission, as did approximately 90% of those with either multisite bony disease or soft tissue disease without organ dysfunction.

The Histiocyte Society has conducted multinational randomized clinical trials in LCH.\textsuperscript{78, 156} In the first international trial (LCH I),\textsuperscript{78} 143 patients were randomized to receive 24 weeks of vinblastine (6 mg/m\textsuperscript{2} intravenously weekly) or etoposide (150 mg/m\textsuperscript{2}/day intravenously for 3 days, every 3 weeks); all patients received a single dose of steroids. Both of those monotherapies were equivalent. Due to the risk of secondary leukemias with etoposide, subsequent studies have been built from the vinblastine arm. One robust finding in this study was that the response at 6 weeks was strongly prognostic, regardless of initial treatment. However, LCH I did not produce superior results compared to studies from the German/Austrian Group, DAK-HX 83 and DAL-HX 90.\textsuperscript{157} Overall survival was similar, but a lower reactivation rate, longer reaction free interval, and fewer permanent disabilities were seen in the DAL studies compared to LCH I.

The Histiocyte Society’s LCH II trial demonstrated that intensified treatment increased early response in patients younger than 2 years with multisystem disease and risk organ involvement.\textsuperscript{156} The study showed that the addition of etoposide to a regimen of vinblastine, prednisone, and daily 6-mercaptopurine reduced the risk of mortality for these patients. The most recent LCH III trial evaluated the effect of adding methotrexate to the combination of vinblastine and prednisone for patients with “risk” organ involvement. Although data from that trial are pending, the current recommendation is that patients with multisystem disease should receive a 6-week course of therapy with weekly vinblastine and daily prednisone, followed by 12 months of maintenance therapy with vinblastine and prednisone pulses every 3 weeks with daily oral 6-mercaptopurine. Treatment should be similar for patients with multifocal bone and CNS-risk lesions, except that there is no proven benefit to 6-mercaptopurine.

Newer agents that have been evaluated for LCH that are refractory to standard therapy include cladribine (2-chlorodexoyadenosine). The early promise of cladribine reported in several small studies prompted further evaluation by the Histiocyte Society.\textsuperscript{158, 159, 161} In a Phase 2 study, cladribine showed benefit to patients with reactivation of disease in nonrisk organs.\textsuperscript{162} However, cladribine proved no more beneficial than standard therapy for patients with multisystem disease and risk organ involvement. The combination of cladribine with other agents such as cytarabine or etoposide may be more effective, but carries the risk of more pronounced bone marrow suppression and hematologic toxicity.\textsuperscript{163} Other agents that have shown promise in small series include clofarabine, bisphosphonates, and etanercept.\textsuperscript{164, 166, 167}
Etanercept inhibits TNF-α, which is highly expressed in Langerhans cells, lymphocytes, and macrophages of LCH lesions and promotes proliferation of Langerhans cells. Several patients with recurrent progressive LCH refractory to conventional therapy have benefited from allogeneic hematopoietic stem cell transplantation (HSCT). However, toxicity from HSCT in these patients has been an issue with high rates of transplant-related mortality. A few patients have undergone HSCT with reduced-intensity conditioning with less transplant-related morbidity and mortality. The most effective conditioning regimens and appropriate timing of HSCT are yet to be determined.

Chapter 61 Pathology of Langerhans Cell Histiocytosis and Other Histiocytic Proliferations

Karen L. Chang
Lawrence M. Weiss

Langerhans cell histiocytosis and other dendritic and histiocytic neoplasms and related proliferations are uncommon diseases.\(^1\) Dendritic cells, also known as classical dendritic cells, arise from the myeloid-derived common dendritic cell precursor and are divided by function and structure to include Langerhans cells, interdigitating dendritic cells, and follicular dendritic cells. Langerhans cells and interdigitating dendritic cells both show strong expression of S-100 protein and HLA-DR, with Langerhans cells positive for CD1a and langerin, and interdigitating dendritic cells negative for CD1a and langerin. Normal Langerhans cells reside primarily in the skin and migrate via lymphatics (as veiled cells) to the lymph nodes as they differentiate into interdigitating dendritic cells, which reside in the paracortical region of the lymph nodes. Langerhans cells are efficient antigen-processing presentation machines, whereas interdigitating dendritic cells interact closely with T-cells, leading to the initiation of strong cellular immunity. Follicular dendritic cells express CD21, CD35, and/or CD23, and not CD1a, langerin or S-100 protein. They are fixed cells that reside in lymphoid follicles, interacting...
with follicular B cells in the formation and organization of the follicles. In addition, they trap and store antigen-antibody complexes and they are important in memory cell formation and affinity maturation of follicular B-cells. Plasmacytoid dendritic cells also arise from the common dendritic cell precursor and are the main source of α-interferon upon viral infection or CD154 stimulation. Plasmacytoid dendritic cells also play an important role in immune tolerance through immune regulation and/or depletion via the uptake of self-peptides captured by the uptake of apoptotic classic dendritic cells. They express CD123 and not S100, CD1a, or langerin. A subset of plasmacytoid dendritic cells has immunoglobulin rearrangements.

Histiocytes are noncirculating cells derived from a bone marrow stem cell known as monocyte/macrophage and dendritic cell precursor, which is the same stem cell that gives rise to the common dendritic cell precursor. Histiocytes are the tissue-based equivalent of monocytes and are normally resident in a variety of organs, including the spleen, lymph nodes, and bone marrow; liver (Kupffer cells); lung (alveolar macrophages); lamina propriety of the gut; and brain (microglia). They express CD163 and CD68 (an antigenic marker of lysosomes). They play an important role in resistance to intracellular microorganisms and tumors through nonimmunologic mechanisms and in the recognition and clearance of apoptotic cells.

Each of these major dendritic and histiocytic cells has corresponding tumors, as summarized in Table 61.1 and discussed in further detail below.

LANGERHANS CELL HISTIOCYTOSIS

Langerhans cell histiocytosis is a neoplastic proliferation of Langerhans cells, albeit at perhaps a more immature state of maturation.^3^ Langerhans cells are dendritic cells that are normally resident in the basal layer of the epidermis and are characterized by immunohistochemical expression of CD1a, S-100 protein, and langerin and the presence of Birbeck granules by ultrastructural examination. Three major syndromes of involvement are recognized.^1^,^4^,^5^ In the most common type, unifocal disease (formerly solitary eosinophilic granuloma), involvement of a single site, usually bone, is seen. This syndrome is seen primarily in adolescents and young adults. In multifocal unisystem disease (formerly many cases of Hand-Schuller-Christian disease), there is involvement of several sites within one organ system, almost always bone. This syndrome is seen primarily in children. In the least common multifocal multisystem disease (formerly many cases of Letterer-Siwe disease), multiple organs are involved, usually including the bones, skin, liver and spleen, and lymph nodes, often in a lymphoma-like distribution. These latter cases are usually seen in infants.

Langerhans cell histiocytosis represents a monoclonal proliferation, as revealed by molecular studies of the X-linked androgen receptor gene.^6^ There is no association with known viruses.^7^ Cytogenetic and other studies have shown abnormalities involving chromosomes 1p and 7.^8^ Recurrent mutations of the oncogene BRAF have been found in a large number of LCH cases, including the allegedly polyclonal pulmonary variant of LCH. ^9^ Some investigators have theorized that immune dysfunction plays a role in the pathogenesis, although direct evidence is lacking. Neoplastic Langerhans cells may aberrantly express chemokines of immature dendritic cells, and abnormal reactions between Langerhans cells and macrophages may contribute to production of a cytokine “storm.”^10^,^11^ Biopsy is essential to the diagnosis of Langerhans cell histiocytosis. The key to the diagnosis is the identification of neoplastic Langerhans cells. Langerhans cells are dendritic cells with characteristic grooved, folded, or indented nuclei, inconspicuous nucleoli, a relative bland chromatin pattern, and thin nuclear membranes (Fig. 61.1). The degree of nuclear atypia or the mitotic rate in general does not correlate with outcome, with the exception that cases with frankly sarcomatous features probably represent rare cases of Langerhans cell sarcoma (see the section “Langerhans Cell Sarcoma”). The cytoplasm is usually moderately abundant and pale to intensely eosinophilic. Langerhans cells may be the only cell type, particularly as seen in cases of multifocal, multisystem disease, but most often they are found admixed in a characteristic cellular milieu that usually includes variable numbers of eosinophils, histiocytes, and neutrophils. Occasionally, eosinophilic microabscesses are seen. More mature lesions have greater numbers of histiocytes, which may be nonstimulated, epithelioid, or multinucleated and simulating osteoclasts. Late lesions tend to have variable numbers of foamy macrophages and plasma cells and are often associated with a significant degree of fibrosis. Ultrastructurally, neoplastic Langerhans cells have Birbeck granules, numerous lysosomes, small vesicles, and multivesicular bodies, and irregular cell membranes with an absence of cell junctions. Birbeck granules are specific to Langerhans cells and are usually “tennis racket”-shaped intracytoplasmic membranous bodies, with an osmiophilic core and a double outer sheath. The langerin antibody is an endocytic receptor associated
with the formation of Birbeck granules and thus is highly specific and sensitive and has in large part supplanted the need for electron microscopy studies.13

FIGURE 61.1. Langerhans cell histiocytosis. Histiocytic cells with frequent nuclear clefts are seen. Scattered eosinophils are present in the background.

Neoplastic Langerhans cells tend to have a similar (but not identical) phenotype as normal Langerhans cells, and are usually identified by expression of CD1a, langerin, and S-100 protein¹⁴ (Fig. 61.2). In addition, Langerhans cell histiocytosis expresses vimentin, HLA-DR, placental alkaline phosphatase (in contrast to normal Langerhans cells), and peanut agglutinin lectin. The tumor has been reported to be variably positive for CD45, CD68, CD163, CD4, and lysozyme; however, expression of these antigens probably represents positivity of the intimately admixed histiocytes. The Ki-67
index is usually low (<25%). Neoplastic and normal Langerhans cells are consistently negative for B- and T-lineage markers, CD30, CD34, and follicular dendritic cell markers CD21 and CD35. By enzyme histochemistry, normal and neoplastic Langerhans cells are positive for adenosine triphosphatase, α-D-mannosidase, α-naphthyl acetate esterase, α-naphthyl butyrate esterase, and acid phosphatase. There is no evidence of antigen-receptor gene rearrangements.

The differential diagnosis includes reactive proliferations of Langerhans cells, including dermatopathic lymphadenitis, so-called pulmonary Langerhans cell histiocytosis, and Langerhans cell histiocytosis-like proliferations associated with malignancy lymphoma. In dermatopathic lymphadenitis, the reactive Langerhans cells occur in the paracortex, in contrast to the sinusoidal or patchy pattern of lymph node involvement by Langerhans cell histiocytosis, and the proliferating Langerhans cells are accompanied by melanin-containing histiocytes and numerous interdigitating dendritic cells. So-called pulmonary Langerhans cell histiocytosis and Langerhans cell histiocytosis-like proliferations associated with malignant lymphoma are morphologically indistinguishable from Langerhans cell histiocytosis. Langerhans cell histiocytosis can be distinguished from most other histiocytic and dendritic disorders by their characteristic expression of CD1a, S-100 protein, and langerin.

FIGURE 61.2. Langerhans cell histiocytosis, S-100 protein stain (same case as Fig. 61.1). Nuclear staining of the Langerhans cells is seen.

LANGERHANS CELL SARCOMA

Langerhans cell sarcoma is an extremely rare neoplasm defined as a neoplastic proliferation of Langerhans cells that have overtly malignant cytologic features. It usually presents de novo but may also represent progression from typical Langerhans cell histiocytosis. There is a wide age range affected, and there may be a female predominance. Typically, multifocal multisystem disease is present. An aggressive behavior is seen, with an overall survival of ~50%.

Histologically, a proliferation of cytologically malignant histiocyte-like cells is seen (Fig. 61.3). The presence of occasional nuclear features characteristic of Langerhans cells may suggest the diagnosis. The mitotic rate is high, and the characteristic cellular milieu of Langerhans cell histiocytosis is not usually seen. Given this histologic picture, the diagnosis is usually established with the identification of the CD1a (which may be focal; Fig. 61.4) and S-100 protein, reactivities that are characteristic of Langerhans cells. The identification of Birbeck granules on ultrastructural examination is also
helpful in confirming the diagnosis. None of the cases reported to date have included langerin study. The Ki-67 index is usually much higher than that seen in typical Langerhans cell histiocytosis.

FOLLICULAR DENDRITIC CELL SARCOMA

Follicular dendritic cell sarcoma is a neoplasm of cells differentiating toward follicular dendritic cells. Normal follicular dendritic cells are the antigen-processing cells of the germinal center. Follicular dendritic cell sarcoma is a very rare neoplasm, occurring in a wide age range and even gender distribution. A subset of cases may occur in association with Castleman disease, and there may also be an association with schizophrenia. Most cases are not associated with known viruses, although a subset of cases, particularly those arising in liver or spleen, may be associated with Epstein-Barr virus (EBV). It most often presents in lymph nodes, but may also present in a variety of extranodal sites. Patients usually present with a slow-growing mass. Treatment usually consists of complete surgical excision, with or without adjuvant radiotherapy and/or chemotherapy. The tumor usually behaves in an indolent fashion, although local recurrence may occur in about one half of cases, and metastasis may occur in one fourth of cases.

FIGURE 61.3. Langerhans cell sarcoma. Although some of the nuclei have features of Langerhans cells, the nuclear atypia is striking. Note the presence of several mitotic figures, including atypical forms.

Histologically, one sees a spindle cell neoplasm, which may resemble a low-grade sarcoma (Fig. 61.5). The spindled cells may form fascicles and whorls, and there is characteristically an admixture of small mature lymphocytes, both amid the spindled cells or architecturally segregated into a second component, which may include secondary lymphoid follicles. The individual cells usually have bland spindled nuclei, although significant atypia may be seen in a minority of cases. The chromatin may vary from vesicular to granular and generally have small nucleoli. Occasional multinucleated cells may be seen. Ultrastructural studies show complex interdigitating cell processes with scattered mature desmosomes, typical of normal follicular dendritic cells, and an absence of Birbeck granules.
Immunohistochemical studies show the presence of phenotypic markers characteristic of normal follicular dendritic cells: expression of CD21, CD35, and/or CD23. They are also usually positive for vimentin, desmoplakin, and HLA-DR, variably positive for S-100 protein and CD68, and negative for keratin, CD45, langerin, and specific markers of B- and T-cell differentiation (although CD20 may occasionally be aberrantly expressed). A germline configuration of the antigen-receptor genes is found.

FIGURE 61.4. Langerhans cell sarcoma, CD1a (same case as Fig. 61.3). Membrane staining with CD1a is seen, characteristic of Langerhans cells.
FIGURE 61.5. Follicular dendritic cell sarcoma. A bland spindle cell proliferation is seen, with scattered mature lymphocytes.

The differential diagnosis includes other dendritic tumors as well as other sarcomas, carcinoma, and malignant melanoma. Other sarcomas and dendritic tumors lack CD21, CD35, and/or CD23, whereas carcinoma is keratin-positive and malignant melanoma expresses specific markers of melanocytic differentiation.

INTERDIGITATING DENDRITIC CELL SARCOMA

Interdigitating cell sarcoma is a tumor differentiating toward normal interdigitating dendritic cells.\(^1\)\(^2\)\(^2\)\(^8\)\(^9\) Normal interdigitating dendritic cells are major antigen-processing cells, usually located in the lymph node paracortical region. Interdigitating dendritic cell tumor is a very rare neoplasm usually occurring in adults, equally in men and women. Tumors may present either primarily in lymph nodes or at extranodal sites. Patients usually present with a solitary mass, although systemic symptoms may be present. The clinical course varies from benign to rapidly progressive lethal disease. Some cases may be associated with B-cell lymphoma; in such occurrences, both entities have been shown to be clonally related.\(^3\)\(^0\)\(^3\)\(^1\)

Interdigitating dendritic cell sarcoma usually shows a paracortical pattern of distribution, with residual follicles (Fig. 61.6). It may be comprised of spindled cells and has a close resemblance to follicular dendritic cell sarcoma, although the cells may be more rounded and occasionally simulate a diffuse large-cell lymphoma. Nuclear atypia may vary widely, as does the mitotic rate. Immunohistochemical studies usually show strong expression of S-100 protein, in the absence of specific markers of follicular dendritic cells (CD21, CD35, and/or CD23), the Langerhans cell markers CD1a and langerin, or B- and T-cell markers. CD45, CD163, and CD68 may be variably positive. There is a germline configuration of the antigen-receptor genes. Ultrastructural studies show an absence of Birbeck granules or well-formed desmosomes, although complex interdigitating cell processes are seen.

Immunohistochemical studies are necessary to distinguish interdigitating dendritic cell sarcoma from follicular dendritic cell sarcoma.
cell sarcoma (CD21-, CD35-, and/or CD23-positive), Langerhans cell histiocytosis (CD1a-positive and langerin-positive), malignant lymphoma (B-, T-, and/or CD30-positive), spindled carcinoma (keratin-positive), or malignant melanoma (which expresses HMB-45, MELAN-A, and/or melanoma-associated transcription factor).

FIGURE 61.6. Interdigitating dendritic cell sarcoma. The cells are epithelioid. This case showed strong nuclear staining for S-100 protein, yet was negative for CD1a.

OTHER RARE DENDRITIC CELL SARCOMAS

Other rare dendritic cell sarcomas described in the World Health Organization Classification of Hematopoietic and Lymphoid Tissues includes indeterminate cell tumor and fibroblastic reticular cell neoplasm. Indeterminate cell tumor is a CD1a-negative, S-100 protein-positive skin-based spindled cell tumor, which lacks Birbeck granules. The tumor comprises bland spindled cells, some of which show irregular grooves and clefts (Fig. 61.7). Ultrastructural studies do not show Birbeck granules, suggesting a transitional neoplasm between Langerhans cell histiocytosis and interdigitating dendritic cell sarcoma. Obviously, such hard-to-classify cases are extraordinarily rare, and not yet well characterized. Fibroblastic reticular cell neoplasms are also extremely rare. They generally occur in the lymph node paracortex and have a spindled to histiocytic appearance, and express vimentin, actin, and smooth muscle actin (in a heterogeneous pattern), and not S-100, CD1a, langerin, CD45, or markers of lymphoid or follicular dendritic cells.
FIGURE 61.7. Indeterminate cell tumor. This cutaneous case showed positivity for CD1a and S-100 protein, yet Birbeck granules were not present on ultrastructural study.

BLASTIC PLASMACYTOID DENDRITIC CELL NEOPLASM

Blastic plasmacytoid dendritic cell neoplasm (formerly, CD4⁺CD56⁺ hematodermic neoplasm or blastic NK-cell lymphoma) is a rare aggressive neoplasm that probably shows differentiation toward plasmacytoid dendritic cells (formerly known as plasmacytoid monocytes). Normal plasmacytoid dendritic cells are predendritic cells of the lymph node paracortex and are a major source of α-interferon in viral infection or CD154 stimulation. The neoplasm consistently expresses CD123 (the interleukin-3 receptor), CD68, and CD4, and a subset of cells expresses CD56 (the neural cell adhesion molecule NCAM). There is no association with known viruses, including EBV. Most patients with CD4⁺CD56⁺ hematodermic neoplasm are elderly and present with skin lesions. Bone marrow, peripheral blood, and lymph nodes are commonly simultaneously involved. The disease is usually rapidly progressive, with the development of disseminated disease in most patients, although some cases localized to skin may have a good prognosis.

Histologically, one sees a diffuse monotonous infiltrate of medium-sized cells with fine, blastic-appearing chromatin, closely resembling a lymphoblastic neoplasm (Fig. 61.8). Immunohistochemical studies show a phenotype resembling normal plasmacytoid dendritic cells, with positivity for CD4, CD56, CD123, and CD68. In addition, there is also consistent positivity for CD45, CD43, HLA-DR, CD62L, and CXCR3, and some cases show positivity for terminal deoxyribonucleotide transferase or CD34. Antigen-receptor genes are germline. The differential diagnosis includes lymphoblastic lymphoma and acute myeloid leukemia, both of which lack the characteristic CD4⁺, CD56⁻, CD123-positive phenotype of CD4⁺CD56⁺ hematodermic neoplasm.

HISTIOCYTIC SARCOMA

Histiocytic sarcoma is a neoplastic proliferation of cells showing histologic, immunohistochemical, and molecular features of histiocytes. By definition, there is the presence of one or more

P.1321
specific histiocytic markers and absence of specific B- and T-cell markers. The neoplasms are tissue-based, and neoplasms associated with monocytic leukemias are excluded.

FIGURE 61.8. Blastic plasmacytoid dendritic cell neoplasm. Note the uniform proliferation of cells with a blastic chromatin pattern.

Histiocytic sarcoma is a rare neoplasm, mostly commonly occurring in adults, although it has been reported in all ages. A subset of cases may be associated with mediastinal germ cell tumor, usually malignant teratoma, with or without yolk sac tumor. Lymph nodes and skin are most commonly involved, although virtually any site may be affected, including liver, spleen, bone, and intestinal tract. The bone may show lytic lesions or diffuse marrow involvement, with the latter occasionally causing pancytopenia. Some patients may show a “systemic” pattern of spread, recalling the old term, “malignant histiocytosis.” Most patients present a high clinical stage. Histiocytic sarcoma is an aggressive neoplasm, generally with a poor response to therapy, with most patients dying of progressive disease.

Histologically, one usually sees a patternless diffuse infiltrate of large cells, with a close resemblance to diffuse large-cell lymphoma (Fig. 61.9). Occasionally, one sees a preferential or exclusively sinusoidal pattern of infiltration. The proliferating cells generally have irregularly shaped nuclei, sometimes eccentrically placed, often with multilobulation and occasionally with multinucleation. Nuclear atypia ranges from mild to severe. The chromatin pattern is usually vesicular, and nucleoli may vary from small to large. Cytoplasm is usually moderate to abundant and eosinophilic, and may show some spindling. There may be some cells with foamy cytoplasm. Cytophagocytosis, usually hemophagocytosis, may be present, but is not considered to be a defining feature.

Phenotyping studies are essential to distinguish histiocytic sarcoma from other malignancies. Histiocytic sarcoma shows expression of at least one specific histiocytic marker in the absence of specific B- and T-cell markers. Positive markers of histiocytic differentiation may include CD163, CD68, CD4, CD11c, CD14, and lysozyme (Fig. 61.10). Additional, albeit nonspecific, antigens expressed by the neoplastic cells of histiocytic sarcoma may include CD45 and HLA-DR. The myeloid markers CD34 and myeloperoxidase are negative, although CD33 is usually positive. There may also be expression of S-100 protein, but CD1a, CD21, CD35, and langerin are negative. Antigen-receptor gene rearrangement studies show a germ
line configuration, with the exception of those with an association with B cell lymphoma, and there is no association with known viruses.

The most important differential diagnostic consideration is with malignant lymphoma. Histiocytic sarcoma is ~0.1% as frequent as malignant lymphoma, which can be identified by the presence of specific B- and T-cell markers and/or CD30. The malignancy most frequently confused with histiocytic sarcoma is anaplastic large-cell lymphoma, which often has a focal or preferential sinusoidal pattern of involvement and may be comprised of highly pleomorphic cells. In fact, most cases previously diagnosed as malignancy histiocytosis on histologic grounds alone probably represent anaplastic large-cell lymphoma, which may be distinguished from histiocytic sarcoma by the former’s constant expression of CD30, with or without ALK staining. Rarely, carcinomas and malignant melanoma may be confused with histiocytic sarcoma. Use of keratin and specific markers of melanocytic differentiation other than S-100 protein (such as HMB-45, melanocytic-associated transcription factor, and Melan-A) should identify these cases.

FIGURE 61.9. Histiocytic sarcoma. The nuclei appear lymphoid-like and closely resemble a diffuse large cell lymphoma.
FIGURE 61.10. Histiocytic sarcoma (same case as Fig. 61.9). CD163: strong positivity for CD163 is seen, consistent with a histiocytic lineage.

DISSEMINATED JUVENILE XANTHOGANULOMA

Juvenile xanthogranulomata are protuberant cutaneous nodules that usually present in the head and neck of children. The lesions may measure up to 1 cm in diameter and may occasionally occur in the soft tissues or internal organs. An aggressive systemic form, known as disseminated juvenile xanthogranuloma, accounts for <5% of cases. This variant also most commonly affects children, although rarely adults are affected (Erdheim-Chester disease). The etiology of disseminated juvenile xanthogranuloma is unknown, but rare patients also have neurofibromatosis-1 and/or juvenile myelomonocytic leukemia. Of note, NF-1 and JMML are also associated with usual type juvenile xanthogranulomata. Pathologically, the lesions of disseminated juvenile xanthogranuloma are cellular, with a mixture of histiocytic, spindled, and giant cells. Nuclear pleomorphism is not prominent. The tumor cells express factor XIIIa, fascin, CD163, and CD68, and do not express S-100 protein.

ROSAI-DORFMAN DISEASE

Rosai-Dorfman disease (sinus histiocytosis with massive lymphadenopathy) is a probably reactive disorder of as yet unknown etiology and whose proliferating cells may derive from a surfeit of sinusoidal macrophages. Patients usually present with markedly enlarged, often bilateral, painless cervical lymph nodes. However, a wider variety of extranodal sites are involved in about one-half of cases, including skin, upper respiratory tract, bone, soft tissue, including orbit, and these extranodal sites may be the presenting or only site of disease. Patients are generally young, presenting at a median age of 20 years, with no sex predilection, but a marked propensity for African Americans. There are usually a wide variety of laboratory abnormalities; including leukocytosis (neutrophilia), polyclonal hypergammaglobulinemia, and elevated
sedimentation rate. The clinical course is usually benign, although there may be persistence or recurrence of disease, and a small subset may be associated with immune dysfunction and have a poor outcome.\textsuperscript{55}

Involved lymph nodes are usually markedly enlarged and have a fibrotic lymph node capsule with massive dilation of the lymph node sinuses (Fig. 61.11). The sinuses show characteristic histiocytes, usually admixed with numerous plasma cells and the adjacent medullary cords also show numerous plasma cells. Extranodal sites usually show strikingly identical features, with dilated lymphatic sinuses, although surrounding fibrosis is usually more prominent. The characteristic histiocytes are very large with round nuclei that have a vesicular chromatin pattern, a delicate nuclear membrane, and one to several distinct nucleoli. Cytoplasm is abundant, amphiphilic to eosinophilic, and occasionally foamy. A distinctive feature is that the cytoplasm often contains numerous lymphocytes (lymphophagocytosis) or other cells (including neutrophils or erythrocytes).

Immunohistochemical studies show that the distinctive histiocytes are strongly positive for S-100 protein, CD163, CD68, CD11c, and CD14.\textsuperscript{56, 57, 58} They may also be focally positive for CD30 or, and more rarely, positive for CD1a. They are consistently negative for the follicular dendritic cell markers CD21 and CD35. Molecular studies show a germline configuration of the antigen-receptor genes, and the cells have been shown to be polyclonal by analyses of the X-linked androgen-receptor gene. There is no convincing evidence of an association with any known viruses.

The differential diagnosis includes sinus histiocytosis, Langerhans cell histiocytosis, hemophagocytic lymphohistiocytosis, and histiocytic sarcoma. The key to the diagnosis of Rosai-Dorfman disease is the recognition of the peculiar proliferating histiocytes, which contain a distinctive nucleus, and prominent lymphophagocytosis. Sinus histiocytosis lacks these peculiar cells, although it may show focal lymphophagocytosis.

![FIGURE 61.11. Rosai-Dorfman disease. Note the peculiar histiocytes with abundant lymphophagocytosis, along with the accompanying infiltrate of mature plasma cells.](image-url)

HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS

Hemophagocytic lymphohistiocytosis is a clinicopathologic syndrome characterized by uncontrolled hyperinflammation caused by a variety of inherited or acquired immune deficiencies.\textsuperscript{59} Most of the genetic defects involve defects in granule-mediated cytotoxicity and NK-cell function.\textsuperscript{60} Familial hemophagocytic lymphohistiocytosis usually presents within the first
year of life, with a symptom-free interval after birth typically seen. EBV is the triggering agent in ~75% of cases of infection-associated hemophagocytic lymphohistiocytosis. The terminal stages of any malignancy, including malignant lymphoma, may be associated with hemophagocytic lymphohistiocytosis. However, EBV-associated T/NK neoplasms are particularly common, and the accompanying hemophagocytic syndromes may occur at an early stage and may even be the presenting symptom of the lymphoma. Patients with hemophagocytic lymphohistiocytosis usually present with fever, hepatosplenomegaly, and cytopenias, and central nervous system symptoms are also common. Laboratory abnormalities include cytopenias of two or more cell lines, hypertriglyceridemia and/or hyperfibrinogenemia, and an increase in serum ferritin and soluble CD25. The prognosis is poor, with the immediate aim of therapy being to suppress the increased inflammatory response by immunosuppressive/immunomodulatory agents and cytotoxic drugs. Hematopoietic cell transplant has been curative in a selected group of patients with primary hemophagocytic lymphohistiocytosis.

Early in the disease course, biopsied lymph nodes may show a marked immunoblastic proliferation in the paracortex, with only minor hyperplasia of histiocytes noted in the sinuses. Later on, however, there is a massive infiltrating of the sinusoid by benign-appearing histiocytes. They show a normal histiocytic phenotype, with CD163 and CD68 positivity, and often show prominent hemo- and platelet phagocytosis (Fig. 61.12). There are also usually scattered to abundant plasma cells. The cortical and paracortical regions become comparatively diminished in size and stimulation. Finally, the lymph node may show lymphocyte depletion, with marked histiocytic hyperplasia with abundant phagocytosis in sinusoids. The hemophagocytic lymphohistiocytosis syndrome is usually established on clinical criteria, with lymph node biopsy performed to rule out coexisting malignant lymphoma.

FIGURE 61.12. Lymphohistiocytic hemophagocytosis, spleen. Note the prominent hemophagocytosis. This case was associated with Epstein-Barr infection.

Chapter 62

Infectious Mononucleosis and Other Epstein-Barr Virus-Related Disorders

Thomas G. Gross
Epstein-Barr virus (EBV) infects the majority of human individuals but usually shows subclinical infections. EBV has been etiologically linked to a wide spectrum of human disease, but it has been shown to be the etiologic agent in relatively few. Although EBV has been identified as the etiologic agent for infectious mononucleosis (IM), the diagnosis is predicated on the presence of a well-described constellation of clinical and laboratory features. EBV has been associated with Burkitt lymphoma (BL) and nasopharyngeal carcinoma (NPC), as well as many other human malignancies, such as non-Hodgkin lymphoma (NHL; B-cell, T-cell, and natural killer [NK]-cell phenotype), Hodgkin lymphoma (HL), leiomyosarcoma, gastric carcinoma, even hepatocellular carcinoma, and breast cancer. EBV has been associated with premalignant conditions or diseases with features of malignancy, such as oral hairy leukoplakia in human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS) and lymphoproliferative disorders (LPDs) in patients with primary or secondary immunodeficiencies. EBV has been associated with several other nonmalignant disorders as well, such as hemophagocytic lymphohistiocytosis (HLH) and chronic active EBV infection (CAEBV), and even has been implicated in diseases such as multiple sclerosis and chronic fatigue syndrome. The role of EBV in the pathogenesis of these disorders remains to be fully understood. This chapter reviews the biology of EBV and IM in detail. The other diseases that have been associated with EBV infection are discussed, focusing on data pertaining to the role EBV may play in their pathogenesis.

**HISTORICAL BACKGROUND**

In the first decade of the 20th century, several cases of glandular enlargement, sore throat, and increased numbers of mononuclear cells on the blood smear were described by Turk, Cabot, Marchant, and others. These cases were sometimes reported as acute leukemia that apparently resulted in spontaneous remission and cure. In the 1920s, Sprunt and Evans classified these cases and six of their own as infectious mononucleosis (IM), emphasizing the peculiar blastlike cells present in the blood. In 1923, Downey et al. published a detailed morphologic description of these cells.

In 1958, Denis Burkitt described an unusual, rapidly growing lymphoma in children of central Africa. In 1961, Dr. Burkitt gave a lecture at the Middlesex Hospital Medical School in London about the epidemiology of this lymphoma that now bears his name. A young doctor named Anthony Epstein was in attendance at this lecture and upon hearing the predilection of this tumor occurring in endemic malaria areas, he hypothesized a viral etiology for this tumor. For 3 years, Dr. Epstein and his colleagues were unsuccessful in finding viruses in the tumor tissue provided by Dr. Burkitt. However, in 1964, Dr. Epstein reported, along with Achong and Barr, the presence of viral particles in lymphoblasts cultured from tumor biopsies.

The discovery of EBV as the etiologic cause of IM was the result of a very astute observation made in 1967. The Henles noted that blood taken from a laboratory technician who had recently contracted IM led to the spontaneous establishment of a lymphoid cell line containing characteristic EBV particles, whereas previous attempts to establish cell lines from this individual’s blood had been unsuccessful. They also observed that sera obtained before the onset of IM were negative for an anti-EBV or heterophile titers, whereas after the onset of clinical IM, the anti-EBV and heterophile titers appeared and rose for a period of time. The Henles and associates studied the sera of a number of students from Yale University, where a prospective study of IM had been in progress for many years. In all instances of clinical IM, the anti-EBV and heterophile titers rose together from a negative baseline. Of even greater interest was the observation that the anti-EBV titer remained persistently elevated, in contrast to the transient nature of the heterophile response.

Confirmation of EBV as the etiologic agent in the majority of cases of IM soon followed.

**PATHOPHYSIOLOGY OF EPSTEIN-BARR VIRUS INFECTION**

EBV is one of eight known human herpes viruses (HHVs) and is subgrouped into the γ-herpes virus subfamily. Immature virus particles that measure 75 to 80 nm can be found in both the nucleus and the cytoplasm of infected cells. Mature, fully infectious particles, with a diameter of 150 to 200 nm, are found only in the cytoplasm. The infectious virus particle has three components: a nucleoid, a capsid, and an envelope. The doughnut-shaped central core, or nucleoid, contains the viral DNA in linear form. Surrounding the nucleoid is the capsid, which is icosahedral and made up of hollow, tubular protein subunits called capsomeres. Finally, the nucleocapsid (the capsid and the contained viral DNA) is enclosed in a protective envelope that is derived either from the nuclear membrane or from the outer membrane of the host cell. The envelope contains a number of viral antigens that are manufactured and inserted into the host cell membrane before the assembly of mature virus particles. The EBV genome (Fig. 62.1) is a double-stranded DNA molecule of approximately 173,000 base pairs (bp) organized into a series of unique coding regions (U1 to U5), divided by interval repeat regions (IR1 to IR4)

P.1325

and terminal repeat domains. The genome encodes approximately 100 proteins.
genes encoded by the genome and are discussed in detail in the section, “Epstein-Barr Virus Infection.” When EBV infects a cell, its linear genome circularizes to form an episome, an extrachromosomal element in the nucleus of the cell. The location of several EBV genes expressed during viral latency and replication is shown. EBER, EBV-encoded RNA; EBNA, EBV-determined nuclear antigen; gp, glycoprotein; LMP, latent membrane protein; ZEBRA, Z EBV replication activator. (From Tosato G, Tata K, Angiolillo AL, et al. Epstein-Barr virus as an agent of hematological disease. Baillere Clin Hematol 1995;8(1):165-199, with permission.)

Many variants have been reported, although the relevance to human disease pathogenesis is unclear. Two variants EBV-1 (A type) and EBV-2 (B type) exist, which are differentiated mainly by their differences in the EBV-determined nuclear antigens (EBNAs) 2, 3A, and 3C. Both types of EBV are found in most populations. The relationship between these different strains and specific diseases remains to be determined. Additional EBV variants with differences in EBNAs have been reported to be associated with specific EBV-affiliated diseases, such as BL, but the incidence of these variants has been shown to be similar in the general population of a particular geographic region. Furthermore, mutations (so-called 30-bp or 69-bp deletions) of latent membrane protein (LMP-1) have been reported to be highly associated with the development of HL, certain forms of T- and B-cell lymphoma, and NPC. But again, when compared with EBV variants found in the geographic regions, there exists no difference between healthy individuals and those associated with tumors. Therefore, caution must be exercised when attributing specific EBV viral strains to particular diseases in the absence of geographically matched control isolates.

Epstein-Barr Virus Infection

The only host that the virus infects naturally is the human, although lymphocytes from other species, namely New World primates (i.e., cottontop marmosets, owl monkeys, and tamarins), are infectible. EBV has been found in a variety of human tissue types associated with disease (i.e., T lymphocytes, NK cells, HL, leiomyosarcoma, gastric carcinoma, hepatocellular carcinoma, and breast cancer). The mechanism of EBV infection in these tumors remains to be fully elucidated.

Infection of B lymphocytes begins with attachment of the virus envelope glycoprotein (gp) 350/220 to the complement receptor C3d, also known as CR2 or CD21. For entry into B lymphocytes, a complex of three viral proteins (gH-gL-gp42) is required, and human leukocyte antigen (HLA) class II molecules serve as a coreceptor for gp42. Epithelium of the oropharynx is a source of viral replication, but it has been difficult to determine the mechanism of infection, inasmuch as these cells do not express CD21 or HLA class II molecules. Recent studies have demonstrated that during primary
infection, the majority of virions are not internalized after binding to B lymphocytes of the oropharyngeal tissue. And these B lymphocytes can form cellular conjugates with epithelial cells that allow for transfer of EBV virions into the epithelial cells. The mechanism for EBV entry into other cell types (e.g., T cells, gastric mucosa, smooth muscle cells, etc.) may also be via direct contact with B cells that have bound virions with subsequent virion internalization. Infection of epithelium leads to the replication of the virus with the release of large quantities of viral particles containing three-part complexes (gH-gL-gp42) that favor infection of HLA class II and CD21-expressing cells (i.e., B lymphocytes located in the oropharyngeal lymphoid tissues of the Waldeyer ring). These B lymphocytes may remain latently infected in the oropharynx, but if viral reactivation and replication occur, cellular lysis and death result, and the virus can be shed into the saliva. Virus contained in infectious saliva is produced by B lymphocytes of the oropharynx. Salivary virus may then be transmitted to another host.

**FIGURE 62.2 Epstein-Barr virus (EBV) gene transcription in the three forms of latency.** The top panel shows the position of the exons on a linear map of the genome. The lower panel shows the direction of transcription from each promoter (arrows) and the splicing structure between the exons. Coding exons are shown in black and noncoding exons in white. EBER, EBV-encoded small RNA; EBNA, EBV-encoded nuclear antigen; LP, leader protein; LMP, latent membrane protein; TR, terminal repeat. (From Young LS, Dawson CW, Eliopoulos AG. The expression and function of Epstein-Barr virus encoded latent genes. J Clin Pathol Mol Pathol 2000;53:238-247.)

The mechanisms underlying viral replication are not completely understood as there exist no in vitro models that recapitulate viral replication in humans. Viral replication is initiated through oriLyt. Two key early immediate genes are first transcribed, BRLF1 and BZLF-1, encoding ZEBRA protein. These proteins then up-regulate the expression of early gene products essential for viral replication, including viral DNA polymerase and viral thymidine kinase. Late gene products follow, including viral capsid antigen (VCA), the major envelope glycoprotein (gp350), and the viral protein BCRF-1, which contains 70% homology to interleukin (IL)-10. Complete viral replication results in the lysis and death of the host cell. Recently, it has been shown that viral proteins associated with type III latency (see below) are associated with viral replication. What role this plays in B-cell transformation and immortalization remains to be determined.

Alternatively, infected B lymphocytes appear to undergo normal B-cell differentiation and disseminate throughout the body into secondary lymphatic organs (i.e., lymph nodes, spleen, and bone marrow). Studies have demonstrated that the reservoir for latent EBV infection is a small percentage of postgerminal center, antigen-selected
resting memory B lymphocytes.\textsuperscript{47} The number of latently infected B cells is approximately 10-5 to 10-6 of all B cells and remains stable for the majority of the life of the infected individual.\textsuperscript{46, 48} P.1326

Latent infection is characterized by the expression of nine virally encoded proteins. Figures 62.1 and 62.2 illustrate the transcriptions of the nine latent proteins of EBV (EBNA-1, EBNA-2, EBNA-3A, EBNA-3B, EBNA-3C, EBNA leader protein [LP], LMP-1, LMP-2A, and LMP-2B).\textsuperscript{13, 15, 49} Two EBV-encoded RNAs (EBER-1 and EBER-2) are expressed abundantly in all EBV-infected cells and are valuable for making the diagnosis of EBV disease, but do not code for proteins and their function remains to be determined.\textsuperscript{13} In addition, the Bam HI-A rightward transcript (BART) is generally found in infected cells, but its function also remains to be fully delineated.\textsuperscript{50}

The state of latent infection is maintained by EBNA-1. The function of EBNA-1 is to bind to a nucleotide sequence called ori-P, part of the DNA origin of EBV replication, thereby allowing the viral genome to be maintained in the nucleus of the latently infected B cell.\textsuperscript{51, 52} By this mechanism, the EBV DNA is assured of being maintained in B cells that undergo replication.

EBNA-2 and LMP-1 appear to be required for B-cell immortalization.\textsuperscript{13, 15, 53} EBNA-2 transactivates the expression of LMP-1 and LMP-2.\textsuperscript{13, 15} EBNA-LP augments the ability of EBNA-2 to up-regulate LMP-1. LMP-1 and LMP-2 are associated with a cellular tyrosine kinase. The function of LMP-1 is similar to that of other members of the tumor necrosis factor (TNF) receptor family and is similar—but not identical—to that of CD40. LMP-1 interacts with TNF-receptor-associated factors and the TNF-receptor-associated death domain in infected cells and activates nuclear factor-kB and c-Jun N-terminal kinase pathways, resulting in B-cell activation and proliferation.\textsuperscript{49, 54-57} Additionally, LMP-1 expression also induces bcl-2 expression and can prevent apoptosis in B cells.\textsuperscript{57} LMP-2 prevents viral reactivation by blocking tyrosine phosphorylation and promotes B-cell survival.\textsuperscript{58} The EBNA-3 proteins regulate expression of certain cellular genes, including specific cellular receptors such as CD28, CD19, CD21, CD23, and CD30; T-cell co-stimulatory molecules CD80/CD86; adhesion molecules such as intercellular adhesion molecule-1, leukocyte factor antigen-1, and leukocyte factor antigen-3, and a member of the src oncogene family, c-fgr.\textsuperscript{15, 59}

Expression of EBV genes varies among the spectrum of EBV-associated diseases and often differs from in vitro immortalized B cells or normal human resting B cells infected by EBV.\textsuperscript{48, 60} The viral gene expression of viral latency is illustrated in Figure 62.2. Briefly, in type I latency- EBNA-1, EBER-1, and EBER-2 and BART are expressed. Type I latency is observed in BL and a portion of EBV-positive gastric carcinoma. Type II latency is characterized by the expression of EBNA-1, LMP-1, LMP-2A and B, EBER-1, and EBER-2 and is observed in NPC, and other EBV-positive lymphomas, such as T- or NK-cell NHL, and the Reed-Sternberg (RS) cells of HL. EBV-infected cells of LPD observed in immunodeficient patients resemble in vitro immortalized B cells and generally express all nine of the EBV-related latent proteins (type III latency). The site of EBV latency in seropositive healthy individuals, the resting memory B cells does not appear to express EBNA-1 but only LMP-2, EBER-1, and EBER-2 together with BART (type IV latency).\textsuperscript{60}

Immune Response to Epstein-Barr Virus Infection

Understanding the immune response to EBV infection is essential to comprehend the pathogenesis of EBV-related disease. EBV is a very potent immune stimulus. The immune system controls lymphoproliferation in the normal host and maintains a host/virus symbiosis. Figure 62.3 illustrates the delicate balance between the host T-cell immune response and control of B-cell proliferation of latently infected B cells. In a healthy individual, although only 10\textsuperscript{-5} to 10\textsuperscript{-6} B cells are latently infected with EBV, approximately 1% to 5% of all circulating CD8\textsuperscript{T} cells are capable of reacting against EBV.\textsuperscript{48, 61, 62, 63} Initially, there is B-cell proliferation, producing both EBV-specific and -nonspecific antibodies. The number of these virus-containing B cells rises during the acute phase of the infection but never exceeds 0.03% to 0.1% of the circulating mononuclear cells.\textsuperscript{64, 65} A cellular immune response follows, which is composed primarily of an expansion of cytotoxic T lymphocytes (CTLs), with the vast majority being EBV-specific, although some are not EBV-specific.\textsuperscript{66, 67} Figure 62.4 illustrates the pathologic consequences of an abnormal CTL response to EBV infection. A deficient CTL response, either quantitative or qualitative, results in an EBV-driven B-cell proliferative process. The lack of an appropriate CTL response can also result in an aggressive, predominantly T-cell and histiocytic reaction that is not EBV-specific. This reaction is characterized by extensive infiltration of lymphoid and parenchymal organs with hemophagocytosis, and tissue destruction is often observed. If unchecked, this reaction can be rapidly fatal.\textsuperscript{58, 69}
The humoral response to EBV is well characterized (Fig. 62.5).\textsuperscript{70, 71, 72, 73} VCA antibodies are the earliest to appear: first immunoglobulin M (IgM) and, later, IgG. IgM antibodies probably arise during the incubation period, peak with symptoms, and then decline rapidly.\textsuperscript{74} IgA anti-VCA antibodies are seen in some patients and, like IgM anti-VCA antibodies, are gone within several weeks.\textsuperscript{74, 75} IgG anti-VCA antibodies reach a peak 2 to 3 weeks after their IgM predecessors and persist for life.\textsuperscript{74, 75} The majority of patients also have a transient response to the EBV early antigen (EA), peaking usually within a month of infection.\textsuperscript{72} Antibodies to EBNA may appear several weeks after the onset of the illness in some patients but, in general, take several months to appear, and titers rise slowly over 1 to 2 years and persist for life. The majority of normal individuals have detectable IgG to EBNA by 6 months after EBV infections, although it may take years to develop detectable anti-EBNA titers.\textsuperscript{76} In young children, the anti-VCA and anti-EA responses may be much less intense, and anti-EBNA may take much longer to be seen.\textsuperscript{77}

An EBV-nonspecific humoral response also occurs with EBV infection. Paul et al.\textsuperscript{78} first described this phenomenon in 1932 when they reported that the sera of patients with IM contained heterophil antibodies against sheep erythrocytes in concentrations far above normal. The use of heterophil antibodies in the diagnosis of IM is discussed in detail in the section, “Infectious Mononucleosis: Diagnosis.” Many of these EBV-nonspecific antibodies function as autoantibodies and include cold reactive anti-i antibodies, Donath-Landsteiner cold hemolysins, and antibodies against smooth muscle, thyroid, and stomach.\textsuperscript{79, 80, 81, 82} In addition, antinuclear antibodies have been found in the sera of some patients\textsuperscript{83, 84} as well as rheumatoid factors,\textsuperscript{85} including anti-Gm antibodies,\textsuperscript{86} anticardiolipin antibodies, and antiactin and anticytoskeletal antibodies.\textsuperscript{87} The serum of some persons with IM may contain cryoglobulins.\textsuperscript{88} Some of these autoantibodies have been reported to be monoclonal.\textsuperscript{84}

Although neutralizing antibodies produced after primary infection may play a role in thwarting the spread to additional B cells, EBV-specific antibodies are most useful for diagnosis,

whereas the cellular response is the most important for control of EBV infections. NK cells and CD4\textsuperscript{+} T cells have been shown to play a role, but CD8\textsuperscript{+} memory cytotoxic T cells (EBV-CTLs) are the primary defense in controlling EBV infections.\textsuperscript{66, 67, 89, 90} The absolute number of NK cells may initially be increased, but a decrease in NK function is usually observed, returning to normal gradually over several weeks.\textsuperscript{91} Initially, these EBV-CTLs account for the majority of cells causing the lymphocytosis and the large, pleomorphic, atypical lymphocytes, or “Downey cells,” characteristic of IM.\textsuperscript{66, 67, 90, 92} Of note, it has been shown that the amount of these T cells in the peripheral blood correlates with symptoms seen in IM, not the number of EBV-infected B cells or the viral load.\textsuperscript{91} Not surprisingly, at first the majority of EBV-CTLs are reactive against lytic viral antigens. During lytic infection three EBV proteins, BNLF2A, BILF1, and BGLF5, function to lower HLA I surface expression, which in effect helps EBV-infected cells evade the immune system.\textsuperscript{94} However, over time the number of EBV-CTLs reactive against latent viral antigens predominates.\textsuperscript{66, 67}
FIGURE 62.4 Immune response to Epstein-Barr virus (EBV) infection.
This symbiosis of EBV and the infected host is maintained by interactions between viral gene expression in latently infected B cells and host EBV-CTL surveillance. The reservoir of viral latency is found among the resting memory B cells.46, 47 These resting memory B cells do not express high levels of adhesion molecules or T-cell co-stimulatory molecules, making them poor antigen-presenting cells. When these cells divide, EBNA-1 is expressed to ensure passage of viral DNA to progeny cells.52 Although CD4+ T-cell responses against EBNA-1 have been documented,95 EBNA-1-specific cytotoxic T cells are not readily generated.96, 97 Thus, the reservoir of latent EBV infection is not recognized readily by the immune system.

Activated EBV-infected B cells express major histocompatibility complex class I antigens; various adhesion molecules make these proliferating EBV-infected B cells good antigen-presenting cells. Proliferating, latently infected B cells express all latent proteins, including EBNA-2, EBNA-3A, EBNA-3C, LMP-1, and LMP-2 (type III latency). These proliferating EBV-infected B cells are highly susceptible to cellular lysis by EBV-CTL and are eliminated during convalescence, whereas memory EBV-CTL provide lifetime immunosurveillance against EBV-driven B-cell proliferation. The immunodominant epitope of the EBV-CTL response is highly restricted by the HLA type of the individual.98 For months after the expansion of EBV-infected B cells is controlled, virus is shed at high titers in the saliva,99 indicated ongoing viral replication in infected B cells of the oropharynx.46 Recent studies have demonstrated that EBV-CTL against latent viral antigens home more efficiently to lymphoid tissue of the oropharynx than EBV-CTL against lytic viral antigens.100 This observation helps explain that the greatest risk of acquiring primary infection is salivary exposure from a recently infected person or a person in early convalescence, although infective virions can be found in the saliva of persons with a long latent infection.
INFECTIOUS MONONUCLEOSIS

Epidemiology

The typical clinical syndrome associated with IM occurs most commonly in young adults, the peak incidence being in persons between 17 and 25 years of age (Fig. 62.6). Children often acquire immunity to EBV without developing the typical clinical manifestations of IM, for reasons still not understood. Because symptoms of EBV correlate with the CTL response, this would suggest that young children generally respond with a less exuberant cellular response. The yearly conversion rate to EBV seropositivity among children in the United States is not known. Past studies suggest earlier conversion with lower socioeconomic status, i.e., 51% of Yale University freshmen and 86% of Marine recruits, had antibodies to EBV. Authors of a British study concluded that 30% to 40% of children had been infected by their fifth year. Generally speaking, the rate of seroconversion is high in developing countries, where standards of hygiene are relatively low compared to higher socioeconomic countries. Under these circumstances, primary infection occurs in almost all children before 10 years of age, leaving few young adults susceptible to develop IM, and the observed incidence of IM in such countries is very low. IM is sufficiently uncommon in individuals older than 30 years of age and is so rare in those older than 40 years of age that special care is needed when making the diagnosis in persons in their middle or late years. Nevertheless, well-documented cases of this illness in patients older than 40 years of age have been reported. Complications such as protracted fever, jaundice, pleural effusion, and Guillain-Barré syndrome often dominate the clinical picture in these patients, detracting from the evidence that would allow the clinician to make the correct diagnosis.

IM is not as contagious as is commonly believed. It is rare for members of a patient’s family, roommates of the same sex, and other close associates to develop symptoms of IM. “Kissing disease,” the colloquial term for IM, underscores the association of intimate kissing with IM. Although oral shedding occurs throughout the life of a carrier, it peaks shortly after infection but often is readily detectable for 18 months or longer. Other modes of acquiring EBV infection include transplantation of organs or hematopoietic cells in which transmission to the transplant recipient is common. Although it is not thought to occur frequently, there are anecdotal reports of transmission from blood transfusions, in utero, or perinatally. Although there are anecdotal reports of virus detected in cervical epithelium and semen, sexual transmission has never been demonstrated.
Clinical Features

Many individuals have held that the manifestations of IM are protean and that many disorders may be simulated by this condition. IM is traditionally characterized by the clinical triad of fever, pharyngitis, and generalized adenopathy, with demonstration of an atypical lymphocytosis, defined as an absolute lymphocytosis with more than 50% lymphocytes and 10% or more atypical forms in the differential count, and the presence of heterophil antibodies. Usually, IM occurs only once in the lifetime of a host, although recurrences have been reported, and exacerbations of unresolved infection or transition to a chronic course may also occur. (See the section, “Chronic Active Epstein-Barr Virus Infections.”)

The signs and symptoms of IM are summarized in Table 62.1. The clinical course based on physical signs and symptoms is illustrated in Figures 62.7 and 62.8. In most young adults, the symptoms are fairly abrupt in onset, although close questioning frequently elicits vague complaints of lassitude and ill-being for several days before the onset of more pronounced symptoms. Most of the early symptoms are nonspecific. Myalgias do occur, but they are usually mild and are often confined to the neck and upper back. Excessive fatigue and general malaise may be accompanied by fever, sweating, and chills. Severe rigors rarely occur, and the patterns of fever are generally moderate and nonspecific. The fever is of no characteristic type. It may be transient and slight in degree, but in as many as one third of patients, it reaches a peak of 40°C. A secondary rise in temperature may occur after an initial drop to normal and may accompany the onset of glandular swelling or sore throat.
Anorexia is a common early symptom. Its intensity and duration are often linked to the severity of sore throat and dysphagia. The anorexia often persists for several weeks. Nausea is equally common and may be one of the earliest symptoms of IM, but vomiting is rare. Sore throat and dysphagia are among the most important manifestations of IM and may be the only symptoms in some patients. These symptoms usually develop gradually and subside in 1 to 2 weeks. For most patients, the symptoms of pharyngitis are mild, but occasionally, even taking sips of water may be painful.

Lymph node enlargement is invariably present at some time.\textsuperscript{123, 124, 125} Adenopathy usually appears during the first week of illness and slowly resolves thereafter. Anterior and posterior cervical node enlargement is almost always present, and palpable axillary and inguinal nodes are common. Radiographically detectable hilar adenopathy is rare (<1%).\textsuperscript{126} Although splenomegaly is expected, the spleen is palpable in only one half to three fourths of all patients, and massive splenomegaly is rare.\textsuperscript{127} Hepatomegaly is detected in 15% to 25% of patients and is usually accompanied by percussion tenderness over the liver and discomfort on palpation. The course of hepatomegaly closely follows that of adenopathy and splenomegaly.\textsuperscript{127} Pharyngeal inflammation usually appears in the first week and then subsides rapidly. In approximately 25% of patients, pharyngitis first occurs after the initial week of illness, and there are no pathognomonic features. It varies in intensity, but rarely, massive tonsillar and pharyngeal edema may cause virtually complete pharyngeal obstruction.\textsuperscript{125} Severe cough is relatively rare, although mild cough is common.

Headaches occur early, as well as photophobia, and ocular muscle pain can occur. Ocular manifestations occur in approximately one third of patients and include eyelid edema, conjunctivitis, dry eyes, keratitis, uveitis, choroiditis, retinitis, papillitis, and ophthalmoplegia. Rashes are also common with primary EBV infection and may be the only symptom in young children. Several observers have noted that patients experiencing IM are peculiarly prone to rashes when treated with ampicillin, which appear to be the result of vasculitis caused by circulating ampicillin-antibody complexes.

Laboratory Findings

Hematologic abnormalities in IM are observed in virtually all patients. The hematologic changes persist for a minimum of 2 weeks and usually persist for 1 to 2 months. One of the classic features of IM is the atypical lymphocytosis. The pleomorphism of the mononuclear cells found in the blood is usually striking. In addition to normal lymphocytes and monocytes, large mononuclear cells, or atypical lymphocytes, are observed in the blood (Fig. 62.9). Although nonspecific because they may be found in the blood of patients with a variety of conditions, including other viral infections, they are a prominent feature of IM. The abnormal cells vary greatly in size and shape. They possess a nucleus that may be oval, kidney-shaped, or slightly lobulated and cytoplasm that most often is nongranular and vacuolated or foamy. The nuclear chromatin forms a coarse network of strands and masses and is not clearly differentiated from the parachromatin. The identity of these cells has been shown to be CD8+ T lymphocytes, as discussed previously (see the section, “Immune Response to Epstein-Barr Virus Infection”). The rapid proliferation of these activated T cells is responsible for the large numbers of atypical cells seen in the peripheral blood, whereas the proliferating B cells are primarily responsible for the generalized lymphadenopathy, hepatosplenomegaly, tonsillar and adenoidal changes, and the cellular infiltration seen in many parenchymal organs; this is discussed in detail in the section, “Infectious Mononucleosis: Histologic Findings.”

Most patients with IM have slightly or moderately increased total white blood cell counts in the range of 10.0 to 20.0 × 10^9 cells/L, with approximately 15% of patients reaching levels in excess of 20.0 × 10^9/L. The absolute lymphocyte count most often exceeds 5.0 × 10^9 cells/L; with atypical lymphocytes usually >20%. Lymphocytosis begins toward the end of the first week of illness and reaches a peak corresponding to symptoms, as does the total leukocyte count (Fig. 62.10). Leukopenia has also been observed and can be manifested as lymphopenia or granulocytopenia. Most patients with IM have normal hemoglobin levels, and severe thrombocytopenia is rare, although mild depressions of platelet counts may be found in perhaps one half of patients. Severe neutropenia and thrombocytopenia may be very ominous signs, as they are frequently seen in the hemophagocytic reactions (VAHS or EBV-HLH).
Nonhematologic abnormalities are also commonly observed in patients with IM. Many patients show mild to moderate abnormal liver function tests.\textsuperscript{136} The reported incidence varies from 40% to 100%, depending on the severity of the disease, the time of testing, and the diligence with which the changes were sought. Reported enzyme changes include elevations of lactate dehydrogenase, alkaline phosphatase, glutamic pyruvate transaminase, phosphohexose isomerase, and aldolase, in roughly that order of frequency. Perhaps one third of patients have mild to moderate elevations of serum bilirubin values; levels above 8 mg/dl (135 \( \mu \)mol/L) are exceedingly rare but have been reported.\textsuperscript{136, 138} Occasionally, proteinuria or hematuria is present, but renal function is usually unimpaired. When the patient is jaundiced, bile and increased concentrations of urobilinogen may be found. When lumbar puncture has been performed to evaluate patients with severe headaches, the cerebrospinal fluid (CSF) pressure may be elevated, and pleocytosis and increased levels of protein are often noted. The sugar content is normal. In a few patients, heterophil antibodies have even been demonstrated in the CSF.\textsuperscript{139}

\end{figure}
Histologic Findings

The main pathologic feature of IM is a notable proliferative response within the reticuloendothelial system, especially by the lymph nodes and the spleen. It can be difficult to distinguish between malignant lymphoma and nonmalignant disease associated with EBV infection, especially in the immunodeficient patient population. In summary, the histologic diagnosis of IM is one of suspicion rather than certainty. The lymph node architecture is generally intact but may be distorted. Other morphologic features mimicking lymphoma include extensive immunoblastic proliferation in sheets and nodules and significant cellular atypia. Clonality studies are often necessary to differentiate IM from malignant disease. The germinal centers are usually identifiable, but follicular prominence is diminished, probably because of the irregular and vaguely defined borders that result from the lymphocytic and reticuloendothelial hyperplasia of paracortical structures and, to a lesser extent, the medullary cords. This intense proliferative activity within the paracortical areas is in keeping with the characterization of atypical lymphocytes as T cells. In addition, focal proliferations of macrophages are noted, as is, most characteristically, the presence of “typical” IM cells throughout the pulp, on the edges of germinal centers, and in the sinuses. RS-like cells are often observed in association with areas of necrosis. Because the presence of EBV has been demonstrated in approximately 50% of HL specimens, the identification of the virus or EBV-determined antigens is not particularly helpful in the differential diagnosis of these two disorders. The spleen is striking for infiltration of its fibromuscular structures by mononuclear cells. Both the capsule and trabeculae are often thin and invaded by proliferating lymphocytes. This may explain the occurrence of splenic rupture in this disease. In vitro hybridization studies can be used to track the distribution pattern of cells carrying the viral genome. Most labeled cells are found in the hyperplastic T-cell zones, the paracortical or interfollicular areas; smaller numbers are found within the epithelioid venules, the lymph node sinuses, and, occasionally, the germinal centers and the mantle zone. In the spleen, labeled cells are found mainly within pulp cords. Most of the labeled cells are small lymphocytes, but occasional labeled blasts, dendritic cells, and macrophages can be identified.
The bone marrow may be cellular with generalized hyperplasia of erythroid, myeloid, and megakaryocytic elements. With special techniques, sarcoidlike granulomas may also be demonstrated. In most instances, however, routine marrow aspiration reveals no abnormalities of note.

Diagnosis

The diagnosis of IM rests primarily on documentation of a primary EBV infection. Because EBV cannot be cultured, the humoral response to EBV infection, which has been discussed in the section, “Immune Response to Epstein-Barr Virus Infection,” is the usual method to discern infection. In summary, a recent, primary EBV infection is characterized serologically by (a) a positive heterophil antibody titer; (b) high titers of anti-VCA antibodies, both IgM and IgG; (c) high titers of anti-EA antibodies; and (d) the absence of anti-EBNA-1 antibodies (Fig. 62.5) Convalescent sera demonstrate the disappearance of IgM anti-VCA antibodies and the appearance of anti-EBNA-1 antibodies. At present, the diagnosis of IM is made by the presence of anti-IgM to EBV VCA. Rapid test systems using recombinant EBV antigens and enzymelinked immunosorbent or other assay technologies have been developed for use in clinical laboratories, but false-positive tests, especially for anti-EBV IgM antibodies, can occur.

Because so many antibodies have been linked to the development of IM, elevation of Ig levels in association with this disease is not surprising. Although this change is especially true for IgM, lesser elevations have also been seen in IgG and IgA. A general increase in titers of IgG antibodies and production of IgM antibodies against heterophile antigens and other infectious agents is common during the primary EBV infection, and must be taken into account when performing a diagnostic workup. Antibodies with recognized antigenic specificities make up only a small proportion of the total γ-globulins of the serum, and the antigenic specificity of most of the increased γ-globulins remains undefined.

A serologic diagnostic test for IM has been available since Paul et al. discovered that the sera of patients with IM contain agglutinins against sheep red cells. They called the antibody heterophile because it reacted with a heterologous antigen that obviously had not elicited its production. Historically, the heterophil antibody test was felt to be a sine qua non in the diagnosis of IM in adults. Investigators soon learned that the antibody reacted not only with sheep red cells, but also with beef and horse erythrocytes. The heterophil antibody is an IgM globulin, which, in some studies, was shown to have A light chains only. The Paul Bunnel (PB) antigen with which the heterophil antibody interacts is thermostable, in contrast to the Forssman antigen. Its immunologically reactive sites appear to be carbohydrate in nature. The carbohydrate nature of the antigen probably explains the observation that the antibody response is almost exclusively IgM. PB antigens are found also on cells other than heterologous erythrocytes. Of particular interest is the demonstration of PB-like antigens on murine T lymphocytes, Thy-1-positive murine lymphoma cells, and murine neutrophil granulocytes. In addition, PB antigens have been demonstrated in various tissues of IM patients during the early stages of the disease, in cultures of some lymphoid cell lines, in fresh BL tissues, and in the spleens of some patients experiencing lymphoma or leukemia. The formation of PB antibodies by cultures of lymphocytes from IM patients also has been demonstrated.

Heterophil antibodies in titers of up to 1:28 are present in most normal persons and, occasionally, in titers of 1:56. A study of more than 3,000 IM patients showed the following age distribution of PB antibodies: 5 to 9 years of age, 4%; 10 to 14 years of age, 8%; 15 to 24 years of age, 80%; 25 to 29 years of age, 3%; and older than 30 years of age, 5%. For these reasons, the test for heterophil antibodies has been called “presumptive,” but in the presence of clinical and hematologic findings suggestive of IM and a titer of 1:256 or higher, the diagnosis of IM is likely. In patients with IM, positive heterophil reactions almost always appear during the first 2 weeks of the illness (Fig. 62.5). Highest titers usually are found during the second and third weeks. As a rule, positive reactions last 4 to 8 weeks, but they have been observed to persist for as short as 7 to 9 days or as long as 18 weeks. The titer bears no relation to the severity of the disease or to the leukocyte changes. Although elevated heterophil antibody titers are quite common in EBV infection, occasionally patients with other disorders produce elevated levels.

Molecular diagnostic techniques are useful for the demonstration of EBV in tissues and body fluids. In situ hybridization techniques and the polymerase chain reaction (PCR) are most commonly used. The use of quantitative EBV PCR has been evaluated for diagnostic and prognostic value in EBV-related diseases. The detection of EBV DNA in peripheral blood or serum by PCR provides good evidence that the patient has been infected by EBV. However, interpretation of quantitative EBV DNA PCR or “viral load” results can be problematic, especially in the immunodeficient patient. Immunocompromised patients tend to have higher amounts of EBV DNA than normal healthy individuals with latent EBV infections. Also, different laboratories use different methods of detection, different specimens (blood vs. serum vs. mononuclear cells), and different measurements (copies per micrograms DNA vs. cells vs. ml of serum/blood). It appears that the amount of EBV DNA detectable in the blood of a patient with EBV-related disease may be useful in

3060
monitoring response to therapy in some diseases, but its value for diagnosis or prognosis still remains to be determined. The best method to diagnose EBV as an etiologic agent is tissue biopsy and in situ hybridization.

Differential Diagnosis

The diagnosis of IM usually is not difficult. In most instances, a young adult complains of malaise, fatigue, anorexia, and a sore throat and is found to have fever, adenopathy, pharyngitis, and splenomegaly. Appropriate changes in EBV titers will confirm the diagnosis. Much has been written about complications that can be devastating or even fatal, but serious complications in IM are rare, occurring in <1% of all diagnosed patients. Therefore, signs of significant respiratory, cardiovascular, intestinal, urinary, or joint disease make considerations of other diagnoses mandatory.

The fever and general malaise can be seen in many infectious diseases including salmonella infections, listeriosis, brucellosis, subacute bacterial endocarditis, the lymphadenopathic form of toxoplasmosis, and malaria. Generalized lymph node enlargement, including the postauricular and occipital nodes, is also characteristic of rubella. The pharyngitis of IM must be differentiated from acute streptococcal pharyngitis, diphtheria, and acute viral pharyngitis of other types. β-Hemolytic streptococci are isolated relatively often from patients with classic IM. Thus, a positive throat culture for streptococci does not make a search for an EBV infection unnecessary. In addition, a palatine exanthem may be present in patients with rubella, and atypical lymphocytes have been described in this condition. Drug fever and serum sicknesslike reactions may also suggest IM, because they often are characterized by fever, jaundice, lymph node enlargement, and atypical lymphocytes. Lymphocytosis, absolute or relative, may be encountered in association with diseases other than IM. These disorders include tuberculosis, tularemia, pertussis, dengue, mumps, chickenpox, German measles, typhoid fever, infectious hepatitis, serum sickness, and various other allergic states. In association with some of these conditions, abnormal lymphocytes resembling those of IM have been observed, as mentioned previously. Leukocytosis due to small lymphocytes of normal appearance and not associated with splenomegaly, lymphadenopathy, or a positive heterophil titer is suggestive of some other acute infectious process.

The hematologist may be called on to differentiate IM from other more serious hematologic diseases, such as acute leukemia or lymphoma. Although many leukocytes of patients with IM appear abnormal, few contain nucleoli, and thrombocytopenia and anemia are rare in these patients. EBV serologies confirming primary infection can be very helpful. Bone marrow examination is rarely necessary to differentiate IM from acute leukemia. Nodal biopsy can be difficult at times to differentiate IM from a malignant process. (See the section, “Histologic Findings.”) Patients who have had IM do not have a higher incidence of leukemia, but a few cases of concurrent IM and leukemia have been reported.

A number of self-limiting diseases are associated with a peripheral blood picture that satisfies all of the morphologic criteria established for the diagnosis of IM; failure to recognize these illnesses can result in unnecessary lymph node or liver biopsies, bone marrow aspiration, or other irrelevant diagnostic tests. The most common causes include cytomegalovirus (CMV), rubella, hepatitis and adenoviruses, Toxoplasma gondii, trichinosis, HIV, and HHV6, as well as a number of bacterial infections, with CMV being the most common.

When CMV-mononucleosis occurs, the illness can clinically be identical to IM with similar laboratory findings. The diagnosis is confirmed by demonstrating the presence of IgM antibodies to CMV in virtually all cases. A few patients have been reported to present with evidence of simultaneous CMV and EBV infection.

Complications

Unusual clinical patterns and serious complications are probably seen in no more than 1% of all patients. Misconceptions about a higher incidence stem from the fact that most of the medical literature concerning IM deals with complications and from impressions of subspecialists who usually do not see patients with uncomplicated disease. The most frequently reported complications are listed in Tables 62.2 and 62.3.

Pancreatitis<sup>253, 254</sup>
Renal failure<sup>255</sup>

Hematologic complications are the most common. The incidence of hemolytic anemia may be as high as 3%. Hemolysis usually is mild; in approximately 70% of the patients with hemolytic anemia, the reaction to the antiglobulin test (or Coombs test) is positive, and in approximately the same number, the titers of cold agglutinins are increased, usually with anti-i specificity. Occasionally, hemolysis has been attributed to Donath-Landsteiner cold hemolysins. In summary, anti-i antibodies are extremely common, but hemolytic anemia is rare. Sometimes, however, no antibody of any kind is detectable. IM has been associated with accelerated hemolysis in patients with underlying hereditary spherocytosis, elliptocytosis, or thalassemia, and in one patient, the onset of paroxysmal nocturnal hemoglobinuria coincided with the development of IM.

Hematologic cytopenias are common. Although mild depression of the platelet count (100 to 140 10<sup>9</sup>/L) may be found in perhaps one half of patients with IM, thrombocytopenic purpura is a rare complication that is seen primarily in younger children. Thrombocytopenia occurring in acute IM has been attributed to increased destruction by an enlarged spleen or the production of platelet autoantibodies. Immune thrombocytopenia preceding the development of severe aplastic anemia has been reported. Mild granulocytopenia is a common finding in patients with IM, but severe granulocytopenia is rare. When marrow examination has been performed, myeloid hyperplasia has been noted.
with increased numbers of promyelocytes, but with depletion of more mature neutrophilic cells.\footnote{234, 235} This picture is compatible with a proliferative response to an earlier marrow injury or peripheral destruction or increased use of granulocytes. Serious suppression of the entire marrow is rare.\footnote{237, 238, 239} Fatal aplastic anemia has been noted after what appeared to be typical IM\footnote{239, 238}, but is more often related to hemophagocytic reactions (VAHS or EBV-HLH).\footnote{239}

One of the most common reported complications is splenic rupture, which has led to death in several cases\footnote{190, 191}, but has been reported to occur with an incidence of 0.1% to 0.2% in North America. Of the 107 cases reported in the world literature up to 1978, only 18 were considered “spontaneous” by one reviewer.\footnote{192} The diagnosis of a ruptured spleen should be entertained whenever a patient with IM has severe or even moderate pain below the left costal margin, especially if the pain is accompanied by radiation to the left shoulder and supraclavicular area, or has evidence of impending peripheral vascular collapse. Other signs include those characteristic of peritoneal irritation, abdominal tenderness, and shifting dullness if massive intra-abdominal bleeding has occurred. Frank rupture may be preceded by one or more episodes of subcapsular hemorrhage or minor capsular tears, which may be difficult to differentiate from rupture. Because potentially fatal bleeding may occur at any time, it is recommended that surgical intervention be pursued whenever the typical pain pattern is accompanied by signs of hemodynamic instability.\footnote{190, 191} Delayed surgical intervention often is attributable to the misconception that abdominal pain is a common feature of the uncomplicated disease. Preservation of splenic function by surgical repair of the capsular tear (splenorrhaphy) or partial splenectomy has been recommended by some but is not generally recommended, as the altered splenic architecture in IM makes it unlikely that such interventions will be successful.\footnote{190, 191}

Complications of almost all organ systems have been described in association with IM\footnote{240} and are listed in Table 62.3. Neurologic manifestaions are infrequent in IM and may occur in 1% to 2% of patients.\footnote{193, 194, 241} When serious neurologic complications occur, the mortality rate may be as high as 8% to 11%,\footnote{242} and, in addition, the incidence of serious residual damage may be as high as 12%.\footnote{242} Cardiac complications are rare, although electrocardiographic abnormalities may occur in approximately 10% of patients,\footnote{129, 243} and fatal myocarditis has been reported in association with IM.\footnote{243} The most serious respiratory complication is acute airway obstruction, which usually is the result of extreme hyperplasia of the tonsils and other pharyngeal lymphatic tissue.\footnote{244, 245} Pleural effusion and pulmonary parenchymal changes are exceedingly rare,\footnote{246, 247, 248, 249} but occasional cases are characterized by extensive interstitial infiltrates (lymphoid interstitial pneumonitis), and severe respiratory insufficiency has been reported.\footnote{247} Evidence for some degree of hepatic involvement is found in most patients but is usually mild; the necrosis and inflammatory exudate seen in association with infectious hepatitis are encountered only rarely.\footnote{239, 250, 251, 252} Liver failure is rare\footnote{239, 250} but can be a prominent feature in fatal cases of IM [fulminant infectious mononucleosis (FIM) or EBV-HLH]\footnote{250}, including those associated with subtle forms of immune deficiency.\footnote{250} Acute pancreatitis has been associated with IM.\footnote{251, 254} An association between IM and irreversible renal failure was postulated in one patient.\footnote{255}

Treatment

Most patients experiencing uncomplicated acute IM require only symptomatic therapy. Bed rest is recommended for patients with fever, malaise, and myalgias. Strenuous exercises, especially contact sports, should be avoided for at least 1 month or until resolution of splenomegaly. Nonsteroidal anti-inflammatory drugs, such as acetaminophen or ibuprofen, should be used to control pain, although in patients with severe hepatitis, these agents should be used judiciously. It has been suggested that aspirin may prolong convalescence.\footnote{256} Aspirin also interferes with platelet function, potentially increasing the risk of bleeding in thrombocytopenic patients, and Reye syndrome has been reported in association with IM, albeit rarely.\footnote{208} Antibiotics are of no value in uncomplicated IM, but many patients show culture or serologic evidence of a recent streptococcal infection,\footnote{121} and these should be treated with appropriate antibiotics. Ampicillin and amoxicillin should be avoided because they often cause a severe rash.\footnote{123, 130, 132}

Corticosteroids have been used in cases of life-threatening complications such as airway obstruction, carditis, lymphoid interstitial pneumonitis, pleural effusions, or cerebral edema. Their efficacy is largely anecdotal and is presumably due to their anti-inflammatory and lympholytic properties. The cumulative results of several small, controlled clinical trials suggest that corticosteroids hasten the resolution of fever and tonsillopharyngeal symptoms but do not provide significant benefits in the therapy of lymphadenopathy or hepatosplenomegaly.\footnote{15, 257, 258, 259, 260} Therefore, caution should be exercised when using corticosteroids.\footnote{260} There are reports of encephalitis or myocarditis in association with steroid use in
IM, and secondary bacterial and fungal infections can occur. However, in the face of severe complications, the use of steroids may well be indicated and necessary.

Several antiviral agents such as acyclovir, ganciclovir, zidovudine, foscarnet, and the interferons (IFNs) have been shown to inhibit the replication of EBV in vitro. Only the linear form of the genome, not the latent circular form, is susceptible to inhibition. The efficacy of acyclovir in the therapy of uncomplicated IM has been assessed in several controlled trials. In general, acyclovir reduces viral shedding during the time of therapy, but viral shedding resumed when therapy was discontinued. Clinical trials have documented few clinical benefits as measured by duration of illness and sore throat, weight loss, or absence from school or work, even when acyclovir was given in combination with steroids. IFN-α has been used in a few patients experiencing persistent EBV infection with severe complications of interstitial pneumonitis, encephalitis, or genital ulcers, apparently with some success. Patients with IM-associated immune thrombocytopenia have responded to therapy with large doses of intravenously administered γ-globulin. A viral protein vaccine has been developed that protects marmosets from developing LPD but not from infection. Several groups are working on the development of EBV vaccines. Although these vaccines can induce a neutralizing antibody response they do not protect against primary infection or reduce the risk of developing clinical disease, i.e., IM.

Prognosis

Complete recovery occurs within 2 months in the majority of patients. Recurrences of IM are so rare that one must question whether the initial diagnosis or the diagnosis of recurrence is accurate. It is estimated that IM is fatal in as many as 1 in 3,000 cases, or approximately 50 cases annually in the United States. In reviewing the world literature on IM, catalogued 87 fatalities attributed to the disease or its complications. Only 20 of these reports, however, contained adequate evidence for an unequivocal diagnosis. Of these 20 cases, 9 fatalities were related to be due to neurologic complications, 4 were related to respiratory failure from peripheral neuropathy of the Guillain-Barré type, and 5 were related to central respiratory paralysis; 3 were related to splenic rupture; and 3 were related to secondary infection. Other fatal complications included hepatic failure (two cases) and myocarditis (one case). In two cases, the cause of death was unrelated to IM. The majority of deaths associated with IM occur in patients who develop VAHS or EBV-HLH.

A recent study has demonstrated that the severity and duration of the illness does not correlate with either control of viremia or rapidity of the antiviral humoral or cellular responses. Therefore, in the nearly 100 years since the first description of IM and the etiologic agent (i.e., Epstein-Barr virus) countless reports of describing the spectrum of potential complications have been published. But despite enormous numbers of studies to define the pathogenesis, it remains a mystery how and why EBV causes the symptoms of IM, and a therapy that reproducibly improves symptoms remains elusive.

P.1334

OTHER EPSTEIN-BARR VIRUS-RELATED DISEASES

Recently, methods for detecting infectious agents in human disease have become highly developed. Consequently, many ubiquitous infectious agents have been etiologically linked to certain human diseases (e.g., EBV infection has been associated with a wide spectrum of human diseases). Classically, EBV is associated with the development of human malignancies such as BL and NPC. EBV infection has also been associated with other human malignancies, such as NHL (B-cell, T-cell, and NK-cell phenotype), HL, gastric carcinoma, leiomyosarcoma, hepatocellular carcinoma, breast cancer, and LPDs associated with immunodeficiency. In addition, EBV infection has been associated with several nonmalignant, but potentially life-threatening human diseases, such as VAHS or EBV-HLH, and CAEBV, in which development of malignant lymphoma can occur. Also, some have linked EBV infection to chronic illnesses, such as chronic fatigue syndrome and most recently multiple sclerosis. Although association has been demonstrated, it remains controversial whether EBV is causative in these disorders (Table 62.4). The following discussion focuses on diagnosis of and evidence for the role of EBV in the pathogenesis of these diseases.

Chronic Active Epstein-Barr Virus Infection

EBV rarely causes recurrent or persistent symptomatic infections in apparently immunocompetent hosts. Diagnostic criteria for CAEBV have been proposed and consist of (a) evidence of severe, progressive EBV illness beginning as a primary EBV infection and lasting more than 6 months with anti-EBV titers of IgG anti-VCA 1:5120, anti-EA 1:640, or anti-EBNA<1:2, or all three; (b) histologic evidence of major organ involvement; and (c) increased amounts of EBV in peripheral
blood or affected tissues, or both. CAEBV is characterized by persistent or recurrent IM-like symptoms, such as recurrent fever, lymphadenopathy, and hepatosplenomegaly, and unusual anti-EBV antibody patterns.\textsuperscript{274} CAEBV occurs most commonly in patients who develop IM as older children or young adults.\textsuperscript{274, 275, 276} This entity may be more prevalent in Asia, as most of the published literature is from Japan. A cohort of 30 patients in Japan diagnosed with CAEBV presented with the following clinical manifestations: Fever (100%), liver dysfunction (90%), splenomegaly (90%), lymphadenopathy (50%), thrombocytopenia (50%), anemia (50%), hypersensitivity to mosquito bites (43%), calcification in the basal ganglia (18%), and oral ulcer (18%).\textsuperscript{275} CAEBV can be lethal, with 30 to 50% mortality within 5 years of diagnosis.\textsuperscript{28} Life-threatening complications include the hemophagocytic syndrome (21%), coronary artery aneurysm (21%), hepatic failure (18%), malignant lymphoma (16%), and interstitial pneumonia (12%).\textsuperscript{276} The majority of deaths are due to hemophagocytic syndromes or hematologic malignancies, which may be of T-cell, B-cell, or NK-cell phenotype.\textsuperscript{28, 274, 276}

CAEBV, chronic active Epstein-Barr virus infection; EBV, Epstein-Barr virus; HLH, hemophagocytic lymphohistiocytosis; NK, natural killer.

It is believed that cellular immunologic abnormalities are responsible for the development of CAEBV. In the peripheral blood of patients with CAEBV, high levels of EBV DNA have been found in CD4\textsuperscript{+} T cells and NK cells, but not in B cells.\textsuperscript{277} The significance of this finding in the pathogenesis of CAEBV and the mechanism of infection of these cells remain to be elucidated. This entity may overlap with severe or fulminant IM (FIM or EBV-HLH).\textsuperscript{68, 274, 277} Further studies are needed to differentiate between these enigmatic disorders and to determine the role of EBV infection in their pathogenesis.

A standard treatment approach to CAEBV has not been established. Most reports are anecdotal but include antiviral agents (acyclovir, ganciclovir, and vidarabine) and/or immunomodulating agents (IFN-\textalpha{} or IL-2).\textsuperscript{274, 275, 276, 277, 278, 279} Because immunochemotherapy (e.g., etoposide, corticosteroids, and cyclosporin A) has been effective in treating the EBV-hemophagocytic syndrome,\textsuperscript{280, 281} it has been used to control symptoms and treat hemophagocytic complications.\textsuperscript{274} Hematologic malignancies have been treated with standard NHL therapy,\textsuperscript{276} but curative therapy for the severely affected patient appears to require the replacement of the patient’s immune system with a normally functioning immune system to control the EBV infection, for instance, by an allogeneic stem cell or marrow transplant\textsuperscript{275, 282} or by allogeneic adoptive T-cell therapy.\textsuperscript{283}

CAEBV infections should be differentiated from the so-called chronic mononucleosis, or chronic fatigue syndrome. Due to the similar symptoms and reports of elevated anti-VCA and anti-EA titers, EBV has been suggested to be the etiologic agent in the chronic fatigue syndrome.\textsuperscript{284} In controlled studies, no specific EBV serologies have been found that differentiate chronic fatigue syndrome patients from controls.\textsuperscript{285} In a randomized, placebo-controlled trial of acyclovir, clinical improvement was seen as frequently with the placebo.\textsuperscript{286} Chronic fatigue syndrome has been associated with other infections (viral and bacterial) and, therefore, should not be considered a disease caused by EBV.\textsuperscript{285, 287}

CAEBV, chronic active Epstein-Barr virus infection; EBV, Epstein-Barr virus; HLH, hemophagocytic lymphohistiocytosis; NK, natural killer.

The self-limited course of IM contrasts with the atypical responses that can occur in FIM, also called VAHS or EBV-associated HLH.\textsuperscript{68} Death occurs in approximately 1 in 3,000 IM cases, or approximately 50 cases annually in the United States.\textsuperscript{68, 272} The median age at presentation of FIM/EBV-HLH is similar to that of uncomplicated IM (i.e., 13 years of age). Whereas FIM/EBV-HLH is the most common manifestation in males affected with X-linked lymphoproliferative disease
(XLP), it often occurs outside the context of XLP.\textsuperscript{68, 69, 272, 278, 289, 290} Outside the context of XLP, the male-tofemale ratio is approximately 1:1.\textsuperscript{272} VAHS has been associated with CMV, herpes simplex virus, and adenovirus, but EBV is the most common.\textsuperscript{68, 280} Clinically, FIM/EBV-HLH is indistinguishable from other types of VAHS, familial HLH, and the accelerated phase of Chédiak-Higashi disease or X-linked inhibitor of apoptosis (XIAP) or sometimes referred to as XLP2.\textsuperscript{68, 69, 280, 291} Because FIM/EBV-HLH is rare, a search for a heritable immune deficiency in family members is mandatory.

Patients who progress to FIM/EBV-HLH initially present with the usual signs and symptoms of IM, but these symptoms usually rapidly progress in severity.\textsuperscript{272} The EBV antibody responses vary considerably from completely lacking to unusually high; therefore, it may be difficult to differentiate FIM/EBV-HLH from other hemophagocytic syndromes, CAEBV, acute leukemia, other malignancies, or even overwhelming sepsis.\textsuperscript{68, 272} The course and progression of the disease are variable, ranging from multiorgan failure developing over hours to persistent or recurring symptoms of IM lasting for months. An atypical lymphocytosis usually is present at early stages of the disease, but patients subsequently develop severe persistent pancytopenia and/or hepatic dysfunction resulting in fulminant hepatitis and varying degrees of multiorgan failure.\textsuperscript{68, 292} The development of hepatic dysfunction, often with coagulation abnormalities secondary to liver failure or disseminated intravascular coagulation, and pancytopenia are ominous signs, as are other signs of hemophagocytic syndromes, such as hypofibrinogenemia and elevated triglyceride levels.\textsuperscript{68, 69, 280, 289, 292}

As discussed previously, EBV is a potent stimulus to the immune system, resulting in a massive EBV-specific and -nonspecific response of both the humoral and cellular immune systems (Fig. 62.4). In FIM/EBV-HLH, the EBV-nonspecific response, primarily the cellular immune response, is uncontrolled. FIM/EBV-HLH is characterized by extensive infiltration of parenchymal organs by lymphoid cells, primarily CD8$^+$ cells in varying degrees of transformation and histiocytes with surprisingly few B cells.\textsuperscript{69, 292} The cells infected by EBV in FIM/EBV-HLH are usually T cells\textsuperscript{68, 277, 292} and are generally CD8$^+$, as opposed to the CD4$^+$ or NK cells observed in CAEBV.\textsuperscript{277, 292}

If this aggressive immune reaction proceeds unabated, all organs ultimately sustain extensive and irreparable damage.\textsuperscript{68, 69, 288, 290, 292} Early in the course of the disease, the bone marrow may be hypercellular with few infiltrating histiocytes; erythrophagocytosis is seen best in smears of marrow aspirates. The marrow later becomes hypocellular with varying numbers of infiltrating histiocytes.\textsuperscript{288, 290} Lymph nodes initially show an intense lymphoblastic proliferative response, again primarily T cells, but later, lymphoid depletion supervenes.\textsuperscript{69, 288, 290} Liver biopsies reveal active portal infiltration with lymphocytes and histiocytes, with occasional erythrophagocytosis in liver sinusoids.\textsuperscript{290} In the spleen, extensive necrosis of white pulp develops. Perivascular mononuclear cell infiltrates of the brain, mononuclear cell myocarditis, and interstitial nephritis also are observed.\textsuperscript{69, 272, 288, 289, 290, 293, 294} The thymus shows thymocyte depletion and necrosis of thymic epithelia.\textsuperscript{295} Increased serum levels of IL-2, IFN-γ, L-6, TNF-α, and soluble IL-2 receptors have been demonstrated.\textsuperscript{68} The T cells that are activated in response to EBV are believed to be stimulated to produce proinflammatory cytokines (e.g., IL-2, IFN-γ, etc.), and it is believed this activates macrophages, which produce more proinflammatory cytokines, such as IL-6 and TNF-α, culminating in the phagocytosis, tissue destruction, and cellular depletion seen in FIM/EBV-HLH; death usually follows shortly thereafter due to multisystem organ failure.\textsuperscript{68}

Once FIM/EBV-HLH develops, therapy is difficult and often unsuccessful, with a median survival time of approximately 4 weeks.\textsuperscript{290} Antiviral drugs, Ig supplementation, IL-2, IFN-α, IFN-γ, plasmapheresis, corticosteroids, and most cytotoxic drugs have been ineffective.\textsuperscript{68, 76} The only therapy that has demonstrated consistent success in the treatment of FIM/EBV-HLH is with the early use of etoposide, which reduces the activity of stimulated macrophages in vitro.\textsuperscript{281, 296} The best results appear to be obtained with a combination of etoposide and concomitant immunosuppression with corticosteroids and cyclosporin A or tacrolimus (FK506).\textsuperscript{281, 297} Others have reported using rituximab (anti-CD20 monoclonal antibody) in combination with chemotherapy and immunotherapy.\textsuperscript{298} The rationale for this approach is that the reduction of EBV (+) B cells decreases immunogenic stimulus for the abnormal T-cell response. Therapy may have to be continued for 6 to 12 months. These patients are profoundly immunocompromised from their disease and the therapy. Therefore, a successful outcome is dependent on control of FIM/EBV-HLH symptoms as well as the prevention and successful treatment of life-threatening infectious complications. Even with remission of symptoms, recurrences are common and carry a poor prognosis. Curative therapy usually involves replacement of the patient's immune system with a normal immune system by allogeneic stem cell or marrow transplantation.\textsuperscript{289, 299, 300} With the advent of therapy with etoposide and immunomodulation therapy to "quiet" the disease and early intervention with allogeneic stem cell transplantation, the outcome has gone from <5% 1-year survival to approximately 50% 3- to 5-year survival.\textsuperscript{300}
Epstein-Barr Virus-Associated Disorders in Immunodeficiency

In the mid-1970s, Purtilo et al. described XLP, in which affected males were thought to have a specific immunodeficiency to EBV, resulting in FIM, malignant lymphoma, hypogammaglobulinemia or agammaglobulinemia, or aplastic anemia. Later, it was noted that patients with ataxia telangiectasia had high antibody titer responses against EBV-replicating antigens, and EBV genome positive malignant lymphomas were observed. Similar antibody patterns and EBV-associated B-cell LPD (EBV-LPD) were also reported in patients with Wiskott-Aldrich syndrome. With more efficacious immunosuppression, EBV-LPD was also observed more frequently in recipients of organ and marrow transplants, whereas stopping or decreasing the dose of immunosuppressants sometimes resulted in the regression of EBV-LPD, suggesting that a deficiency of immunosurveillance is responsible for the development of EBV-LPD in such patients. In the late 1980s, an increased incidence of EBV-LPD, including BL, was reported in association with a growing number of patients with AIDS. In recent years, advances in the treatment of patients with immune disorders have resulted in longer survival, and the number of patients at risk of EBV-associated diseases has increased.

In LPD of immunodeficiency, EBV has been identified predominantly in the B-cell phenotypes, but EBV (+) T-cell LPD and HL can also be observed. However, not all LPD of immunodeficiency is EBV-associated. Even in XLP, where affected boys have a very aberrant immune response to EBV infection, many of the NHLs have been found to be EBV-negative. Primary Immunodeficiencies

As mentioned previously, the main immune defense against EBV-driven B-cell proliferation are EBV-CTL. Patients with primary immunodeficiencies often lack T-cell functions, which may manifest as insufficient EBV-CTL activity.

Immunodeficiencies primarily affecting B cells or neutrophil function are not at increased risk of EBV-associated disease unless treated with T-cell immunosuppression. There are numerous reports of the occurrence of EBV-LPD in patients with a primary immunodeficiency disease (e.g., ataxia telangiectasia, Wiskott-Aldrich syndrome, Chédiak-Higashi syndrome, severe combined immunodeficiency, and common variable immunodeficiency). Type III EBV latency is predominantly seen in these lymphomas, suggesting a lack of appropriate EBV-CTL immunosurveillance (see the section, “Immune Response to Epstein-Barr Virus Infection”). In addition, relapses are common but may not represent failure to eradicate the original clone, instead indicating a new clonal proliferation. These data underscore the role of immunosurveillance in the pathogenesis of these malignancies.

The treatment is often difficult because of the underlying serious immunodeficiency and/or genetic susceptibility to chemotherapeutic agents. Antiviral therapy has had little effect in the treatment of EBV-LPD associated with immunodeficiency. Although complete remissions can be achieved with chemotherapy, immunodeficient patients with NHL have a far inferior outcome compared to those expected for immunocompetent children with NHL receiving similar therapy. These poor results are due to increased toxicity of chemotherapy, especially in defects of DNA repair such as ataxia telangiectasia patients, but infection-related deaths are also greatly increased compared to immunocompetent patients. Because recurrences can be of different clonal origin, successful treatment depends on controlling B-cell proliferation by developing appropriate EBV-CTL immunity. In the majority of cases, the only way to achieve this is allogeneic bone marrow transplantation (BMT).

X-Linked Lymphoproliferative Disease

In 1974, there were two reports of maternally related boys dying of IM. In 1975, Purtilo et al. described a kindred in which 6 of 18 boys died of an LPD associated with EBV infection. XLP has also been called Duncan disease, after the original kindred, or Purtilo disease. XLP is a rare disorder, affecting an estimated 1 out of a million male individuals. Initially, three phenotypes were described in XLP patients, and these continue to characterize the majority of patients: FIM (or EBV-HLH), malignant lymphoma (LPD), and dysgammaglobulinemia. Less commonly reported manifestations include disorders such as vasculitis, pulmonary lymphomatoid granulomatosis, and hematologic cytopenias, including aplastic anemia and pure red cell aplasia. The “disease state” is capricious, as it may feature a single phenotype or two or more phenotypes, which may develop sequentially in susceptible individuals.

Reflecting on the ubiquitous nature of EBV infection, FIM is the most common XLP phenotype, affecting approximately 50% of patients. FIM is decidedly the most lethal of the XLP phenotypes; historically, most of the boys died within 1 month and historically only 7% of FIM patients survived. Treatment should be the same as for FIM or EBV-HLH as discussed previously. The median age of onset for XLP-associated FIM is 5 years of age, but the condition has occurred up to 40 years of age. The pathology and clinical findings of FIM associated with XLP are identical to those seen in patients.
with EBV-­‐HLH but without XLP, and have been discussed previously. It is interesting that over a third of XLP patients with evidence of current or prior EBV infection never develop FIM.\textsuperscript{308}

Dysgammaglobulinemia is the second most common XLP phenotype, affecting approximately one fourth of boys.\textsuperscript{289, 308} Most boys manifest this phenotype demonstrate global decreases of serum Ig levels. However, some have featured increased levels of IgM or IgA, or both, as well as variable deficiencies in IgG1 and IgG3 subclasses.\textsuperscript{318} Although hypogammaglobulinemia often occurs after EBV infection, some XLP patients develop hypogammaglobulinemia without prior evidence of EBV infection.\textsuperscript{308} Mice with the XLP gene “knockout” can manifest progressive hypogammaglobulinemia and abnormalities in Ig switching.\textsuperscript{319} The pathogenesis of dysgammaglobulinemia in XLP has not been delineated, but appears to be due to a defect in T-­‐cell help and affects B-­‐cell memory.

An LPD develops in approximately one fourth of XLP patients.\textsuperscript{289, 308} Most lymphomas are of B-­‐cell phenotype and are characterized by Burkitt or diffuse large-­‐cell histology.\textsuperscript{69, 320} Karyotypic analysis has not been extensively performed; however, the t(8;14) associated with classic BL is rare.\textsuperscript{321, 322} Approximately 10% of LPD are not of B-­‐cell phenotype, including a small number of patients with HL or T-­‐cell LPD.\textsuperscript{309} As in other immunodeficiencies, the role of EBV in the LPD of XLP is unclear, inasmuch as approximately one half of the boys with LPD have had no evidence of prior EBV infection, and EBV is detectable in only 25% of tumor specimens.\textsuperscript{308}

Distinct from the marrow depletion seen with FIM, a limited number (4%) of boys have developed isolated hematologic cytopenias.\textsuperscript{289, 308} Most manifest with suppression of two or more hematologic cell lines, although aplastic anemia and pure red cell aplasia have been observed.

Initially, it was thought that males affected with XLP only manifested symptoms after primary EBV infection. Although IM is, by definition, caused by EBV, other XLP phenotypes develop in EBV-­‐seronegative patients.\textsuperscript{308} About 10% of affected boys will manifest symptoms of XLP before exposure to EBV.\textsuperscript{289, 308} There is no difference in the age of onset of clinical symptoms between males who have or have not been previously exposed to EBV.\textsuperscript{308} Therefore, prevention of EBV infection in boys with XLP does not avert clinical manifestations. In addition, whereas approximately 60% of the boys develop FIM after primary infection with EBV, others develop LPD, dysgammaglobulinemia, and hematologic cytopenias, and a few have no symptoms at all.\textsuperscript{308} These data suggest that the genetic defect in XLP is more global and not EBV-­‐specific as once thought. There must be other genetic and/or environmental factors that influence the host susceptibility to EBV and are important in determining the clinical phenotype of XLP.

Now, the diagnosis can be made easily by identifying a mutated SH2D1A gene\textsuperscript{308, 323, 324, 325} or lack of the corresponding SLAM-­‐associated protein (SAP) protein expression.\textsuperscript{326} Female carriers on average express SAP on only 50% of their lymphocytes, due to random X-­‐chromosome inactivation,\textsuperscript{327} but do not develop overt clinical manifestations of XLP. Molecular analysis should be pursued in females at risk to provide accurate genetic counseling.

Spontaneous mutations in SH2D1A in affected males where mothers do not have mutations have been reported.\textsuperscript{328} One might predict that mutations that delete the XLP gene or truncate the protein would be more likely to be associated with a severe phenotype, whereas missense mutations would occur preferentially in mildly affected patients. Attempts to correlate mutations of the SH2D1A gene and the clinical manifestations of XLP found that it was not uncommon to observe different phenotypes and severities with identical mutations, even within the same family.\textsuperscript{308} No significant differences were observed in the phenotypes or severity of disease based on the type (missense, nonsense, truncating) or localization of SH2D1A mutations. The age of onset of clinical manifestations of XLP varied considerably, from younger than 1 to 40 years of age, as did survival, but there was no correlation with the type of mutation. Therefore, genetic analysis does not predict the phenotype or severity of disease.\textsuperscript{308}

The SH2D1A gene codes for a protein of 128 amino acid residues that consists of an SH2 domain and a 25-­‐amino acid C-­‐terminal tail.\textsuperscript{323, 324} SH2D1A is expressed throughout thymocyte development, as well as in CD4+ and CD8+ peripheral T cells, NK and NKT cells, but not on B cells.\textsuperscript{291, 325} SAP appears to function in the regulation of immune response by interacting with several proteins, including SLAM (signaling lymphocyte activating protein; CD150), also called SAP.\textsuperscript{324} SAP also has been demonstrated to interact with members of the CD2 superfamily of molecules, including CD2, CD48, CD58, CD84, Ly-­‐9, and 2B4, and with a new family of RasGAP adapter proteins such as p62Dok (Dok [downstream of kinases]-­‐1), p56Dok (Dok-­‐2), and Dok-­‐3.\textsuperscript{329, 330, 331, 332} The immunologic effects of SAP interactions with these proteins are under investigation but appear to be very important in NKT cell development and terminal B-­‐cell differentiation.\textsuperscript{291}

Mice genetically deficient in Sh2d1α (the murine homolog) expression have been generated.\textsuperscript{333} Consistent with human XLP, mutant animals are viable and fertile, transmit the gene defect in an X-­‐linked Mendelian fashion, and display no significant defects in the number and phenotype of developing thymocytes or circulating T, B, or NK cells. After infection with lymphocytic
choriomeningitis virus, Sh2d1α-deficient mice recapitulate important aspects of the human disease. For example, these mice exhibit abnormal lymphocyte responses to a virus resulting in a large CD8+ cytotoxic T-cell response that is fatal to the mice. As mentioned previously, these mice also have defects in humoral responses and develop hypogammaglobulinemia over time. XLP is highly lethal, with historically 75% of patients dying by 10 years of age, although the oldest known survivor with XLP is over 50 years of age and has not required allogeneic transplantation. Antiviral therapies, including acyclovir, ganciclovir, intravenous Ig, and IFN-α, have been used to treat primary EBV infection; none has been particularly effective. The only therapy that has been consistently beneficial for males with FIM is etoposide and immunosuppression, as discussed previously. Several affected males have been treated successfully with anti-CD20 (rituximab) following primary infection with EBV but before they develop all the clinical signs and symptoms of FIM or EBV-HLH. With FIM or EBV-HLH, even with remissions, relapses are invariable. Therefore, an allogeneic BMT is recommended once the patient’s condition is stabilized and a suitable donor has been identified. As with EBV-HLH not associated with XLP, the outcome has improved from a <10% 1-year survival to perhaps half of the boys with FIM surviving with the early initiation of etoposide, immunosuppression, and allogeneic stem cell transplantation. Patients with hypogammaglobulinemia require regular Ig supplementation to prevent bacterial and viral infections. However, Ig infusions do not offer the guarantee of protection from primary EBV infection in an EBV-seronegative patient. For patients with lymphoma or hematologic cytopenias, standard therapeutic protocols suffice. Although treatment can induce disease remissions, relapses and other XLP phenotypes invariably occur, and allogeneic BMT is recommended. With definitive diagnosis by genetic mutational analysis, BMT now can be performed before the appearance of clinical manifestations of the disease, and is recommended to prevent the life-threatening complications of the disease.

In 2006, another X-linked disorder that was characterized by EBV-HLH was described to be caused by deficiency in the BIRC4 gene. Of note, BIRC4 resides in close proximity to the SH2D1A gene. Further studies demonstrated that these patients have defects in their antiapoptotic functions and the disorder has been named deficiency of the XIAP. Because XIAP patients frequently have problems with EBV-HLH, XIAP has also been called XLP2. However, unlike SAP which is limited to T, NK and NKT cells, XIAP is widely expressed on human tissue. As the name suggests, the XIAP function is to inhibit apoptosis; therefore deficiency leads to increased sensitivity to apoptosis and hypogammaglobulinemia is observed in XIAP patients. The immune mechanism for susceptibility to complications of EBV infection, including EBV-HLH is unclear, but XIAP patients do not have an increased incidence of lymphoma. Therefore, it is best to differentiate XLP and XIAP as distinct clinical entities.

Secondary Immunodeficiencies

It is well recognized that patients infected with HIV, as well as transplant recipients, are at increased risk of developing LPD that are often associated with EBV. Rarely, elderly patients, malnourished patients, and those with cancer develop EBV-associated atypical lymphoproliferation. Indeed, the World Health Organization (WHO) now recognizes a EBV-positive diffuse large B-cell lymphoma as a distinct entity. EBV-induced LPD have been reported in patients without severe immunodeficiency (e.g., individuals who received methotrexate as treatment for rheumatoid arthritis). Therefore, a high index of suspicion is warranted in any patient who may be immunosuppressed.

Human Immunodeficiency Virus/Acquired Immunodeficiency Syndrome

EBV has been found in several diseases associated with HIV infection, including oral hairy leukoplakia, leiomyosarcoma, and NHL. Oral hairy leukoplakia is characterized by white raised plaques on the lateral surfaces of the tongue. EBV has been found in the lesions of oral hairy leukoplakia in HIV patients, and these lesions have been reported to respond well to therapy with acyclovir. The EBV-associated leiomyomas and leiomyosarcomas account for 3% to 15% of all cancers in HIV-infected children. For reasons that are not clear, leiomyomas and leiomyosarcomas do not appear to be increased in HIV-infected adults. Tumors can be found in the lung, brain, adrenal glands, and spleen. How EBV gains access to smooth muscle cells and its pathogenic role in tumorigenesis remains unclear. The clinical course is highly variable, but aggressive treatment with highly active antiretroviral therapy (HAART) and primary excision of tumors, if feasible, are recommended in all patients, but chemotherapy and/or radiation are often required.

The clinical spectrum of HIV-related NHL typically includes systemic NHL, primary central nervous system (CNS) NHL, and pleural effusion lymphoma (PEL). Although EBV is detected in essentially all the primary CNS NHL and most PEL, only
approximately 50% to 60% of systemic HIV-related NHL have detectable EBV.\textsuperscript{351} PEL is not typically associated with solid masses and is associated with HHV8, but most also have EBV present in tumor cells.\textsuperscript{350} The relative contribution of HHV8 and EBV in the pathogenesis of PEL is unclear. Following the introduction of HAART into clinical practice in the 1990s, there has been a dramatic effect on the incidence of AIDS-defining diseases. In the HAART era, there has been a decrease in primary CNS NHL and systemic diffuse large B-cell lymphoma; however, the incidence of BL has appeared to be unchanged.\textsuperscript{352} PEL etiologic agent. These late PTLD may be a different disease and appear more akin to LPD observed in other immunodeficient states (e.g., AIDS and primary immunodeficiencies), in which B-cell origin and EBV association are not universal.\textsuperscript{372}

Post-transplant Lymphoproliferative Disease

Figures 62.3 and 62.4 illustrate the importance of a qualitatively and quantitatively appropriate T-cell response in maintaining homeostasis and preventing EBV-driven B-cell proliferation. Therefore, with chronic immunosuppressive therapy following the transfer of EBV-infected B cells via blood, marrow, or organ grafts, complications due to EBV are frequently seen in transplant patients.

Post-transplant lymphoproliferative disease (PTLD) represents a spectrum of clinical and morphologic heterogeneous lymphoid proliferations.\textsuperscript{356} PEL, EBV LPD post-transplant may manifest as isolated hepatitis, lymphoid interstitial pneumonitis, or meningoencephalitis, or as an IM-like syndrome with peripheral adenopathy, fever, or hepatitis, or all three. Frequently, the definition of PTLD is limited to lymphomatous lesions (localized or diffuse) that are often extranodal (often in the allograft). Although less frequent, the most fulminant presentation of PTLD is a disseminated systemic disease that clinically resembles septic shock and histologically resembles FIM.

Histologically, EBV disease is quite heterogeneous as well. There have been several histologic classifications for PTLD over the years,\textsuperscript{356} 357 358 360 but the WHO has now proposed a classification, which includes (a) early lesions not considered PTLD and that are polymorphic hyperplasia, without disruption of the normal tissue architecture and often accompanied by more classic clinical signs and symptoms of IM; (b) polymorphic PTLD, where T-cell infiltration and disruption of normal tissue architecture are observed; and (c) monomorphic PTLD, which resembles

P.1338

intermediate- to high-grade NHL and tissue necrosis is more frequent.\textsuperscript{338} Distinguishing between a polyclonal and a monoclonal PTLD can be difficult as up to 50% of PTLDs do not express surface Ig.\textsuperscript{69} Cytogenetic abnormalities are rare in PTLD, even with Burkitt histology, and abnormalities in genes observed in NHL (i.e., c-myc; N-, H-, and K-ras; p53; and bcl-2, etc.) are rare in PTLD.\textsuperscript{338} 358 361

The diagnosis of PTLD should be made by biopsy and evaluated by in situ hybridization with EBER probes or immunohistochemical staining for LMP-1, although LMP-1 staining is not as sensitive as EBER staining.\textsuperscript{362} PTLD must be distinguished from the increased background number of EBV-positive cells in lymphoid tissue in the post-transplant patient, where up to 10 EBV-positive cells per high powered field (hpf) can be observed without PTLD compared to the nontransplant patient where up to 1 cell/hpf is normal.\textsuperscript{363} Perhaps the greatest difficulty in making the diagnosis of PTLD occurs in the proliferations that do not produce a mass lesion but have disseminated or infiltrative disease in solid organs. The diagnosis can sometimes be suspected upon examination of the peripheral blood, bone marrow, CSF, or other body fluids for the presence of plasmacytoid cells or large B cells. This type of PTLD is often first discovered at autopsy, with pre-mortem diagnosis being sepsis or graft-versus-host disease (GVHD).\textsuperscript{364} 365

The majority of PTLD is CD20+,\textsuperscript{70} 369 but not all PTLD is of B-cell phenotype and not all are EBV positive. T-cell PTLD tends to occur late, often more than 10 years after transplantation.\textsuperscript{366} PTLD with HL phenotype can also occur but tends to occur later (i.e., >4 years post-transplant) and is generally EBV positive.\textsuperscript{367} The validity of the Hodgkin phenotype of PTLD has been questioned and it has been suggested that it may be a variant of polymorphic B-cell PTLD.\textsuperscript{368} The diagnosis of HL in the posttransplant patient should be reserved for disease where the RS cells are CD45(-) and/or CD15 (+).\textsuperscript{368} The reason for the long latency in non-B-cell PTLD is unknown, but probably reflects a lesser role for EBV and/or deficient immunosurveillance in the pathogenesis.

More than 90% of early (<1 year post-transplant) PTLD is EBV positive, when EBV-CTL immunity is lowest,\textsuperscript{365} 369 370 whereas late (>2 years post-transplant) PTLD are frequently EBV negative, can be of T-cell origin, and may have a poorer prognosis.\textsuperscript{366} 371 372 373 374 The etiology of EBV-negative PTLD is not known, and no other virus has been identified as an etiologic agent. These late PTLD may be a different disease and appear more akin to LPD observed in other immunodeficient states (e.g., AIDS and primary immunodeficiencies), in which B-cell origin and EBV association are not universal.\textsuperscript{372}
The risk factors for PTLD are well described and in general include anything that favors B-cell proliferation and/or suppresses T-cell activity. The reported incidence of PTLD ranges from 1% to 5% in low-risk procedures (e.g., renal, heart, liver, and non-T-cell-depleted bone marrow transplants) to >10% in the high-risk procedures (e.g., lung, small bowel, and T-cell-depleted bone marrow transplants). In children receiving a solid organ transplant, the effect of the type of allograft appears to be much less. This is likely due to the fact that age and EBV-seronegativity at the time of transplant are very strong risk factors.

Successful treatment of PTLD necessitates controlling the B-cell proliferation and facilitating the development of an appropriate memory cytotoxic T-cell (EBV-CTL) response to maintain an asymptomatic state of viral latency (Figs. 62.3 and 62.4). Additional factors that contribute to the difficulty of treating these patients include increased toxicity from therapy, secondary infections, and the increased risk of organ rejection or GVHD due to the enhancement of alloreactive T-cell immunity. Surgery, radiotherapy, or both are effective in curing localized disease, but this benefits only a small percentage of patients. The use of antiviral agents such as acyclovir or ganciclovir and/or intravenous Ig may reduce viral replication and thereby limit the number of infected B cells and may be useful in prophylaxis or preemptive therapy.

The efficacy of antiviral drugs in treating PTLD is controversial because they are seldom used without other interventions (e.g., reduction of immunosuppression); in addition, if viral replication, which is lytic to the infected B cells, is suppressed, B-cell proliferation could theoretically be enhanced.

The approach most widely used as initial therapy for PTLD is reduction of immunosuppression. In some cases, this is sufficient for controlling the disease, especially in localized polymorphic cases or cases that present like IM. As opposed to PTLD after solid organ transplantation, reduction of immune suppression is rarely successful following BMT, because the major immunosuppression after BMT is from delayed EBV-CTL recovery, not suppression of EBV-CTL function. Patients who do not tolerate reduction of immunosuppression because of graft rejection or GVHD, or who do not respond to immunosuppression reduction, require more aggressive therapy and have a much poorer prognosis.

Anti-B-cell monoclonal antibodies have been used successfully, including anti-CD21 and anti-CD23 and, more recently, anti-CD20. Chemotherapy has also been used successfully for PTLD. Chemotherapy is attractive because it kills proliferating B cells and is immunosuppressive enough to treat or prevent GVHD or organ rejection. However, at conventional doses used in the treatment of NHL, post-transplant patients have more end-organ toxicity and susceptibility to infection, with as many as 35% of patients dying of toxicity caused by the therapy. A low-dose chemotherapy approach has been shown to be at least as effective in treating PTLD in children following organ transplant with little toxicity.

Because the problem in most cases of PTLD is an inadequate number of EBV-CTL, replacement of EBV-CTL is a logical therapeutic intervention. Infusion of donor lymphocytes has been demonstrated to be successful in the treatment of PTLD post-BMT. To avoid the GVHD and other associated toxicities with infusion of donor lymphocytes, ex vivo-generated EBV-specific CTL have been shown to be effective in treating and preventing PTLD post-BMT. The ex vivo generation of EBV-specific CTL takes several weeks and requires a high level of technology and cost. Therefore, due to the cost and regulatory oversight necessary to generate and administer the in vitro-generated EBV-CTL, this approach is not feasible for most centers. The use of adoptive T-cell therapy in an organ transplant recipient is more complex. First, cadaver organs are most widely used; therefore, donor lymphocytes are often not available. Second, as opposed to BMT, after organ transplant, the PTLD cells are usually of recipient origin, so the immunologic recognition, specificity, and efficacy of donor lymphocytes are uncertain. Third, the use of closely matched relatives' lymphocytes runs the risk of both rejection and GVHD. It has been shown that in organ transplant patients EBV-specific CTL can be given safely, and when given prophylactically no PTLD developed. However, despite detection of an increased number of EBV-specific CTL, EBV DNA levels in the peripheral blood decreased very little and the infused cells persisted only 2 to 6 months. EBV-specific CTL have been used to treat PTLD successfully following organ transplant, but again multiple infusions were required as the adoptively transferred EBV-specific CTL did not last. Although a logical and exciting therapeutic strategy, at present adoptive cellular therapy is not available for the majority of patients with PTLD.

Epstein-Barr Virus-Associated Malignancies

Burkitt Lymphoma

The neoplastic cells in BL have a mature germinal center B-cell phenotype as demonstrated by the expression of B-cell-associated antigens (CD19, 20, and 21) and the presence of surface Ig.
compared with 20% of sporadic BL occurring mainly in Europe and North America. Regardless of EBV status, BL is characterized by specific chromosomal translocations that involve chromosomes 8 and 14 (t[8;14]) in 70% of cases, or 8 and 22 (t[8;22]) and 8 and 2 (t[8;2]) in the remaining cases. As a result, the MYC oncogene becomes juxtaposed to one of the Ig gene loci (i.e., chromosome 14 [heavy chain], chromosome 22 [\(\lambda\)-light chain], or chromosome 2 [\(k\)-light chain]) and is constitutively expressed.

The role of EBV in the pathogenesis of BL remains to be fully defined. It has been hypothesized that chronic B-cell stimulation by EBV, HIV, and/or malaria plays a key role by enhancing the chances of a MYC translocation. The very restricted EBV viral gene expression of type I latency EBV gene expression (i.e., EBNA-1 and the EBERs only) seen in EBV-positive BL makes it difficult to explain the role of EBV in transformation of BL. In vitro systems have demonstrated that latency III viral gene expression is incompatible with high c-myc expression and maintenance of BL cells, and that EBV gene expression, although not promoting cellular proliferation, inhibits apoptosis in MYC-expressing BL cells.

**Nasopharyngeal Carcinoma**

NPC is another important EBV-associated malignant disorder. This tumor is mainly observed in Southeast Asia, Southern China, and a few other limited regions of the world. In these areas, NPC is one of the most frequent malignancies observed. A genetic predisposition appears to be a major factor in the development of this epithelial malignancy. The first generation of southern Chinese immigrants to the United States has an incidence of NPC that is approximately one half that of native Chinese, suggesting that both genetic and environmental factors contribute to the development of NPC.

The evidence linking EBV to NPC is more compelling than with BL, with essentially all cases being EBV positive. The etiologic link between NPC and EBV was first suggested by serologic evidence, especially with anti-IgA antibodies directed against EA, present in high titers in NPC patients as compared with matched controls, IM patients, and BL patients. In fact, prospective screening for these IgA antibodies or quantitative PCR of EBV DNA in the serum has been useful in detecting preclinical NPC and in anticipating recurrences after therapy.

Despite the universal association of EBV with NPC, the role EBV plays in the pathogenesis is unclear. The finding of monoclonal EBV found in precancerous lesions of NPC is noteworthy, as it suggests EBV infection takes place early in the pathogenesis and is essential in the development of NPC. However, all attempts to transform nasopharyngeal epithelium with EBV in vitro have failed. As stated before, NPC tumor cells demonstrate type II viral latency gene expression (i.e., EBERs, EBNA-1, LMP-1 and LMP-2, and BARF1). It is hypothesized that because LMP-1 and BARF1 have effects on expression of cellular genes associated with proliferation, they are important in the pathogenesis of NPC.

Other studies have identified genetic defects with presumed inactivation of tumor suppressor genes on chromosomes 3p, 9p, and 14q. For some time, environmental factors such as exposure to toxins contained in traditional Chinese medicines, including Euphorbia plant extracts, which induce EBV replication, and the ingestion of nitrosamines or other oncogenic substances in salted fish, have also been felt to play an important role in the development of NPC.

**Hodgkin Lymphoma**

A pathologic link between EBV and HL has been suspected for some time on the basis of serologic studies that demonstrated unusually high titers of antibodies to VCA and EA, as well as the observation that individuals with high antibody titers to EBV have an increased risk of developing HL. The presence of EBV has been demonstrated conclusively within the RS cells and their mononuclear variants in 40% to 50% of HL specimens. The virus appears to be monoclonal in any given individual, suggesting that infection occurred before the clonal expansion of RS cells. EBV positivity is most frequent in mixed cellularity histology, followed by nodular sclerosing, whereas lymphocyte-predominant and lymphocyte-depleted types are usually negative. Again, as in NPC, the viral gene expression is latency type II.

What role EBV plays in HL also remains undetermined. A large epidemiologic study demonstrated that individuals who developed signs and symptoms of IM following primary infection had a 1 in a 1,000 chance of developing HL. This risk is small, but it was found to be statistically significant compared to the general population and to individuals who did not develop IM following primary infection. In addition, the increased risk was only for developing EBV-positive HL. It has recently been shown that in individuals who develop IM following primary EBV, a persistent deficit in their T cells to respond to IL-15 in vitro is prevalent, although this deficit was not found in individuals who did not develop IM following primary EBV infection. LMP expression in RS cells occurs at very high levels, which usually are immunogenic. It is hypothesized that individuals with IM have a lessened ability in immunosurveillance for EBV-induced lymphoproliferation, and this explains the increased incidence of EBV-positive HL in IM patients. Inasmuch as only 1 in 1,000 individuals with IM ever develops HL, there must be other co-factors important in the pathogenesis.
T-cell Lymphoma

EBV genome-positive T-cell lymphoma was first described unexpectedly in three patients who had extraordinarily high IgG antibody titers to EBV-VCA and EBV-EA.417 After this report, EBV genome-positive peripheral T-cell lymphoma had been increasingly reported mainly in Asian populations.526 Type II latency is predominantly shown in these malignancies.73 The mechanism of EBV infection into human T cells still remains to be elucidated. CD21 expression has been reported on some T-cell lines418,419; however, in vitro experiments have failed to demonstrate continuous presence of EBV in such T-cell lines. Variable clinical manifestations are observed in patients with T-cell lymphoma. This may be in part due to cytokine production and cytotoxic functions that can be observed in these tumor cells. It is interesting that this type of lymphoma is often associated with severe CAEBV.424,426 These malignancies are highly resistant to the standard therapies and the outcome is very poor despite aggressive therapy including transplantation.

Natural Killer-Cell Lymphoma/Leukemia

Patients with EBV genome-positive, CD3- NK-cell proliferations were initially reported by Japanese investigators.420 Type II latency is predominant in these malignancies as well.23 NK-cell lymphoma/leukemia has often been associated with mosquito bite sensitivity421 and CAEBV (see discussion in the section, “Chronic Active Epstein-Barr Virus Infection”). Midline granuloma, which is predominantly of T-/NK-cell origin, was first reported in Asia,422 but now cases in North America and Europe have been shown to be EBV genome positive, with monoclonal viral episomes detected in virtually all tumor cells. In general, these malignancies have the same poor prognosis as EBV-positive T-cell malignancies.

Gastric Carcinoma

Gastric carcinoma is a leading cause of death due to cancer in Japan. Shibata and Weiss initially reported the presence of the EBV genome by in situ hybridization.29 The incidence of the EBV genome in gastric carcinoma is 2% to 16% worldwide.29,423,424,425 The viral gene expression pattern is unique. All EBV-positive gastric carcinomas express EBERs, EBNA-1, and BARF1 (BART) consistent with type I latency. However, some tumors express LMP-2A and/or lytic genes such as BZLF1 (ZEBRA protein).426

Miscellaneous Epstein-Barr Virus-Associated Human Disease

There are anecdotal reports of numerous human diseases that have been associated with EBV or that EBV DNA has been detected in pathologic tissues. The association of EBV to leiomyoma/leiomyosarcomas in immunodeficient children is strong, but the role in their pathogenesis is far from being understood.32,33 Reports of EBV being detected in other malignancies include hepatocellular carcinoma,40 lymphoepithelial carcinomas of the salivary glands, tonsillar carcinoma, parotid gland carcinoma, and thymoma (reviewed in Ref. 76). EBV has been found in breast carcinoma,31 but epidemiology studies have failed to demonstrate an association.327 One of the more intriguing associations is with multiple sclerosis (MS). There have been several epidemiology studies attempting to determine whether there is a link between the development of IM followed by MS. Published results are conflicting, but a recent meta-analysis suggested that an association does exist.428 Because EBV is so ubiquitous in the human population, associations of disease with EBV must be interpreted with caution.

INTRODUCTION

The primary immunodeficiency disease (PIDD) are a group of clinical syndromes originally described in patients with marked susceptibility to particular types of infections. This group of disorders has now expanded to include more than 150 clinically defined entities that span the full spectrum of immune dysfunction ranging from virtually absent immune responses to overwhelming uncontrolled autoimmunity. In this “genomic era” we have come to understand that the majority of immunodeficiency disorders are caused by defects in single genes. There are now approximately 200 known single gene defects associated with immune deficiency. It has also become evident that mutations in different genes can lead to a similar clinical phenotype. For example, defects in more than 20 different genes have now been associated with a clinical phenotype of severe combined immune deficiency (SCID). This has led to an explosion in our understanding of the role of specific molecular pathways in the human immune system but has created some confusion when discussing the clinical syndromes themselves. Consequently, it has become the practice to refer to disorders by their molecular defect, either in combination with, or in lieu of, their clinical name or eponym (i.e., “ADA-deficiency” or “ADA-SCID” rather than “SCID”). This practice is followed here.

MAJOR COMPARTMENTS OF THE IMMUNE SYSTEM

To provide a framework for this overview of immunodeficiency, it is worthwhile to divide the immune system into four major compartments: complement, phagocytes, B cells and antibodies, and T cells. The complement and phagocyte compartments are part of the “innate” arm of the immune system, whereas the B-cell and T-cell compartments are components of the “adaptive” arm of the immune system (see Table 63.1). Many immunodeficiency disorders are caused by a defect in only one compartment of the immune system, whereas others are “combined” immunodeficiencies with defects in multiple compartments. In general, defects in each compartment of the immune system are associated with susceptibilities to particular types of infections. In addition, each specific immunodeficiency typically has unique features that differentiate it from other immunodeficiencies, often making it possible to identify the disorders based on clinical and laboratory findings (see Table 63.1).

bacteria (S. pneumoniae, H. influenzae, etc.)

- Recurrent, invasive Neisserial infections
- Hereditary angioedema
- Autoimmunity (lupus, glomerulonephritis)
- Familial hemolytic uremic syndrome (HUS)

abscesses, boils, and lymphadenitis

- Infections with Catalase+ organisms (S. aureus, Serratia, Aspergillus, etc.)
- Poor wound healing
- Chronic gingivitis and periodontal disease
- Mucosal ulcerations, colitis
- Delayed separation of the umbilical cord/omphalitis

sinopulmonary infections

- Unexplained bronchiectasis
- Chronic or recurrent gastroenteritis (giardia, cryptosporidium, enterovirus, etc.)
- Echovirus encephalomyelitis

- Recurrent, severe, or unusual viral infections (CMV, EBV, adenovirus, papillomavirus, etc.)
- Invasive fungal or mycobacterial infections
- GVHD (rash, abnormal LFTs, chronic diarrhea)
- Failure to thrive

COMPLEMENT

The complement system consists of a series of proteins that are present in the plasma and become activated upon encountering pathogens. Activation of early complement components initiates a cascade of protein cleavage and activation events that ultimately leads to formation of the membrane attack complex (MAC) consisting of complement proteins C5, 6, 7, 8, and 9. A number of regulatory proteins including Factor H, Factor I, and membrane cofactor protein (MCP) control complement activation at the level of C3, thereby preventing inappropriate complement fixation. The complement cascade is activated via three major mechanisms: (1) the classical pathway, which is initiated by antigen/antibody complexes; (2) the alternative pathway, which is initiated directly by bacterial cell wall components; and (3) the lectin pathway, which is initiated by carbohydrate moieties present on bacteria.

Complement deficiencies make up only a small portion (~2%) of all primary immune deficiencies. Defective activation of the entire complement cascade can be caused by the absence or dysfunction of only 1 of more than 20 complement proteins. The proteins most often affected are C2, C3, and C4.

Clinical Presentation

Patients with defects in the C1 esterase inhibitor have hereditary angioedema (HAE) in which allergic or mechanical stimuli can trigger massive, localized, severe attacks of edema that can be life-threatening if they involve the airway. Patients with deficiency of early complement components in the classical pathway (C1-C4) typically present with symptoms of autoimmunity (lupus or glomerulonephritis) or with recurrent invasive infections caused by encapsulated organisms (particularly Streptococcus pneumoniae). Patients with defects in the late complement components (C5-C9) that are involved in formation of the membrane attack complex typically present with recurrent or severe Neisserial infections. Patients with defects in complement regulatory proteins (Factor I, Factor H, and MCP) are at risk of developing familial hemolytic uremic syndrome and age-related macular degeneration (see Fig. 63.1).
FIGURE 63.1. The classical complement pathway showing activation by immune complexes and ultimate formation of the membrane attack complex. Factor I, Factor H, and MCP (membrane cofactor protein) control complement activation primarily at the level of C3. Boxes indicate the clinical syndromes or infections that result from defects of the indicated complement proteins.

Specific Disorders

C1 Esterase Inhibitor Deficiency

Deficiency of C1 esterase inhibitor is the cause of HAE. Unlike many of the other early complement component deficiencies, absence of C1 esterase inhibitor does not lead to an increased risk for infection. Instead, this protein regulates the activity of kallikrein, blocking its ability to act on Factor XII and kininogen. As a consequence, minor irritants cause unabated production of bradykinin and other mediators of vascular permeability, leading to rapid swelling of the soft tissues (angioedema), severe abdominal pain, and at times, acute obstruction of the airway. Effective treatments are now available for HAE including purified C1 esterase inhibitor, a kallikrein inhibitor, and a bradykinin B2 receptor antagonist.\(^8\), \(^9\), \(^10\) Because of the expense of these agents, they are often administered at the beginning of an attack to abort symptoms rather than being administered prophylactically to prevent the onset of an attack.

C2 Deficiency
C2 deficiency is the most common complement component deficiency associated with susceptibility to infections, occurring in approximately 1 of 20,000 people. As indicated above, patients with early complement cascade defects (C1-C4) are susceptible to invasive infections with encapsulated organisms, S. pneumoniae being a particularly fulminant pathogen in these patients. The infectious susceptibility is compounded by functional antibody deficiency in some patients. In addition, patients with C1, C2, or C4 deficiency are at high risk of developing autoimmunity (lupus or glomerulonephritis). In the case of homozygous C2 deficiency, approximately 50% of patients develop lupus or glomerulonephritis.11

Diagnosis

Screening for complement deficiency should be performed in patients with recurrent episodes of bacteremia, meningitis, or disseminated gonorrhea. Because more than 30% of patients with recurrent Neisseria infections have complement deficiency, it is imperative that prompt testing of the complement system be done in these individuals. The screening test of choice for complement deficiencies is the CH50 test, which measures functional complement activity in the plasma. The CH50 will only identify defects in the classical pathway, which is typically sufficient inasmuch as alternative pathway defects are exceedingly rare. If an alternative pathway defect is suspected, however, an analogous test (the AH50) can be performed. In order for the CH50 to give accurate results, the blood specimen needs to be handled carefully because complement is very heat labile. In general, it is recommended that any abnormal CH50 test should be repeated to confirm a complement deficiency. The CH50 is typically very low or absent in patients with a complement component deficiency. A CH50 result that is only moderately low is often seen in situations where the specimen was handled incorrectly or in patients with autoimmune disease such as lupus or mixed connective tissue disease. Once an abnormal CH50 test is confirmed, specialized testing to identify the specific complement component that is absent can be performed.

Treatment

Patients with complement deficiency are susceptible to fulminant sepsis and other deep-seated infections caused by encapsulated organisms. For this reason, patients should be given a letter or laminated card that they can keep with them at all times with contact information for their primary care physician and clinical immunologist, and a message indicating that they have a complement deficiency and there should be no delay in giving parenteral antibiotics should they be ill. For patients who live at a distance from skilled medical care, consideration should be given to providing a dose of parenteral antibiotic such ceftriaxone that can be administered by the patient or a family member when they become ill, prior to a lengthy trip to the hospital. The efficacy of chronic prophylactic antibiotics to prevent infection in patients with complement deficiency is not well studied and remains a significant question in this group of disorders. In addition to preparing for and treating infections, patients should also be regularly screened for autoimmunity by history, physical exam (i.e., blood pressure monitoring), and laboratory testing including BUN, creatinine, and urinalysis to monitor for signs of glomerulonephritis inasmuch as this is a common autoimmune manifestation.

PHAGOCYTES

One of the major roles of phagocytic cells (neutrophils and macrophages) is to continuously survey the body for signs of infection. Upon sensing an infection, they migrate from the circulation into the tissues toward the site of the infection where they begin to ingest both opsonized and nonopsonized pathogens and debris. The ingested material is processed and fragments of digested proteins are loaded into class II MHC molecules that are presented at the cell surface where they can be recognized by cells of the adaptive immune system. Phagocytes that ingest pathogens and debris can either remain at the site of infection or migrate back to local draining lymph nodes to present antigen. Phagocytic disorders can occur in one of three ways: (1) a lack of phagocytes (congenital neutropenia); (2) defective phagocyte migration (leukocyte adhesion deficiency [LAD] and WHIM syndrome); and (3) inability of phagocytes to process or degrade organisms that have been ingested (chronic granulomatous disease [CGD]).

Clinical Presentation

Because of the role that phagocytes play in controlling bacterial and fungal pathogens, patients with phagocytic defects often present with infections and abscesses of skin, deep tissues, and organs caused by bacteria and fungi. Symptoms can include boils and/or cellulitis with or without pus, lymphadenitis, pneumonia, delayed shedding of the umbilical cord, hepatic abscesses, gastrointestinal disorders, gingivitis, and unexplained fever, malaise, and fatigue. The onset of symptoms of phagocytic cell disorders is typically in infancy or early childhood.
Specific Disorders

Severe Congenital Neutropenia

The congenital neutropenias are described in more detail elsewhere (Chapter 57) so are covered only briefly here. Mutations in five different genes have now been associated with severe congenital neutropenia (SCN): ELANE, which is inherited in an autosomal dominant manner, causes increased myeloid cell apoptosis and can present either with SCN or with a cyclic neutropenia phenotype; GF11, which is also inherited in an autosomal dominant manner, causes defective myeloid cell differentiation; HAX1, which is inherited in an autosomal recessive manner, is associated with increased myeloid cell apoptosis, and is the cause of the classic “Kostmann” syndrome; G6PC3, which is inherited in an autosomal recessive manner, causes excessive myeloid cell apoptosis, and is associated with a variety of other congenital defects including cardiac, urogenital, endocrine, auditory, and facial anomalies; and WAS, in which specific activating mutations in the CDC42 binding domain are inherited in an X-linked recessive manner, leading to abnormal and dysregulated actin polymerization that causes defective neutrophil chemotaxis and increased apoptosis.12

In all cases, clinical management involves a heightened suspicion for infections and aggressive treatment if these arise. Treatment of acute infections may require antibiotics combined with G-CSF to increase neutrophil counts. Despite there being little evidence specifically in SCN supporting the use of prophylactic antibiotics, extrapolation from data in leukemic patients with neutropenia suggests a benefit so these are used in most patients. Prophylactic, long-term therapy with G-CSF is typically utilized only in those patients who have recurrent, severe bacterial infections in spite of antibiotic prophylaxis or in patients with fungal infections. Bone marrow transplantation is effective in SCN although there is little to no reported experience in those genetic disorders that are more rare such as G6PC3 deficiency.

Leukocyte Adhesion Deficiency

LAD is caused by the absence of functional adhesion receptors that are required for the migration of phagocytes from the circulation into the tissues. The characteristic clinical features of LAD include recurrent skin and soft tissue infections that often lead to development of deep ulcers despite there being highly elevated peripheral blood leukocyte counts. Interestingly, the inability of leukocytes to migrate to these sites of infection leads to an absence of pus in the lesions, which can be a useful diagnostic clue. Wound healing is also compromised and patients typically have marked gingivostomatitis. Three forms of LAD have been described: LAD-I, the most common form of LAD, is caused by mutations in the ITGB2 gene encoding the β2-integrin CD18. Mutations cause an absence of the CD11/CD18 integrin complex on the surface of leukocytes, which can be readily discerned by flow cytometry. LAD-II is caused by mutations in the SLC35C1 gene encoding the GDP-fucose transporter. These mutations cause defective expression of Sialyl Lewis X (sLeX), a fucose-containing ligand on neutrophils. sLeX is the ligand for E- and P-selectins, which are expressed on the surface of cytokine-activated endothelial cells and allow neutrophil rolling. As a result of the fucose defect, all patients with LAD-II also have the rare Bombay blood group, which is a useful diagnostic test for suspected LAD-II. LAD-III is caused by mutations in the FERM3 gene that encodes Kindlin-3, a coactivator that is required for activation and function of β1-, β2-, and β3-integrins. Absence of functional Kindlin-3 leads to dysfunction of CD18 and causes an LAD phenotype (see LAD-I above). In addition, patients with LAD-III also have a Glanzmann-type bleeding disorder resulting from dysfunctional integrin-mediated aggregation of platelets.13

Patients with LAD-I and LAD-III typically present in childhood and often have a severe course with early mortality, whereas patients with LAD-II often have milder cases and may live into adulthood. Treatment of LAD can be more complicated than some of the other phagocytic disorders because in addition to treating infections aggressively with antibiotics, active soft tissue infections may require recurrent donor white cell infusions of functional neutrophils in order to clear the infection. The primary defects of LAD are intrinsic to hematopoietic cells, thus bone marrow transplantation can be curative.14, 15, 16

WHIM Syndrome

WHIM syndrome (warts, hypogammaglobulinemia, recurrent bacterial infections, and myelokathexis [retention of neutrophils in the bone marrow]) is caused by autosomal dominant mutations in CXCR4, the receptor for the chemokine CXCL12 (SDF-1). Patients with WHIM typically present in childhood with recurrent bacterial otitis media, sinusitis, bronchitis, pneumonia, and cellulitis. The bacterial susceptibility is a result of the combination of hypogammaglobulinemia and neutropenia. In addition to bacterial infections, patients with WHIM have a particular susceptibility to papillomavirus infections, which can be severe and lead to early malignancy. The mechanisms that underlie the viral susceptibility are not entirely understood but are thought possibly to be intrinsic to the epithelial cells. In the hematopoietic system, CXCL12 causes homing of cells to the bone marrow and controls release of these cells from the marrow. Neutrophils and lymphocytes from patients

P.1345
with WHIM have an increased chemotactic response to CXCL12, suggesting that the neutropenia and lymphopenia observed in WHIM are the result of inappropriate cell retention in the marrow.\textsuperscript{17} Treatment with G-CSF or GM-CSF can normalize the neutrophil counts although these often cause significant bone pain at the doses required.\textsuperscript{18} Recent studies using the CXCR4 antagonist plerixafor in adults with WHIM syndrome have shown promise for improving neutrophil counts by mobilizing neutrophils from the bone marrow.\textsuperscript{19, 20} Antibiotics and immunoglobulin replacement can significantly reduce the risk of bacterial infections. There is very little reported experience regarding bone marrow transplantation for WHIM although anecdotal evidence suggests that it may correct the neutropenia and hypogammaglobulinemia but may not alter the papillomavirus susceptibility.\textsuperscript{21}

Chronic Granulomatous Disease

CGD is the most frequently diagnosed phagocytic cell immune defect. The most common form is X-linked, caused by mutations in the CYBB gene and accounting for approximately two thirds of all CGD patients. The remaining forms, caused by mutations in the CYBA, NCF1, NCF2, or NCF4 genes are all autosomal recessive. All mutations affect the formation or function of the NADPH oxidase complex, on neutrophil phagolysosomes. The NADPH oxidase is required to generate a burst of reactive oxygen species in response to phagocytosis of pathogens. Reactive oxygen species activate proteases in the phagolysosomes that destroy ingested bacteria. In CGD, the oxidative burst cannot be generated, leading to defective processing of ingested organisms and an inability to eliminate bacterial and fungal pathogens appropriately. Catalase-positive organisms including Staphylococcus species, Aspergillus species, Burkholderia cepacia, Serratia marcescens, and others are the most common pathogens. The most common types of infection at presentation are pneumonia, lymphadenitis, cellulitis, and hepatic abscesses (particularly with Aspergillus sp.). The most common cause of premature death is Aspergillus infection.\textsuperscript{22} In addition to the infectious susceptibilities of CGD, a substantial percentage of patients struggle with inflammatory complications that are common to this disorder including an inflammatory colitis that occurs in approximately 40%, hepatic dysfunction, gingivitis, and others.

Treatment of CGD revolves around aggressive management of acute infections followed by prophylaxis against future infections using a combination of daily antibiotic (typically trimethoprim-sulfamethoxazole), daily antifungal (typically itraconazole), and thrice-weekly Interferon-\gamma injections. This combination has dramatically improved outcomes in CGD; however, despite appropriate use of this regimen, some patients ultimately have increasing symptoms that lead to a decline in survival beginning in the late teens or early twenties. The prospects for long-term survival appear to be correlated with the amount of residual oxidative burst activity that can be generated by a particular patient's phagocytes.\textsuperscript{23} This has led to a renewed interest in bone marrow transplantation for CGD, which has been quite successful in the modern era, likely due to improved antimicrobials and transplant-conditioning regimens with reduced toxicity. Many now recommend that for patients who have mutations that severely affect oxidative burst activity, bone marrow transplant should be considered preemptively, early in life before patients develop comorbidities.\textsuperscript{24}

Diagnosis

Assessment of patients for a possible phagocytic disorder requires that both the number and the function of phagocytes be evaluated. Numbers are easily evaluated using a complete blood count with differential. If there is a concern for cyclic neutropenia, neutrophil counts may need to be evaluated 3 times weekly for 3 to 4 weeks to identify the nadir.\textsuperscript{25} Functional testing includes evaluation of CD11/CD18 integrin expression on myeloid cells by flow cytometry if the patient has symptoms suggestive of leukocyte adhesion deficiency. In cases of suspected CGD, evaluation of neutrophil oxidative burst function is essential. Traditionally this was done using nitroblue tetroxide (NBT) but is now performed using dihydrorhodamine (DHR), a reagent that permeates neutrophils and fluoresces when reduced by a normal neutrophil oxidative burst. Fluorescence is measured by flow cytometry. The DHR test is sensitive enough to differentiate most cases of X-linked CGD from autosomal recessive CGD, making it a particularly useful clinical assay.\textsuperscript{26, 27}

Treatment

As noted above, management of phagocytic disorders revolves around having a heightened suspicion for infections, aggressively treating acute infections using antibiotics and G-CSF as necessary, and developing a prophylaxis regimen that is both effective and reasonable from a patient standpoint. At times, patients continue to have recurrent or severe infections despite these efforts and require more definitive therapy. As indicated above, hematopoietic stem cell transplantation (HSCT) has been shown to be effective in many, but not all, phagocytic disorders. Gene therapy has been attempted for both X-linked CGD\textsuperscript{28} and for LAD-\textsuperscript{1}\textsuperscript{29} but neither has been particularly successful thus far and at this point is considered to be experimental. Ongoing research to address the challenges of gene therapy that are unique to these two disorders is underway.
The predominant role of B cells in the immune system is to make antibodies (immunoglobulins) in response to antigen challenge (pathogens, vaccines, etc.). The absence of functional antibodies causes susceptibility to bacterial and viral infections. Antibody deficiency can occur in one of three different ways: (1) hypogammaglobulinemia or low levels of one or more immunoglobulin classes (IgG, IgA, IgM, or IgE) occurring as a result of decreased antibody production, often associated with a specific single-gene defect; (2) hypogammaglobulinemia as a result of excessive antibody loss, typically through the kidneys as proteinuria or through the gut as protein-losing enteropathy; or (3) functional antibody deficiency, in which immunoglobulin levels are normal but the Ig lacks the quality required to bind and opsonize pathogens.

**Clinical Presentation**

Patients who lack sufficient levels of functional antibody present clinically with recurrent bacterial sinopulmonary infections (sinusitis, otitis media, bronchitis, and pneumonia). In addition, patients may develop bowel infections caused by microorganisms such as Giardia or Cryptosporidium that are often only modestly pathogenic to normal individuals. In addition to these symptoms, patients with certain antibody-deficiency disorders have characteristic clinical features that can provide clues to the specific diagnosis. These are covered below.

**Specific Disorders**

**X-Linked Agammaglobulinemia**

X-linked agammaglobulinemia (XLA) is caused by mutations in the Bruton's tyrosine kinase (BTK) gene. BTK is a member of the Tec family of cytoplasmic tyrosine kinases and is required for the maturation of B-cell precursors in the bone marrow. Mutations in BTK therefore cause an arrest of B-cell development at the pre-B-cell stage leading to virtual absence of circulating B cells in the peripheral blood. Mutations that only partially interfere with the enzymatic function of BTK have also been described and are associated with milder forms of the disease that only have defects in the generation of specific antibody responses.

XLA is typically suspected in male patients with recurrent bacterial sinopulmonary infections and <2% circulating CD19⁺ B cells. Other infections that occur relatively frequently in patients with XLA prior to the initiation of IgG replacement therapy include skin infections (furunculosis, pyoderma, and cellulitis) and sepsis. The diagnosis can be confirmed either by identifying a mutation in the BTK gene or by demonstrating absence of the BTK protein in monocytes or platelets. A positive family history suggestive of an X-linked recessive mode of inheritance increases the suspicion for XLA. It is uncommon for patients with XLA to develop symptoms in the first months of life because newborns are protected from most infections by transplacentally acquired maternal IgG. There are few distinguishing physical features of XLA that can provide clues to the diagnosis but absence of visible tonsils or adenoids (by X-ray or CT scan) is a useful clue.

In addition to the common sinopulmonary pathogens, patients with XLA are also susceptible to infections by particular opportunistic organisms that are more rare and fastidious, which can cause unusual clinical syndromes. For example, Helicobacter cinædi can cause a syndrome of dermatomyositis and cellulitis that presents with cutaneous ulcerations, particularly on the lower legs. The organism can sometimes be recovered from the blood but is fastidious and difficult to culture using usual methods. The ability to culture the organism and evaluate its antibiotic sensitivity is crucial in many cases because it is frequently resistant to various antibiotics. A combination of antibiotics is often needed to clear the infection effectively. Similarly, Mycoplasma species, including M. hominis, can cause lung, abdominal, or bone infections that are remarkably hard to eradicate and Ureaplasma urealyticum infections are a rare cause of arthritis, urethritis, and pneumonia.

Prior to the widespread use of IgG supplementation in these patients, opportunistic viral infections, particularly with viruses that require an extracellular phase, were especially problematic. For example, echovirus encephalitis was estimated to be the cause of death in ~10% of boys with XLA in the 1970s but that number has fallen dramatically with aggressive use of IgG supplementation. There continue to be rare cases of echovirus encephalitis in patients with XLA, even in those on adequate IgG replacement therapy, but these are thought to be caused by viral strains for which there may not be high antibody titers in the particular IgG preparation being used. Similarly, a mink astrovirus strain was recently identified by deep sequencing from the brain of an XLA patient who developed a neurodegenerative disorder as a teen. Interestingly, he had lived next to a mink farm as a child but was started on immunosuppression early in his teens for inflammatory bowel disease, which may have allowed the virus to escape control. Lastly, infections with vaccine-strain poliovirus were pathogenic in undiagnosed patients with XLA who were immunized with the live-viral vaccine after
transplacentally acquired maternal antibody had waned. The shift from live attenuated to killed poliovirus for immunization has essentially eliminated new cases.

Hyperimmunoglobulin M Syndromes

Under normal circumstances, binding of antigen to cell surface IgM on naive B cells induces activation of the B-cell. The antigen that is bound to surface IgM on the B-cell is ingested, proteolytically digested, and antigenic peptide fragments are displayed on the B-cell surface in MHC Class II molecules. Antigen-specific T cells then engage the B-cell via MHC II/TCR interactions. Once engaged, the activated helper T-cell (Th) provides additional costimulatory signals to the B-cell that are critical to promote immunoglobulin class-switching from IgM to IgG, IgA, and IgE. The most important of these costimulatory signals comes via the interaction of CD40 ligand on activated T cells with CD40 on B cells. Additional costimulatory signals come from ICOS on activated T cells and ICOS ligand (B7-H2) on B cells. Activation of the B-cell through CD40 and cytokines that are secreted by the helper T-cell cause it to undergo class-switch recombination (CSR) during which the \(\mu\)-heavy chain gene segment within the immunoglobulin gene, is replaced by either a \(\gamma\), \(\alpha\), or \(\varepsilon\) gene segment. This is accomplished by nicking and double-strand breakage of the DNA in the immunoglobulin heavy-chain locus, which requires a series of enzymatic steps that involve activation-induced cytidine deaminase (AID), uracil DNA glycosylase (UNG), and others. Genetic defects that affect CD40 ligand (CD40L), CD40, AID, or UNG can therefore prevent class-switch recombination thus thwarting the B-cell's ability to make significant amounts of any antibody isotype in addition to IgM.

The overwhelming majority of patients with hyper-IgM syndrome have the X-linked form caused by X-linked recessive mutations in the CD40 ligand (CD40L/CD154), which is encoded by the CD40L gene on the X-chromosome. CD40L and its receptor CD40 are members of the tumor necrosis factor (TNF) superfAMILY of ligands and receptors. In lymphocytes, CD40L is expressed only on activated T cells but is also expressed on platelets where its role is unknown. Affected boys may present with recurrent bacterial sinopulmonary infections caused by low IgG, IgA, and IgE, whereas IgM is normal or elevated. In addition to the usual bacterial pathogens, patients with CD40L mutations also demonstrate unique susceptibilities to fungal infections, particularly Pneumocystis jiroveci (PJ) that causes pneumonia, and to a protozoan, Cryptosporidium parvum (CP) that causes bowel infections. B lymphocytes are present, and T-cell numbers are generally normal. In almost all cases, the diagnosis can be made by using flow cytometry to evaluate the expression and function of the CD40L protein on activated T cells. Expression is evaluated using antibodies specific to the CD40L protein and the function is evaluated by measuring the binding of a CD40-Ig heavy chain fusion protein to the expressed CD40L. Gene sequencing can then be performed in order to identify a specific mutation.

The susceptibility to Pneumocystis and possibly other fungal pathogens has been somewhat of a puzzle because patients do not have other signs of a significant cellular immune defect such as severe or recurrent viral infections. Interestingly, the susceptibility to Pneumocystis jiroveci pneumonia (PJP) appears to go away in most patients by the age of 5. PJP is almost always diagnosed by staining bronchoalveolar lavage fluid for the presence of the organism. PJP can be readily prevented by prophylactic trimethoprim-sulfamethoxazole administration and active disease is amenable to treatment using higher doses of the same drug. Recent data have suggested that the fungal susceptibility in CD40L deficiency may be a result of defective CD40L signaling into dendritic cells and monocytes that express CD40.

C. parvum bowel infections are more difficult to diagnose and manage in patients with CD40L deficiency. CP may cause abdominal pain, bloating, diarrhea, malabsorption, and weight loss. It may require multiple stool samples to identify the oocysts and occasionally, the diagnosis can only be made on endoscopically obtained biopsy specimens. Treatment with paromomycin or nitazoxanide can clear the infection although prolonged courses are typically needed in hyper IgM patients and treatment failures are not uncommon. CP infections can result in chronic inflammation of the gut and biliary tree, which seems a likely contributor to the high incidence of bile duct cancers seen in these patients.

Treatment involves the use of IgG replacement therapy combined with prophylactic antibiotics for prevention of PJP at least until the age of 5. The role of bone marrow transplantation for CD40L deficiency is still being evaluated. Even though a number of patients have undergone successful bone marrow transplantation, the role of BMT remains somewhat controversial in this disease although in patients with ongoing CP infection, the prognosis for the patients who develop bile duct disease is so poor that the risks of transplantation are well justified.

CD40 deficiency is inherited as an autosomal recessive defect that has been described primarily in two cohorts from Italy and the Middle East. It results in a syndrome that is almost identical to CD40L deficiency in which both sexes are affected.
Homozygosity for a null mutation occurs, but heterozygosity is more common and can result in a partial phenotype because CD40 functions as a trimer (defects of even one chain of the trimer interfere with its function).

Autosomal recessive mutations in AID and UNG also cause a hyper-IgM phenotype but it tends to be milder than either CD40L or CD40 deficiency, likely because the defect is limited to B cells, whereas CD40L/CD40 signaling plays a role in other cell types including dendritic cells and monocytes. Patients with AID or UNG typically live into adulthood and do not demonstrate the same susceptibility to PJP and CP bowel infections. Patients with mutations in AID do, however, have a significant propensity to develop autoimmunity affecting various organ systems. Patients are typically treated with IgG replacement therapy and antibiotics for acute infections. There are no reports of bone marrow transplantation for AID or UNG deficiency.

Common Variable Immunodeficiency Syndromes

Common variable immunodeficiency (CVID) is a heterogeneous disorder that is likely caused by a variety of molecular mechanisms that ultimately lead to a similar clinical phenotype. The European Society of Immunodeficiency (ESID) has proposed diagnostic criteria in an effort to standardize the diagnosis of CVID. These include: (1) plasma IgG levels that are less than 2 standard deviations below the mean for age combined with a “marked decrease” in either IgM or IgA; (2) age of onset of immunodeficiency >2 years of age; (3) absent isohemagglutinins or poor responses to vaccines; and (4) defined causes of hypogammaglobulinemia have been excluded.

The peak age of onset of CVID is in the second or third decade of life and 50% to 60% of patients have a clinical phenotype consisting almost exclusively of increased bacterial sinopulmonary infections. With IgG supplementation, this group of patients has a relatively benign course with long-term survival that is not unlike the normal population. The other half of patients have a complicated disease course with autoimmunity or lymphoproliferative disease that can involve the hematopoietic system, lungs, lymph nodes, liver, and bowel. The long-term outcome of this population is significantly worse, approaching only 40% survival over 40 years.

Among the disorders seen in this population, a granulomatous, lymphoproliferative, interstitial lung disease (GLILD) affects approximately 30% to 40% of patients. This often presents with decreasing lung function that is manifested by cough, decreased exercise tolerance, and sometimes hypoxemia. Typical findings on chest CT scan include diffuse nodules within the lung, opacities that have a “ground glass” appearance, bronchial wall thickening, and sometimes bronchiectasis. Lung biopsy generally demonstrates a lymphocytic interstitial pneumonitis with noncaseating granulomas and a follicular bronchiolitis with lymphoid aggregates of both B and T cells. This pattern is sometimes mistaken for sarcoidosis although there are differences. Over time, this inflammatory process in the lungs will cause destruction of alveoli and will contribute to development of bronchiectasis. There continues to be some debate among providers about whether this process should be treated if the patient is not demonstrating pulmonary compromise. If left unchecked, however, there is evidence that irreversible damage and fibrosis develops in many patients. High-dose steroids are often used as first-line therapy to treat this process and in many cases they are effective but do not typically lead to a lasting remission on their own. A recent study using a combination of anti-CD20 monoclonal antibody (rituximab) therapy and azathioprine in a small cohort of CVID patients with GLILD demonstrated dramatic responses with a prolonged remission of disease in many patients.

In addition to pulmonary symptoms, gastrointestinal complaints are common in CVID, affecting 20% to 30% of patients. Patients who develop disease demonstrate a hypertrophic lymphoproliferation of Peyer’s patches that causes a nodular lymphoid hyperplasia in the bowel. This is associated with abdominal discomfort, diarrhea, malabsorption, and weight loss and can cause significant morbidity. A variety of approaches have been taken to treat this process but none have offered particularly dramatic results although nonabsorbable steroid preparations have shown some benefit with minimal side effects. A more troubling complication observed in 5% to 10% of patients is a hepatitis that can cause severe hepatic dysfunction with development of hepatosplenomegaly and ascites. Infectious causes are almost never identified and liver biopsy demonstrates a nodular lymphoid hyperplasia in the liver parenchyma, not unlike that observed in the bowel. Liver disease is among the complications associated with a poor outcome.

Some 20% of subjects have additional clinical findings that are suggestive of autoimmunity/immune dysregulation including immune thrombocytopenia and hemolytic anemia, neuropathy, endocrinopathies, and skin disease. Skin involvement ranges from alopecia and vitiligo to psoriasis and granuloma annulare.

In most cases of CVID, the molecular etiology of disease is unknown. There has, however, been some progress in identifying genetic defects associated with a CVID phenotype. The most common mutations identified are autosomal recessive defects in the transmembrane activator, calcium modulator, and cyclophilin ligand interactor (TACI), which are found in 7% to 10% of patients with CVID. Unfortunately, even in patients who have mutations that abrogate protein
expression, the penetrance of disease seems to be highly variable with individuals from one family harboring the same mutation, having either a CVID phenotype, a selective IgA deficiency phenotype, or no disease. This inability to correlate disease phenotype or prognosis with the presence of a TACI mutation has raised the question of whether TACI genotyping offers clinical value. In addition to TACI, autosomal recessive mutations in the genes encoding the Baff receptor (BAFFR), the inducible T-cell co-stimulator (ICOS), CD19, CD20, CD21, CD81, and the LPS-responsive vesicle trafficking, beach- and anchor-containing protein (LRBA) have been identified in rare patients with features of CVID. These mutations have provided insight into basic immune mechanisms in humans but explain only a handful of all patients with CVID. Lastly, hypomorphic mutations in BTK (X-linked agammaglobulinemia), CD40L (X-linked hyper-IgM syndrome), SAP/SH2D1A (X-linked lymphoproliferative syndrome), and RAG1/RAG2 can be associated with a CVID-like phenotype and according to the diagnostic criteria for CVID, need to be excluded prior to making this diagnosis.

B-cell numbers in peripheral blood are typically normal but a subset of CVID patients have B-cell lymphopenia. In those patients with normal B-cell numbers, B-cell maturation, memory development, and immunoglobulin class-switching are often abnormal and can be assessed by detailed flow-cytometry-based immunophenotyping of B cells. Varying classification schemes have been proposed to subtype patients according to their B-cell phenotype and these subsets have been correlated with differences in risk for autoimmunity, and the like. B-cell immunophenotyping has therefore become a useful clinical tool in caring for patients with CVID. In addition to the humoral immune deficiency, many patients with CVID have impaired T-cell function with decreased CD4 or CD8 T cell numbers as well as abnormal T-cell proliferative responses in vitro to mitogens and antigens. Regulatory T-cell numbers and function have also been found to be decreased in patients with CVID.

Selective Immunoglobulin A Deficiency

There are two isoforms of IgA that are made predominantly at mucosal surfaces where they play a critical role in neutralizing pathogens and maintaining mucosal integrity. Subjects >4 years of age with serum IgA levels consistently <7 mg/dl but normal IgG and IgM levels are considered selectively IgA deficient. Selective immunoglobulin A deficiency (SigAD) can be difficult to diagnose in childhood because adult blood levels of IgA (50 to 200 mg/dl) are not usually attained until 12 years of age or older. The molecular mechanisms by which this occurs are largely unknown. Interestingly, despite low IgA, the frequency of cell-surface IgA-positive B cells is normal in patients with SigAD. Up to 20% of IgA-deficient subjects have reduced levels of at least one IgG subclass: mostly IgG2.

Selective IgA deficiency is the most common immunodeficiency with an incidence as high as 1 in 300 in blood bank studies. The majority (>50%) of patients with selective IgA-deficiency have no apparent symptoms that can be directly linked to their immune defect. In the patients who do have symptoms, they are typically more suggestive of immune dysregulation and autoimmunity (allergy, arthritis, diarrhea, celiac disease, etc.) than immune deficiency (sinusitis, otitis media, bronchitis, and pneumonia). In patients who are truly IgA deficient, sensitization to IgA itself can be a problem, leading to anaphylactic reactions during infusions of blood products including IVig, red blood cells, platelets, and so on. This is, however, quite uncommon and can often be managed by pretreatment with benadryl, acetaminophen, and steroids before the start of the infusion.

Transient Hypogammaglobulinemia

Maternal IgG is actively transported across the placenta from mother to infant. The rate of transfer increases in the last month of pregnancy. Premature infants will therefore have low IgG levels but term newborns have IgG concentrations virtually equal to their mother’s. Because the half-life of IgG is approximately 21 days, the levels of maternal immunoglobulin fall as the infant grows and the IgG is catabolized. For most term infants, the IgG level in the blood reaches a nadir between 200 to 400 mg/dl, typically between 3 and 4 months of age. As the infant’s own immune system matures and begins to generate more IgG of its own, the immunoglobulin levels begin to rise again. There are, however, children whose IgG levels dip below 200 mg/dl and may remain low for a prolonged period of time before they begin to rise into the normal range again. Despite this, the response to protein antigen vaccines is often normal. This phenomenon is termed transient hypogammaglobulinemia of infancy (THI) and immunoglobulin levels typically return to normal by 2 to 6 years of age. There are almost no data about the mechanism by which THI occurs although it has been suggested that it may be the result of delayed B-cell maturation. This has, however, not been borne out by B-cell immunophenotyping studies. The true incidence of THI is unknown because immunoglobulin levels are usually only requested if patients are having symptoms (i.e., recurrent infections). There is no consensus on how to manage THI although most would agree
that if patients are having frequent infections, they might require IgG supplementation until their own IgG levels normalize. One approach has been to immunize affected infants with killed vaccines and to start supplemental IgG therapy on those who make no significant antibody response. Infants who do respond to immunization with a protective specific antibody titer are usually safe with symptomatic management or with prophylactic antibiotics alone.

Immunodeficiency, Centromere Instability, and Facial Anomalies Syndrome

Immunodeficiency, centromere instability, and facial anomalies (ICF) syndrome is a complex syndrome that includes centromeric instability, a variable immune deficiency (often with normal B-cell counts), facial anomalies including hypertelorism, a flat nasal bridge, and low-set ears, and developmental delay. The immunoglobulin deficiency is variable but IgA, IgG, and/or IgM are frequently low. Lymphocyte proliferation can also be abnormal. The centromeric instability leads to chromosomal breaks, deletions, and multiradial chromosome junctions in activated lymphocytes that typically affect chromosomes 1, 9, and 16. ICF syndrome typically presents in childhood with recurrent bacterial sinopulmonary infections and patients generally require chronic IgG supplementation. The diagnosis is usually suspected in patients who have the facial phenotype and recurrent infections. ICF syndrome is caused by mutations in the DNMT3B gene, which encodes one of a family of DNA methyltransferases. Hypomethylation of the DNA is hypothesized to cause disease but the precise mechanism by which this generates the facial and immune phenotypes is unknown. Evaluating the karyotype of activated peripheral blood lymphocytes can demonstrate the characteristic chromosomal abnormalities in chromosomes 1, 9, and 16, which can be highly suggestive of the diagnosis. Ultimately, sequencing of the DNMT3B gene can confirm a diagnosis of ICF syndrome.

Diagnosis

The diagnosis of antibody deficiency needs to evaluate both the quantity and the quality of the antibody response. Quantity is easily evaluated by measuring quantitative immunoglobulin levels (IgG, IgM, IgA, and IgE) in the blood and comparing these to the age-appropriate normal ranges. Evaluating the quality of the antibody response can be done by measuring specific antibody titers to vaccines that the patient has received. Generally, responses to both protein antigens (tetanus, diphtheria, hepatitis B, etc.) and carbohydrate antigens (23-valent unconjugated Pneumovax) need to be assessed to confirm normal antibody responses. Patients who respond appropriately to protein antigens but do not respond to carbohydrate antigens may have specific antibody deficiency and may require additional workup. Recent guidelines regarding the interpretation and use of diagnostic vaccination have recently been published.

In addition to evaluating antibody quantity and quality, it is essential to determine whether patients have normal B-cell numbers by evaluating lymphocyte subsets. The use of more detailed B-cell immunophenotyping to evaluate B-cell development, the presence of CD27+ memory B cells, and the ability of memory B cells to undergo immunoglobulin class switching has become standard-of-care in many clinics as it provides valuable diagnostic and prognostic information.

Flow cytometry testing to assess the expression of specific proteins that are defective in B-cell and antibody deficiency disorders including BTK, CD40 ligand, CD40, ICOS, CD27, BAFF receptor, and the like, can be performed in specialty laboratories and offer the ability to rapidly obtain a molecular diagnosis. This is typically supplemented by sequencing of specific genes.

Treatment

Immunoglobulin Replacement

In patients with antibody deficiency, replacement of IgG is critical to maintaining health and preventing long-term complications associated with recurrent infections. Immunoglobulin replacement therapy has been found to be effective when administered intravenously (IVig), subcutaneously (SCIg), and intramuscularly (IMIg) and there are currently FDA-approved products that support administration via any of these routes. That said, because of significant discomfort associated with IMIg administration, this route is rarely used in the United States. Most patients are maintained on either IVig or SCIg depending on patient preference and provider recommendations related to each patient’s clinical need. Because the half-life of IgG in the circulation is ~21 days under normal circumstances, IVig is typically administered every 3 to 4 weeks providing high peak levels followed by a decline over the ensuing weeks to a trough prior to the next infusion. In contrast, SCIg is typically administered 1 to 2 times per week in smaller doses providing a more “steady-state” level of IgG in the circulation. IgG products are prepared from the pooled plasma collected from thousands of healthy donors and therefore they contain a broad range of antibodies. A reasonable starting dose of either IVig or SCIg is 400 to 500 mg/kg/month. This can be divided into the
number of doses required to administer the necessary monthly volume (IgG preparations range in concentration from 5 g/100cc (5%) to 20 g/100cc (20%). In most patients, a trough IgG level of 600 mg/dl in the blood is a reasonable initial target but the dose can then be increased or decreased to achieve a trough IgG level that prevents both acute infections and development of progressive lung disease. There is evidence that at least for bacterial pneumonia, higher IgG trough levels are directly correlated with a decreased risk of infection. Supplemental IgG is generally very effective at preventing lower respiratory tract infections (bronchitis and pneumonia), but the response of upper tract disease (particularly sinusitis) is more variable. Some patients have persistent sinus symptoms that can be a significant clinical problem despite IgG therapy. In these patients, the addition of prophylactic antibiotic therapy or increasing the frequency or dose of IgG infusions may be beneficial.

Side effects with IVlg therapy are relatively common, occurring in as many as 25% of treated patients. Side effects include headaches, nausea, vomiting, chills, fatigue, fever, rash, and aseptic meningitis. These can often be managed by changing the IgG product being used, pretreating with benadryl, acetaminophen, and steroids (0.5 to 1 mg/kg) prior to infusion, or slowing the rate of infusion. Patients who have persistent symptoms despite these measures can often tolerate subcutaneous IgG supplementation (SCIg).

Prophylactic Antibiotics

It has been increasingly recognized that in many patients with antibody deficiency, replacement of IgG (even to normal levels), may not prevent all clinically significant infections. The addition of prophylactic antibiotics has been used as an adjunct to IgG therapy to try to improve control of infections and decrease morbidity. Unfortunately, to date, there have been no well-performed studies that argue strongly either for or against the use of prophylactic antibiotics to improve outcomes. Similarly, there have been virtually no studies that support a particular antibiotic regimen as being superior for prophylaxis. Many patients with antibody deficiency have evidence of bronchiectasis and chronic lung disease, therefore some providers, extrapolating from the lung transplant and cystic fibrosis literature, have utilized thrice weekly macrolide antibiotics as a prophylactic regimen in an attempt to prevent progression of lung pathology. Further studies are needed to clarify the role of prophylactic antibiotics and to define the optimal regimen.

T CELLS

Disorders characterized by the absence of T cells have been known for some time but the identification of several new genetic defects has expanded this group of disorders. Some are characterized by significant, generalized T-cell lymphopenia whereas others are characterized by the absence of specialized subsets of T cells.

Clinical Presentation

In general, absence of T cells causes susceptibility to unusual or severe infections caused by viruses including cytomegalovirus (CMV), Epstein-Barr virus (EBV), and adenoviruses, fungal infections caused by organisms such as P. jiroveci that commonly causes pneumonias in this group of patients, and mycobacteria such as Bacilli Calmette-Guerin (BCG) in areas of the world where this is used. In addition, patients with T-cell deficiencies frequently have symptoms of autoimmunity including diarrhea (secondary to autoimmune enteropathy), cytopenias (autoimmune hemolytic anemia [AIHA] and idiopathic thrombocytopenic purpura [ITP]), and hepatitis.

Specific Disorders

22q11.2 Deletion Syndrome (DiGeorge Syndrome)

Deletions within the 22q11.2 region of the long arm of chromosome 22 have been associated with various clinical syndromes including DiGeorge syndrome (DGS), velocardiofacial syndrome (VCFS), conotruncal anomaly face syndrome (CTFS), CATCH22 syndrome, and others. Digeorge syndrome is the name most commonly associated with immune deficiency and thus is the focus of this discussion. Although DGS is a complex syndrome that has been associated with a wide array of symptoms, the diagnostic criteria proposed by the European Society of Immune Deficiency (ESID) are relatively straightforward. These propose that a diagnosis of DGS should be strongly considered in patients who have <500 CD3+ T cells/mm3 and any two of the following three characteristics: (1) conotruncal cardiac defect (truncus arteriosus, tetralogy of Fallot, interrupted aortic arch, or aberrant right subclavian); (2) hypocalcemia requiring therapy for >3 weeks; (3) deletion of chromosome 22q11.2. This chromosomal deletion syndrome occurs in approximately 1 in 4,000 to 5,000 births and causes haploinsufficiency of the genes encompassed in the deletion that can extend to include as much as 3 Mb of the chromosome.

The characteristic T-cell lymphopenia of DiGeorge syndrome is thought to arise primarily from the absence of adequate thymic tissue and at times, the diagnosis is suspected when the cardiac surgeon correcting a congenital heart defect finds little or no thymic tissue in the mediastinum. Most affected infants have low, but not absent T cells and absolute counts
tend to improve over the first year of life. Both CD4+ and CD8+ T cells are low, however, CD8+ T-cell numbers tend to be more affected in most patients. Despite low T-cell counts, most patients do not have significant problems with recurrent or severe viral or fungal infections. Some patients may have recurrent candidiasis. Bacterial infections of the upper respiratory tract including otitis media and sinusitis do occur but may be related more to anatomical issues associated with the facial anomalies than to the immunodeficiency per se. Rare patients have severe T-cell lymphopenia with essentially no T cells and are termed “complete” DiGeorge. These patients may have a clinical phenotype similar to SCID.67, 68

Other prominent clinical features include: hypocalcemia that can be severe and persistent due to parathyroid hypoplasia, dysmorphic facial features that include small low-set ears, hypertelorism, and micrognathia, renal anomalies including horseshoe kidney and a duplicated collecting system, and developmental delay including problems with speech acquisition, learning disabilities, and behavioral problems. Patients with DiGeorge syndrome have also been found to have an increased incidence of autoimmunity including cytopenias (particularly affecting red cells and platelets), juvenile idiopathic arthritis (JIA), and thyroiditis.

In symptomatic patients, the diagnosis of DiGeorge syndrome is typically made by confirming a deletion within the 22q11.2 region by fluorescence in situ hybridization (FISH) or by quantitative PCR for deletion of the TBX1 gene that lies within the deletion.69 In approximately 10% of patients, deletion of this region cannot be detected despite the presence of classic clinical features.

Treatment of DiGeorge initially involves supportive care that may include cardiac support and calcium supplementation. In patients with severe T-cell lymphopenia or evidence of decreased T-cell function, prophylaxis against PJP pneumonia and IgG supplementation may be utilized. Blood for these patients should be irradiated to prevent the risk of graft-versus-host disease. For those patients with the severe “complete” form of the syndrome, grafting of allogeneic thymus slices into the thigh muscle has proven to be successful in recovering the T-cell lymphopenia, improving T-cell responses to mitogens, and correcting the infectious susceptibility.70, 71 HSCT has been utilized in a handful of patients with mixed results.72, 73 In general, HSCT restores the T-cell counts and protects patients against further infection but in the absence of a thymus, the T-cell graft is thought to consist primarily of long-lived committed lymphoid progenitor T cells and not of cells derived from donor bone marrow stem cells. As a result, there is concern that the T-cell grafts may senesce over time, once again leaving the patient lymphopenic and susceptible to infection. There are currently no long-term therapies that can successfully correct the parathyroid defect.

Severe Combined Immune Deficiency

Made famous by The Boy in the Plastic Bubble, a 1976 made-for-TV movie starring John Travolta, SCID is among the most severe immunodeficiencies. It is now known that this category of diseases is made up of a variety of related disorders caused by mutations in more than 20 different genes. The one thing that is common to all forms of SCID is deficiency of one or more subsets of T cells. In many cases, there are no circulating T cells. Depending on the genetic defect, patients may also lack B cells and/or NK cells. This has led to the useful convention of defining cases of SCID by their cellular phenotype (i.e., T<sup>neg</sup>B<sup>neg</sup>NK<sup>neg</sup>, T<sup>neg</sup>B<sup>pos</sup>NK<sup>neg</sup>, T<sup>neg</sup>B<sup>pos</sup>NK<sup>pos</sup>, T<sup>pos</sup>B<sup>pos</sup>NK<sup>neg</sup>, etc.). The cellular phenotype suggests what the underlying genetic defect may be (see Table 63.2).2 Because of the absence of functional T cells, patients with SCID typically come to medical attention because of severe or chronic viral infections, fungal infections, or autoimmunity. In the overwhelming majority of SCID cases, this leads to death in infancy or early childhood if patients do not undergo curative treatment such as HSCT or gene therapy. Unfortunately, the presence of infections makes HSCT or gene therapy much more complicated and substantially decreases the chances of survival. Because of this, efforts have been underway in the United States and other countries to perform screening of all newborns using dried blood spot cards obtained at birth to identify those who may have SCID. These efforts have led to the recognition that the incidence of SCID is approximately 1 in 40,000 live births in the United States.74, 75

X-Linked Severe Combined Immunodeficiency

The X-linked form of SCID is the most common type, accounting for ~40% of all SCID cases. It occurs as a result of mutations in the IL2RG gene, encoding the γ receptor chain (γc) utilized by a number of cytokine receptors including those for IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 (see Fig. 63.2). In the absence of a functional γc chain, cells are unable to respond to these cytokines. Because IL-2 and IL-7 are key growth factors for T cells, and IL-15 is the key growth factor for NK cells, patients with X-SCID lack T and NK cells but usually have normal numbers of B cells in their blood. The ability to make antibodies is nevertheless severely impaired due to the lack of T-cell help.
If not identified by newborn screening, infants with X-SCID typically present with severe infections. P. jiroveci pneumonia is common and often accompanied by severe viral infections with cytomegalovirus (CMV), EBV, respiratory syncytial virus (RSV), rotavirus, metapneumovirus, and others. Adenovirus is particularly lethal in SCID, causing not only pneumonitis but also a severe fulminant hepatitis. In countries where BCG is still used for vaccination, X-SCID patients may develop severe, systemic BCG-osis. Other symptoms that are frequently associated with X-SCID include diarrhea, failure to thrive, and candidiasis. The physical exam and associated studies offer few clues to the diagnosis of X-SCID other than a paucity of palpable lymph nodes and absence of a thymic shadow on a chest X-ray.

Flow cytometry testing to evaluate tyrosine phosphorylation of the STAT3 transcription factor in response to IL-21 stimulation can provide a rapid assessment of whether a patient may have an IL2RG or JAK3 defect (see below). Under normal circumstances, IL-21 stimulation of B cells causes rapid tyrosine phosphorylation in B cells that is absent in patients with IL2RG or JAK3 deficiency (see Fig. 63.2). The diagnosis is ultimately confirmed however by sequencing of the IL2RG gene.

HSCT has been the mainstay of therapy for X-SCID using a variety of pretransplant conditioning regimens. Some have strongly advocated the use of T-cell depleted grafts from one of the haploidentical parents because they are readily available but many patients transplanted using that approach have failed to obtain significant donor chimerism in the B-cell compartment, so have remained dependent on IgG supplementation posttransplant. X-SCID was also the first disorder successfully treated by gene therapy. Unfortunately, the retroviral gene therapy vector used to deliver the normal copy of the IL2RG gene had an unknown propensity to integrate within the T-cell oncogene LMO2, causing T-cell leukemias in a subset of treated patients. Further studies are underway using alternative viral vectors with the hope that these may have a better safety profile.

**JAK3 Deficient Severe Combined Immune Deficiency**

JAK3 is the tyrosine kinase immediately downstream of the common gamma chain (γc). It transduces signals from cytokine receptors to the STAT5 transcription factor and to other intracellular signaling molecules (see Fig. 63.2). Approximately 30 different mutations have been identified that impair JAK3 function to varying degrees. Those that are severe have a T<sup>-</sup>B<sup>−</sup>NK<sup>−</sup> cellular phenotype similar to mutations in IL2RG. Approximately one third of patients have milder mutations that allow some JAK3 function. These patients can develop some T cells although the T cells that develop are functionally abnormal. The clinical presentation is similar to that observed in yc deficiency. Sequencing of the JAK3 gene is required to confirm the diagnosis.

**Interleukin-7 Receptor, CD3 Components, and CD45-Deficient Severe Combined Immune Deficiency**

Defects in the α-chain of the IL-7 receptor (IL7RA), CD3 subunits (γ, δ, ε), or CD45 can cause SCID with a T<sup>−</sup>B<sup>−</sup>NK<sup>−</sup> phenotype. As noted above, IL-7 is one of the two key growth and differentiation factors for T cells. As a result, mutations in the IL-7 receptor α-chain (CD127) lead to selective T-cell deficiency but allow normal development of B and NK cells. Similarly, absence of any of the CD3 subunits specifically affects the ability of T cells to develop because CD3 makes up an essential part of the T-cell receptor complex. The T-cell receptor, including CD3 subunits, assembles in the endoplasmic reticulum and Golgi complex before trafficking to the cell surface. If any of the receptor subunits are absent (including any of the CD3 chains), the receptor is recycled and never makes it to the outer cell membrane. As a result, cells are unable to receive the TCR stimulation needed as they traffic through the thymus and they die by “neglect.” Because the number of T cells entering the thymus is normal, the CD3 defects are unusual among SCID disorders in that the size of the thymus is normal. Of the three known CD3 defects (γ, δ, and ε), CD3ε deficiency may have a somewhat milder clinical phenotype that can present with moderate T-cell lymphopenia and recurrent pneumonia and otitis.

CD45 is a transmembrane tyrosine phosphatase present on most white blood cells. It regulates intracellular Src-family tyrosine kinases that are important for T-cell receptor function and activation. Autosomal recessive mutations of CD45 lead to T-cell deficiency and a SCID phenotype in affected infants.

DNA Recombination and Repair Defects in Severe Combined Immune Deficiency

Rearrangement of the V, D, J, and constant regions of the T-cell receptor gene and the B-cell immunoglobulin gene requires that double-stranded breaks be made in the DNA and that these breaks then be repaired after removal of intervening chromosomal fragments. The recombinase activating genes RAG1 and RAG2 are expressed in T and B cells and play an essential role in creating the necessary double-stranded DNA breaks in the TCR and immunoglobulin loci. A large complex of proteins including Artemis (DCLRE1C), DNA-PKcs, Cernunnos/XLF (XRCC4-like factor), and DNA ligase IV (LIG4) then play a role in the repair of the DNA double-stranded breaks needed to create the final, recombined TCR or Ig locus. Inasmuch as productive rearrangement of the TCR or Ig locus is a necessary developmental step during T- and B-cell maturation, complete failure in one of these processes results in lymphopenia, with few if any T- or B cells in the blood, whereas generation of NK cells is generally unaffected. Because radiation induces double-strand breaks in DNA, cells from patients with mutations in any of the proteins involved in DNA repair (Artemis, DNA-PKcs, cernunnos, ligase IV) demonstrate decreased survival in vitro after radiation exposure (radiation-sensitivity). This can be a valuable diagnostic clue in making a diagnosis.
FIGURE 63.2. Interleukin-2 signaling. Under resting circumstances, the transcription factor STAT5 is present in the cytoplasm in a nonphosphorylated state. Upon binding of IL-2 to its receptor made up of \( \alpha \), \( \beta \), and \( \gamma \) chains (1), the common \( \gamma \) chain is phosphorylated on tyrosine by the receptor-associated JAK3 kinase (2). STAT5 then binds to the phototyrosine residues on the receptor via its Src-homology 2 (SH2) domains, where it is also phosphorylated on key tyrosine residues by JAK3 (3). After undergoing a conformational change, the phosphorylated STAT5 dimer localizes to the nucleus where it binds DNA and mediates gene transcription. Mutations in the common IL-2 receptor \( \gamma \) chain or in JAK3 cause severe combined immunodeficiency (SCID).

Patients who have null mutations of any of these proteins have a clear \( T^{neg}B^{neg}NK^{+} \) cell phenotype. There are, however, many mutations, particularly missense mutations or small inframe deletions that allow expression of a partially functional protein that can occasionally productively recombine a TCR or Ig gene locus. The cell in which this occurs is then able to
pass the developmental block and proliferate in an attempt to fill the lymphopenic void that is otherwise present in SCID. These forms of SCID are termed “leaky” because they allow a small number of T- (and occasionally B-) cells to “leak” past the developmental block. Omenn syndrome, originally described in leaky RAG1 or RAG2 mutants, is a clinical phenotype that results from this leaky form of SCID. Affected infants typically develop a desquamative erythroderma after birth that is associated with the presence of oligoclonal, activated T cells in the skin, hepatosplenomegaly, lymphadenopathy, eosinophilia, and elevated IgE. Some develop autoimmune enteropathy and cytopenias. Affected patients are typically treated with T-cell-directed immunosuppression such as cyclosporine or FK506, followed by bone marrow transplantation. Leaky forms of SCID have now been described in a number of SCID-associated molecular defects including RAG1, RAG2, Artemis, ligase IV, IL7RA, IL2RG, RMRP, and others. 

Adenosine Deaminase and Purine Nucleotide Phosphorylase Deficient Severe Combined Immune Deficiency

Adenosine deaminase (ADA) deficiency was the first molecularly defined immunodeficiency with discovery of patients with SCID who lacked the enzymatic activity of ADA in the peripheral blood in the early 1970s. ADA catalyzes the conversion of adenosine triphosphate (ATP), guanosine triphosphate (GTP), and their deoxy counterparts to adenosine diphosphate (ADP) and guanosinediphosphat (GDP). When enzyme activity is impaired or absent, intracellular levels of deoxy-ATP (dTATP) rise to interfere with ribonucleotide reductase, such that DNA synthesis and repair are slowed and lymphocyte apoptosis is increased. Purine nucleotide phosphorylase (PNP) works farther down this same metabolic pathway to convert deoxyxynosine to hypoxanthine. Mutations interfering with this function cause deoxy-GTP accumulation and the inhibition of ribonucleotide reductase and DNA synthesis. In both cases, affected infants typically have a T^negB^negNK^neg/low cellular phenotype due to the toxic nature of the accumulated metabolites on lymphocyte development. Patients typically present with severe or recurrent viral infections or recurrent sinopulmonary infections in the first year of life.

Both syndromes are associated with other, nonimmune symptoms including skeletal abnormalities and osseochondrosis dysplasia in ADA deficiency and neurologic deficits, developmental delay, and spasticity, in PNP deficiency. In both cases, the diagnosis can be made by detecting high levels of the toxic metabolites that build up in the peripheral blood in the absence of enzymatic activity. Sequencing of the ADA1 or PNP genes can be done to confirm the diagnosis. ADA deficiency accounts for 20% or more of autosomal-recessive SCID cases.

Aside from bone marrow transplantation, ADA deficient infants can be treated with polyethylene glycol-conjugated ADA, which is injected intramuscularly once per week. Treatment efficacy is gauged by measuring plasma ADA activity and red cell dATP levels. Enzyme treatment has the advantage of speed of response coupled with safety. The treatment is very expensive and many treated patients develop antibodies to the bovine protein that may neutralize the effect of the enzyme. HSCT is effective in ADA deficiency but less so in PNP deficiency as it does not correct the neurologic deficits. Gene therapy for ADA deficiency has been quite successful and unlike X-linked SCID and WAS, there have been no reported cases of leukemia despite the retroviral gene therapy vector backbone being similar.

Zap-70 Deficient Severe Combined Immune Deficiency

Zap-70 is a tyrosine kinase that is downstream of CD3 in the T-cell receptor signaling pathway. Absence of functional enzyme results in a characteristic SCID phenotype with decreased CD4^+ T cells but virtually absent CD8^+ T cells. Immunoglobulin levels are often decreased and antibody responses to vaccination are typically absent because of the lack of effective T-cell help. The CD4^+ T cells that are present do not respond to antigen or mitogen stimulation that utilizes the T-cell receptor but they do proliferate and make cytokines in response to phorbol and ionomycin stimulation, which mimics TCR stimulation by activating kinases and calcium flux through downstream mechanisms. Bone marrow transplantation is effective in this disorder.

Defects in Antigen Presentation by MHC I or MHC II

The class II MHC complex generally presents peptide antigen derived from ingested material (either by phagocytosis or via the B-cell antigen receptor). Defects that interfere with the assembly or cell-surface expression of the Class II MHC-peptide complex prevent effective antigen recognition by CD4^+ T cells, resulting in a SCID syndrome that presents in infancy with chronic diarrhea, failure to thrive, and occasionally with autoimmune cytopenias. MHC II deficiency can result from defects in one of four

P.1353

DNA-binding proteins that regulate transcription of the MHC class II gene (CIITA, RFXANK, RFX5, and RFXAP). Founder mutations (particularly in RFXANK) that are common in the Mediterranean region have led to most affected patients.
having some familial ties to this geographical area. Because MHC class II presentation of antigen is abnormal, CD4+ T-cell counts are often low whereas CD8 counts are normal. A rapid preliminary diagnosis can be made by evaluating peripheral blood cells for expression of the class II complex by flow cytometry, which will detect reduced expression. Some patients can have a mild disease course and can live well into adulthood with only supportive care although others with the same mutation (even in the same family) may have a more severe phenotype. Bone marrow transplantation for MHC II deficiency has been challenging with survival rates typically approaching approximately 50%. In addition, there is a high rate of severe graft-versus-host disease (GvHD) in these patients, possibly because thymic epithelial cells that play a role in positive and negative T-cell selection are not replaced by transplant and still do not express MHC II.85

The class I MHC complex presents peptide antigens derived from intracellular proteins where proteolytically derived peptides are bound to the MHC I complex as it is generated and trafficked through the endoplasmic reticulum. Peptides that are generated in the cytosol are transported into the inner lumen of the endoplasmic reticulum by the peptide transporters TAP1 and TAP2. Mutations in either of these, or of Tapsin to which they bind, have been identified. TAP mutations are typically associated with recurrent viral infections, and recurrent sinusitis and bronchitis. The diagnosis is usually suspected when serologic typing for HLA Class I antigens fails to give interpretable results, but molecular typing indicates intact MHC DNA. CD8+ T-cell and NK-cell counts are frequently (but not uniformly) decreased in these patients. Other cell subsets are typically normal. Heterogeneity in the phenotype may reflect differences in the underlying mutation and in the gene affected. Some patients may survive into the third decade. The role of HSCT in MHC I deficiency is unclear.

Treatment of Severe Combined Immunodeficiency Syndromes

SCID was uniformly lethal in the first years of life until Good and colleagues successfully reconstituted an affected infant with a transplant of sibling bone marrow. Experience in subsequent years has shown that patients with B-cell-positive SCID (IL2RG, JAK3, IL7RA, etc.) readily reconstitute their T-cell deficiency but may not develop significant B-cell chimerism. The reasons for this are not entirely understood but various hypotheses have been put forward. From a practical standpoint, a lack of donor B-cell engraftment may lead to a chronic need for IgG replacement therapy even after transplant inasmuch as patients may not be able to mount sufficient antibody responses. Patients with B-cell-negative SCID are more likely to have successful donor engraftment of both T- and B-cell lineages and are more likely to recover full humoral immune function.

One of the most significant challenges in the treatment of SCID is that in the absence of a family history, most patients come to attention because of infections. These are most commonly PJP and severe viral infections (see above). PJP can be treated but may lead to lung damage, whereas the viral infections may or may not be controllable. In addition, many SCID infants have significant diarrhea and weight loss by the time they reach a transplant center. Together, these complications increase the risk of adverse outcomes during transplantation for SCID and have been the major impetus for adding SCID to state newborn screening panels. Initial management prior to transplant involves aggressive supportive care, antimicrobials to treat any intercurrent infections (bacterial, viral, and fungal), antimicrobial prophylaxis to prevent future infections, and IgG replacement therapy.

There is significant debate about the best pretransplant conditioning regimen for patients with SCID to balance safety and efficacy. In general, those patients that have a matched sibling donor receive no conditioning prior to receiving unmanipulated bone marrow. For other patients, a variety of conditioning regimens ranging from no conditioning to fully myeloablative regimens have been tried. Similarly, a range of manipulated and unmanipulated stem cell sources have been tried including matched bone marrow, matched peripheral blood, cord blood, and haploidentical. Last, a variety of prophylactic immunosuppressive regimens have been used in the early posttransplant period to limit GvHD and prevent graft rejection. Each option has advantages and disadvantages, which has led to the spectrum of transplant regimens that have been attempted for SCID. Current efforts are underway to assess which regimens offer the best outcomes and lowest risk.86,87,88,89

Cartilage-Hair Hypoplasia

Cartilage-hair hypoplasia (CHH) is a complex disorder characterized by skeletal dysplasia with short limbs (metaphyseal chondrodysplasia), sparse hypoplastic hair, gastrointestinal problems, and a variable immunodeficiency. CHH is caused by mutations in the RMRP gene, which encodes the 267 base-pair RNA component of the RNase MRP complex that plays a role in processing of precursor ribosomal RNA. The mechanism by which autosomal recessive mutations in RMRP cause the clinical features of CHH is unknown. The largest populations of CHH patients have been identified among the Old Order Amish and Finnish populations. Virtually all patients with CHH have some degree of immunodeficiency that can range from a mild humoral defect with decreased vaccine responses to a SCID-like phenotype associated with progressive lymphopenia and severe infections with bacteria, viruses, and fungi. A leaky-SCID phenotype has also been described in
RMRP deficiency. The diagnosis of CHH can be made based on the clinical phenotype and confirmed by sequencing of the RMRP gene. The immunologic features of CHH can be corrected by HSCT but the other features persist. \(^90\)

Imune Dysregulation, Polyendocrinopathy, Enteropathy, X-linked Syndrome

Imune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) is a syndrome of regulatory T-cell deficiency. Natural regulatory T cells comprise a subset of CD4\(^+\) T cells that regulate immune responses and play a critical role in peripheral immune tolerance. IPEX syndrome is caused by mutations in the FOXP3 gene located on the X chromosome that encodes a key transcription factor that is required for the generation of functional regulatory T cells (Treg). In the absence of FOXP3, patients present with severe, early-onset, systemic autoimmunity that is the result of having decreased Treg cell function. Almost all patients with IPEX syndrome present with enteropathy within the first 6 months of life. The enteropathy is typically characterized by profuse watery diarrhea (often nonbloody) and villus atrophy. The majority of patients have an eczematous dermatitis that typically begins in the first months of life. An early onset endocrinopathy that is almost exclusively either thyroiditis or Type I diabetes is also developed by 60% to 70% of patients. The most consistent laboratory abnormality among patients is a significantly elevated serum IgE level. In addition to these characteristic clinical and lab features, patients also have a high incidence of other severe autoimmune disorders including: hemolytic anemia, thrombocytopenia, neutropenia, hepatitis, renal disease, and others.

Recognition of the clinical features of IPEX syndrome is the first step in diagnosing this disorder. Sequencing of the FOXP3 gene remains the gold standard for making a diagnosis of IPEX syndrome although sequencing needs to encompass noncoding areas of the gene including the upstream noncoding exon and the polyadenylation signal sequence in order to cover all regions in which pathogenic mutations have been identified. \(^91\), \(^92\) Flow cytometry to measure FOXP3 protein expression and FOXP3\(^+\) Treg is a helpful adjunct to gene sequencing although only ~25% of patients have mutations that are predicted to abrogate FOXP3 protein expression completely. The remainder of patients have varying degrees of FOXP3\(^+\) Treg deficiency due to the fact that mutant FOXP3 may not support normal Treg development. As a result, flow cytometry by itself is not considered to be a sufficiently reliable screening test for IPEX syndrome. Initial therapy for IPEX syndrome typically consists of aggressive supportive care (parenteral nutrition, insulin, thyroid hormone, etc.) combined with T-cell-directed immune suppression using agents such as tacrolimus, cyclosporine, or rapamycin. HSCT is currently the only curative therapy for IPEX syndrome. Early HSCT using a nonmyeloablative conditioning regimen prior to the onset of autoimmunemediated organ damage usually leads to the best outcome and limits the adverse effects of therapy. \(^93\), \(^94\) Because Tregs constitutively express the high-affinity IL-2 receptor, they have a selective growth advantage in vivo. As a result, complete donor engraftment in all hematopoietic lineages may not be necessary because preferential engraftment of donor Treg cells can be sufficient to control the disease. \(^95\)

OTHER COMPLEX OR COMBINED IMMUNODEFICIENCY DISORDERS

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome (WAS) is unique among immunodeficiency disorders because affected patients have both an infectious susceptibility and a bleeding disorder. The bleeding problems are caused by the platelets being small (mean platelet volume <5 fl), dysfunctional, and decreased in number (usually platelet counts <70,000/µl). Patients with WAS typically present in infancy with bloody diarrhea and/or bruising, recurrent upper respiratory tract infections, and eczema. The incidence of hematopoietic malignancies is high. IgE levels are often elevated. Serum IgG levels and T-cell counts are often normal in infancy but may decrease over time. Responses to vaccination, particularly with carbohydrate antigens such as Pneumovax are often abnormal.

WAS is caused by mutations in the WAS gene that is located on the short arm of the X chromosome. Inheritance is X-linked recessive. There is a distinct genotype/phenotype correlation of mutations in WAS: Mutations that destroy WAS protein (WASP) expression lead to the full syndrome of immunodeficiency and platelet dysfunction. Mutations that allow expression of a mutant WASp protein are typically associated with a milder X-linked thrombocytopenia (XLT) phenotype in which the platelet dysfunction persists but the immunodeficiency is very mild. Point mutations in the CDC42 binding domain of the WASp protein lead to a third phenotype of X-linked neutropenia (XLN) that is generally not accompanied by bleeding abnormalities. \(^96\), \(^97\)

The WASp protein is expressed primarily in lymphoid and myeloid cells where it functions to nucleate actin polymerization in the cell. Patients with WAS therefore have problems with directed migration of neutrophils and with clustering and
signaling through T-cell and B-cell antigen receptors (this causes decreased signaling into the cell and abnormal proliferative responses). A diagnosis of WAS can be confirmed by demonstrating the absence of WASp protein in cells by flow cytometry or western blotting, or by identifying a mutation in the WAS gene.

Treatment of WAS initially involves supportive care including treatment of any acute infections and management of any bleeding episodes. In general, repeated platelet transfusions are avoided because of the concern that patients will become sensitized to a wide array of HLA types, which may increase the risk of complications during subsequent HSCT. Splenectomy can increase platelet counts, however, it also increases the risk that patients may die of sepsis with encapsulated organisms so there continues to be significant controversy surrounding the role of splenectomy in WAS. Patients with the full WAS phenotype should be evaluated for HSCT with matched related or unrelated donor bone marrow or cord blood. Haploidentical transplants have proven risky in this disease and therefore are generally avoided. The role of HSCT in XLT remains controversial. Some have advocated that the benefits for curing the bleeding problems are worth the risk if a matched sibling donor is available. Gene therapy has been successful in a small number of patients with WAS but as in the X-SCID gene therapy trials, some treated patients developed T-cell leukemias as a result of integration of the viral gene therapy vector near an oncogene.

Radiation Sensitive Disorders: Ataxia Telangiectasia and Nijmegen Breakage Syndrome

Ataxia telangiectasia (AT) is a disorder associated with progressive neurologic decline, immunodeficiency, and propensity to malignancy. It is caused by autosomal recessive mutations in the ATM gene that encodes a serine/threonine kinase that acts together with the NBS1 protein as one of the major sensors of double-stranded DNA breaks in the cell. ATM phosphorylates key proteins involved in the activation of the DNA damage repair checkpoint, leads to cell-cycle arrest, and then double-stranded DNA break repair. In the absence of functional ATM or NBS1, cells have a marked sensitivity to ionizing radiation. Because rearrangement of the TCR gene and the immunoglobulin gene loci also require double-stranded DNA break repair, these processes may be affected as well.

Patients with AT usually present in early childhood (most commonly between 2 and 5 years of age) with cerebellar ataxia that progresses to unsteady gait and over time, to choreoathetosis. Telangiectasias (small tufts of dilated blood vessels under the surface of the skin or mucus membranes) typically develop first on the conjunctivae and later are seen on the nose, ears, and shoulders. They can be an important diagnostic clue in a child with progressive ataxia. The majority of patients have immunoglobulin deficiency of varying degrees and can develop sinopulmonary symptoms and sepsis. The progressive neurodegeneration can compromise coughing, thus it is hard to determine whether respiratory infections occur more as a result of the immunodeficiency or the motor defects. Most affected individuals have elevated serum α-fetoprotein levels, which can be useful diagnostically. Malignancies are an important complication as a result of the DNA-repair defect. Acute T-cell leukemias are common and often demonstrate chromosomal translocations that affect the chromosomal regions involved in T-cell receptor gene rearrangements. B-cell lymphomas also occur and are usually associated with 11q22-23 chromosomal deletions. There is also an increase in the frequency of epithelial tumors in both homoyzogotes and ATM mutation carriers. Affected patients usually die in the second or third decade of life.

Other DNA repair defects that cause varying degrees of ataxia and/or mild mental retardation include an ataxialike syndrome caused by mutations in MRE11 and the Nijmegen breakage syndrome (NBS), caused by mutations in NBS1. In addition to an immunodeficiency like that observed in AT, patients with NBS have marked microcephaly, mild developmental delay/mental retardation, and a strong propensity to develop lymphomas. Another DNA repair defect, Bloom syndrome, caused by mutations in a DNA helicase (RecQ proteinlike-3), results in excess sister chromatid exchanges; it is associated principally with lymphomas and cancer. Multiple primary tumors occurring at an early age are common. Reduced growth in childhood results in a proportional dwarfism that, with cutaneous telangiectasias, is a useful physical sign. Inheritance is autosomal recessive, and the disease occurs with increased frequency in Ashkenazi Jewish populations. Chronic lung disease occurs and may be related to the low levels of IgA and IgM.

Mammalian Susceptibility to Mycobacterial Disease

Under normal circumstances, intracellular pathogens such as mycobacteria induce production of IL-12 and IL-23 that play a role in driving maturation of naive T cells into activated T helper type 1 (Th1) cells that produce interferon-γ (IFN-γ). IFN-γ then acts on a variety of cells including phagocytes (neutrophils, monocytes, and dendritic cells) to induce a number of interferon-inducible genes. Multiple molecules in this signaling pathway have been found to be defective in patients with intact cellular immunity who have invasive, nontuberculous mycobacterial infections. Mutations in the genes encoding the
IL12 p40 subunit (IL12B), the IL-12 receptor β1 chain (IL12RB1), the TYK2 tyrosine kinase that is associated with the IL-12 receptor and required for phosphorylation of the STAT4 transcription factor (TYK2), the IFN-γ receptor subunits (IFNGR1&IFNGR2), and the STAT1 transcription factor that is activated in response to IFN-γ (STAT1), and the mutations in this pathway are also associated with other infections including invasive salmonellosis and severe viral infections (STAT1).

In addition to these genetic defects, patients with invasive mycobacterial disease have now been identified with neutralizing autoantibodies to IFN-γ. Together these discoveries demonstrate a major role for the IL-12/IL-23/IFN-γ axis in normal human immunity. For patients with the milder, autosomal dominant IFN-γ receptor defects, IL-12 p40 defects, IL-12 receptor defects, and TYK2 defects, antimicrobial therapy and IFN-γ treatment are often sufficient to treat invasive mycobacterial infections and to prevent future infections. For patients with the more severe, autosomal recessive IFN-γ receptor defects, IFN-γ supplementation provides no benefit and HSCT is warranted.

Susceptibility to Hemophagocytic Lymphohistiocytosis and Severe Epstein-Barr Virus Infection

Several defects affecting intracellular trafficking of vesicles and granules are associated with susceptibility to hemophagocytic lymphohistiocytosis (HLH). This group includes some phenotypes that are quite distinctive including Chédiak-Higashi (CHS) and Griscelli (GS) syndromes, which are both associated with a partial oculocutaneous albinism. Patients with CHS have poikilodermic infections and periodontitis; their neutrophils have reduced chemotaxis and contain giant inclusion bodies (lysosomes). Patients with GS also have neurologic defects ranging from developmental delay to fatal neurodegeneration. Their neutrophils are dysfunctional, but they lack the giant granules of CHS. In vitro tests show low natural killer cell and cytotoxic cell function. CHS, GS, and X-linked lymphoproliferative syndrome (XLP) share susceptibility for HLH, an accelerated inflammatory process that in the case of XLP may be triggered by EBV. The genes responsible for these syndromes are LYST, RAB27A, SH2D1A, and XIAP/BIRC4, respectively, whereas genes for a further group of proteins (Perforin, Munc 13-D, and Syntaxin 11) are associated with familial hemophagocytic lymphohistiocytosis.

Toll-like Receptors and Innate Signaling Pathway Defects

The Toll-like receptors are a family of at least 10 pattern recognition receptors that are expressed in varying combinations on a broad array of immune and nonimmune cells. They recognize particular types (patterns) of molecules derived from pathogens (e.g., bacterial lipopolysaccharide, flagellin, mannann, CpG nucleotide, viral dsDNA, etc.). Triggering of Toll-like receptors activates intracellular signaling pathways, many of which converge on a common pathway utilizing the IRAK proteins and MyD88, which in turn activate the IκB kinase complex (NEMO/IκBζ/IκKβ), ultimately leading to phosphorylation and degradation of IκBα and activation of the NF-κB transcription factor complex.

Mutations in TLR signaling pathways have now been associated with major infectious susceptibilities: mutations in IRAK4 and MyD88 have been identified in patients with susceptibility to invasive pyogenic bacterial infections including particularly S. pneumoniae, Staphylococcus aureus, and Pseudomonas aeruginosa. Interestingly, patients with IRAK4 or MyD88 deficiency tend to have problems with invasive pyogenic bacterial infections in childhood but these subside over time, presumably as a result of the adaptive immune response covering for this innate defect. Mutations in TLR3, TRIF, TRAF3, and UNC-93B have been identified in patients with susceptibility to herpesvirus encephalitis. Defects in NEMO and IκBα also cause susceptibility to infections with pyogenic bacteria and mycobacteria and are associated with an anhydrotic ectodermal dysplasia phenotype. The severity of immunodeficiency and ectodermal dysplasia is quite variable and depends on the specific mutation that is present.

Chronic Mucocutaneous Candidiasis Syndromes

Chronic mucocutaneous candidiasis (CMC) is a clinical syndrome associated with chronic and recurrent candidal infections of mucosae, particularly oral and vaginal, together with nailbed infections but generally without systemic infection. CMC can occur in isolation or as part of a broader clinical syndrome such as in APECED (autoimmune polyendocrinopathy, candidiasis, ectodermal dystrophy). Recent discoveries have determined that in almost all cases, CMC is associated with abnormalities in development of Th17 effector T cells or with the production of, or responses to, the cytokine IL-17. These include autosomal recessive mutations in IL-17F or the IL-17 receptor α-subunit, dominant loss-of-function mutations in STAT3, and dominant gain-of-function mutations in STAT1.

Recently, the CMC associated with APECED was found to be the result of autoantibodies to IL-17 and IL-22. APECED is caused by mutations in AIRE1, a nuclear protein that regulates the expression of self-antigens by thymic medulary epithelial cells where it plays a role in T-cell selection and maturation. Other features of this disorder include endocrinopathies (hypoparathyroidism, adrenal insufficiency, and diabetes), alopecia areata, nail dystrophy, and vitiligo.

Autoimmune Lymphoproliferative Syndrome
The clinical phenotype of autoimmune lymphoproliferative syndrome (ALPS) is characterized by massive lymphadenopathy and hepatosplenomegaly in most cases. In addition, patients have problems with recurrent episodes of autoimmune hemolytic anemia and thrombocytopenia. The defects that have been identified in patients with this group of disorders are all associated with abnormalities in lymphocyte apoptosis. These include FAS (CD95), Fas ligand (FASL), FADD, caspase 10 (CASP10), NRAS, and KRAS. Peripheral blood T- and B-cell counts are generally normal, but in almost all cases, there is an increased percentage of αβ-TCR+ double-negative T cells that lack expression of both CD4 and CD8. A predisposition to developing lymphoid malignancies has been described in ALPS but is thought to be primarily in those patients who have mutations in the death domain of FAS. In addition to elevated double-negative T cells, patients with ALPS frequently have elevated levels of IL-10 and vitamin B12 in the blood, which can be valuable diagnostically in patients with suspected ALPS. Patients with mutations in caspase 8 (CASP8), were previously classified as ALPS but are now considered to have a unique syndrome that may include lymphadenopathy and splenomegaly, but recurrent respiratory tract infections and mucocutaneous herpesvirus infections are prominent, both unusual features in ALPS.

Chapter 64 Acquired Immunodeficiency Syndrome

HUMAN IMMUNODEFICIENCY VIRUS INFECTION AND ACQUIRED IMMUNODEFICIENCY SYNDROME

Human immunodeficiency virus (HIV) infection is a true pandemic, an infection that affects individuals in every country of the world. A diagnosis of acquired immunodeficiency syndrome (AIDS) is made when a person with HIV infection progresses to develop severe immunodeficiency as demonstrated by a CD4 lymphocyte count of less than 200/µl or the development of specific AIDS-associated diseases. The first cases of AIDS were described in 1981 in five young gay men in Los Angeles. Since the beginning of the HIV pandemic, an estimated 70 million people worldwide acquired HIV infection and over half of them died. Currently, an estimated 34 million people are living with HIV infection, with over two thirds of them living in sub-Saharan Africa. There are an estimated 1.1 million people currently living with HIV infection in the United States. The development of effective antiretroviral treatment in 1996 changed the natural history and clinical course of HIV infection dramatically, with remarkable decreases in HIV-associated illnesses and deaths. In parallel, many of the hematologic complications of HIV infection also occur much less commonly today. Cytopenias due to HIV disease or its treatment occurred frequently in the past, but now are uncommon. Coagulation abnormalities occur occasionally. Hematologic malignancies remain an important challenge, even in the setting of effective HIV treatment. This chapter discusses HIV infection and the diagnosis and management of associated hematologic complications. A complete discussion of antiretroviral therapy and opportunistic diseases can be found elsewhere.

Background

HIV-1 was discovered by two independent groups in 1983 to 1984. A related virus, HIV-2, was discovered in 1986, but remains localized to Western Africa and countries with historic ties to Western African countries. HIV is transmitted most commonly worldwide by sexual contact and also by intravenous drug use, transfusion of infected blood or blood products, and perinatally from an infected mother to her child. HIV may be transmitted by infected blood, blood products, bloody fluids, or genital secretions, but not by saliva, sweat, urine, other nonbloody fluids, or feces. In the absence of HIV treatment, the time from initial HIV infection to the development of severe immunodeficiency and AIDS is approximately 10 years. The U.S. Centers for Disease Control and Prevention define AIDS in individuals who are HIV-1 antibody positive with a CD4 cell count <200/µL (regardless of symptoms) or have one of 25 AIDS-defining illnesses, including opportunistic infections and malignancies. Effective antiretroviral therapy changes the natural history of the disease and prevents HIV disease progression and prolongs survival.

Pathophysiology

HIV-1 is a retrovirus with a genome that contains the structural genes gag, pol, and env that code for viral core proteins that control viral replication (e.g., HIV reverse transcriptase, HIV integrase, and HIV protease), as well as the envelope glycoproteins, gp 160, 120, and 41. Additional regulatory genes, rev and tat, code for viral-specific proteins that control viral transcription and processing of viral messenger RNA. Other viral genes mediate infectivity and interactions with the host cell (nef, vif, vpr, vpu).

HIV entry is the first step in HIV-1 infection and consists of three substeps: CD4 receptor binding, co-receptor binding, and membrane fusion. In the first substep, the viral outer membrane glycoprotein, gp120, binds to the CD4 receptor on the surface of the target cell. Cells that express CD4 receptors include the CD4 lymphocyte, macrophages, and dendritic cells. Following binding of gp120 to the CD4 receptor, gp120 undergoes a conformational change and allows binding to a second co-receptor, the chemokine receptor, either CCR5 or CXCR4. Individuals who lack the gene that codes for the
CCRS receptor are relatively resistant to HIV infection; individuals who are heterozygotes for this gene demonstrate a slower progression of HIV disease. Following binding to the co-receptor, gp120 undergoes a second conformational change that allows a second HIV membrane glycoprotein, gp41, to bind and attach to the cell surface and then allows the viral membrane to fuse with the host cell membrane.

After HIV entry, the contents of the viral particle, including viral RNA and viral proteins, are extruded into the cytoplasm of the target cell. Viral RNA is transcribed to complementary viral DNA by the viral specific enzyme, HIV reverse transcriptase. The viral DNA forms a double-stranded complex that migrates to the nucleus of the cell where the viral-specific protein HIV integrase inserts the viral DNA randomly into the host cell genome. An HIV-infected CD4 lymphocyte may enter a latency period that can extend to 70 years, constituting a long-lived viral reservoir. The latently infected cell may be activated, and then genomic DNA along with incorporated viral DNA is transcribed to viral RNA that is translated to viral proteins, including gag and pol gene products that assemble at the surface of the cell and then bud off into new viral particles. Post-budding, precursor viral proteins are cleaved by another viral-specific enzyme, HIV protease, in a step that is required for viral maturation and infectiousness. A single latently infected cell can produce hundreds to thousands of virions. When enough viral particles have budded off from an infected cell, the membrane becomes compromised and cell death occurs.

The characteristic decrease in CD4 lymphocytes over the course of untreated HIV disease occurs from a combination of increased apoptosis and decreased lymphopoiesis, although this is not completely understood. An estimated one million latently infected CD4 lymphocytes exist in an HIV-infected individual with controlled infection on antiretroviral therapy. Although the relative number of latently infected CD4 cells is small, apoptosis may occur in uninfected CD4 cells. Untreated HIV infection also was recognized early on to be associated with immune activation, CD8 cell dysfunction, B-cell dysfunction and impaired antibody production and general immune dysregulation.

Diagnosis

The U.S. Centers for Disease Control currently recommend routine HIV testing for all individuals aged 13 to 64, not based on risk. Standard HIV testing detects HIV-1 antibody by using a screening test, a repeatedly positive enzyme-linked immunosorbent assay (ELISA), followed by a confirmatory test, a Western blot that demonstrates at least two among three major HIV-1-specific bands: p24, gp41, and gp120/160. False-positive ELISA may occur because of the low specificity of the test. False-negative HIV antibody tests can occur due to the window period (4 to 6 weeks), the time between viral infection and the development of the detectable antibody response.

Newer rapid tests use a technology similar to the ELISA to detect HIV antibody in blood or oral fluids and results are available within 20 minutes. Although the rapid test is very specific (>99%) with a high positive predictive value (>90%), a positive rapid test must be confirmed by a conventional confirmatory Western blot. Some rapid tests are now CLIA-waived and may be performed in nonhealth care settings (e.g., street fairs, mobile vans or even self-administered at home) allowing more widespread testing.

Another method of HIV testing detects the virus directly, either the viral p24 antigen or HIV RNA, and reduces the window period: p24 antigen testing was added to the standard HIV antibody ELISA test, the so-called 4th generation ELISA test, to detect HIV infections earlier. Nucleic-acid-based testing has been used both in individual cases and in blood bank screening programs. Using these newer tests along with pre-transfusion screening, the risk of acquiring HIV infection through a blood transfusion in the United States is less than 1 per 1.5 million units transfused and is decreasing.

Clinical Features of Hiv-1 Infection

Acute HIV infection can present as a nonspecific illness characterized by fever, oral ulcers, and maculopapular rash; however, at least 50% of newly infected individuals may be completely asymptomatic. The clinical illness will subside over several weeks and then the patient enters an asymptomatic phase, often with nonspecific generalized lymphadenopathy, that may last years as the CD4 lymphocyte count gradually declines over time. HIV-related diseases occurring at higher CD4 counts (>300/µL) include those caused by more aggressive pathogens (e.g., tuberculosis, herpes zoster, and pneumococcal pneumonia) as well as Kaposi's sarcoma. As the CD4 cell count declines below 300, other HIV-related illnesses also occur, including oral hairy leukoplaikia, oral thrush, and seborrheic dermatitis. As the CD4 cell count declines below 200, the case definition of AIDS is met and AIDS-defining illnesses may also occur including Pneumocystis jiroveci (formerly carinii) pneumonia, central nervous system (CNS) toxoplasmosis, and cryptococcal meningitis. Multiple opportunistic illnesses can occur simultaneously in a single patient.
Hematologic disorders such as leucopenia, anemia, immune and thrombotic thrombocytopenia, bone marrow failure, coagulation disorders including thrombosis, and malignancies all occurred commonly in HIV-infected individuals.\textsuperscript{29, 30} Some of these complications were due to viremia and immune dysregulation, and others were due to toxicity from HIV therapies.\textsuperscript{31} With the development of effective antiretroviral therapy, hematologic disorders and HIV-associated malignancies have decreased markedly.\textsuperscript{32}

**Treatment**

In the 1980s and early 1990s, the average life expectancy of a patient with AIDS was less than 1 year. Today, it is estimated that an individual diagnosed with HIV infection and appropriately managed with antiretroviral treatment will live close to the average life expectancy of the general population.\textsuperscript{33} Antiretroviral therapy changes the natural history of HIV infection by inhibiting viral replication. Currently, there are 27 U.S. Food and Drug Administration-approved unique drugs for the treatment of HIV infection; combination regimens with 3 or more drugs are standard treatment. Current U.S. HIV treatment guidelines recommend starting antiretroviral therapy in all HIV-infected individuals, regardless of symptoms, HIV viral load, or CD4 cell count.\textsuperscript{6} The life cycle of the virus and the specific sites targeted by antiretroviral therapy are shown in Figure 64.1.

The oldest mechanistic classes of drugs are the HIV reverse transcriptase inhibitors of two kinds, the nucleoside analogs and the nonnucleoside analogs. The nucleoside analogs mimic the structures of the four DNA bases and when bound to the active site and incorporated into the elongating viral DNA, result in chain termination: adenosine analogs, didanosine (ddl) and tenofovir (TDF); cytosine analogs, emtricitabine (FTC), lamivudine (3TC), zalcitabine (ddC); guanine analog, abacavir (ABC); and thymidine analogs, stavudine (d4T) and zidovudine (AZT, ZDV). The nonnucleoside analogs also inhibit the HIV reverse transcriptase enzyme, but do so by binding a site remote to the active site and include delavirdine (DLV), efavirenz (EFV), etravirine (ETR), nevirapine (NVP), and rilpivirine (RPV).

In the mid-1990s, the third antiretroviral drug class was approved, the HIV protease inhibitors that target a step late in the viral life cycle. Following budding of the viral particles from the infected cell, viral precursor proteins must be chemically cleaved by the viral-specific enzyme, HIV protease. These compounds were the most potent known against HIV and when used in combination regimens resulted in suppression of HIV RNA levels and dramatic decreases in morbidity and mortality.\textsuperscript{5} The 10 approved protease inhibitors bind in the active site of the protease and block this cleavage: amprenavir (APV) and its prodrug fosamprenavir (FPV), atazanavir (ATV), darunavir (DRV), indinavir (IDV), lopinavir (LPV), nelfinavir (NFV), ritonavir (RTV), saquinavir (SQV), and tipranavir (TPV).

The three newer mechanistic classes of approved HIV drugs are two different HIV entry inhibitors and the HIV integrase inhibitors. The approved chemokine receptor antagonist is maraviroc (MVC) that binds to the host cell CCR5 receptor and prevents viral binding. The approved HIV fusion inhibitor is a small peptide, enfuvirtide (ENF, T-20) that targets the viral glycoprotein gp41 and prevents fusion of the viral and cellular membranes; as a peptide it requires twice-daily subcutaneous dosing and is used uncommonly. Raltegravir (RAL) and elvitegravir (EVG) inhibits the viral-specific enzyme HIV integrase that inserts the viral DNA into the host cell DNA.
The human immunodeficiency virus (HIV) life cycle, deciphered with the help of genomic analyses, is unusually complex in its details, but all viruses undergo the same basic steps to infect cells and reproduce. Points at which antiretrovirals act are marked.

Current treatment guidelines recommend four preferred combination antiretroviral regimens on the basis of potency, tolerability, and convenience: (1) tenofovir/emtricitabine/efavirenz (co-formulated as a single pill taken once daily); (2) tenofovir/emtricitabine (co-formulated) + atazanavir and ritonavir (given as a low-dose pharmacologic booster; 3 pills once daily); (3) tenofovir/emtricitabine (co-formulated) + darunavir and ritonavir (booster; 3 pills once daily); and (4) tenofovir/emtricitabine (co-formulated) + raltegravir (3 pills divided twice daily). The goal of current HIV treatment is maximal virologic suppression; current virologic suppression rates on initial therapy regimens approach 90%. CD4 cell counts typically increase 100/µL over baseline in the first weeks or months following initiation of therapy and then continue to increase at a slower rate. The reconstituted CD4 cells generally are of the memory type (CD45RO⁺ or CD34RA⁺), with naïve cells increasing more slowly; thymic function also improves. Immune reconstitution may result in IRIS, the immune-related inflammatory syndrome that is usually managed symptomatically. Appropriate increases in CD4 cell counts allow discontinuation of opportunistic maintenance therapy and prophylaxes. Specific immune-based
therapies, including interleukin-2, have failed to demonstrate additional clinical benefits and are not recommended currently.\textsuperscript{36}

An HIV-infected individual who is stable taking antiretroviral therapy will typically see the treating physician every 3 to 6 months to check for side effects and monitor the HIV RNA and CD4 cell count.\textsuperscript{6} In the case of virologic failure, drug resistance testing is performed and a new regimen selected on the basis of treatment history, drug resistance testing results, and available drug options. The goal is to construct a regimen with 2 to 3 fully active drugs and this will result in resuppression of HIV RNA in the majority of patients. HIV therapy currently is lifelong. Treatment interruptions are associated with clinical events\textsuperscript{37} and should be avoided.

Several ongoing challenges remain in the management of HIV disease. Despite suppression of virologic replication, some patients experience ongoing inflammation and immune activation and this has been linked to nontraditional HIV illnesses such as cardiac, hepatic, renal, neurologic, and non-AIDS malignancies. In addition, despite dramatic improvements in life expectancy, cure of HIV disease remains elusive. The unique case of a man with HIV disease virologically controlled on antiretroviral therapy who developed acute myelogenous leukemia necessitating totalbody irradiation, cytotoxic chemotherapy, and bone marrow transplant from a donor with a deletion in the gene coding for the CCR5-receptor who ultimately experienced a course complicated by rejection and a second transplant is thought to be the only patient cured successfully of HIV disease.\textsuperscript{38} Cure, or complete eradication of HIV, remains challenging because of the long-lived latently infected CD4 cell reservoir; much current research is focused on this goal.\textsuperscript{39}

HEMATOLOGIC COMPLICATIONS OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Anemia

Anemia is the most frequent cytopenia observed in HIV-1 infection. Striking anemia with transfusion dependence was common early in the epidemic when high doses of zidovudine (ZDV) were in use, but severe depression of hemoglobin levels are now rarely observed, except in patients with advanced disease.\textsuperscript{40} In several large multicenter studies, persistent anemia was associated with shorter survival, independent of the degree of immunosuppression.\textsuperscript{41, 42}

As in other persons, anemia occurs due to one of three major factors: either ineffective hematopoiesis; blood loss due to involvement of the intestines by infection such as cytomegalovirus (CMV) or Kaposis’s sarcoma; or red blood cell destruction.

Red blood cell production can be affected by HIV itself due to cytokines that interfere with hematopoesis,\textsuperscript{43, 44, 45} highly active antiretroviral therapy (HAART) and medications used to treat HIV-associated infections (Table 64.1 including high-dose trimethoprim-sulfamethoxazole (TMP-SMX) for P. carinii pneumonia and ganciclovir for CMV), HIV-associated cancers such as lymphomatous infiltration of the marrow, low erythropoietin, or HIV-associated hypogonadism.\textsuperscript{46}

The Effect of HAART on Anemia

Nucleoside analogs other than ZDV are not associated with anemia. Zidovudine is commonly associated with marrow toxicity, particularly with long-term administration. Use of lower ZDV doses in combination with other nonmyelosuppressive antiviral drugs (such as the protease inhibitors or other nucleoside analogs) has significantly decreased the frequency of anemia, although patients with advanced disease on doses of ZDV of <500 mg/day still demonstrate significantly decreased hemoglobin levels when compared to similarly immunosuppressed HIV-infected patients not taking the drug.\textsuperscript{47} Although the mechanism responsible for ZDV-associated anemia, inhibition of thymidine kinase, and DNA chain termination should theoretically also affect cells of other lineages, neutropenia is less frequent a toxicity and thrombocytopenia is very uncommon. In contradistinction to zidovudine, protease inhibitors, such as indinavir, ritonavir, crixivan, and nelfinavir, alone or in combination with ZDV or other nucleoside analogs, have little or no effect on hematopoiesis.\textsuperscript{51, 48} It is important to note that HAART itself improves anemia as shown in a single center retrospective series in the HAART era. HAART was associated with hemoglobin levels >140 g/L in 42% of patients, irrespective of use of zidovudine as part of HAART regimen, compared with 31% of patients who did not use HAART.\textsuperscript{49}

Treatable causes of anemia include nutritional/vitamin deficiency, gastrointestinal losses, parvovirus B19 infection, HIV related kidney disease, and low erythropoietin levels independent of normal renal function. In HIV infection, erythropoietin levels are low in some patients, in part because tumor necrosis factor-α (TNF-α) acts to block erythropoietin release in response to low hemoglobin levels. Patients with low erythropoietin levels respond better to its administration than do patients with normal or elevated levels of the hormone. In one meta-analysis, patients with erythropoietin levels below 500 IU/L demonstrated significant increases in hemoglobin levels, decreases in transfusion requirements, and improvement in quality of life, whereas replacement was ineffective in patients with high erythropoietin levels.

Some patients with HIV infection have significant anemia, requiring frequent transfusion. Clinical and experimental evidence suggests transfusion may be associated with substantial morbidity in HIV-infected patients. In one study, transfused patients with advanced disease had an increased incidence of CMV infection and death. Laboratory data suggest transfusion may be associated with HIV viral activation. Allogeneic lymphocytes present in transfused blood components activate viral production by HIV-infected lymphocytes in vitro. When quantitative polymerase chain reaction (PCR) was used to measure circulating HIV, viral load was increased in HIV-infected patients 5 days after transfusion. However when leuko-depleted blood components were used, no significant differences in viremia or infectious complications occurred.

Red Blood Cell Destruction

Red blood cells can be destroyed in the setting of HIV infection through a variety of mechanisms. This includes autoimmune disease, hemophagocytic syndrome, disseminated intravascular coagulation typically seen with infection or cancer, sulfa use in the setting of 6-GPD deficiency, or thrombotic thrombocytopenic purpura (TTP) (dealt with separately below). Drugs can also cause hemolysis.

Parvovirus is a rare, but treatable cause of anemia. Parvovirus affects erythroid lineage cells. In immunocompetent patients this is a self-limited infection, but is serious in patients who cannot clear the infection, or have other hemolytic problems. For parvovirus infection, commercial immune globulin infusion (400 mg/kg/day for 5 to 10 days) is almost always associated with marked improvement in hemoglobin levels with resolution of anemia. HIV-infected patients frequently develop repeated episodes of B19 infection and need repeated treatments with intravenous immune globulin.

Thrombocytopenia
Thrombocytopenia occurs in the setting of HIV infection due to decreased production, increased destruction, or splenic sequestration secondary to other causes such as lymphoma or hepatitis C. Although mild to moderate thrombocytopenia is common in patients with HIV, it is rarely associated with bleeding. Thrombocytopenia is generally associated with decreased platelet survival, except in patients with advanced disease where bone marrow failure is more prominent. Opportunistic infection, splenomegaly, and fever all decrease platelet survival.

Autoimmune thrombocytopenia (ITP) is a feature of HIV infection and is a diagnosis of exclusion. Notably, patients can present in advance of other symptoms of HIV. Consequently, HIV should be ruled out in new cases of ITP. CD4+ lymphocyte counts in reported series of patients with HIV-ITP have averaged between 0.3 and 0.6 \( \times 10^9/L \).

Although platelet-associated antibodies increase in prevalence with HIV disease progression, it is not clear if they play a major role in most patients. Technical difficulties in detecting platelet-associated antibody have led to a very high false-positive rate. Furthermore, for any condition (including sepsis and TTP) associated with platelet injury, antibody can be detected on the platelet surface. Specific platelet-associated antibody has nonetheless been carefully characterized in a limited number of patients. One study demonstrated that platelet-associated immune complexes are made up of antiplatelet integrin, glycoprotein IIIa (β3), antibody (Ab), and its anti-idiotypic blocking Ab. Some of the antibodies also bound epitopes with homology to HIV-1 proteins nef, gag, env, and pol, suggesting molecular mimicry. The presence of this Ab was associated with thrombocytopenia and produced thrombocytopenia when infused into mice. The associated platelet fragmentation was due to generation of the membrane-damaging peroxide and other reactive oxygen species. Antibodies to a cleavage product of talin, which can be generated by platelet activation or exposure to HIV-1 protease, have also been characterized. These may result from an immune response to talin-H, a neoantigen that may have been created by platelet fragmentation.

Defective megakaryocytopoiesis may also contribute to thrombocytopenia, particularly in patients with advanced disease. Megakaryocytes can be infected with certain strains of HIV, some of which can be cytopathic for the megakaryocytes. In addition, megakaryocytes arising from HIV-infected CD34+ progenitor cells are defective in their ability to produce platelets.

Treatment

Generally, patients with modest thrombocytopenia (platelet count >50 \( \times 10^9/L \)) require no treatment. For others with clinically significant thrombocytopenia, short-term steroids produce rapid responses in 60% to 80% of patients. However, steroids are immunosuppressive and are associated with long-term infectious complications and can accelerate the development of Kaposi's sarcoma. HIV-specific antiretroviral therapy will result in improvements of platelet counts in most patients. Although most of the original work was done with ZDV, other antiretrovirals are effective. Both antiretroviral agents and steroids improve thrombocytopenia by increasing platelet production, without significantly affecting platelet survival. Splenectomy will increase platelet counts in those not responding to antiretroviral therapy and does not appear to accelerate the underlying HIV disease. Intravenous immune globulin also is effective but its high cost, limited availability, and short duration of action make this a less attractive treatment. Anti-Rh immune globulin has the advantages of wide availability and cheaper cost, but is also limited by its short duration of action and is associated with a mild hemolysis which can be clinically problematic in patients with pre-existing anemia, requiring transfusion prior to administration of anti-Rh immune globulin. Vincristine is effective when given monthly, although its administration is complicated by neuropathy. IL-11, a cytokine that promotes megakaryocyte maturation, is licensed for treatment of chemotherapy-related thrombocytopenia, but no studies have reported efficacy in HIV-infected patients. Rituximab is effective in some patients with idiopathic thrombocytopenic purpura (ITP) without HIV but has not been studied extensively in patients with HIV infection for this indication. Three newer treatments for ITP in the general population include the anti-B cell antibody rituximab, effective in 60% of patients, and the thrombopoietin mimetics, romiplostim and eltrombopag, each associated with a 60% to 85% response. Remarkably, these drugs have not been systematically studied in HIV-associated ITP.

P.1362

Neutropenia

Mild neutropenia is relatively common in patients with HIV infection. Although generally not of clinical significance, a deficiency in bone marrow reserve may become clinically apparent when administration of cytotoxic chemotherapy or other marrowsuppressive drugs becomes necessary. In fact it is generally held that most cytotoxic chemotherapy requires prophylactic use of hematopoietic growth factors. Antineutrophil antibodies can frequently be seen, but their presence
does not correlate with the degree of neutropenia. Progenitor cell numbers are generally normal except in patients with advanced disease when they are modestly decreased. Parenteral treatment with ganciclovir (GCV) or cytotoxic chemotherapy results in leukopenia in the majority of patients, frequently necessitating dose reduction and cytokine treatment.

Treatment

Neutropenic (absolute neutrophil count, <1.0 × 10^9/L) HIV-positive patients may experience increased frequency of significant bacterial infections. In a case-controlled study, Tumbarello et al. compared the neutrophil counts of groups of HIV-infected patients with and without bacteremia. An absolute neutrophil count of <1.0 × 10^9/L as present in 38% of bacteremic patients was compared with 19% of asymptomatic patients. A matched cohort study found the frequency of bacteremia increased in neutropenic patients to 12.60 events per 100 patient months compared with 0.87 events per 100 patient months in the nonneutropenia controls. In another study of 1,645 patients with an absolute neutrophil count of <0.5 × 10^9/L the risk of Gramnegative infection increased eightfold.

A number of studies have looked at the effect of recombinant growth factors on the incidence of infection and number of hospitalizations. Granulocyte colony-stimulating factor (G-CSF) enhances the proliferation and differentiation of neutrophils and improves neutrophil function, whereas granulocyte-macrophage colony-stimulating factor (GM-CSF) stimulates the proliferation and differentiation of a variety of myeloid progenitor cells and inhibits migration of neutrophils, enhancing the function of mature neutrophils and macrophages. G-CSF is the most widely used hematopoietic growth factor in HIV-infected patients, has fewer side effects, and increases the neutrophil count more rapidly. Although GM-CSF has been associated with an increase in HIV-1 replication in vitro, no consistent observation of acceleration of disease progression or increase in p24 antigen levels in patients receiving the drug has been demonstrated. GCSF is primarily used to increase the tolerance of patients undergoing chemotherapy.

HIV-infected patients can also have a number of defects in neutrophil function. These include reduced L-selectin shedding and decreased H2O2 production as well as defects in leukocyte migration, chemotaxis, and chemiluminescence during phagocytosis. These defects were more prominent in patients with advanced disease. G-CSF and GM-CSF both improve leukocyte function in vitro. A number of studies have looked at potential benefits of these cytokines in animal models of immunosuppression. In a murine model of Pneumocystis jiroveci pneumonia, CD4-depleted immunosuppressed mice that received G-CSF after experimental pulmonary infection with P. jiroveci demonstrated improved survival when compared with control mice receiving placebo. Similar benefits were demonstrated using mouse models of disseminated Mycobacterium avium infection, systemic candidiasis, and streptococcal pneumonia. No clinical study using either G-CSF or GM-CSF to enhance leukocyte function has been performed.

Lymphopenia

Increases in both CD4 and CD8 cell death and impairment in function are the sine qua non of HIV infection. IL-2 partially corrects the impaired lymphocyte proliferation and cytotoxicity seen in HIV infection in vitro. It also can partially block the enhanced tendency of lymphocytes obtained from HIV-infected patients to undergo programmed cell death (apoptosis). In phase I trials of IL-2 in HIV-infected patients, it increased CD4 cell number and improved lymphocyte function. The development of a longacting polyethylene glycol-modified IL-2, which increases the half-life by 10- to 15-fold, allows for intermittent administration of the drug. Administration of doses of 1 to 5 million IU/m², two to three times weekly, resulted in modest but sustained increases in CD4 counts and improvement in natural killer activity in a patient with CD4 counts >0.4 × 10^9/L in 3 to 6 months. Fever, rash, and capillary leak are the most common toxicities. More recently, administration of very high doses of IL-2 (7.5 million IU twice daily to patients with early HIV infection) resulted in substantial increases in CD4 counts, compared with those seen in the group administered lower doses (1.5 million IU twice daily). Of greater importance is the suggestion that intermittent administration of IL-2 in combination with HAART may lead to reduction in CD4 T-lymphocyte cells that contain replication-competent HIV. None of these approaches is currently standard of care.

Thrombotic Thrombocytopenic Purpura

TTP is more common among patients with HIV infection. HIV-1 infection has been reported to account for up to 30% of TTP/hemolytic-uremic syndrome. The risk of microangopathy has declined significantly after institution of HAART for unclear reasons. Although no controlled studies comparing HIV-related TTP with classic TTP have been conducted, HIV-related TTP is generally thought to be associated with a milder course and a better response to therapy than classic TTP.

A number of different possible pathophysiologic mechanisms have been proposed. HIV can infect endothelial cells, and viral p24 antigen has been detected by immunohistochemical stain in splenic endothelial cells, spinal cord specimens, and bone marrow microvascular endothelial cells. Whether infection results in vascular dysfunction has not been clearly
patients supported growth of normal CD34+ bone marrow progenitor cells. In another study, stroma obtained from HIV-infected patients may be infected by the virus, demonstrating the importance of stromal infection in causing dysregulation of marrow stromal function in HIV infection. Results have implied that direct infection was not necessary for marrow suppression.

Thus, it appears that although some committed and long-term colony-initiating cells (i.e., the secondary colonies generated from clonogenic cells harvested from stroma). It appears that although some committed and long-term colony-initiating cells (i.e., the secondary colonies generated from clonogenic cells harvested from stroma).

The effects of HIV-1 on colony formation have been studied, either using bone marrow cells derived from HIV-1-infected patients or after in vitro infection of hematopoietic cells from bone marrow of normal donors. Results have been surprisingly divergent. Although the growth potential of committed bone marrow progenitor cells in methylcellulose cultures after challenge with HIV-1 appears to be diminished, normal growth frequently has also been reported. Similar disparity exists in the results of studies performed with patient bone marrow. Such differences may be related to techniques in assaying colony growth (total bone marrow vs. purified CD34+ cells), culture conditions (use of specific cytokines or growth factors), or patient selection. In some reports, inhibition of colony formation by virus was only observed in cultures of total bone marrow cells and not with isolated CD34+ cells. Of interest is one report of abnormal progenitor cell function in HIV-negative infants born to infected mothers, implying that direct infection was not necessary for marrow suppression.

Marrow stromal function has been examined in patients with HIV infection. Stromal cells from some HIV-1-infected patients may be infected by the virus, demonstrating the importance of stromal infection in causing dysregulation of hematopoiesis. In one study, decreased colony formation has been observed when stroma infected in vitro was used to support growth of normal uninfected bone marrow progenitor cells. In another study, stroma obtained from HIV-infected patients supported growth of normal CD34+ cells equally as well as stroma obtained from normal uninfected controls.
Although the stem cell compartment appears to be relatively well preserved early in the disease, in patients with low CD4 counts and history of OIs, there is a modest reduction of longterm colony-initiating cell numbers. However, the long-term colony-initiating cell numbers were far better preserved in this population than in patients with aplastic anemia with similar blood counts, implying that OIs; pharmacotherapy with antiparasitic, antimicrobial, antiviral, or cytotoxic agents; vitamin deficiencies; or poorly understood virally mediated immunomodulatory changes were the major contributors to bone marrow failure in patients with advanced HIV disease.

Inconsistencies in the results of experiments attempting to demonstrate the role of direct infection of HIV-1 on hematopoiesis have stimulated further search for pathophysiologic mechanisms of bone marrow suppression. Several cytokines that are released during the course of HIV-1 infection are potent inhibitors of hematopoiesis. Not only native virus and productive infection, but also viral products, such as gp120, gp160, and viral tat proteins, induce the secretion of an array of cytokines, including TNF-α, lymphotoksin-β (TNF-β), and IL-6. Perhaps the most prominent cytokine implicated in an array of pathophysiologic reactions in AIDS is TNF-α (or cachexin). In addition to its effect on body metabolism and the immune system, TNF-α has inhibitory effects on hematopoiesis. High levels of interferon-γ (IFN-γ) were not only associated with a poor prognosis in HIV-1 infection, but also correlated with the degree of anemia. Although disordered cytokine production by both lymphoid tissue and bone marrow clearly occurs in HIV-1 infection, it is difficult to determine its ultimate role in suppression of hematopoiesis. Many inhibitory cytokines are produced in greatest quantities early in the course of HIV-1 infection when marrow suppression is least, and their levels decline as the disease progresses (when marrow suppression becomes most marked). In addition, increased levels of stimulatory cytokines have been observed in HIV-1 infection, and many cytokines never reach significant levels in the circulation. Local production of growth factors in bone marrow may be more important than systemically secreted factors. In support of this hypothesis, one study of genetically engineered stromal cells, designed to produce low levels of IFN-γ constitutively, showed significant suppression of normal hematopoietic colony growth on IFN-γ stroma, which could only be replicated by addition of large amounts of exogenous IFN-γ to marrow grown on normal stroma.

Apoptosis of hematopoietic progenitor cells through the Fas-L/Fas-R pathway is a mechanism by which activated T-cells can kill virus-infected cells. It is likely that Fas-L and other cytokine products of activated T-cells contribute to the hematopoietic inhibition seen in HIV-1 infection. Increased levels of Fas-L have been reported in patients with AIDS, and triggering of Fas-R on hematopoietic cells results in apoptosis.

Bone Marrow Examination in Human Immunodeficiency Virus 1 Infection

The majority of bone marrow samples from HIV-1-infected patients will exhibit morphologic abnormalities, but most are nonspecific except in OI, in which the bone marrow examination provides valuable diagnostic information. Therefore, the bone marrow examination rarely yields substantial clinical information except in the diagnosis of concurrent M. avium-intracellulare, tuberculosis, or fungal infection or as part of staging for malignancy.

The histopathologic findings in the bone marrow of HIV-1-infected patients are varied. In one large study of 216 bone marrow examinations performed in 178 HIV-1-infected patients for evaluation of cytopenia, 69% of patients exhibited hypercellular marrow, 69% showed myelodysplastic changes, and 20% showed significant fibrosis; only 5% of the biopsies were hypocellular. Granulomas were found in 13% and lymphoid aggregates in 36% (but in other studies, in up to 50%) of specimens. Higher numbers of plasma cells and elevated numbers of eosinophils were also present, especially in conjunction with increased reticulum. Hyperplasia involving the granulocytic and erythrocytic lineages has been most commonly reported; the myeloid-to-erythroid ratio has varied from 2:1 to 5:1.

P.1364
A number of retrospective epidemiologic studies have found that the incidence of thrombosis in HIV-infected patients was increased two- to tenfold over what would be expected in a healthy control population of the same age. However, except for isolated cases of protein S deficiency, no study has compared these patients to equally sick uninfected patients whose immobility, lymphedema, and hypoalbuminemia predispose them to hypercoagulability. Patients with HIV are more likely to develop antiphospholipid antibodies such as lupus anticoagulant (found in 1% of patients) and antiphosphatidylcholine and anticardiolipin antibodies (found in about 50% of patients with HIV infection), however, many of these studies were performed before HAART became standard of care. Apart from diagnostic problems related to a falsely elevated partial prothrombin time, these antibodies do not appear to be associated with an increased frequency of thrombosis, as they are in uninfected patients.

Increased levels of complement-binding protein 4, which attaches to protein S and renders the protein inactive, can be detected in as many as 27% to 73% of patients. These patients demonstrate decreased functional protein S when a functional assay is used to measure activity. The risk of thrombosis in these patients is substantially increased. No clear guidelines are available for treatment or other protein S-deficient patients, but most hematologists recommend anticoagulation for an undefined period of time for those with a history of unprovoked thrombosis.

ACQUIRED IMMUNODEFICIENCY SYNDROME-RELATED MALIGNANCIES

Cancer is the leading cause of death for HIV-1-infected persons on HAART. Twenty-five to forty percent of HIV-positive patients will develop a malignancy. Although Kaposi sarcoma, aggressive B-cell lymphomas, and cervical cancer are said to be AIDS defining when occurring in the setting of HIV infection and occur more frequently in HIV infection, death from non-AIDS-defining cancers is more common. The development of malignancies is related to a number of factors, including immunosuppression and concurrent infections with other viruses such as human herpes virus 8 (HHV8) and Epstein-Barr virus (EBV), or the human papillomavirus, which foster malignant transformation. These viruses carry oncogenic proteins and cytokines that contribute to malignant pathogenesis. Additionally, HIV infection reduces the ability to clear the viral infection. The SMART study demonstrated that HAART interruptions in so-called drug conservation strategies increase the risk of cancer sixfold.

Although the incidence of KS and certain lymphomas has decreased after HAART was introduced, the frequency of other tumors such as cervical cancer has undergone little change. CNS lymphoma, although once accounting for 18% of AIDS-related lymphomas, now is extremely rare. Several new drugs and therapies have been developed for KS and AIDS-related lymphomas, and these treatments, plus the development of HAART, have contributed to improvements in morbidity and mortality. Given the introduction of HAART and our increased ability to treat infections effectively, the life span of patients with HIV has increased, eventually leading to substantial increases in individuals living with HIV-1. One analysis projected a median life expectancy of 75 years assuming a high rate of HIV diagnosis (median CD4 cell count at diagnosis, 0.432 × 10^9/L), and 71.5 years with a low diagnosis rate (diagnosis only when symptomatic, median CD4 cell count 0.14 × 10^9/L. Cumulative risks of death by 5 and 10 years after infection were 2.3% and 5.2%, respectively. This makes treating malignancies more attractive than in the pre-HAART era. Although these malignancies also occur in the HIV-uninfected population, their presentation, as well as their appropriate treatment, is quite different in the HIV-infected patient.

ACQUIRED IMMUNODEFICIENCY SYNDROME-RELATED LYMPHOMA

Non-Hodgkin lymphoma (NHL) and Hodgkin lymphoma (HL) occur with increased frequency in patients infected with HIV. Approximately 10% of HIV-positive people will develop NHL, and although the incidence has greatly reduced during HAART, it is still increased 25- to 150-fold compared to the general population. These recent studies also demonstrate the duration and depth of the CD4 nadir and the duration of viremia increase the incidence of NHL. Decreased immune surveillance, B-cell dysregulation and, in certain subtypes, infections with HHV8 and EBV, are also involved in the pathophysiology of the disorder.

A number of changes have occurred in the HIV-related lymphomas since widespread institution of HAART. The overall incidence of HIV-associated lymphomas has declined for NHL. This decrease has primarily affected lymphomas occurring at low CD4 counts, whereas NHL occurring at higher CD4 counts has been relatively unaffected. Among patients with systemic, AIDS-related NHL, there has been decreased high-grade histology and improved survival. Three types of lymphoma are now recognized as AIDS-defining by the CDC: Burkitt lymphoma, immunoblastic lymphoma which is a subtype of diffuse large B-cell lymphoma, and primary CNS lymphoma. The World Health Organization (WHO) more recently provided a classification system for the HIV-associated lymphomas (Table 64.2; Fig. 64.2). The frequency of NHL increases with the degree of immunosuppression, particularly for CNS lymphoma. Thus CNS lymphoma is rarely seen in developed countries where HAART is available, except in socioeconomic sectors where standard of care HIV therapy is not ubiquitous. In addition, patients with poorer virologic control on HAART suffer a significantly higher incidence of
lymphoma and worse outcomes following therapy. Some studies have suggested genetic factors play a role in the development of NHL. One study demonstrated that HIV-infected patients who are heterozygous for the CCR5D32 deletion are less likely to develop lymphoma, whereas those with stromal-cell-derived factor-1 mutations are more likely to develop lymphoma.

For patients receiving combination chemotherapy, the optimal timing of HAART with combination chemotherapy is controversial. Many oncologists continue antiretrovirals during chemotherapy, and some temporarily discontinue them, citing fears of drug-drug interactions and increased toxicities. The latter stance has been challenged by six randomized studies in infections showing immune reconstitution occurring within the first month of HAART leading to a decrease in infection mortality. This suggests that HAART discontinuation or deferment of initiation after a concurrent HIV and lymphoma diagnosis could be detrimental. Nonetheless, in a retrospective Italian study comparing toxicities between patients receiving CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) plus HAART versus CHOP or a comparable regimen without HAART, the group receiving HAART experienced greater neurotoxicity and anemia but a decreased frequency of infection. The differences in favor of HAART may have been due to improvements in supportive care gained during the 1990s. Moreover, with an expansion of the panoply of HAART medications, it is now possible to avoid specific HAART components to minimize drug-drug interaction. However, no controlled clinical trial has yet been performed to assess the contribution of continuing HAART therapy to improvement in viral replication and lymphoma control. It is unlikely that such a study will be conducted.
FIGURE 64.2. Human immunodeficiency virus (HIV)-associated lymphomas. A: HIV-associated Burkitt lymphoma. Tumor cells show plasmacytoid differentiation, which is often associated with positivity for HIV. B: Diffuse large B-cell lymphoma, immunoblastic variants. Lymphomas with this morphology often present in advanced AIDS. C: Primary effusion lymphoma, positive for human herpes virus 8/Kaposi sarcoma herpes virus. (Contributed by Dr. Elaine Jaffe, Chief Hematopathology Section and Acting Chief Laboratory of Pathology, National Cancer Institute.)

The three main pathologic types of HIV-NHL are the Burkitt and those with Burkitt features, diffuse large B-cell lymphomas, and primary effusion lymphomas (PELs). These differ in their clinical presentations, in their underlying pathogenesis, and in their response to therapy. The majority of HIV-related lymphomas are of B-cell origin. T-cell lymphomas are rare, as are PELs, which lack B-, T-, and hematopoietic cell markers. Burkitt and lymphomas with Burkitt features usually present with widespread disease and have a risk of CNS involvement. Other less common lymphomas include polymorphic lymphoproliferative disorders resembling post-transplant-associated lymphoproliferative disease and lymphomatoid granulomatosis.

The role of viruses in the pathophysiology of HIV-related lymphomas is dependent on subtype. For example, CNS lymphomas are virtually always associated with EBV infection, and PEL is associated with HHV8 infection. EBV encodes for a number of cytokines promoting cell growth. AIDS-Burkitt is variably associated with EBV, but also contains activating mutations in the cMYC proto-oncogene, frequent inactivation of p53, as well as point mutations in BCL-6. One study showed that loss of EBV-specific CD8+ T-cells in subjects progressing to EBV-related NHL correlated with loss of CD4+ T cells and that these cells were better preserved in equally immunocompromised patients not developing lymphoma.

Patients with HIV-NHL frequently present with advanced stage III or IV disease. The majority will present with a rapidly growing mass or the development of systemic B symptoms (i.e., fever, night sweats, and unexplained weight loss). The clinical presentation is dependent on the site of involvement. Extranodal involvement including the bone marrow (25% to 40%), gastrointestinal tract (26%), and CNS (17% to 32%) is common.

Leptomeningeal disease may be present and detected by flow cytometry only at a higher frequency than the immunocompetent population, where it is rare, with a surprising 22% among 51 newly diagnosed patients in one study in which 11 (22%) were detected by flow cytometry and only 1 by cytology. Involvement of the small bowel and rectum is also prevalent, particularly in those with large cell histology. Several prognostic factors predict response to therapy and overall survival including CD4 count, Karnofsky performance, age, and LDH level.

Clinical Manifestations

Therapy

Initially prior to HAART, patients with lymphoma were more debilitated and experienced significant toxicity associated with chemotherapy. Multiple trials focused on reduced-intensity chemotherapy, which generally resulted in shorter remission durations. Treatment of HIV lymphoma has changed radically after the institution of HAART and remission has been reported after institution of HAART alone. However, this is not the standard of care and most trials now focus on more intensive therapy.

The French Italian Cooperative Group recently tailored treatment to the level of pre-existing immunosuppression, examining low- versus high-dose therapy in patients with moderate and severe immunosuppression. Patients with CD4 counts over 0.2 × 10^9/L received a dose-intensified regimen of ACVB (doxorubicin, cyclophosphamide, vindesine, bleomycin, methylprednisolone, methotrexate) versus standard CHOP because of evidence from previous trials of NHL unrelated to HIV showing that patients receiving an intensified regimen had more durable remissions. Both groups of HIV-infected patients in this trial had comparable responses, but toxicity was better in the CHOP arm. Patients with one adverse prognostic factor were randomly assigned to CHOP or dose-reduced CHOP. High-risk patients were treated with doxoruced CHOP or vincristine plus prednisone. In the intermediaterisk group, standard-dose CHOP was superior to dose-reduced CHOP, but overall survival remained similar in the two groups. This risk-adapted approach has not been adapted universally due to the results of other trials.

A number of regimens administering chemotherapy by slow infusion appear effective without causing significant toxicity. Patients receiving cyclophosphamide, doxorubicin, and etoposide (CDE) as an infusion had median survivals of 18.4 months. A multicenter phase II trial of infusional CDE in 48 systemic NHL patients not on HAART had only a 46% median survival at 8 months. This infusion regimen has been combined with HAART with few problems other than increased mucositis in the HAART group.

EPOCH (etoposide, prednisone vincristine, cyclophosphamide, and doxorubicin-cyclophosphamide dose adjusted to CD4 count) has produced responses of 79% in a preliminary study. Antiviral therapy was suspended during treatment in this protocol, for fear of concurrent toxicities, leading to transient increases in viral load and decreases in CD4 counts. A multicenter trial by the AIDS malignancy consortium investigated EPOCH with concurrent versus sequential rituximab and found the CR rate to be higher in the concurrent arm. The vast majority of patients remained on HAART during treatment, challenging the earlier assertion that HAART must be suspended.

Anti-CD20 monoclonal antibody (rituximab) has become a ubiquitous component of B-cell NHL in the general population. Preliminary studies show that it can be added to EPOCH without evidence of added toxicity. Rituximab administered with CDE and concomitant HAART has yielded 2-year survivals of 80%. However, a randomized phase III study of CHOP with or without rituximab failed to demonstrate any added benefit of rituximab and suggested increased toxicity in those with a CD4 count less than 0.05 × 10^9/L. In contrast, another study, rituximab adjunction to CHOP produced a complete response rate of 77% and a 2-year survival rate of 75% in patients with AIDS-related NHL, without increasing the risk of life-threatening infections. The current standard of care is to use rituximab with attention to infection including hematopoietic growth factors and antibiotic prophylaxis in those at highest risk.

Primary Central Nervous System Lymphoma

Primary CNS NHL (PCNSL) typically affects the most immunocompromised with CD4 lymphocyte counts <0.05 × 10^9/L and now is rarely seen in patients receiving HAART. Most are diffuse large B-cell lymphomas and are multifocal (reviewed in Ref. 168). Confusion, memory loss, lethargy, and focal neurologic findings are the most frequent presenting symptoms and signs. The response to therapy in patients with primary CNS lymphoma has been very disappointing. Palliation with steroids and whole-brain radiation (3,000 to 5,400 Gy) has response rates of 75% and treatment with high-dose methotrexate has reportedly given similar results, but the response duration is short with a median survival of 2 to 4 months regardless of CD4 count. A pilot study using only antivirals and immunomodulation was very promising with two of five patients treated remaining in complete remission at 28 months and 52 months, respectively, but closed early due to low accrual.

Primary Effusion Lymphoma
PEL comprises approximately 1% to 5% of AIDS-related lymphoma cases. Clinically, the disease is characterized by malignant effusions with the absence of nodal disease. Diagnosis is made by pericardiocentesis, thoracentesis, or paracentesis with cytologic examination of the fluid and immunohistochemical evaluation. PEL cells have pleomorphic morphology and lack expression of B-cell-associated genes, including surface immunoglobulin, although immunoglobulin gene rearrangements are usually positive, indicating a clonal B-cell origin. The gene expression profile of PEL cells suggests plasmablastic derivation.\textsuperscript{170} The malignant clone is almost always found to be infected with HHV8, whereas concurrent infection with EBV is frequent. PEL may extend into tissues underlying the serous cavities, including the omentum, lymph nodes, mediastinum, and lung. In one study of 277 NHL patients, PEL was diagnosed in 11 patients (4%). Patients treated with doxorubicin, vincristine, and prednisone achieved a complete response rate of 42%. However, median survival time was only 6 months.\textsuperscript{171} The decision to undergo therapy should be based on the functional status of the patient, the degree of immunosuppression, and the likelihood that the quality of life would be improved. A report of antiviral therapy alone leading to sustained remission has been documented.\textsuperscript{172}

Burkitt Lymphoma

Burkitt lymphoma is highly overrepresented in patients living with HIV. Before the era of HAART, treatments were curtailed due to fears of prolonged and profound neutropenia associated with the intensive therapies that had become standard in the general population. One small retrospective\textsuperscript{173} and one small prospective study\textsuperscript{174} initially challenged the prevailing dogma and found that intensive therapies such as CODOX-M/IVAC or hyper-CVAD with methotrexate and high-dose cytarabine could be safely given with HAART with success rates of 80% to 90%. More recent publications have also suggested the same.\textsuperscript{175, 176} Another retrospective study has supported the use of R-EPOCH as more efficacious and less toxic.\textsuperscript{177} A recently completed clinical trial by the AIDS Malignancy Consortium was designed to reduce toxicity while maintaining efficacy, and may confirm these results prospectively in a multicenter setting.\textsuperscript{178} The NCI has also reported early results with EPOCH-rituximab in a prospective study.\textsuperscript{179}

Plasmablastic Lymphoma

Plasmablastic lymphoma is a very rare CD20 negative variant of HIV-associated NHL. It was originally described as almost exclusively associated with HIV and nearly always fatal in the pre-HAART era.\textsuperscript{180} The sine qua non of stage I disease is a mass in the jaw, but disseminated disease including numerous bone lesions is common. A retrospective study suggested curability in the HAART era in both HIV-positive and HIV-negative patients.\textsuperscript{181} Optimal management will be difficult to define due to the rarity of the disease.

Hodgkin Lymphoma

Although HL is not considered an AIDS-defining illness, a marked increase is seen in HIV.\textsuperscript{182, 183, 184} Although risk of NHL has decreased with better therapy, the incidence of HL among patients with HIV infection has increased.\textsuperscript{182, 185} Unlike HL in HIV-uninfected patients, B symptoms are almost often present; mixed cellularity HL is the predominant pathologic subtype of disease; and advanced, extranodal disease is expected in the majority. One study showed 70% to 90% of patients present with B symptoms, and 74% to 96% of patients have advanced disease (stage III or IV) at the time of diagnosis with frequent involvement of extranodal sites (60%), including bone marrow, liver, and spleen involvement. Unlike those not infected with HIV, noncontiguous spread of disease is common and mediastinal involvement is far less. Bone marrow involvement occurs in 40% to 50% of patients and may be their first indication of the disease. Another characteristic distinguishing the HIV-associated HL from that not associated with HIV is the predominance of Reed-Sternberg cell-rich cases. AIDS-HL, like AIDS-NHL, is characterized by a high frequency of EBV infection when compared to HL in the HIV-negative population. The pathologic role of EBV in HL is evidenced by the Reed-Sternberg cell expression of EBV-transforming protein.

Treatment

Although standard multiagent chemotherapy may be curative in most HIV-negative patients with stage III or IV HL, the median survival for HIV-infected patients has been in the range of 1 to 2 years.\textsuperscript{186} Response to standard chemotherapy ABV (doxorubicin, bleomycin, vinblastine, and dacarbazine) is lower than that of patients without HIV infection, but may be better in the HAART era. Poor tolerance to chemotherapy results in dose reduction or delay of chemotherapy, but this may be ameliorated by the use of GCSF. The median overall survival of patients is approximately 1.5 years.\textsuperscript{184, 186, 187} Because 85% to 95% of HL patients have widespread disease, no data exist on the impact of radiation therapy in
treatment of AIDS-HL. Recent studies in the HAART era include trials suggesting better outcomes. Currently an ongoing US intergroup study (S0816) is examining midtreatment risk adaption and regimen modification based on interim PET scan after cycle 2 of ABVD. The novel and highly potent brentuximab vedotin, an anti-CD30 antibody conjugated to an antitubulin drug approved for relapsed and refractory non-HIV Hodgkin has not yet been tested in the setting of HIV, but will be investigated in an upcoming AIDS Malignancy Consortium study of untreated advanced stage HIV-HL.

Transplantation for Hodgkin Lymphoma and Non-Hodgkin Lymphoma
Myeloablative autologous transplants have been performed in patients with both NHL and HL. The City of Hope reported the first prospective study of 12 patients with NHL beyond first complete remission.\(^\text{186}\) Opportunistic infections were seen in three patients; transient increases in viral load were seen in seven (related to HAART noncompliance). Three patients died, including two with relapsed lymphoma, but all others were alive at 18.5 months. Another study included eight patients with relapsed or resistant lymphoma, four with HL, and four with NHL. Seven of eight continued HAART during transplant and seven engrafted successfully. Although six of seven patients engrafted, only four patients went into complete remission.\(^\text{189}\) Another pilot of 16 patients with relapsed and refractory lymphoma reported 6/16 alive at a median of 8 months after secondline therapy, high-dose conditioning and autologous stem cell support.\(^\text{190}\) The European Cooperative Study Group on AIDS and Tumors (GECAT) reported the largest study and the only one enrolling patients before second-line therapy with 27/50 going onto autologous transplant and a median overall survival of 33 in all 50 eligible patients.\(^\text{191}\) In addition, two retrospective case control studies have suggested no difference in outcome between HIV-positive and HIV-negative patients undergoing autologous transplant for the same indications.\(^\text{187, 188}\) The AIDS Malignancy Consortium and Bone Marrow Clinical Trials Network have partnered in an ongoing trial to demonstrate multicenter feasibility and study biologic correlates. Finally, gene therapy pilot studies are ongoing to test the feasibility of engineered hematopoietic stem cell HIV resistance at the time of transplant for malignancy.\(^\text{194}\)

Nonmyeloablative allogeneic transplantation has been used in patients with refractory disease and has produced short-term remissions (12 months), but was associated with little toxicity and few opportunistic infections.\(^\text{195}\) A case has been reported of simultaneous treatment of acute myelogenous leukemia and eradication of HIV infection using a donor with homozygous CCR5 deletion, a receptor necessary for HIV infection. However, the rarity of this deletion makes this approach unique. The AIDS Malignancy Consortium and Bone Marrow Clinical Trials Network have recently opened an allogeneic transplant pilot study for HIV-infected patients with a wide variety of hematologic malignancies.

CONCLUSION
Patients with HIV infections are living longer and having better quality of life than ever before. Life expectancy can approach the general population. Treatment of HIV-infected patients with

P.1368

HAART has altered the natural history of HIV infection by decreasing the frequency of opportunistic infections and altering the expected frequency of hematologic complications and AIDS-related malignancies. Cytopenia, particularly anemia, is more common in advanced stages of HIV and results both from bone marrow failure and peripheral destruction. With the development and application of HAART, both AIDS-defining and non-AIDS-defining malignancies represent an ever-increasing cause of death in this population. Lymphomas are highly prevalent among HIV-infected patients, although CNS lymphoma is now very rare on HAART. Intensive curative therapies are now the norm except in patients with advanced AIDS. In the future, different strategies directed toward controlling the underlying inciting viral infections associated with malignancy (EBV, HHV8) and focusing on immune reconstitution in addition to standard chemotherapy may improve response rates and survival.

Chapter 65 Disorders of the Spleen
Disorders of the Spleen
Matthew R. Porembka
Majella Doyle
William C. Chapman

The spleen is a small, purplish, sponge-like organ found in the left upper abdominal quadrant. Although there is no mention of the spleen in the Bible, it receives considerable attention in the Talmud and post-Talmudic literature. Classically identified as the seat of laughter, there has been much debate over whether the spleen is truly necessary. It is said that Galen called it an “organ full of mystery” as early as the second century A.D. Although we have come to understand much about the structure and function of the spleen since those times, much of what intrigued Galen still remains a mystery today. The spleen has been classified into different organ systems including the circulatory system, the hematopoietic system, the mononuclear phagocyte system, or the lymphatic system. However, it is probably more accurate to describe the spleen as a clearinghouse for circulating cellular elements—a place where multiple organ systems converge in both structure and function.

DEVELOPMENT AND ANATOMY

The spleen is derived from embryonic mesoderm. The developing organ first becomes apparent during the fifth week of gestation as mesodermal cells coalesce between the leaflets of the dorsal mesogastrium, posterior to the developing stomach. As development continues, independent lobules enveloped by mesogastrium become evident. In time, they fuse to form a multilobulated mass that eventually differentiates into a well-formed organ by late fetal life. Occasionally, a stray lobule may fail to fuse with the others, develop independently, and give rise to an accessory spleen, a functioning mass of splenic tissue set apart from the body of the organ proper. The mesogastrium enveloping the lobules eventually gives rise to the organ's capsule and trabecular skeleton, and the posterior and anterior attachments give rise to the primary supporting structures: the splenorenal and gastroplenic ligaments, respectively. The colonization of the cellular elements of the spleen occurs first with the erythroid and myeloid progenitors, followed by the first hematopoietic stem cells. Finally, lymphoid-tissue-inducer cells are observed and provide the necessary local cellular signals to trigger the unique architecture of the splenic cellular elements. This development is highly similar to that of lymph nodes.

Gross Anatomy

Grossly, the spleen may appear in a variety of shapes. It may be wedge-shaped (44%), tetrahedral (42%), or triangular (14%), depending on its relationships with the stomach, left kidney, pancreas, and colon. The average adult spleen measures 13 to 15 cm in length, 8 to 10 cm in width, and 4 cm in thickness, with a weight of 150 g and a corresponding blood volume of ~300 mL. However, the size of the spleen varies with age, immunologic status, and nutritional status.

The nonperfused organ appears purplish in color with a solid, sponge-like texture throughout. It is covered by a fibrous connective tissue capsule that is 1.5 mm thick and composed of collagen and elastin fibers. This capsule surrounds all but the hilum of the spleen. Continuous with the capsule, involutions penetrate the body of the organ to form trabeculae, the fibrous supporting skeleton of the spleen. Finally, a serosal membrane, derived from peritoneum, covers the organ externally and adheres to the capsule. This mesothelial membrane covers the entire organ except at its hilum and the reflections of its primary supporting ligaments.

In the majority of people, the spleen is divided into the superior lobe and inferior lobe, but further division into subsegmental lobes can be seen. Avascular planes separate each lobe and they are defined by discrete, nonanastomosing circulatory pathways.

Location and Relationships

The spleen is located in the left upper quadrant of the abdominal cavity, posteriorly, at the level of the ninth to eleventh thoracic vertebrae. The superior, or diaphragmatic, surface of the organ is convex in shape, smooth, and related to the left hemidiaphragm; whereas the inferior, or visceral, surface is somewhat triangular and rests on the splenic flexure of the colon.

The medial portion of the spleen is concave and divided by a longitudinal ridge into a gastric surface anteriorly and a renal surface posteriorly. The gastric surface contains the hilum of the organ and relates to the fundus of the stomach and the tail of the pancreas. The tail of the pancreas touches the spleen in 30% of cases and is within 1 cm of it in 73% of the population, contributing to the risk of pancreatic injury in patients undergoing splenectomy. The renal surface borders the superolateral surface of the left kidney and left adrenal gland. Figure 65.1 shows the gross appearance of the spleen as well as its relationship to the adjacent pancreatic tail and branch vessels of the splenic artery.
The spleen is supported by a number of suspensory ligaments: the splenorenal posteriorly, the gastroplenic anteromedially, the splenophrenic superiorly, and the splenocolic inferiorly.\(^1\) The splenorenal and gastroplenic ligaments provide the majority of support to the organ and are considered primary. The splenorenal ligament supports the organ posteriorly and serves as a conduit for the organ’s neurovascular bundle, whereas the gastroplenic ligament stabilizes the spleen anteromedially to the greater curvature of the stomach and contains the short gastric and gastroepiploic vessels. The other ligaments of the spleen play a secondary role in the support of the organ and are generally avascular.\(^1,4\) However, in certain pathologic states, such as portal hypertension, significant collateral circulation through these planes may occur.

Vascular Supply

The spleen is a highly perfused organ. Although it represents only \(\sim 0.2\%\) of the total body weight, it receives > 5% of the total cardiac output.\(^8\) The main blood supply to the spleen is the highly variable splenic artery, which delivers 250 to 300 ml of arterial blood per minute. It arises as a branch of the aorta’s celiac trunk in the midline and follows a tortuous course to the left, enveloped within the splenorenal ligament, to supply the organ.\(^1\)

The splenic artery is a highly unpredictable vessel that displays variations in course and dimension. In 95% of the population, it travels along the upper border of the pancreas, but it may also travel in front of, within, or behind the pancreatic tissue. Along its tortuous course, the splenic artery gives rise to the left gastroepiploic artery and the short gastric arteries, both of which run within the gastroplenic ligament. At its terminal end, the splenic artery branches into a number of smaller arteries, or segmental branches, before penetrating the hilum of the organ. These smaller arteries are
also highly variable but are most often four in number and include the superior polar, superior middle, inferior middle, and inferior polar splenic arteries. The segmental branches penetrate the organ by traveling within the trabeculae (sheaths of fibrous connective tissue derived from the involution of the spleen's fibrous capsule) and ramify within the body of the organ. Additional sources of arterial blood to the spleen include direct tributaries and collateral circulation provided by branches of the pancreatic and short gastric arteries.1, 4

Venous drainage is facilitated primarily by the splenic vein. It is formed by the coalescence of the segmental splenic veins, as they leave the hilum of the organ, and the left gastroepiploic vein. Occasionally, short gastric veins may also participate. The splenic vein courses toward the midline along the superior border of the pancreas, where it joins the superior mesenteric vein to form the portal vein. Along the way, the splenic vein receives venous tributaries from the pancreas and, in 60% of cases, also receives the inferior mesenteric vein.1, 4

Lymphatics
The spleen, which is considered by many to be a lymphatic organ, has no afferent lymphatics, yet a significant amount of lymph fluid is expressed by the organ and drains via efferent vessels that form around the arterioles. The lymphatics travel with the neurovascular bundle through the trabeculae, exiting at the hilum.3, 9 In turn, the lymphatic fluid is directed toward the nodes of the splenic hilum, the splenic artery, and the pancreas (the pancreaticosplenic nodes), and eventually drains to the nodes of the celiac axis.4

Innervation
The spleen is innervated by fibers of the sympathetic nervous system which originate at the level of T-6 to T-8 and pass with the greater thoracic splanchnic nerve to the celiac ganglion.15 From there, they pass to the organ via the arterial tree, with resulting vasomotor function.1 It is believed that, similar to other mammals, the autonomic nervous system regulates changes in spleen volume, resulting in the expulsion of stored red blood cells during times of physiologic need.18, 25

Of interest are studies that relate the sympathetic innervation of the spleen to the immune system.10, 11, 12 These studies suggest that spleen innervation also supplies branches to the lymphocytic tissue of the white pulp, and that the innervation is plastic and able to be remodeled depending on the host’s current immune state.13 In this respect, these investigators argue, the central nervous system is hard-wired to the immune system and may mediate the observed immunosuppressive effects of stress.

Accessory Spleens
An accessory spleen is a functioning lobule of splenic tissue set apart from the body of the spleen proper. It is an anatomic variant present in 10% to 30% of the general population and appears to be found with greater frequency in patients with hematologic disorders. Figure 65.2 shows a typical example of an accessory spleen.

These supernumerary organs arise during embryologic development when an encapsulated lobule of precursor cells fails to fuse with others forming the spleen proper; they are solitary in ~88% but can be multiple in 10% of cases.14 In the majority of cases, accessory spleens receive their blood supply from a tributary of the splenic artery and are found most often near the hilum of the organ or within one of the primary supporting ligaments. However, they may be found within secondary supporting ligaments or within the greater omentum or even in as remote a location as the pelvis of the female or the scrotum of the male. They may be mistaken for malignancy on imaging studies, such as computed tomography (CT) or endoscopic ultrasound.

Because accessory spleens perform the same functions as the spleen proper, they are subject to the same pathologic conditions that affect the parent organ. Therefore, they may enlarge after splenectomy, causing a relapse of the disease process for which the spleen was removed. The presence of an unrecognized accessory spleen can account for failure of certain surgical procedures such as splenectomy for immune thrombocytopenic purpura (ITP). 15, 16, 17, 18 In patients who continue to have thrombocytopenia after splenectomy, a search for a missed accessory spleen should be considered. Diagnosis may be made using abdominal sonography, CT, magnetic resonance imaging, nuclear scintigraphy, or Doppler sonography.19

Splenosis
In addition to accessory spleens, extrasplenic tissue may occur via traumatic autotransplantation in the form of splenosis. This is the migration and subsequent proliferation of dislodged splenic tissue, and it is reported to occur in up to 75% of patients who undergo splenectomy for traumatic injury. Rarely, splenosis
may be found in the gynecologic patient or in the thorax after rupture of the spleen and left hemidiaphragm.\textsuperscript{20, 21, 22} Histologic examination of splenetic tissue reveals the same elements of the parent organ: white pulp, red pulp, and marginal zones.\textsuperscript{20} It follows, therefore, that splenetic tissue should preserve at least some splenic function. Indeed, it has been observed that postsplenectomy patients with splenetic tissue do retain the ability to clear erythrocytes of undesirable inclusion bodies. However, it has not been demonstrated that this provides sufficient protection from postsplenectomy infectious complications, and the practice of splenic tissue reimplantation after splenectomy has been abandoned.\textsuperscript{23}

Wandering Spleen

Wandering spleen refers to migration of the spleen from its normal location in the left upper quadrant. With an incidence of <0.5\% in splenectomy series, the major complication of an ectopic spleen is torsion, either acutely or chronically. Signs and symptoms include vague or chronic abdominal discomfort and a tender abdominal mass; and CT assessment of viability leads to the decision of splenectomy versus splenopexy.

Microscopic Anatomy

Splenic tissue is supported by a scaffold of trabeculae, a dense, fibrous connective tissue skeleton that gives rise to an intrasplenic meshwork of collagen fibers. Vascular elements enter the spleen at the hilum, branch through the trabeculae,
and penetrate the body of the organ to supply the microcirculation. As the arterial elements enter the parenchyma, they become surrounded by an aggregate of lymphoid tissue, which follows vessels in a sheathlike distribution. Aggregates of lymphoid tissue are collectively called the white pulp. White pulp may be arranged in this coaxial fashion, or it may appear as isolated follicles within the parenchyma of the organ. The balance of splenic tissue beneath the capsule is known as the red pulp. It is composed of vascular, circulatory, and mononuclear phagocytic elements. Additionally, an intermediate region can be observed at the junction between the white and red pulp; it is known as the marginal zone. Nerves and lymphatics follow the distribution of the larger vessels throughout the body of the organ.

White Pulp

The white pulp structure resembles that of a lymph node, with organized T and B cell compartments surrounding branching arterial vessels. The organization of the cellular elements within the white pulp is created and maintained by local chemokine gradients specific to T and B cells. White pulp may be observed in one of two arrangements: a periarteriolar lymphatic sheath (PALS) or a lymphoid follicle. The PALS is a collection of T lymphocytes that surrounds intraparenchymal arterioles and follows these vessels in a coaxial fashion for several millimeters throughout their terminal distribution. Within the PALS, T cells interact with dendritic cells and passing B cells. The lymphoid follicles are spherical collections of B lymphocytes. These follicles are usually distributed along the length of the PALS in an eccentric fashion and house activated B cells undergoing clonal expansion.

Red Pulp

The red pulp represents approximately three-fourths of the splenic volume and is composed primarily of vascular elements surrounded by a fibrocellular reticulum that contains mononuclear phagocytic cell lines and circulating elements of blood in transit. The chief vascular component of the red pulp is the splenic sinus, a preliminary venous element whose structure is unique to this organ. The sinus is composed of an incomplete lining of elongated endothelial cells surrounded by a highly fenestrated basement membrane. The structure is supported externally by reticulin fibers wrapped in a transverse fashion. These stress fibers also have actin- and myosin-like filaments which regulate the porosity of the sinus. The unique architecture of the splenic sinus has been compared to the structure of a wooden barrel, with the elongated endothelial cells resembling the planks or staves and the external reticulin fibers representing the hoops.

The splenic sinuses permeate the surrounding fibrocellular reticulum that supports them. Two-dimensional histologic observation reveals an intervening reticulum arranged in cords called splenic cords or cords of Billroth. These cords actually are a three-dimensional meshwork of densely packed elements (fibroblasts, collagen fibers, and cells of the mononuclear phagocytic lines). Terminal arterioles and capillaries deliver circulating blood to this meshwork that percolates through the cord toward the sinuses. Thus, circulating elements of blood in transit are also packed within the cords: erythrocytes, platelets, macrophages, lymphocytes, plasma cells, and granulocytes.

Marginal Zone

The marginal zone is a transitional region between the white and red pulp and contains both lymphocytic and mononuclear phagocytic elements. Within this transitional zone, three distinct regions can be identified. Moving from white to red pulp are the marginal sinus, the marginal zone proper, and the perimarginal cavernous sinus plexus.

The marginal sinus is a vascular sinus that surrounds the white pulp and is a region where arterioles terminate into an anastomosing complex of vascular spaces. External to the marginal sinus is the marginal zone. This transitional region contains elements of both white and red pulp and is where much of the circulating blood is presented to lymphocytic and mononuclear phagocytic cells. Figure 65.3 illustrates a schematic view of the microcirculation within the spleen.

Many different cell types reside in the marginal zone. Its foundation is a framework of reticular fibroblasts which is continuous with the reticular fibroblasts of the red pulp and the cells lining the marginal sinus. The marginal zone macrophage, metallophilic macrophage, and B cell are the key cell types in this transitional zone. The marginal zone B cell is a specialized subset of B cells that differ phenotypically and functionally from follicular B cells and are considered a bridge between the innate and adaptive immune systems. Interactions between these cells are key in the marginal zone’s organization and integrity. Many transient cells pass through this area as they circulate into the red pulp and back into the bloodstream. Diapedesis of lymphocytes and dendritic cells occurs through a barrier cell layer from the marginal sinus into the white pulp; however, the exact mechanism of this localization remains unknown.
Microvasculature

As the splenic artery approaches the body of the organ, it divides into a series of branches, the proper splenic arteries. On average, four proper splenic arteries then enter the organ at the hilum and branch into trabecular arteries, so named because they run within the framework of the fibrous connective tissue skeleton, the trabeculae. Trabecular arteries leave the fibrous trabeculae and penetrate the parenchyma by branching into central arteries that immediately become surrounded by a cuff of white pulp, the PALS. The central arteries pass through the white pulp, they give off lateral branches at right angles, most of which terminate in and supply the marginal sinuses, and others that terminate within the marginal zone or red pulp. The right angle by which these lateral tributaries branch off from the central artery is thought to mediate a plasma-skimming effect which functions to hemoconcentrate the blood with a greater number of cellular elements. This skimming effect may also help regulate plasma volume. Central arteries continue from the white pulp sheath through the marginal zone and eventually terminate in the red pulp, giving off additional lateral branches along the way that are known as penicillar arterioles. The penicillar arterioles, which are named for their resemblance to Penicillium molds, terminate in one of three fashions: They may circle back and supply the marginal sinus; they may terminate in the red pulp, supplying the splenic cords; and a minority may terminate directly into the venous sinuses for direct venous return. Eventually, the central artery itself terminates within the red pulp.

Circulating elements of splenic blood flow begin their return by first entering the splenic sinuses, the preliminary venous vessels. Flow may enter the sinuses directly from arterial connections in a closed circulatory fashion. Alternatively, plasma and blood cells may reach the sinuses only after percolating through the reticulum of the parenchyma in an open circulatory fashion. Eventually, the venous sinuses coalesce and drain into trabecular veins that give rise to the segmental veins and, finally, the splenic vein.

The exact details of splenic microcirculation remain elusive despite much research since its first description in 1901. The currently accepted models that describe the flow of blood through the vessels of the spleen discuss this in terms of the pathway taken, or route, and the kinetics, or speed of flow. Closed circulation implies that blood passes directly from artery to capillary to vein. In terms of the spleen, blood traveling along a closed circulatory path follows the terminal arterioles to capillaries and, eventually, into the venous sinuses. Indeed, such direct connections have been observed.
The term open circulation implies that cells and plasma circulate outside of endothelium-lined vascular channels. As it pertains to the spleen, circulating blood may follow one of two open pathways: It may leave the endothelium-lined marginal sinus, traverse the white pulp, and drain into the open-ended sinuses of the perimarginal cavernous sinus plexus; or it may leave penicillar arterioles that terminate in stroma of the red pulp, traverse the splenic cords, and reenter the venous sinuses through their fenestrations. Indeed, the unique vascular channels and microarchitecture of the spleen can support these open circulatory pathways, which also have been observed.

Another model for discussing splenic microcirculation describes it in terms of kinetics or speed of flow. Accordingly, intrasplenic circulation may be fast, intermediate, or slow, traversing the organ in seconds, minutes, or hours. Fast flow occurs along paths of low resistance, traverses the organ in seconds, and accounts for ~90% of splenic flow. Pathways that support fast flow include the open circulation of the marginal zone and, to a lesser extent, the closed circulation of direct arterial, capillary, and sinus connections.

Elements that flow at an intermediate speed cross the circulation within minutes rather than seconds and represent ~9% of flow across the organ. These elements are thought to follow the open circulation through the cords where red cell processing—pitting and culling—occurs.

Finally, slow-flowing elements may take more than a day to traverse the organ and represent 1% of splenic flow. This is thought to represent a pool of maturing reticulocytes, which travel to the spleen from the bone marrow and undergo maturation before being released into the circulation. The role of the spleen in this function is well documented and supported by the fact that asplenic patients have a high concentration of immature reticulocytes in their peripheral circulation.

Another model for discussing splenic microcirculation describes it in terms of kinetics or speed of flow. Accordingly, intrasplenic circulation may be fast, intermediate, or slow, traversing the organ in seconds, minutes, or hours. Fast flow occurs along paths of low resistance, traverses the organ in seconds, and accounts for ~90% of splenic flow. Pathways that support fast flow include the open circulation of the marginal zone and, to a lesser extent, the closed circulation of direct arterial, capillary, and sinus connections.

Elements that flow at an intermediate speed cross the circulation within minutes rather than seconds and represent ~9% of flow across the organ. These elements are thought to follow the open circulation through the cords where red cell processing—pitting and culling—occurs.

Finally, slow-flowing elements may take more than a day to traverse the organ and represent 1% of splenic flow. This is thought to represent a pool of maturing reticulocytes, which travel to the spleen from the bone marrow and undergo maturation before being released into the circulation. The role of the spleen in this function is well documented and supported by the fact that asplenic patients have a high concentration of immature reticulocytes in their peripheral circulation.

SPLENIC FUNCTION

The functions of the spleen are probably best understood in terms of its unique structure. Composed of several different tissue types, it lies at the crossroads between the arterial supply and venous return. In this respect, the spleen functions as a unique lymphoid organ where elements of the circulatory, reticuloendothelial, and immune systems interact. Thus, it is ideally suited to play a critical role in the surveillance of circulating blood.

The spleen functions as a filter of the circulating blood, a coordinator of the immune response, and a reservoir for circulating cells and platelets. Additionally, the spleen may have a number of other responsibilities, including hematopoiesis, hemoglobin degradation and iron recovery, and plasma volume regulation.

Filter Function

One of the primary functions of the spleen is to filter blood. Elements removed from circulation by the spleen include aging or abnormal red cells, intraerythrocyte inclusions, and foreign particulate matter.

Culling

The removal of aging or abnormal red blood cells by the spleen occurs within the cords of Billroth and is known as culling. Cells bound for destruction become trapped within the reticulum meshwork and, as their splenic transit time increases, they succumb to phagocytosis by resident macrophages.

Another theory contends that as erythrocytes age, they lose significant amounts of cytoplasmic membrane. Senescent cells therefore lack the deformability necessary to negotiate the meshwork and ultimately become trapped. This theory applies to red cells that are morphologically abnormal secondary to congenital disorders such as sickle cell anemia and hereditary spherocytosis. Finally, it has been proposed that as erythrocytes age, they expose surface antigens that are recognized by self-directed antibodies. Once opsonized with antibody, senescent cells are easily trapped by cordal macrophages.

Pitting

In addition to culling, the spleen also functions to remove intraerythrocyte inclusions from circulating red cells. The ability of the spleen to clear these inclusions while maintaining the integrity of the red cell itself is known as pitting and is an exclusive function of splenic tissue.

Undesirable intracellular elements removed by the spleen include circulating particulate matter, Heinz bodies (denatured hemoglobin), Howell-Jolly bodies (nuclear remnants), and Pappenheimer bodies (iron granules). Pitting occurs as cells
within the cords attempt to reenter the circulation through the splenic sinuses. To do this, they must pass through slit-like fenestrations of the sinus endothelium. As this occurs, the deformable portion of the cell bends to negotiate the opening, whereas the inclusion, which is nondeformable, is unable to pass through the narrow passage; thus, it is left behind to be phagocytized by resident macrophages. The passage of red cells through the slits is mediated by active changes within the sinus endothelial cell stress fibers. These cells have been shown to have cytoskeletons that include the contractile protein components actin and myosin. Figure 65.4 is a schematic representation of the process of pitting.

Evidence that supports the role of the spleen in culling and pitting is found in the fact that, after splenectomy, asplenic and hyposplenic patients lose their ability to clear damaged red cells and intraerythrocyte inclusion bodies from the circulation. These patients display peripheral blood smears with an abnormal variety of erythrocytes, many with intracellular inclusions. In fact, determination of the percentage of pitted erythrocytes is a well-established method of assessing splenic function.

Clearance of Particulate Matter

Another important filtering function of the spleen is its ability to remove particulate matter from the circulation. As blood travels through the meshwork of the cords, foreign particles are exposed to splenic macrophages that clear them by phagocytosis. Experiments with injected carbon particles have confirmed this process and have identified the cells chiefly responsible for this function: The macrophages surrounding the splenic sinuses.

FIGURE 65.4. Schematic representation of process of pitting by the spleen. This process is believed to be responsible for removal of undesirable elements from circulation, including particulate matter, Heinz bodies (denatured hemoglobin), Howell-Jolly bodies (nuclear remnants), and Pappenheimer bodies (iron granules). A: Red blood cell (RBC) flows from open circulation and approaches fenestration of sinus. B: RBC begins to enter sinus through fenestration; note inclusion body within RBC. C: RBC transverses sinus; membrane-bound inclusion body lags behind. Sinus macrophage begins to approach inclusion body. D: RBC within sinus returns to venous circulation. Inclusion body succumbs to sinus macrophage. (Modified from Weintraub LR. Splenectomy: who, when, and why? Hosp Pract (Off Ed) 1994;29.)

Immune Function
Because the spleen is composed of lymphocytic tissue, circulatory elements, and mononuclear phagocytic cell lines, it is ideally suited to play a coordinating role in the immune response. The organ’s function in this respect includes its role in the nonspecific as well as the specific arm of the immune response, making it an important organ for immune homeostasis. The nonspecific immune functions of the spleen include the clearance of pathogens, the clearance of opsonized erythrocytes and platelets, and the production of complement. The ability of the spleen to clear blood-borne microorganisms and debris combined with its highly organized lymphoid compartment makes the spleen the most important organ for antibacterial and antifungal immune reactivity.

The spleen plays a significant role in the removal of bloodborne pathogens from the circulation. Once coated with complement, bacteria and viruses become circulating immune complexes. Although the liver clears some of these complexes, many others are delivered to the spleen and eliminated by marginal zone cells expressing specific receptors including pattern-recognition receptors, C-type lectin SIGNR1, and type 1 scavenger receptor MARCO. Marginal zone metallophilic macrophages also function to concentrate pathogens in the spleen, leading to their opsonization, and produce high levels of interferon-α and interferon-β.

After viral exposure, Marginal zone B cells are specialized to detect circulating pathogens, after which they rapidly differentiate into immunoglobulin (Ig) M producing plasma cells or antigen presenting cells capable of CD4⁺ T cell activation. The contribution of the spleen to this process is supported by the fact that asplenic patients display a higher level of circulating immune complexes than do spleen-competent subjects.

The ability of the spleen to clear encapsulated bacteria is especially significant. Because these organisms have the ability to evade antibody and complement binding, their clearance depends on prolonged contact between pathogen and macrophage. It is well recognized that asplenic or hyposplenic patients are prone to a syndrome of fulminant septicemia, most often involving encapsulated bacteria: Overwhelming postsplenectomy sepsis.

The spleen also plays a major role in the removal of opsonized erythrocytes and platelets from the circulation. In certain pathologic states, such as autoimmune hemolytic anemia or ITP, circulating elements become opsonized with IgG antibody. The resulting cell-antibody complexes enter the spleen and encounter Fc receptor-laden macrophages in the marginal zone, where they are destroyed.

Several proteins and glycoproteins of the complement system are synthesized by mononuclear phagocytic cells in the spleen, namely properdin and tuftsin. Properdin is an opsonin that plays a critical role in the alternative pathway and has been detected in the monocytes of the spleen. Tuftsin stimulates interleukin-1 production and binds to granulocytes to initiate phagocytosis. Although these elements are also produced at other locations including tissue macrophages and the liver, the spleen’s contribution is significant, and they are found in lower concentrations in the circulation of asplenic or hyposplenic patients. Patients who have lost their spleens also display a decreased concentration of C3 and factor B.

Specific Immune Response

The spleen is also uniquely suited to play a coordinating role in the specific arm of the immune response. Because white pulp and vascular elements lie adjacent to each other, this may serve as an interface between the lymphocytic populations of T and B cells and the elements of circulating blood.

As circulating blood enters the spleen, 90% of it passes through the marginal sinuses and surrounding zones. Here, foreign antigens are exposed to the lymphocytic tissue of the PALS and the follicles, stimulating them to respond. After antigen-specific differentiation in the white pulp follicles, plasmablasts migrate to the bridging channels of the marginal zone within the red pulp. The anatomic localization of the plasmablasts in the spleen resembles that found in lymph nodes. Antibodies produced at this location rapidly enter the circulation. The spleen also plays an important role in the induction of cell-mediated immunity. Once activated, antigen presenting cells enter the white pulp, resulting in the activation of T cells. Activated T cells then localize to the periphery of the B cell follicles where costimulatory signals are exchanged, resulting in B cell isotype switching in the follicle. These activated B cells then either migrate to the marginal zone, or remain in the germinal center. It should be noted that although these functions also occur within lymph nodes, asplenic patients demonstrate a specific response to blood-borne antigens. For example, the production of IgM in asplenic patients is both delayed and diminished. On the other hand, specific immune factors that rise in the circulation after a splenectomy include IgE and selfdirected autoantibodies. This is likely due to structural differences between the lymph nodes and spleen which carry antigen to each. Antigens transported to the white pulp are from the circulating blood, whereas those delivered to lymph nodes are carried by the lymph.
Cellular Reservoir Function
The ability of the spleen to function as a reservoir for circulating elements has been the subject of much study. Platelet sequestration by the spleen is well documented. Newer evidence supports the spleen as a primary site of production and a reservoir for white blood cells.\(^3\)

The spleen is considered a reservoir for platelets because it can sequester large quantities of thrombocytes and, in turn, release them on demand. In nonpathologic states, the spleen sequesters ~30% of the body's platelets and can release them into the circulation in response to certain stimuli. For example, in response to an increase in circulating catecholamines, the spleen releases significant numbers of sequestered thrombocytes into the circulation.\(^37\)

The role of the spleen as a platelet reservoir is most dramatically demonstrated by the fact that pathologically enlarged spleens sequester greater quantities of platelets. In splenomegaly secondary to portal hypertension, the organ can sequester up to 90% of the body's reserves and result in severe thrombocytopenia. On the other hand, in the postoperative period after splenectomy, there is a significant rise in circulating platelet counts. Sometimes this effect is transient, possibly because the liver compensates by increasing its ability to sequester thrombocytes.\(^38\)

The spleen has been also demonstrated to sequester a significant portion of red cell volume during times of inactivity, reducing blood viscosity and heart workload.\(^39\) Increases in the hematocrit after exercise reproducibly occur secondary to release of erythrocytes from the spleen. Splenic volume and the retention of erythrocytes in the splenic sinuses is thought to be mediated though the contractility of the stress fibers supporting the splenic sinuses.\(^3\) The mechanism of splenic volume change likely involves both direct innervation by autonomic fibers as well as the hormonal effects of catecholamines. α-Adrenergic blockade abolished the responses of the spleen to norepinephrine and direct neural stimulation.\(^10\)\(^11\)\(^12\)

The ability to produce and sequester various groups of leukocytes allows the spleen to act as a mediator between the different arms of the immune response. One study has shown that as blood enters the spleen, lymphocytes selectively migrate to their respective zones: T cells to the lymphatic tissue of the PALS, and B cells to the follicles and red pulp. Mitogen-stimulated B lymphocyte proliferation can be upregulated in the setting of inflammation by the serotonin-rich platelets located in the spleen.\(^4\) The spleen is also a reservoir for granulocytes, readily mobilized under stress, and memory B cells.\(^40\) The spleen also plays an important role in the coordination of the cellular innate immune response. It has been shown that a subset of innate immune cells including undifferentiated myeloid cells reside in the spleen and greatly outnumber those cells found in the circulation. These myeloid cells cluster in the cords of the subcapsular red pulp and can be released in response to injury, inflammation, and sepsis to regulate the host's immune response.\(^41\) In addition, this population of undifferentiated myeloid cells has been implicated as an important mediator of tumor-induced immune suppression. In cancer patients, these cells have been termed myeloid-derived suppressor cells and are upregulated in the spleen and peripheral circulation. The degree of this upregulation correlates to the disease stage.\(^42\)

Erythropoietic Function
The spleen produces red blood cells during fetal development and during certain pathologic states. During the fifth month of fetal development, it is a major source of red blood cell production, after which it loses this ability. Pathologic states associated with splenic hematopoiesis include myeloid metaplasia. However, the production of cells by the spleen under these abnormal conditions results not from the reactivation of fetal stem cells but from displaced bone marrow cells that take up residence in the confines of the organ.\(^14\)

Iron Metabolism
As red blood cells are destroyed within the splenic cords, their contents are degraded in the phagolysosome of sinusoid macrophages. The hemoglobin is recycled into heme and sent to the bone marrow for use in the manufacture of new erythrocytes or stored as ferritin. Large complexes of ferritin form into hemosiderin, both of which can be mobilized into the circulation during times of iron deficiency.\(^43\)\(^44\) The spleen's storage ability of iron is clearly demonstrated by the fact that asplenic patients display lower serum iron levels for a considerable amount of time after splenectomy.\(^31\)

The spleen also scavenges hemoglobin that is released from intravascular destruction of erythrocytes. Intravascular hemoglobin is rapidly bound by haptoglobin, which is removed in the spleen through a receptor-mediated endocytosis directed by CD163, a hemoglobin-specific receptor on the surface of macrophages.\(^45\)
The ability to scavenge for iron also plays an important antibacterial role. Iron is a necessary nutrient for many bacterial pathogens which secrete siderophores to compete for iron in the host's serum and tissues. Specialized macrophages in the red pulp of the spleen can be stimulated by these bacteria through toll-like receptors resulting in the secretion of lipocalin-2, a molecule that complexes with siderophores limiting bacterial growth.\textsuperscript{46}

**SPLENIC DISORDERS AND INDICATIONS FOR SPLENECTOMY**

The causes of splenomegaly and indications for splenectomy can often be confusing. There are many potential causes of splenomegaly that must be considered in any patient undergoing evaluation with an unknown diagnosis. It cannot be overstated that patients without a known cause of splenomegaly should rarely undergo splenectomy and then only after a thorough workup has been completed to assess the likely etiology of this finding.

Splenomegaly is often the result of some other condition, not the result of a primary pathologic state. The spleen rarely harbors a primary malignancy such as lymphoma that is not apparent at other sites after a careful survey by history, by physical examination, with limited imaging studies, and with peripheral blood studies. The temptation to perform a splenectomy for diagnostic purposes early in the workup of the stable patient should be strongly resisted. It is unlikely to yield a diagnosis, and, in some situations, may entail significant risk to the patient with no benefit (as in splenomegaly resulting from portal hypertension).

It is important to remember that splenic size is not always a reliable guide to splenic function, because palpable spleens are not always pathologic and abnormal spleens are not always palpable. In a survey of healthy first-year college students, 3\% were found to have splenomegaly, and 5\% of all hospitalized patients have been noted to have splenomegaly.\textsuperscript{47} Patients with cirrhosis and portal hypertension almost always have splenomegaly, but even with significant thrombocytopenia, which is often present, no specific therapy is indicated because this condition rarely results in specific complications. The important clinical issue involves determining when abnormal splenic function is occurring, ascertaining the responsible etiology, if possible, and only then assessing therapeutic options.\textsuperscript{48}

Chauffard introduced the concept of hypersplenism in 1907, although the exact clinical definition remains confusing in practice even today. The criteria for this diagnosis generally include four features: cytopenia with anemia, thrombocytopenia, leukopenia, or some combination; compensatory bone marrow hyperplasia; splenomegaly; and improvement or resolution in these findings after splenectomy. Hypersplenism has been further classified into primary hypersplenism, when no etiologic factor for splenomegaly has been found; and secondary hypersplenism, when splenomegaly is the result of another recognized condition (such as portal hypertension or an infiltrative process). With continued progress in diagnosis of the causes of splenomegaly, there has been a continued drop in the frequency of cases of primary hypersplenism. Given the nonspecific nature of this diagnosis and uncertainties regarding its therapeutic implications, it is used less often today.

Perhaps a more useful guide in the assessment of splenomegaly is to consider the mechanisms responsible for the splenic enlargement. Eichner et al. divided the causes of splenomegaly into six major categories, listed in Table 65.1.\textsuperscript{47} The likely mechanisms for resulting cytopenias in specific disease states are shown in Table 65.2. It is interesting that the degree of splenomegaly on physical examination, radiographic assessment, or at the time of splenectomy does not appear to correlate with the magnitude of cytopenia.

Although most attention regarding splenic dysfunction relates to splenomegaly and related cytopenias, occasionally patients develop hyposplenic conditions, usually from splenic infarction (such as sickle cell disease). In this group, consideration should be given to vaccination against encapsulated organisms, and potential infectious complications should be considered if unexplained fever or signs of sepsis develop, similar to postsplenectomy patients.

**Indications for Splenectomy**

A recent review of indications for splenectomy demonstrates the evolution of surgical management for splenic disorders. Over a 10-year period, the most common indications for splenectomy (trauma, incidental, hematologic malignancy, iatrogenic, and cytopenia) saw a drop of between 30\% and 50\%. In addition, the absolute number of splenectomies decreased over the period of review.\textsuperscript{70} Nevertheless, splenectomy is an accepted and often definitive treatment modality for a number of diseases, as discussed below.

**TABLE 65.1 CLASSIFICATION OF SPLENOMEGALY BY MECHANISM**

---

3154
**Mechanism** | **Causative Diseases**
---|---
Immune response work hypertrophy | Subacute bacterial endocarditis
| Infectious mononucleosis
| Felty syndrome
Red blood cell destruction work hypertrophy | Spherocytosis
| Thalassemia major
| Pyruvate kinase deficiency
Congestive (venous outflow obstruction) | Cirrhosis and portal hypertension
| Splenic vein thrombosis
Infiltrative | Sarcoidosis
| Amyloidosis
| Gaucher disease
Neoplastic | Lymphoproliferative
| Myeloproliferative
| Sarcoma
| Metastatic carcinoma
Miscellaneous | Trauma
| Splenic cysts
| Hemangioma

**Immune Thrombocytopenic Purpura**

ITP is an acquired isolated thrombocytopenia in which circulating antiplatelet antibodies bind to platelets and are cleared by phagocytic cells from circulation (see Chapter 47). The humoral cause of the disease was established in 1951, when a hematologist in training infused himself with the plasma from a patient with ITP and developed thrombocytopenia and
platelet destruction. Today, between 40% and 80% of patients with ITP have identified autoantibodies to platelet-specific glycoproteins, including GPIIb/IIIa and GPIb/IX. In addition, dendritic cells with upregulated costimulatory molecules appear to play a major role in the pathophysiology of the disease through the enhancement of B and T cell responses to platelets. Macroage-mediated platelet destruction is believed to play an important role in refractory disease through the presentation of new antigens. The spleen likely has a dual role in this disease by both producing IgG and providing the location for removal of platelets from the circulatory system.

ITP most commonly presents in women in their 20s and 30s, and they often present with bleeding after minor trauma, with nosebleeds or petechiae. There are often no physical findings, and importantly, the spleen is almost always normal in size. The primary laboratory abnormality is thrombocytopenia with platelet counts typically <50 × 10^9/L and sometimes as low as 10 × 10^9/L. There is evidence of immature platelets on peripheral smears, and bone marrow smears show increased numbers of megakaryocytes. ITP can occur in childhood and often follows a viral illness. Most cases are acute and resolve spontaneously within 6 months to 1 year. However, a small number is at risk for major bleeding, and ~5% of children develop chronic severe thrombocytopenia that requires treatment, including splenectomy in some cases.

First-line treatment of patients with ITP and symptomatic bleeding or platelet counts <30 × 10^9/L is with corticosteroids, with the goal of achieving and maintaining a hemostatic platelet count. Typical regimens include daily oral prednisone or pulses of high-dose dexamethasone. Both regimens are effective and currently are being compared in a randomized clinical trial (NCT00991939). For thrombocytopenic crises and overt bleeding, a rapid increase in platelet count may be achieved with IV Ig (1 g/kg) or anti-D (for Rh-positive patients) followed by platelet transfusion and steroid administration.

Almost all patients with ITP will progress to second-line treatment as remission with corticosteroids is often not durable and the long-term side effects are unacceptable. Options for patients who fail steroid treatment include splenectomy, rituximab, and the TPO-receptor agonists. The timing of second-line treatments is not well studied, is inconsistent among recent consensus statements, and should be a shared decision between patient and physician that is tailored to fit the patient’s condition and goals.

Splenectomy remains the most effective treatment of ITP. Initial response to splenectomy ranges from 40% to 86%. In a systematic review evaluating the efficacy of splenectomy in patients with ITP over 58 years of age, complete remission was achieved in 66% of patients, partial response in 22%, and recurrence was uncommon. Splenectomy can usually be performed electively unless patients have active, ongoing bleeding. Despite the thrombocytopenia, the circulating platelets function normally, and preoperative platelet transfusions are usually unnecessary and may be ineffective in raising the platelet count because of the rapid sequestration by the spleen.

Rituximab is a chimeric monoclonal antibody against B cells expressing CD20. Although normal platelet counts (>150 × 10^9/L) were achieved in 44% of patients and a partial response was seen in 63% (>30 × 10^9/L), median duration of response was only 10.5 months. Rituximab carries significant risks: 3.7% of patients experienced a severe or life-threatening toxicity and 2.9% died.

TPO-receptor agonists effectively achieve durable increases in platelet counts, but require continuous treatment. Platelet counts respond in approximately 80% of patients, including those who have failed splenectomy and rituximab. Although the risk profile appears to be favorable, long-term risks have not yet been fully studied.

When patients fail splenectomy or rituximab, third-line treatments with TPO-receptor agonists or immunosuppressive agents may be indicated. Failure after splenectomy should prompt a search for accessory spleens, as their removal may induce remission. Accessory spleens have been reported in 10% to 30% of patients with ITP. Technetium sulfur-colloid scanning or 111indium-labeled scanning is useful to demonstrate accessory splenic tissue.

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP) generally occurs between the ages of 10 and 40 years and is more common in women than in men (see Chapter 48). TTP is associated with genetic mutations in ADAMTS13 gene, the von Willebrand factorcleaving protease, or acquired autoantibody inhibitors usually formed after therapy with ticlopidine or clopidogrel. The disorder occasionally occurs during pregnancy or in the postpartum period, and a familial form of the disease exists. TTP is characterized by thrombocytopenia, microangiopathic hemolytic anemia, neurologic abnormalities, renal failure, and fever. TTP is likely to be the result of the abnormal presence of a platelet-aggregating agent in the circulation. Studies suggest that this agent is von Willebrand factor, which is found in excess in patients with TTP. Platelet aggregation leads to microvascular thrombi, typically in the brain, heart, spleen, kidneys, pancreas, and adrenals. Nearly 90% of adults with ADAMST13 deficiency will respond to daily plasma exchange with plasmapheresis and transfusion of fresh-frozen plasma. Patients with acquired autoantibodies can be treated with high-dose glucocorticoids, rituximab, or splenectomy. Surgical
treatment is considered in patients who have frequent relapses of TTP and may prolong the disease-free interval.\textsuperscript{56, 57, 58, 59}

Hereditary Anemias

Hereditary spherocytosis is inherited as an autosomal dominant disease in which the red cell membrane includes a defective protein, spectrin (see Chapter 27). The spleen destroys the resulting defective, spherical red cells. These patients have an anemia and significant reticulocytosis. Peripheral smears demonstrate spherocytes, and these patients have a negative Coombs test. Elective splenectomy will correct the anemia. Ideally, splenectomy is performed after the age of 5 or 6 years to minimize the potential risks of postsplenectomy infections. Because of the rapid red cell turnover, these patients often develop calcium bilirubinate gallstones, and consideration should be given to concomitant cholecystectomy at the time of splenectomy if they are present.\textsuperscript{58}

Sickle cell anemia is an autosomal recessive condition that also results in defective red blood cells (see Chapter 33). Because of the frequency of sludging and thrombosis in small vessels, these patients more often develop infarcts in the spleen, which over time results in autosplenectomy. In rare patients, however, splenectomy may be indicated for acute splenic sequestration crisis, hypersplenism, massive splenic infarction, and splenic abscess.\textsuperscript{60} Unlike hereditary spherocytosis, splenectomy has little effect on anemia related to the sickle cell condition.

Thalassemia major is an autosomal dominant condition in which abnormal hemoglobin forms protein precipitates in the red cell, recognized as Heinz bodies on a peripheral smear. These patients can develop significant splenomegaly with resulting cytopenia. In this condition, splenectomy can lessen the need for transfusion.

Malignant Tumors of the Spleen

Malignant diseases affecting the spleen can be divided into lymphoproliferative disorders, myeloproliferative disorders, metastatic lesions, and primary splenic neoplasms. Metastatic disease is not uncommon. Melanoma, breast, lung, renal, and ovarian lesions are the main source. Metastatic lesions usually reflect vastly disseminated disease secondary to hematogenous spread. Autopsy series have demonstrated splenic metastasis in 2.3\% to 7.1\% of cancer patients.\textsuperscript{61}

Primary tumors of the spleen are exceedingly rare. They include hemangiosarcoma, hemangiopericytoma, plasmacytomas, and malignant fibrous histiocytomas. All of these conditions may present with splenomegaly and are uniformly treated with splenectomy.

Lymphoma

Lymphoma is a common tumor leading to splenomegaly or a splenic mass (see Chapters 88 and 89), although the spleen is rarely the primary site. Non-Hodgkin lymphoma, including splenic marginal zone lymphoma, can present with massive splenomegaly. Although splenectomy has been shown to be a therapeutic treatment of hypersplenism by increasing blood counts, it has not improved long-term survival.\textsuperscript{62}

Hodgkin Lymphoma

Hodgkin lymphoma, described by Thomas Hodgkin in 1832, is a highly curable malignant lymphoma characterized by typical multinucleated giant cells (Reed-Sternberg) (see Chapters 93 and 94) and predictable stepwise progression from one lymph node basin to another. Histologic subtypes fall into five categories: lymphocyte-rich classical, lymphocyte-predominant, nodular sclerosing, mixed cellularity, and lymphocyte-depleted. Most patients initially present with asymptomatic peripheral lymphadenopathy, most often in the cervical region (60\% to 80\%). Other nodal regions, including the mediastinal, axillary, inguinal, and retroperitoneal regions, are less often involved at initial presentation. The presence of B symptoms, including fever, weight loss > 10\%, and night sweats, is noted. Extralymphatic and splenic involvement is also used to stage patients. Below the diaphragm, the first nodal tissue involved is the spleen, with 35\% of stage I or II patients having occult splenic disease.\textsuperscript{63}

Historically, staging laparotomy was used in patients with Hodgkin lymphoma suspected of harboring subdiaphragmatic disease. In this procedure, lymph nodes were sampled from the para-aortic, paracaval, and iliac regions, and liver biopsies were performed along with splenectomy. With the enhanced accuracy of CT and other imaging studies for staging purposes, the increased effectiveness of medical treatments, and the associated surgical risk, the need for surgical staging has essentially been eliminated.\textsuperscript{63}

Leukemia
In chronic lymphocytic leukemia and less often in chronic myelocytic leukemia, massive splenomegaly can result in significant symptoms from the mass effect of the enlarged spleen, necessitating splenectomy (see Chapters 90 and 81). Likewise, patients may develop significant cytopenia that is refractory to conventional medical measures (i.e., corticosteroids, immunosuppression) and may be candidates for splenectomy. The decision to undertake splenectomy must be made with caution, because these patients often are immunosuppressed and malnourished and have a higher operative mortality risk as well as a higher rate of perioperative complications.

Hairy cell leukemia can lead to infiltrative splenomegaly and pancytopenia, which may limit cytotoxic chemotherapy (see Chapter 91). With the introduction of effective medical therapies, the indications for splenectomy are now limited to spontaneous splenic rupture and severe thrombocytopenia with bleeding. Resistant disease should prompt investigations to confirm an accurate diagnosis.

Myelofibrosis describes a group of disorders characterized by acquired mutations that target the hematopoietic stem cells, and induce dysregulation of normal hematopoiesis results, and can be associated with enlargement of the liver and spleen as a result of extramedullary hematopoiesis (see Chapter 83). Massive splenomegaly may lead to pancytopenia, portal hypertension, early satiety, and pain. Splenectomy remains a viable treatment for refractory, symptomatic massive splenomegaly in myelofibrosis. Approximately 50% of patients will be rendered transfusion-independent. In addition, most experience resolution of mechanical symptoms and subjective improvement in constitutional symptoms. The median response is 12 months. Caution must be taken with splenectomy in patients with myelofibrosis, as the procedure carries a perioperative mortality rate of 5% to 10% and a morbidity rate of approximately 25%.

Splenic Cysts

Cystic lesions of the spleen are rare and represent a challenge for physicians to diagnose and treat. The number of asymptomatic cysts incidentally diagnosed continues to rise because of increased utilization of abdominal imaging, including computer tomography, ultrasound, and magnetic resonance.

Splanic cysts are categorized based on the presence or absence of an epithelial lining. Cysts with an epithelial lining are considered primary and can be further subdivided into parasitic or nonparasitic. Secondary cysts, or pseudocysts, lack an epithelial lining and are believed to result from trauma in the majority of cases. Primary cysts possess an epithelial lined lumen and can be divided into parasitic and nonparasitic. Parasitic cysts are most often multilocular, associated with hepatic cysts, and occur after infection with Echinococcus granulosus. They make up the majority of splenic cysts worldwide and are endemic in South America and the Mediterranean. Parasitic cysts, however, are rare in the Western world. Surgery must be undertaken carefully, as rupture can result in anaphylactic shock or disseminated scoliceal infection. In the presence of large numbers of cysts, surgical treatment is contraindicated and medical treatment with mebendazole, an effective antiparasitic therapy, is an alternative. Treatment of a single or few cysts can be managed sequentially with medical treatment, chemical sterilization (cetrimide 0.1%), and cyst evacuation.
FIGURE 65.5. Large symptomatic splenic pseudocyst developing after blunt trauma to the spleen.
Nonparasitic cysts are usually congenital and can be further divided into endodermoid, dermoid, or epidermoid cysts. Epidermoid cysts are the most common congenital cysts (~90%) and present most often in children and young adults. They are derived from inclusions of splenic surface epithelial lining into the splenic parenchyma during development or from an accelerated secretion of lining cells from an unknown cause. Dermoid cysts are exceedingly rare; they contain all three embryonic germ layers and make up the remainder of nonparasitic congenital cysts. Endodermoid cysts are not true cysts, but rather cystic vascular lesions composed of several ectatic vessels that are best described as lymphangioma or hemangioma (Fig. 65.6). These benign tumors are most often incidental findings when imaging studies or laparotomy are performed, or they may be found at autopsy. Occasionally, the patient may develop significant splenomegaly and cytopenia, leading to the need for splenectomy. Usually, however, the diagnosis can be made on the basis of imaging studies alone and splenectomy avoided. In cases of doubt, follow-up imaging studies demonstrating the absence of change over time should avoid unnecessary splenectomy.

The spleen is the intraperitoneal organ that is most often injured after abdominal trauma. Although 75% of nonparasitic splenic cysts are posttraumatic, 30% of patients cannot recall the inciting event. Pseudocysts may contain a mixture of blood and necrotic debris, as they commonly form after intraparenchymal or subcapsular hematomas organize and subsequently degenerate (Fig. 65.7). Pancreatic pseudocysts have been reported to burrow into the substance of the spleen, and this should be kept in mind in the patient with a history of pancreatic trauma or pancreatitis. Assessment of cyst fluid amylase levels may provide a clue to the pancreatic origin in such a case. Management of cysts in these cases is usually directed toward treatment of underlying pancreatitis.
FIGURE 65.6. Computed tomographic scan (A) and gross photograph (B) of spleen in 35-year-old woman with marked splenomegaly from splenic hemangioma. The arrow demonstrates central hemangioma with surrounding uninvolved splenic parenchyma. This benign tumor had caused significant thrombocytopenia, resulting in spontaneous bleeding before splenectomy.
Splenic cysts are often asymptomatic (70%) but can also present with vague abdominal pain. The pain can be constant or intermittent, left-sided or epigastric, and occasionally radiates to the left shoulder. Physical exam can reveal a painless abdominal mass in 50% of patients. Radiologic examination with ultrasound, CT, or magnetic resonance imaging can characterize the cyst as unicellular or multilocular and provide insight into anatomic relationships. Prior to any invasive procedure, determination of parasitic antibody titers are of great importance to rule out parasitic infection. Ultrasound-guided percutaneous cyst aspiration may be useful for obtaining definitive diagnosis, decreasing the size of the cyst, and excluding communicating pancreatic origin.

The majority of patients with splenic cysts are asymptomatic and do not require specific treatment. Nonoperative treatment is recommended for small cysts up to 5 cm in diameter. In patients with symptomatic cysts, surgical intervention is recommended. Although percutaneous drainage and alcohol ablation is often successful in initially reducing the size of the cyst, the procedure is often plagued with a high incidence of recurrence, necessitating definitive surgical correction. 73, 74 For single, unilocular superficial cysts, laparoscopic marsupialization or fenestration with splenic preservation should be undertaken. Deep cysts, or those located at either splenic pole, can be resected with partial splenectomy, which provides immunologic protection and improved outcomes when compared to splenic autotransplantation. Complete splenectomy is indicated in cases of giant cysts surrounded by splenic parenchyma or multilocular cysts. 18, 69, 71

FIGURE 65.7. A: CT of a 43-year-old woman who was scanned after developing left upper quadrant pain. She had no history of trauma. CT showed a splenic pseudocyst. B: After aspiration, some blood is seen in the cyst lumen. The cyst rapidly reaccumulated, and the patient subsequently had a successful laparoscopic cyst deroofing.

Splenic Abscess

Splenic abscesses may also occur when a simple cyst is secondarily infected, for example, after aspiration, or as a primary abscess, usually from a hematogenous source. Splenic abscesses usually develop from hematogenous seeding, from a distant site of infection, in the setting of intravenous drug abuse, or after splenic infarction, as in patients with sickle cell disease. Immunocompromised patients are at higher risk. There are rarely specific symptoms present, suggesting the spleen as the specific site of infection, although left upper quadrant tenderness may be present in patients with significant abscess cavities. Abdominal CT scanning is the most helpful imaging technique, demonstrating low-density lesions in the spleen, which may contain gas and present peripheral enhancement. 74 CT can also be used to direct placement of percutaneous drainage catheters, which can provide successful treatment in the majority of cases. Multilocular abscesses with thick septations or necrotic debris generally require surgery, although percutaneous catheter drainage may lead to improvement of the patient’s general condition without adverse effect on subsequent operation. 73, 74 Antimicrobial therapy is based on aspirate culture data, with Staphylococcus and Streptococcus species being common pathogens.

Felty Syndrome

Felty syndrome composes a triad of rheumatoid arthritis, neutropenia, and splenomegaly in <1% of patients with rheumatoid arthritis. Clinically, patients present with severe joint destruction and other systemic manifestations such as leg ulcers, rheumatoid nodules, vasculitis, lymphadenopathy, and hepatomegaly. Antibody-coated neutrophils are cleared from the circulation in the spleen, and neutropenia can develop. Recurrent bacterial infections, a major source of morbidity, are due to the decreased granulopoiesis, increased peripheral destruction of neutrophils, and defects in
neutrophil function. Methotrexate, or other disease-modifying antirheumatic drugs (DMARDs), is the first-line treatment for Felty syndrome with granulocytopenia and increased infection rate. If DMARD treatment is unsuccessful, low-dose granulocyte colony-stimulating factor is recommended. Splenectomy is indicated only in treatment-resistant cases in which splenomegaly is present; splenectomy is contraindicated in patients with large granular lymphocyte (LGL) expansion, as the procedure has no effect and may actually cause deterioration. 18, 75, 76

Abdominal Trauma and Splenic Injury

Splenic preservation is the main goal of the modern management of blunt traumatic splenic injuries. Nonoperative management is often successful in about 90% of patients. The degree of splenic injury is measured using contrast-enhanced CT scans and graded according to the American Association for the Surgery of Trauma (AAST) criteria (Table 65.3). The finding of active arterial contrast extravasation from the spleen, referred to a “blush,” is an indicator of failure of conservative management in adults. Most injuries of grade 3 or less are successfully managed nonoperatively, whereas the presence of a high grade injury (Grade 4 or 5) or a contrast blush predicts the need for intervention (Fig. 65.8). 77 The primary requirement for nonoperative management is hemodynamic stability, and therefore close monitoring is required in all cases. A continued transfusion requirement and/or hypotension in the face of adequate resuscitation are indications for urgent intervention. A recent meta-analysis of 24,615 patients demonstrated that 12% of patients failed conservative management, ultimately requiring intervention. It also suggested that failure of conservative management in older patients may be associated with increased mortality. 78, 79

FIGURE 65.8. A: Contrast-enhanced CT showing a grade 1 splenic laceration in the inferior pole, with associated...
hemoperitoneum; the patient was successfully managed conservatively. B: Contrast-enhanced CT showing a grade 5 splenic laceration with evidence of active extravasation and perisplenic hematoma. This patient required urgent splenectomy.

Options for operative invention consist primarily of open splenectomy, with splenic repair and partial splenectomy utilized rarely. In addition to splenectomy, splenic artery embolization has become an integral adjunct in the management of high-grade splenic injuries and in patients with active contrast extravasation. With adequate patient selection, angioembolization has decreased the failure rate of nonoperative management to 4% in some recent series. 77

Delayed Splenic Rupture

Delayed splenic rupture has been reported in patients experiencing blunt abdominal trauma, a setting in which patients develop splenic hemorrhage >7 days after their original injury. 80 This problem most likely represents an injury in evolution, when the initial imaging study (most commonly CT or ultrasound) at the time of the trauma fails to demonstrate a significant injury. These patients usually have an initial splenic contusion that continues to slowly enlarge and, at some later date, results in disruption of the splenic capsule. This is an uncommon occurrence, but should be considered in any patient who develops significant left upper quadrant pain, distention, and signs of bleeding or shock after an episode of trauma. 81, 82 The treatment is urgent intervention with angiography or splenectomy, depending on the patient’s clinical picture.

Spontaneous Splenic Rupture

Spontaneous rupture of the spleen is extremely rare and for unknown reasons occurs predominantly in males. Predisposing conditions include splenic infarctions, coagulation disorders, thrombocytopenia, portal hypertension, vasculitis, venous thrombosis in the spleen and focal splenic lesions, lymphoma, and leukemia. Spontaneous rupture is most often secondary to a neoplastic etiology. Overall mortality with rupture is about 12% with splenomegaly, advanced age (>40 years), and a neoplastic etiology predicting an increased risk of death. 83

These patients usually develop acute left upper quadrant pain that may be associated with referred pain in the left shoulder. Initially, this may be contained beneath the splenic capsule as a subcapsular hematoma, but if intraperitoneal rupture occurs, patients may present with acute severe pain and hypovolemic shock. Ultrasonography or CT scanning is a confirmatory study, demonstrating intraperitoneal fluid (blood) and subcapsular hematoma. Urgent or emergent splenectomy is definitive treatment for these patients. Splenic conservation may be an option in some, because the grade of injury tends to be less severe compared to traumatic splenic injury.

Splenectomy: Surgical Technique

Open Splenectomy

Historically, splenectomy has been performed via a midline or left subcostal incision, depending on the surgeon’s preference and the presence or absence of significant splenomegaly. In patients with massive splenomegaly (>2,000 g), a midline incision may be preferred to allow adequate mobilization and delivery of the spleen into the operative field.

Once the abdomen is entered, a careful search is made for accessory spleens, which may be found anywhere in the abdomen but are most often found in the splenic hilum or in the mesentery of the intestine.

In patients with significant splenomegaly, initial ligation of the splenic artery causes the spleen to decrease in size, lessen its distention, decrease the risk of capsular avulsions, and decrease splenic bleeding should a capsular tear occur. This portion of the procedure is performed by dividing the avascular gastrohepatic ligament above the pancreas and isolating the artery near its point of origin from the hepatic artery. Care must be taken to avoid injury to the adjacent pancreas. This step is optional and can be omitted if the artery is not readily accessible, because aggressive attempts at splenic artery ligation can result in pancreatic injury.

There are ligamentous attachments to the spleen that must then be divided before the inflow vessels in the hilum can be ligated. The phrenosplenic attachment is avascular and can be divided with sharp dissection. The gastrosplenic ligament (and short gastric vessels) and the splenocolic ligament are divided. Finally, the inflow vessels to the splenic hilum are individually ligated, taking care during this portion of the procedure to avoid injury to the tail of the pancreas. Closed suction drainage of the splenic bed is not routinely used, but a drain can be placed if there is suspicion of a possible pancreatic injury. If this occurs, evacuation of pancreatic fluid minimizes the risk of abscess formation and allows for a controlled pancreatic fistula that will usually seal with observation alone. Conversely, if a
symptomatic fluid collection develops in the bed of an undrained spleen in the postoperative period, then a percutaneous drain can be placed under CT or ultrasound guidance.

Partial splenectomy is unlikely to be a realistic option for patients with marked splenomegaly, but may be an option for patients with splenic pseudocysts in whom unroofing of the cyst is the primary objective. This may also be an option in patients with splenic trauma in whom splenorrhaphy may allow splenic preservation. Uranus et al. report successful partial splenectomy using a surgical stapler, and this may occasionally be helpful. Partial splenectomy has also been reported in patients undergoing splenectomy for Gaucher disease.

Laparoscopic Splenectomy

Since laparoscopic splenectomy was first described in 1991 by Delaitre et al., it has become the standard operative approach for the elective treatment of many benign and malignant diseases of the spleen. Numerous studies have demonstrated the advantages of the laparoscopic approach compared to open splenectomy, including decreased blood loss, shorter hospital stays, accelerated recovery, and decreased convalescence. As outcomes have continued to improve, the procedure has been applied to an increasing array of splenic pathologies, and is now one of the most common laparoscopic solid-organ procedures. The indications for laparoscopic splenectomy have been expanded and now include ITP, hereditary spherocytosis, hemolytic anemia, TTP, leukemias, splenic myelofibrosis, sickle cell disease, lymphomas, myelodysplastic syndrome, multiple myeloma, and accessory splenectomy.

Massive splenectomy is no longer an absolute contraindication for laparoscopic splenectomy. Superior outcomes over open splenectomy in patients with massive spleens have been demonstrated, including decreased blood loss, reduced transfusion requirement, fewer reoperations for bleeding, and an average reduction in hospital stay by 8 days. Decreased blood loss continues to be the greatest advantage of laparoscopic splenectomy in patients who are coagulopathic and at risk for massive hemorrhage. The decision to perform laparoscopic splenectomy in a patient with splenomegaly is a multifactorial decision that depends on the underlying disease process, comorbidities, and surgeon experience. The effect of the surgeon’s learning curve has been clearly demonstrated in laparoscopic splenectomy, with the average conversion rate depending on experience and ranging from 1.2% to 15%.

The operative approach for laparoscopic splenectomy continues to evolve with the introduction of new surgical technology. After induction of general anesthesia, a nasogastric tube and Foley catheter are placed to decompress the stomach and bladder, respectively. The patient is placed into the right lateral decubitus position, and three or four working ports are placed for the introduction of the laparoscopic instruments, including an angled laparoscope. The lateral port is most often placed at the level of the eleventh rib tip, the medial port in midline, and the middle port halfway between the two, ~4 cm below the inferior tip of the spleen. In patients with a supramassive spleen (>22 cm in craniocaudal length or 19 cm in width), the addition of a hand port has been shown to greatly reduce operative time without increasing length of stay or convalescence. This approach allows the insertion of the surgeon’s nondominant hand into the abdominal cavity while maintaining pneumoperitoneum. Positioning is slightly altered by placing the patient’s side at a 45-degree angle. After positioning and setup is complete, a careful inspection of the abdomen is carried out to identify other disease or the presence of accessory spleens, focused on the hilum, omentum, and lesser sac.

The dissection then proceeds in five stages: division of the short gastric vessels, division of the splenocolic ligament, ligation of the inferior polar vessels, hilar control, and division of the phrenic attachments of the spleen. Much of the dissection may be carried out with harmonic shears, and the hilar structures are ligated and divided with an endoscopic stapling device. The spleen is then placed in an extraction bag, morcellated in situ, and the fragments removed.

COMPLICATIONS OF SPLENECTOMY

The overall complication rate for laparoscopic splenectomy is ~9%. The most common complications of splenectomy include bleeding, injury to the adjacent pancreas with resulting pancreatitis, and pancreatic pseudocyst, abscess, or fistula formation. These patients can also develop injury to the adjacent stomach or splenic flexure of the colon if care is not taken in dividing the ligamentous attachments to these structures.

Postoperative thrombocytosis can occur, and aspirin (one low-dose aspirin per day) should be considered if the platelet count is >1,500 × 10^9/L, to minimize the risks of thrombosis or embolism. The thrombocytosis is usually transient, with return of platelet counts to normal ranges by 2 years after splenectomy.

Thrombosis of the portal venous system is a unique, and potentially life-threatening, complication after splenectomy. Although this complication was once believed to be rare, improvements in radiologic techniques have demonstrated portal venous thrombosis much more frequently than previously thought, with a number of cases occurring asymptptomatically. The reported incidence of portal venous thrombosis varies greatly within the literature. Initial
retrospective reviews demonstrated incidences between 5% and 15%. When prospectively analyzed, however, the incidence was found to be greatly unappreciated, with 19% to 55% of patients developing portal venous thrombosis. Asymptomatic thrombosis was observed in 33% to 66% of postsplenectomy patients. Patients with larger diameter splenic veins and those operated on for hematological malignancy were found to be at increased risk for thrombosis.

When symptomatic, portal venous thrombosis most often presents between 2 and 22 days postoperatively with vague, nonspecific complaints including decreased appetite, vague abdominal pain, nausea, and malaise. Abdominal pain is a rare sign that is present only in cases of severe ischemia. Fever and leukocytosis are common. Risk factors highly associated with portal venous thrombosis include splenomegaly, hematologic malignancy, and thrombocytosis. Normal D-dimer levels have a 98% negative predictive value. Contrast-enhanced CT scanning is the preferred method of evaluation as it can assess the portal circulation as well as other common etiologies of abdominal pain.

Once the diagnosis of portal venous thrombosis is made, systemic anticoagulation should be started immediately. With prompt anticoagulation, recanalization can occur rapidly in over 90% of patients. However, patients who received treatment 10 days after the procedure uniformly failed. Although treatment with thrombolytics and antiplatelet agents has been reported, indications for routine use are still yet to be determined.

Infection Risk Postsplenectomy

Infectious complications are increased after splenectomy, and this can occur both in the early postoperative period and after a significant time has passed. The rate of early postoperative infections is particularly high when multiple other procedures are performed (e.g., after complex injuries in the setting of multiple trauma). The complication of overwhelming postsplenectomy infection (OPSI) has received significant attention. In addition to...

OPSI, postsplenectomy patients are at risk for multiple and recurrent episodes of severe infection requiring hospitalization. Overwhelming Postsplenectomy Infection

One of the most important developments affecting the splenectomy procedure has been the recognition of the life-long increased risk of severe infection and sepsis after splenectomy. In 1969, Diamond described a case of postsplenectomy fulminant bacteremia leading to rapid death and popularized the term OPSI.

Pathophysiology

In the early postoperative period, infection is usually caused by Staphylococci and enteric Gram-negative bacilli. Outside this interval, the most common organisms responsible for OPSI are encapsulated bacteria, with Pneumococcus being most common (incidence, 50% to 90%). Other responsible organisms include Neisseria meningitidis, Escherichia coli, Haemophilus influenzae, Staphylococcus, and Streptococcus; and infections occur at rates that range from 7% to 12%.

The special susceptibility of the asplenic patient to encapsulated organisms is likely due to compromised humoral immunity. After splenectomy, a subset of IgM memory B cells that responds to bacterial polysaccharides is severely depleted. These memory B cells have undergone mutation, selection, and class switch in response to a specific antigen and produce antibodies rapidly on second challenge from the same antigen. The IgM memory B cells are responsible for the T cell-independent response and require a functional spleen for their generation and survival. Studies confirm that bacteria-specific IgM production in asplenic patients is both delayed and diminished.

Also, it has been demonstrated that asplenic patients have lower circulating levels of certain complement factors, including properdin, tuftsin, C3, and factor B. Tuftsin is a tetrapeptide that stimulates phagocytosis by binding to specific receptors on granulocytes, monocytes, macrophages, and natural killer cell-modulating biologic activity. The spleen also produces properdin, a crucial factor in the alternative pathway of complement activation. The alternate pathway is activated in the absence of antibody and forms C3 convertase. Properdin binds to C3 convertase, preventing its rapid decay, and allows for conversion of C3 to C3b.

There is also evidence that splenectomy results in defects of cellular immunity. After splenectomy for trauma, a cohort of patients was found to have a significant reduction in the percentage of CD4+ T cells, specifically in the CD45RA+ subset. This was accompanied by impairment in primary immune responsiveness in a number of cellular and humoral assays. Incidence
OPSI is most common in the very young, in patients with underlying malignancies or other medical conditions, and within the first 2 years after splenectomy, although it has been reported 20 to 40 years after surgery. The precise incidence of OPSI is controversial, but is estimated between 0.18 and 0.89 person-years.\textsuperscript{95, 96, 97, 98, 102, 103} Published estimates vary widely secondary to different disease definition, duration of follow-up, age stratification, indication for splenectomy, and age. OPSI is greatest in the very young and diminishes with age: 15.7\% in infants, 10.4\% in children <5 years old, 4.4\% in children <16 years old, and 0.9\% in adults.\textsuperscript{95} Although the incidence in adults is similar to that of the general population, mortality from sepsis is increased 58-fold in the asplenic population, with a fatality rate between 50\% and 90\%.\textsuperscript{95, 96, 97, 98, 102, 103} Underlying pathology, like youth, also imparts an increased risk of OPSI with the highest risk associated with underlying immune disorders and Hodgkin lymphoma.\textsuperscript{97}

Clinical Course
OPSI usually presents with fever and brief upper respiratory tract infection, and pursues a rapid course with evolution to sepsis, shock, disseminated intravascular coagulation, and multiple organ failure within hours. Any asplenic patient with fever should be evaluated for possible OPSI. Key to successful treatment is prompt administration of broad-spectrum intravenous antibiotics. A complete septic workup, including routine laboratory tests, appropriate imaging, and microbiology cultures, should be performed, but should never delay the initiation of antibiotics. In fully developed OPSI, mortality rates of 50\% to 90\% have been reported; 80\% of deaths occur within 48 hours.\textsuperscript{95, 97} More recent information suggests that when informed patients seek medical attention promptly, mortality rates may be reduced to 10\%.

Prevention of Overwhelming Postsplenectomy Infection
The guidelines for the prevention of OPSI center around vaccination, antibiotic prophylaxis, patient education, and strategies aimed at preserving splenic function. Recommended vaccines include the meningococcal vaccine, 23-valent polysaccharide pneumococcal vaccine for patients between 2 and 64 years old, and the H. influenzae conjugate vaccine. For patients undergoing elective splenectomy, vaccination should be performed at least 2 weeks before surgery to maximize the antibody against T cell-dependent immunogens. In emergent cases, patients should be vaccinated 14 days after their surgery.\textsuperscript{98, 104}

Repeat vaccination is safe in those who mount an antibody response based on measurement of antibody levels.\textsuperscript{104, 105} Currently, a single revaccination with the 23-valent polysaccharide pneumococcal vaccine is recommended at least 5 years after the first dose, with no further dosing recommended routinely. Reimmunization against meningococcal and H. influenzae are not recommended.\textsuperscript{106} Regardless, many patients do not receive any revaccination because of a general lack of understanding about their condition and the unclear role of revaccination.\textsuperscript{94}

Children <5 years old also require aggressive immunization and antibiotic prophylaxis after splenectomy. Initial vaccination is provided with the H. influenzae vaccine, meningococcal vaccine, and 7-valent pneumococcal conjugate vaccine. If not previously immunized against pneumococcus, an additional dose of the 7-valent vaccine is recommended no less than 6 to 8 weeks after the last dose, with a final 23-valent vaccine booster 3 to 5 years after the last dose. Daily antibiotic prophylaxis with penicillin V potassium (125 mg twice a day until 3 years of age and 250 mg twice a day thereafter) is recommended for all children under the age of 5 years. If no invasive pneumococcal infections are experienced, prophylaxis may be discontinued after the age of 5 after appropriate immunizations have been obtained.\textsuperscript{106}

One of the most important, and most overlooked, aspects of prevention is patient education. Up to 50\% of asplenic patients are unaware of their increased risk of serious infection, and 30\% to 40\% do not recall being vaccinated.\textsuperscript{97} Few are provided with antibiotics to take empirically at the onset of fever, and one-half would not spontaneously tell an uninformed emergency department doctor about their splenectomies.\textsuperscript{98} Asplenic patients should be extensively counseled about their health risks, the need for reimmunization, and the importance of informing future caregivers of their condition.

Autoantransplantation of Splenic Tissue
Extrasplenic tissue may emerge secondary to traumatic autotransplantation, known as splenosis. Although this tissue appears as normal spleen, with white pulp, red pulp, and marginal zones, extrasplenic tissue is insufficient to recapitulate the host immune response and is not a recommended practice for patients undergoing splenectomy.\textsuperscript{21, 23}

Chapter 66

Tumors of the Spleen

Daniel A. Arber

A variety of tumors and tumorous proliferations may involve the spleen, and there are several that are unique to this organ. This chapter focuses on the unique proliferations as well as other neoplastic causes of splenomegaly. Splenomegaly, however, is not restricted to neoplastic causes and may occur with secondary hypersplenism, which may be secondary to autoimmune or para-neoplastic causes, infectious processes, and passive congestion due to other nonneoplastic medical disorders.

PATTERNS OF TUMOROUS SPLEEN PROLIFERATIONS

Although splenomegaly is often present with splenic neoplasia, some tumors and tumorous proliferations may be found incidentally in normal-sized spleens during radiologic staging or in spleens removed due to traumatic rupture or incidentally removed during other surgical procedures. The pattern of splenic infiltration may be helpful in the differential diagnosis of splenic tumors and the gross disease patterns tend to mimic histologic patterns (Fig. 66.1 and Table 66.1). The most common disease patterns are diffuse, miliary, and nodular disease. Diffuse disease generally results in splenomegaly with complete infiltration of the splenic parenchyma. This often imparts a glassy and homogeneous red appearance to the cut surface of the spleen. This usually is due to obliteration of the normal splenic white pulp by a cellular proliferation of the red pulp. This disease pattern has traditionally been attributed to leukemic infiltration, T-cell lymphomas, and histiocytic tumors. Many of the red pulp proliferations previously considered to be histiocytic, however, have now been shown to represent T-cell neoplasms. The miliary pattern shows small, punctate tan or white areas throughout the cut surface of the spleen. These usually represent expansion of the splenic white pulp, the normal B-cell compartment of the spleen. However, a similar gross appearance may occur with granulomatous infections. The white pulp expansion pattern most commonly occurs in florid reactive hyperplasia and with low-grade B-cell lymphomas. The nodular disease pattern is characterized by one or more distinct tumor nodules in the spleen which may be identified.
incidentally on imaging studies. These nodules are usually firm and tan or white in cases of large cell lymphoma, Hodgkin disease, or metastatic tumors, and are bloody with a beefy-red appearance in vascular proliferations. Cystic lesions of the spleen may also show a nodular pattern of involvement.

**CYSTS AND ABSCESSES**

Cysts of the spleen are found in <1% of splenectomy specimens.\(^2\) They occur most commonly in men in the third decade of life. They are usually asymptomatic; however, they may cause a splenic mass and be associated with abdominal pain. Splenic cysts may be essentially any size but are on average 10 cm in diameter.\(^3\) Splenic cysts may be designated as primary or secondary, also considered true and false cysts, respectively. Both types are usually unilocular, but some small primary cysts are multilocular. Primary cysts are reported to represent approximately 20% of all splenic cysts, but small primary cysts of the spleen are probably underrepresented in older studies and more extensive evaluation of nonparasitic cysts shows that the vast majority are true cysts.\(^4,\,5\) Primary cysts have a firm, rough, and trabecular cyst wall that shows fibrosis and an epithelial lining on histologic examination (Fig. 66.2). The lining may be of mesothelial or squamous epithelium with the latter probably representing a metaplastic change.\(^6\) The epithelial lining of primary cysts may be patchy, with denuded areas present that may simulate a secondary cyst. Primary cysts can be further subdivided into parasitic and nonparasitic types. Primary parasitic cysts related to echinococcal infection (hydatid cysts) are common worldwide, but are uncommon in Western countries. Parasitic cysts are readily identified by the presence of parasite scolices in the cyst contents. Nonparasitic primary cysts appear to arise from congenital inclusions of capsular mesothelium.\(^7\) Small multilocular primary cysts of the spleen occurring at the splenic capsule have in the past been mistaken for lymphangiomas.\(^8\) Patients with primary cysts may have elevations of CA19-9 and carcinoembryonic antigen.\(^9,\,10\) Primary cysts are usually treated with splenectomy, and partial resection by laparoscopic methods often leads to recurrence.\(^11,\,12\)

Secondary cysts are reportedly more common, representing approximately 80% of splenic cysts in most studies, but more detailed evaluation can confirm many of these as having a focal epithelial lining and thus they are really primary.\(^4\) The true secondary cysts are often associated with a history of abdominal trauma and are probably acquired after hematoma or infection. The cysts are unilocular and usually have a smooth lining. They differ histologically from primary cysts by the complete absence of an epithelial lining, and are thus unlikely to recur even if only partially resected. The cyst wall may contain hemosiderin or calcification.

Some secondary cysts of the spleen may represent resolved abscesses. Multiple small splenic abscesses usually do not develop associated fibrosis with resolution, but larger abscesses are often single and develop a wall of surrounding fibrosis virtually identical to that seen in secondary cysts. Although relatively uncommon, splenic abscesses are most often associated with sepsis or endocarditis. They may also occur following abdominal trauma, including splenic rupture, by contiguous spread of infection from other organs, or in association with functional asplenia in sickle cell anemia.\(^13,\,14,\,15\) Most splenic abscesses are due to polymicrobial infection, but common organisms include Streptococcus, Staphylococcus, Escherichia coli, and Salmonella.\(^16\)
FIGURE 66.1. Gross patterns of splenic tumor involvement. Nodular tumor infiltrates may form solid firm masses or may be hemorrhagic masses. The miliary pattern shows small punctate white foci that usually correspond to expansions of the white pulp. The diffuse pattern shown is usually associated with massive splenomegaly and corresponds to a red pulp expansion. Mixed patterns may be seen when the spleen is involved by more than one process or when a low-grade lymphoma transforms to high-grade disease.

More than one pattern may occur with some diseases.

Partial splenectomy has been used successfully in the treatment of nonparasitic splenic cysts. 17

VASCULAR PROLIFERATIONS

Vascular tumors are the most common tumors of the spleen. Vascular proliferations may be diffuse or may form a tumor mass. Peliosis is a rare, diffuse vascular proliferation that is usually an incidental finding occurring in adults. 18, 19, 20 It may be associated with hepatic peliosis and may occur with anabolic steroid use, in association with malignancies, and following solid organ transplantation, as well as in patients with hepatic cirrhosis, tuberculosis, and aplastic anemia. Peliosis results in dilated vascular spaces, usually 1 mm or less in diameter, that involve the entire splenic parenchyma (Fig. 66.3). Splenic peliosis appears to be associated with an increased risk of splenic rupture. 19, 21, 22

Hemangiomas are benign tumors that are also usually asymptomatic, but may cause splenomegaly, abdominal pain, and hypersplenism. 2, 23, 24, 25 Most hemangiomas are localized and form single or multiple tumor nodules that contain cystic blood-filled spaces grossly. These spaces are lined by endothelial cells, and papillary projections may occur in areas with thrombi. The tumor nodules are usually surrounded by fibrosis and may show calcification. Plain abdominal radiographs, computed tomographic scans, and sonograms are nonspecific, but all show discrete solid and cystic masses, often with evidence of calcification. 26, 27 Diffuse hemangiomatosis of the spleen is less common, is often associated with systemic hemangiomatosis, results in massive splenomegaly, and may be associated with coagulopathies. 28, 29 Diffuse hemangiomatosis differs from peliosis by the presence of intervening fibrosis in hemangiomatosis, which is not a feature of peliosis.

FIGURE 66.2. Primary cysts. A: Primary cyst of the spleen showing a trabeculated inner surface on gross examination. B: The cyst shows an epithelial lining on histologic sections, a feature that is definitional of a primary cyst.

Localized lymphangiomas of the spleen may be difficult to distinguish from hemangiomas or primary cysts, but usually contain proteinaceous fluid rather than the blood of an hemangioma. 2, 23, 30 Diffuse lymphangiomatosis may be localized to the spleen, but is usually a systemic process and most commonly occurs in children and young adults with massive splenomegaly. 30, 31, 32, 33, 34 The splenic parenchyma is replaced by multiple cysts, up to 3 cm in diameter, imparting a spongy appearance (Fig. 66.4). The cysts are filled with thick pink to brown fluid. Large localized lymphangiomas and lymphangiomatosis of the spleen may be treated with splenectomy. 30
Peliosis of the spleen shows expanded small vessels that diffusely involve the spleen without forming a nodular mass and without intervening fibrosis.

Although hemangiomas and lymphangiomas of the spleen are similar to those of other sites, there are two unique vascular proliferations of the spleen. Littoral cell angioma is a tumor presumably derived from the normal splenic lining cell, also known as the littoral cell. These tumors may occur at any age and usually cause mild to moderate splenomegaly. Many tumors, however, are found incidentally. The tumor forms multiple spongy dark red nodules that can measure up to 9 cm in diameter (Fig. 66.5). Histologically these tumors differ from hemangiomas in that the vascular spaces are lined by plump cells with nuclear enlargement and often show papillary areas and lining cells sloughing into the vascular spaces. The lining cells of littoral cell angioma have a unique immunophenotype, expressing vascular, histiocytic, and dendritic-associated markers CD31, CD68, CD163, and CD21. In contrast to hemangiomas and normal sinus lining cells, the lining cells of littoral cell angioma do not express CD34 or CD8. Most cases of littoral cell angioma are treated with splenectomy without recurrence, but there are two reports of late abdominal and liver metastasis after 4 and 8 years. Both cases showed solid foci of clear cells and probably represent littoral cell hemangioendotheliomas.

Sclerosing angiomatoid nodular transformation (SANT) is the other vascular proliferation unique to the spleen. To date, SANT has only been reported in adults, usually presenting as an incidental mass, and less commonly with splenomegaly or abdominal pain. It usually forms a single fibrotic nodule that contains vascular spaces, including slitlike spaces, fibrosis with spindled cells, and splenic sinus lining cells without nuclear atypia, mitotic figures, or necrosis. Cases of this type have been interpreted in the past as epithelioid and spindled hemangioendotheliomas or as inflammatory pseudotumors (see below), but they have not recurred or metastasized after splenectomy. SANT is now felt to be a reactive fibrous entrapment of altered red pulp, presumably following some form of splenic injury, rather than a true neoplasm. More recent reports have described an increase in IgG4-positive plasma cells in SANT and some studies suggest an association with Epstein-Barr virus (EBV) in this proliferation. However, the EBV-positive cases appear to be overlap proliferations with splenic inflammatory pseudotumor and SANT is typically EBV-negative.
Angiosarcoma of the spleen occurs most commonly in adults and is usually associated with splenomegaly, abdominal pain, and cytopenias. Splenic rupture is common in these patients. Because most angiosarcomas involving the spleen are high-grade sarcomas with dissemination, it is often difficult to determine whether the splenic tumor is primary or secondary. The tumor forms an infiltrating mass that may have areas of cystic hemorrhage. The histologic appearance may be varied; however, angiosarcomas characteristically show cytologic atypia, high mitotic activity, and necrosis. Many cases may be difficult to differentiate from other high-grade sarcomas, and immunohistochemical detection of vascular antigen expression, such as CD31, CD34, and von Willebrand factor, is necessary to diagnose such cases. High-grade angiosarcomas involving the spleen have a
generally poor prognosis, with most patients dying of disease within 1 year of diagnosis; however, rare cases with long-term survival following splenectomy have been reported.\textsuperscript{46}

Low-grade angiosarcomas, also known as epithelioid hemangioendotheliomas, are much less common than high-grade tumors.\textsuperscript{47, 48, 49} These are reported to occur in both children and adults, but some of the adult cases have features similar to those more recently described for SANT (see above). Patients usually present with anemia and may have hyper- or hyposplenism. These tumors are better circumscribed than high-grade angiosarcomas with more bland epithelioid cells, vascular spaces, and prominent fibrosis. They also usually lack necrosis. The cells may show intracellular lumina and will express vascular-associated antigens. These tumors may be incidental findings, are usually localized to the spleen, and do not tend to recur after splenectomy.

LYMPHOID PROLIFERATIONS

Essentially any lymphoproliferative disorder may involve the spleen and splenic involvement may be the first evidence of disease. Despite this, most lymphoid proliferations involving the spleen are disseminated at the time of splenic involvement and are accompanied by lymphadenopathy.\textsuperscript{50, 51, 52, 53} Two types of splenic lymphoma, however, are unique to the spleen and present with splenomegaly without lymphadenopathy.

Splenic marginal zone lymphoma was originally described as a splenic lymphoma with features that mimicked hairy cell leukemia.\textsuperscript{54} Although sharing some morphologic and immunophenotypic features, splenic marginal zone lymphoma appears to be distinct from both nodal and extranodal (nonsplenic) marginal zone lymphomas.\textsuperscript{55} It is the most common lymphoma type in patients with so-called splenic lymphoma with circulating villous lymphocytes.\textsuperscript{56, 57, 60} Splenic marginal zone lymphoma most commonly occurs in elderly patients with massive splenomegaly (Fig. 66.6).\textsuperscript{53, 61, 62, 63, 64, 65}

Although splenic hilar lymph nodes are often involved by disease, other adenopathy is not usually present. Patients frequently have a lymphocytosis. The abnormal lymphoid cells may vary in appearance, but some cases have circulating lymphocytes with villous cytoplasmic projections that differ from hairy cell leukemia lymphocytes by having only unipolar or bipolar projections as opposed to the more uniform villous projections of hairy cell leukemia. The spleen is uniformly enlarged without a distinct mass. The white pulp is massively expanded by a biphasic population of small lymphocytes that may cause a gross miliary pattern of the spleen parenchyma. The central white pulp lymphocytes are small with scant cytoplasm and are surrounded by a bandlike proliferation of more irregular small lymphocytes with abundant clear to pink cytoplasm on histologic sections. These cells are CD20\textsuperscript{+} B cells that express BCL2, but do not express CD10, or CD43. A subset of cases may express CD5. The pattern of infiltration is distinct from hairy cell leukemia, which causes a diffuse red pulp infiltrate, and splenic marginal zone lymphoma does not usually demonstrate tartrate-resistant acid phosphatase (TRAP) positivity or expression of Annexin A1, CD25, or CD103 of hairy cell leukemia.

\begin{figure}
\centering
\includegraphics[width=\textwidth]{image.png}
\caption{Splenic marginal zone lymphoma and metastatic carcinoma. A: Gross appearance of the miliary pattern of splenic involvement by splenic marginal zone lymphoma. Note the white, larger mucoid lesion at the left, which represents metastatic papillary serous ovarian carcinoma resulting in a mixed disease pattern of infiltration. B: The splenic marginal zone lymphoma shows biphasic white pulp with small round cells in the center and larger lymphocytes with more cytoplasm in the outer marginal zones. Similar cells with clear cytoplasm are also present in the adjacent red pulp. Although peripheral blood and bone marrow involvement by splenic marginal zone lymphoma are common,\textsuperscript{66} most cases are indolent and do well with splenectomy with or without chemotherapy.\textsuperscript{61, 67} In a series of 60 patients, all treated with splenectomy and almost half receiving chemotherapy, the overall survival was 103 months with a range of 2 to 164 months. The subset of more aggressive cases tended to show involvement of bone marrow and nonhematopoietic sites.\textsuperscript{57} Other features reported to be associated with more aggressive disease include increased numbers of large lymphoma cells, p53 overexpression, and loss of chromosomal regions 7q and 17p.\textsuperscript{67, 68, 69, 70} A large series of 309 patients found a}
76% 5-year cause-specific survival, with factors associated with worse survival on multivariate analysis being hemoglobin <12 g/dl, lactate dehydrogenase levels greater than normal, and albumin levels <3.5 g/dl. More recently, patients have shown excellent responses to rituximab alone or with chemotherapy without splenectomy. Rare cases have recurred in lymph nodes with transformation to diffuse large B-cell lymphoma, and one report described cases with transformation to micronodular T-cell-rich large B-cell lymphoma. Cases of splenic marginal zone lymphoma with hepatitis C virus infection and mixed cryoglobulinemia are reported to have regressed with hepatitis C antiviral therapy. Most cases, however, occur in the absence of hepatitis C infection, and rituximab with or without chemotherapy appears to have major activity in these patients. Splenic red pulp small B-cell lymphoma and hairy cell leukemia variant share some similarities with splenic marginal zone lymphoma and are both considered as provisional entities in the 2008 World Health Organization classification. They differ from splenic marginal zone lymphoma by being primarily red pulp small B-cell proliferations. All are CD5 and CD10 negative B-cell proliferations. Hairy cell leukemia variant is typically composed of cells similar to prolymphocytes with prominent nucleoli, but these cells also show cytoplasmic projections suggestive of hairy cells. Despite the morphologic similarity to hairy cell leukemia, hairy cell leukemia variant does not usually express CD25 or Annexin A1, markers typically expressed in hairy cell leukemia. It is important to distinguish hairy cell leukemia variant from splenic marginal zone lymphoma, because hairy cell leukemia variant is a more aggressive disease.
